In India, the juicy pulp strained from ultrafibrous ripe mangoes has been dehydrated and utilized as 'cereal flakes.' Mango juice powder was developed in the Philippines years ago and technologists in Puerto Rico, Hawaii, and elsewhere are developing uses for the great numbers of mangoes that are out of

reach of markets or do not meet fresh-market or export specifications. Canadian scientists have proved osmotic dehydration feasible. Solar drying is giving good results in underdeveloped tropical countries. (*See* **Drying**: Drying Using Natural Radiation.)

Utilization of Mango Waste

In India, mango peel has been found to be a useful source of pectin equal to that derived from the apple. The seed kernel contains 11% fat usable in food industries, and the residual starch has been used to extend conventional flour stocks during times of food shortage in South-east Asia.

Food Values

The chemical constituents of the ripe mango, especially sugars (sucrose, glucose, and fructose) and acids, vary considerably with the cultivar (Table 1). Total sugars may be 11.20–16.80%. Ascorbic acid, according to analyses in Central America, ranges from 41.8 to 172.0 mg per 100 g. In India, ascorbic acid values may be as low as 13 mg per 100 g. Carotene ranges from 0.283 to 1.872 mg per 100 g. The mango is a poor source of calcium, phosphorus, and iron. Refer to individual nutrients.

Toxicity

It should be kept in mind that the mango is a member of the plant family Anacardiaceae, to which belong poison ivy, poison sumac, the marking nut, and other well-known sources of severe dermatitis. Mango propagators, making cuttings of budwood or other grafting material and rootstocks, may suffer chronic skin reactions, and some have to give up such work or wear protective plastic disposable gloves, or barrier creams. Those who wash and pack mangoes for shipping should also be gloved.

The sap of the tree is irritant, as is that of the fruit stem and, to a lesser extent, the peel of the fruit, especially before complete ripening. The fruit flesh can be contaminated by being sliced with the same knife that has been used to peel the fruit. Sensitive people (especially those who have been previously sensitized by the tree's sap or by contact with poison ivy or some other member of the family) may be able to eat the flesh of the mango if someone else does the peeling, provided that a fresh, clean knife is utilized to cut the flesh. Excessive contact with the peel, as in peeling a number of mangoes for making preserves, can induce a rash and blisters on the hands of someone not normally affected by handling whole mangoes.

When the mango tree is in bloom it does not disperse airborne pollen, but the flowers on the tree exhale an irritant chemical into the atmosphere which is a common source of itching ears, swelling of the eyelids, and respiratory irritation.

MARASMUS

P Codoñer-Franch and V Valls Bellés, Universidad de Valencia, Valencia, Spain

Introduction

Marasmus is the most prevalent severe form of malnutrition and the most important nutritional disease in developing countries. Deficiency of energy-giving foods predominates over protein deficiency. Its origin may be primary, due to insufficient food intake, often associated with infectious or parasitic diseases, or secondary, due to other conditions that interfere with the absorption or assimilation of nutrients. It contributes significantly to high rates of morbidity and mortality in childhood. It is now recognized as a public health problem, and action to reduce its extent is the responsibility of government nutrition policies and health personnel.

Malnutrition or undesirable physical or disease conditions related to nutrition can be caused by eating too little, too much, or by an unbalanced diet that does not contain all nutrients necessary for good nutritional status. Undernutrition is a lack of adequate energy, protein, and micronutrients to meet basic requirements for body maintenance, growth, and development. Today, the more comprehensive term of protein-energy (or protein-calorie) malnutrition (PEM) is universally accepted for describing undernutrition. PEM is really a term describing different types of clinical disorders resulting from several combinations and degrees of protein and energy deficiency. It includes a wide spectrum of clinical manifestations conditioned by the relative intensity and duration of protein and energy deficits. Its severity ranges from weight loss or growth retardation to distinct clinical syndromes. It is the most important nutritional disease in the developing countries; this accounts for its high prevalence and its relationship with child mortality rates, impaired physical growth, and inadequate social and economic development.

Dietary energy and protein deficiencies usually occur together, and are frequently associated with deficiencies of minerals and vitamins. Sometimes one predominates and, if severe enough, may lead to the major forms of PEM: marasmus, in which the deficiency is primarily of energy-giving foods, and kwashiorkor, with predominant protein deficiency. Frequently there are mixed pictures, with a combination of energy deficiency and chronic or acute protein deficit – marasmic kwashiorkor.

These conditions are diagnosed mainly on the basis of anthropometric measurements, especially weight and height. The two severe forms of malnutrition present very different appearences and clinical features; the overriding feature of nutritional marasmus is severe underweight. The degree of malnutrition is almost always based on the child's percentage of standard weight-for-age, and the weight in marasmus is $\leq 60\%$ of that expected for a child of that age (Table 1).

Today a cut-off point using standard deviations (SD) with respect to the mean weight-for-height is considered more appropriate, and expert clinicians

Table 1 Wellcome classification of types of protein-energy malnutrition (PEM)

Percentage of standard weight for age	*Edema*	
	Present	*Absent*
60–80	Kwashiorkor	Undernourishment
< 60	Marasmic kwashiorkor	Nutritional marasmus

diagnose marasmus using a constellation of clinical findings (visible severe wasting), and very low weight-for-height *Z*-score (≤ 3). Low weight-for-height is identified as the indicator of choice for screening severely malnourished children who are at increased risk of dying.

Epidemiology

The global magnitude of PEM is difficult to estimate with precision because many patients had not been recorded or had not received medical attention.

PEM young children is the most important nutritional problem in nonindustrialized countries. The World Declaration on Nutrition produced by the Food and Agriculture Organization (FAO) and World Health Organization (WHO) International Conference on Nutrition (ICN) held in Rome in 1992 states that about 780 million people in developing countries still do not have access to enough food to meet their basic daily needs for nutritional well-being. An estimated 50 million preschool children were wasting in 1995. Wasting rates change rapidly, however, especially in situations of emergency food shortage and population displacement.

It is especially distressing that there is such a high prevalence and increasing numbers of malnourished children under 5 years of age in different parts of Africa, Asia, Latin America, and the Caribbean. Malnutrition causes more than half of the mortality in children of this age; thus, 55% (or more than 6 million) preschool children died annually as a result of preventable diseases (12 million) which had a direct or indirect relationship with undernutrition. It has a potentiating effect on mortality, rather than acting in a simple additive fashion, and multipled the numbers of deaths caused by infectious diseases (Table 2).

It was recognized that nutritional marasmus is more prevalent than kwashiorkor and that these two serious clinical forms of PEM constitute the small tip of an iceberg of all malnourished children. They are relatively easy to detect by their clinical manifestations, and children with moderate or mild malnutrition can remain undiagnosed because often they do not have clear manifestations of malnutrition; rather, they are shorter (stunted) and/or thinner than would be expected for their age. Thus, energy deficiency plays a more important part than protein deficiency in global malnutrition.

Table 2 Prevalence and number of wasted preschool children, 1998

UN regions and subregions	*Prevalence of wasting < 5 years (%)*	*Population < 5 years (thousands)*	*Number wasted < 5 years*

Data from UNICEF (2000) *The State of the World's Children*. New York: Oxford University Press.

Causes

The etiology can be complex and three factors contribute principally to undernutrition:

1. Inadequate intake of food, with chronic insufficiency of nutrients.
2. Nutrient losses because of improper digestion and absorption, or infections that also hinder nutrient absorption and utilization.
3. Incremental requirements in physiologic circumstances (growth, gestation, lactation).

The origin of PEM can be primary, when it is the result of inadequate food intake and is almost always linked to conditions such as poverty, ignorance, infectious diseases, and low food availability. The PEM may be secondary, when it is the result of other diseases that lead to low food ingestion because of poor appetite or an inadequate digestion, absorption, or utilization of nutrients or conditions that result in increased nutritional requirements. This form of malnutrition is seen in malignancies, acquired immune deficiency syndrome (AIDS) or tuberculosis, and eating disorders such as anorexia nervosa. Primary malnutrition is most prevalent in developing countries and in disadvantaged groups (immigrants, refugees) who live in similar conditions in the developed world.

Therefore inadequate dietary intake and disease are immediate causes of malnutrition but the factors that contribute are related to the host, the agent (diet), and the environment. Availability of food, however, is just part of the picture. It is now recognized that malnutrition is only the overt sign, or symptom, of much deeper problems in society.

PEM is not confined to children but is much more prevalent during early childhood, mainly affecting infants and preschool children because of the young child's high needs for both energy and protein per kilogram and the impossibility for children to obtain food by their own means. Most descriptions of the condition concentrate on this age group.

The chronic intake of insufficient food can result in marasmus that develops gradually over several months or years. This process allows a series of metabolic adjustments that result in decreased nutrient demands and a nutritional balance compatible with a lower level of cellular nutrient availability. In marasmus there is a metabolically dynamic state change to which the affected person adapts to survive in a compensated manner. The cost of this adaptation includes functional limitations and metabolic adjustments are more stable when the situation develops slowly.

Hormonal and Metabolic Changes in Severe Malnutrition (Figure 1)

Hormones play important roles in the adaptive processes of energy and protein metabolism in severe PEM. Metabolic adaptation in wasting is associated with a decline in insulin and a rise in glucagon concentrations which results in increased rates of gluconeogenesis. During early starvation, protein catabolism is increased to provide amino acids for gluconeogenesis; decreased plasma insulin concentrations also allow for a decrease in glucose use by peripheral tissues. If the situation is prolonged, metabolic adjustments are made to spare muscle protein such as increased reliance by the central nervous system on ketone bodies as an oxidative fuel, thereby decreasing the need for increased rates of gluconeogenesis. Insulin decrease enhances lipolysis and results in increased conversion of free fatty acids (FFA) to ketone bodies.

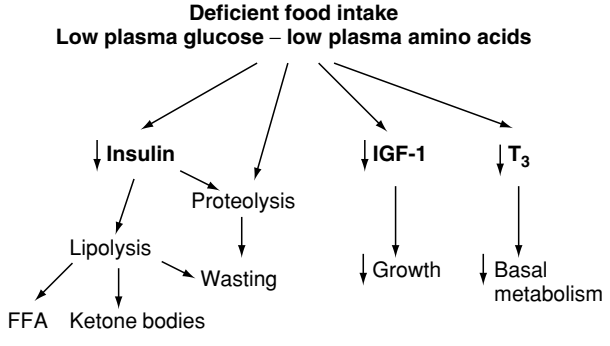

Figure 1 Endocrine changes in marasmus. IGF-1, insulin-like growth factor-1; T_3, triiodothyronine; FFA, free fatty acids.

Malnutrition frequently coexists with infection. Infection can stimulate the production of glucocorticoids that increase the release of gluconeogenic precursors, that is, amino acids from peripheral tissues, and accounts for increased proteolysis in this situation.

In the liver the synthesis of insulin-like growth factors (IGF) is decreased. This results in an alteration in the feedback for growth hormone (GH) and the increase of this hormone that contributes to lipolysis, mediated by direct catabolic effects on glucose and lipid metabolism.

The active thyroid hormone triiodothyronine (T_3) is decreased owing to deficient capturing of iodine by the gland and alteration in thyroxine (T_4) conversion. This produces a reduced thermogenesis and a spare in oxygen consumption. This metabolic adaptation leads to reduced metabolic cost.

Clinical Features

Growth Failure

A child's body responds to malnutrition with a deceleration or cessation of growth. In all cases the child fails to grow properly and presents a marked retardation in length or height-for-age. Maintenance of a satisfactory growth rate in the child depends on an adequate supply of energy. Subnormal intakes lead to a decline in growth velocity. Somatomedin C (IGF-1) is synthesized by the liver and other tissues in response to stimulation by GH. One of the major effects of GH is the promotion of linear growth and skeletal maturation. Somatomedin C is responsible for these effects and for increased synthesis of DNA, RNA, and protein in fibroblasts and chondrocytes. It also increases the rates of protein synthesis and cell proliferation in other tissues. Both adequate dietary protein and total energy contents are necessary for maintenance of somatomedin concentrations.

Undernutrition retards growth and this is true for all different parts of the body. Some parts are affected more than others; adipose tissue loses its fat, and muscle and liver lose some of their protein. If the undernutrition is severe, the adipocytes become unrecognizable as cells and the spaces between them are occupied by extracellular material. There is less change in the composition of the kidneys and heart, and the brain is the least affected of all.

If undernutrition is imposed early in life, when growth is faster, then complete recovery in size may never be possible. If, at the stage of development when the cells are dividing rapidly, cell division is hindered, the cell divisions lost during the period of undernutrtion will never be regained, even after

rehabilitation. The result is a child shorter than normal (stunting).

In severe malnutrition there is a relative increase in body water and decrease in body potassium. The extracellular fluid volume is better preserved than cell mass; the shrunken cells retain their fluid covering. The noncollagen proteins are reduced to about one-half and the collagen protein do not change significantly. Skin and bone account for about 70% of total body collagen. The child appears to be 'skin and bones.'

Wasting

Loss of tissue mass during starvation involves oxidation of endogenous fuel stores in order to generate energy required for life-sustaining metabolic activities. A decrease in energy intake is quickly followed by a decrease in energy expenditure. When the decrease in energy expenditure cannot compensate for the insufficient intake, body fat is mobilized with a decrease in adiposity and weight loss. Lean body mass diminishes at a slower rate, mainly as a consequence of muscle protein catabolism with major flow of amino acids, primarily alanine, that contributes to energy sources. As the cumulative energy deficit becomes more severe, subcutaneous fat is markedly reduced, and protein catabolism leads to muscular wasting.

Clinically, the muscles are always extremely wasted and loss of subcutaneous fat makes the ribs prominent. The loss of flesh is obvious, with little or no remaining subcutaneous fat. In contrast to the rest of the body, the belly is sometimes relatively protuberant. The skin, particularly over the buttocks, hangs in wrinkles. There may be pressure sores over bony prominences. These features and the sunken cheeks caused by disappearance of the Bichat fat pads give the marasmic child's face the appearance of a monkey or an old person (Figure 2).

Hair Changes

The hair usually shows changes. There is more frequently a change of texture and it becomes sparse, thin, and dry, without its normal sheen. It is easily pulled out without causing pain.

Appetite

Some children are anorexic while others may be ravenously hungry; they often violently suck their hands or make sucking noies, but they seldom tolerate large amounts of food and vomit easily.

Mental and Physical State

The child's mood may be anxious rather than apathetic. Marasmic children have a rather wide-awake appearance and cry easily, with an expression of misery and sadness (Figure 3). There is a marked weakness and the child frequently cannot stand without help.

Figure 2 Marasmic infant, Rwanda 1997. Courtesy of Dr M Gracia.

Vital Constants

Heart rate, blood pressure, and body temperature may be low.

Biochemical and Metabolic Features

In severe PEM all the processes of the body show a reductive adaptation to current nutritional conditions that is better if harmonic changes in the metabolism of proteins, energy, and other nutrients occur.

Hemoglobin and hematocrit are usually moderately low. The serum iron may be normal, but iron body stores are usually depleted. Following nutritional rehabilitation there may be an additional decrease in iron stores because of the increased requirements for tissue synthesis and the greater needs for hematopoietic factors. If iron is not available, the patient is prone to develop severe anemia. Plasma ferritin is increased because of concurrent infections.

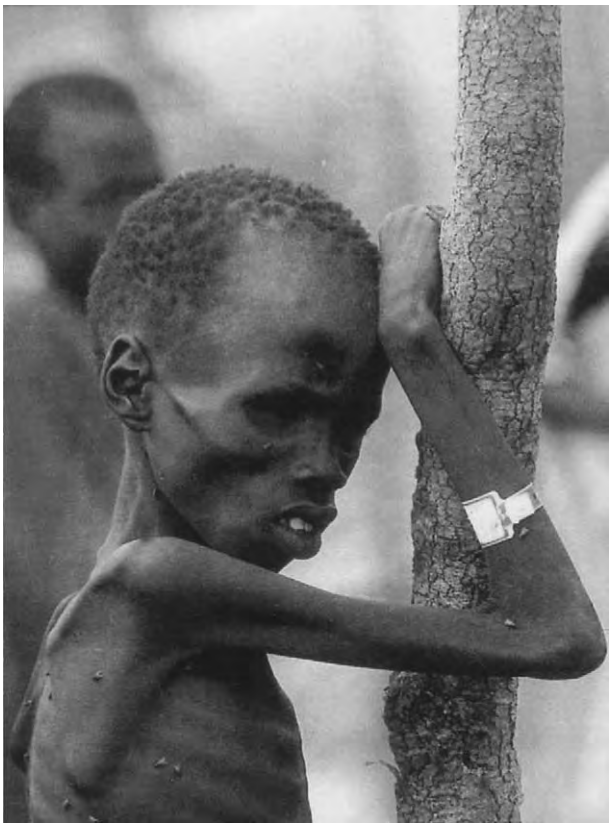

Figure 3 (see color plate 103) Expression of sadness in a marasmic person. Courtesy of Cruz Roja España.

Serum concentrations of total proteins are normal or moderately low, and the ratio of nonessential to essential amino acids in plasma is usually normal.

Excretion of hydroxyproline, 3-methylhistidine, creatinine, and urea nitrogen in urine is reduced.

Prealbumin and retinol-binding protein, two proteins with a short mean life (< 2 days) whose synthesis is energy-dependent, are decreased.

Blood glucose concentration remains normal, mainly at the expense of gluconeogenic amino acids and fats. Hypoglycemia is present especially after prolonged fasting or when malnutrition is complicated by serious infections.

Concentrations of cholesterol and triglycerides are low.

There is a deficiency in essential fatty acids and a imbalance between the *n*-3 and *n*-6 families that accounts for adverse effects (phospholipid deficiency in the retina).

Fluid and Electrolyte Disturbances

There is water and electrolyte characteristics in severe PEM, namely:

1. Intracellular potassium depletion, as body potassium is almost entirely stored within the lean tissues and muscle makes up most of the lean tissue.
2. Mild to moderate metabolic acidosis: due to rising circulating levels of ketone bodies in response to a change from a glucose-based to a lipid-based (FFA and ketone bodies) energy supply to minimize protein catabolism in skeletal muscle by reducing the need for amino acid-derived gluconeogenesis.
3. Decreased body magnesium, with or without hypomagnesemia.

Changes in Body Systems and Organs

In the gastrointestinal tract it is common that villi are flattened and atrophic, and the amount of almost all digestive enzymes is reduced. This condition leads to poor digestion and absorption and may contribute to diarrhea. Severely malnourished children are prone to diarrhea because of these alterations and possibly also because of irregular intestinal motility and gastrointestinal bacterial overgrowth. There is an alteration in pancreatic function, with a decrease of lipase and consequent steatorrhea.

Myocardial changes produced by atrophy of the cardiac muscle may lead to reduced cardiac output and electrocardiographic changes. Cardiac work decreases as does the function.

Renal function may be abnormal. Renal plasma flow and glomerular filtration rates may be reduced as a consequence of the decreased cardiac output, but water clearence and the ability to concentrate and acidify urine appear unimpaired.

Effect of Malnutrition on Immune Responses

Deficiencies in the immune system explain the high susceptibility of severely malnourished patients to infections and a greater predisposition to severe complications of otherwise less important infectious diseases. There is a marked impairment of both humoral and cell-mediated immune functions.

Severe thymic atrophy, tonsils, and other lymph tissues smaller in size than normal account for a T-cell deficiency that is particularly common in undernourished children. A depression of T-helper cells and possibly an increase in T-suppressor cell can also occur. There is decreased killer-cell activity because of reduced leukocytosis, lowered phagocytic activity of neutrophils, poor antibody formation, and decreased production of interferon and complement.

Reduced levels of secretory immunoglobulin A in secretions could be responsible for the compromised resistance to organisms that cause respiratory or

gastrointestinal infections. Atrophy of gut-associated lymphoid tissue contributes to diarrheal diseases.

Concomitant infections may lead to an increased concentration of serum immunoglobulins.

Although marasmus is a macronutrient deficiency due to insufficient food intake, and energy deficiency is more important and frequent than protein deficiency, it is usually complicated by multiple simultaneous nutrient deficiencies (vitamin and minerals) that also contribute to the effects and all the features can also be worsened by infection, thus establishing a vicious circle.

Treatment

Treatment strategies can be divided into three stages;

1. Resolving serious complications
2. Nutrient repletion
3. Ensuring nutritional rehabilitation

Resolving serious complications

Nutritional rehabilitation can be delayed until life-threatening conditions are solved. The most frequent conditions are described below.

Dehydration and electrolyte disturbance These children need careful attention and can usually be treated by appropriate oral fluids rather than by intravenous therapy. Rehydration can be achieved using the WHO standard oral rehydration solution (ORS) by mouth or by nasogastric tube. Intravenous fluids must be used in severe dehydration with hypovolemia, impending shock, frequent vomiting, and persistent abdominal distention. Careful attention must be displayed because cardiac failure may develop during or after administration of intravenous fluids. These may be the result of impaired cardiac function, sudden expansion of the intravascular fluid volume, severe anemia, or impaired membrane function.

Infections Infections are so common in severely malnourished children that antibiotics are often routinely recommended when an infection is suspected. Appropriate antibiotic therapy must be started, even before obtaining the results of microbiologic cultures. A broad-spectrum antibiotic or a combination, such as ampicillin and gentamicin, is usually given intravenously.

Treatment for intestinal parasites is rarely urgent and can be deferred until nutritional rehabilitation is under way.

Severely malnourished children not infrequently have tuberculosis or AIDS and should be examined. If the disease is found to be present, specific treatment is needed. In areas where malaria is prevalent, an antimalarial is desirable.

Hypothermia/hypoglycemia The seriously malnourished child has difficulty in maintaining normal body temperature. This may be due to impaired thermoregulatory mechanisms, reduced fuel substrate availability, or severe infection.

Untreated hypothermia is a common cause of death in malnourished children. If the child's temperature is below 36 °C, efforts must be made to warm the child. The child's temperature should be checked frequently as the patient may rapidly become hyperthermic.

Body temperature usually rises in the hypothermic patient shortly after the introduction of glucose-containing diets.

Asymptomatic hypoglycemia can be prevented or treated by the frequent feeding of small volumes of glucose-containing diets or solutions. Severe symptomatic hypoglycemia must be treated intravenously.

Nutrient Repletion

As recovery begins, restoration of nutritional status rapidly and safely as possible becomes the principal consideration. Children with severe nutritional marasmus may consume very high amounts of energy, and weight gain may be quite rapid.

It is best to begin with a liquid formula fed orally or by nasogastric tube, divided equally into 5–12 feedings per day, depending on the patient's age and general condition. If the child is still being breast-fed, breast-feeding should continue. Initially a mixture providing 120 kcal and 3 g protein per kg body weight should be provided.

In many hospitals in developing countries an aqueous mixture containing dried skimmed milk, vegetable oil, casein, and sugar is used. A marasmic child during the early part of recovery may be capable of consuming and utilizing 150–200 kcal and 4–5 g of protein per kilogram of body weight per day. As the appetite improves and no signs of intolerance or complications are evident, the energy intake may be increased to 250 kcal kg^{-1} body weight.

The various regimens must provide a diet that meets daily maintenance requirements, compensates for continued losses, and meets the requirements for growth. Adequate amounts of vitamins and minerals must be assured. Some evidence now suggests that zinc supplementation may be beneficial. Extra vitamin A and iron is often advisable since deficiency can develop as a result of increased demands when adequate protein and energy feeding begins.

In developed countries hydrolyzed milk formulas are preferred because of their digestibility and better absorption.

Ensuring Nutritional Rehabilitation

In all cases it is particularly important that the patient is not discharged from treatment until follow-up is assured and adequate feeding is continued. A mixed diet should gradually be introduced, aimed at providing the energy, protein, minerals, and vitamins needed by the child. Emotional and physical stimulation must be provided.

As a general guideline, vigorous dietary therapy should continue for 15 days after the marasmic patientq reaches an adequate weight-for-height and his or her clinical and overall performance are good. If he or she continues growing at a normal rate and has no functional impairments, treatment can be terminated after 1 month of adequate dietary intake. Specific treatment of other nutritional problems (iron deficiency) must sometimes be prolonged.

Instruction about the causes of PEM and nutrition education about the rational and nutritious use of foods, personal and environmental hygiene, appropriate immunizations, and early treatment of diarrhea and other diseases are vital for the person who will be responsible for the child.

Prevention

It is now understood that good nutrition lies in adequate levels of three factors:

1. Household food security
2. Appropriate care and feeding practices
3. Adequate health care

The prevention of PEM poses a huge challenge. Various strategies include appropriate nutrition policies with improving food security and care practices to insure good nutrition. These measures should be accompanied by promoting healthy lifestyles, suitable immunizations, growth monitoring, and early treatment for common diseases as well as prompt rehydration therapy for diarrhea and regular deworming. Severe malnutrition is more often associated with deficient food intake than with deficient protein intake. Cereal-based diets meet energy needs and also meet protein needs. Its necessary to pay attention to increasing total food intake, to protect and promote breast-feeding and sound weaning, and to encourage higher consumption of oil and fats that reduce bulk and increase the energy density of foods.

Severe malnutrition may manifest as a health problem but health professionals alone cannot solve it. This problem requires the contribution of agricultural professionals, educators, and professionals in economics, social development, and politics.

MARGARINE

Contents

Types and Properties

M Vaisey-Genser, The University of Manitoba, Winnipeg, Manitoba, Canada

Background

Margarine was invented in France by Hippolyte Mèges-Mouries in response to Napoleon III's call for a cheap alternative to butter for French workers and for his armies in the Franco-Prussian war. The first margarine, consisting of beef tallow churned with milk, was patented in 1869. Dutch entrepreneurs at Jurgens & Co., an established butter trader, purchased the margarine patent and popularized its use. Margarine production was limited by the availability of beef tallow until 1902 when Wilhelm Normann in Germany patented a process to harden oils by hydrogenation. This greatly expanded the market opportunities for vegetable oils and the availability of margarine. (*See* **Vegetable Oils**: Oil Production and Processing.)

By its centennial in 1969, margarine production in parts of Europe and in the USA began to rival that of butter. By 2000, margarine had become the table spread of choice for many people for reasons of either health or economics. Where this is the case, it also serves as a versatile fat in the home and in the food-service industry for preparing pan-fried foods, sauces, and bakery goods. This review considers the patterns of margarine consumption, the types of margarine available at the beginning of the twenty-first century, the physical structure of margarine, and its functionality, that is, its physical and sensory properties and their stability.

Margarine Consumption Patterns

The rate of margarine adoption has varied among countries, reflecting the relative strength of consumer groups and the oilseed industry in overcoming restrictive legislation achieved by dairy lobbies. Margarine was welcomed throughout Europe from its earliest introduction. However, the reverse was true in North America. In Canada, dairy farmers succeeded in imposing, in 1886, a countrywide ban on the manufacture, sale, and importation of margarine. Its prohibition endured until 1948, when the responsibility for margarine was transferred to each province. However, a federal excise tax was imposed on manufacturers until 1967. It took until the late 1990s for margarine to be sold legally in all 10 provinces, and even then, several imposed a color restriction on margarine to distinguish it from butter. In 1950, the USA abolished federal restrictive margarine taxation opening the door for liberal marketing. Nevertheless, some states resisted the legal sale of margarine for several years.

Contrary to Napoleon III's original expectation, the tablespread competition between margarine and butter has not centered solely on price. Some margarines have the advantage of being easy to spread, even at 4 °C, fresh from the refrigerator. This performance feature, coupled with a perceived nutritional advantage for vegetable oil-based spreads, led to early increases in margarine acceptance. In the USA, per-capita consumption of margarine surpassed that of butter in 1965 and more than doubled it 10 years later, a dominance which has been sustained into the last years of the twentieth century (Table 1). In both Canada and the UK, the shift from butter to margarine has been slower. Consumer research in Finland reported equal use of the two spreads in 1992 for a total of 15 kg per person per year. In France, butter apparently continues to be dominant.

In North America, there has been a gradual decrease in total table spread consumption over the last four decades of the twentieth century. In Canada, for example, the sum of margarine plus butter disappearance shown in Table 1 dropped from 13 kg per capita in 1955 to less than 8 kg per capita in 1995. In the USA, a decrease was also evident; total table spread disappearance dropped from almost 8 kg per capita in 1965 to only 5.8 kg per capita in 1995. Total table spread use in the UK also moderated between

Table 1 Examples of changes over time in margarine and butter consumption (kilograms per capita per annum, retail weight)

Year	USA[a]		Canada[b]		UK[c]

1975 and 1985. Reductions in table spread consumption appear to be a positive response to nutrition educators' emphasis on the importance of lowering dietary fat to 35% of total energy intake to reduce the risk of cardiovascular disease. Health-conscious seniors and maturing baby boomers are paying attention, at least in their consumption of table spreads.

Market Form: Classification

The worldwide standard for margarine has been set by the Codex Alimentarius Commission for products containing a minimum of 80% fat and a maximum of 16% water (No. 32-1981, Rev.1-1989). It defines margarine as a 'food in the form of a plastic or fluid emulsion, which is mainly composed of the type water/oil, produced principally from edible fats and oils, which are not mainly derived from milk.' The standard lists permitted additives, which include vitamins, flavorings, colorants, emulsifiers, and preservatives.

By Firmness

Margarine table spreads are marketed in forms which are broadly classed as either hard or soft. The distinguishing feature is the degree of fluidity at the time of packing. Hard margarines are firm enough to be molded into a stick, print, or brick form. Soft margarines, which contain more oil than hardened fat, are too fluid to hold their shape and so require packaging in plastic or coated paperboard tubs. Stick-type margarines vary widely in their degree of hardness as the liquid oil in the formulation may range from as low as 5–10% to an upper limit of 60–65%. In contrast, the liquid oil in soft products may range from 60–65% to 80–85%. To enhance the spreadability, either type may be whipped with nitrogen or air, usually to a 33% volume increase. Liquid margarine was introduced in Europe and the USA in the 1960s. Its use continues to be modest.

In 1980, stick forms accounted for about two-thirds of the nondairy table spread market in the USA and continue to be popular. However, in Canada, where brick margarines have typically been firmer than those in the USA, the soft tub types had captured about 75% of market sales by 1995. With continuing emphasis on decreasing the intake of fat, particularly saturated fat, it is likely that soft margarines, which 'go farther' on spreading, and their low-fat counterparts will continue to retain a substantial proportion of the consumer market for table spreads in developed nations.

By Fat Combinations

Blends of margarine with butter, known in some areas as butterines, are popular in a number of countries within the EC and Scandinavia. For example, Sweden introduced the butter spread Bregott in 1969. The acceptance of this product, in which 20% of the milk fat was replaced with liquid oil, was credited with successfully reversing a decline in Swedish dairy sales. However, in some parts of the world, butter–margarine blends are still viewed as adulteration of dairy products. In Canada, for example, by 1999, blends were permitted in only five of 10 provinces, where either 50:50 or 20:80 blends of butter to margarine, respectively, could be marketed. Limiting the replacement of butter by margarine to only 20%, as in Sweden's Bregott may be the better choice as far as flavor is concerned. Sensory tests carried out in 1982 and summarized in Table 2 showed that both margarine and a blend of 80% margarine with 20% butter had significantly less buttery flavor than the butter prototype. However 'half-and-half' mixtures could be mistaken for either margarine or butter.

By Fat Content

'Reduced fat' margarines are those with less than 80% fat. They have been introduced in several parts

Table 2 Buttery flavor in margarine, butter, and blends[a]

Table spread (brick form)	Mean relative intensity of buttery flavor[b,c]
Butter	1.21[d]
Blend, 50 butter:50 margarine	0.80[de]
Blend, 20 butter:80 margarine	−0.29[e]
Margarine	−1.00[e]

[c,d,e]Values with the same letter are not significantly different ($P < 0.05$).

of North America and Europe, with the goal of decreasing consumers' total fat intake to lower the risk of heart disease. The amount of fat reduction varies. Where the fat content is approximately half of the prototype, i.e., ~40%, the spread may be referred to as minarine, halvarine, calorie-reduced (Canada), 'lite' or light margarine (USA), Mini-Light (Poland).

Structure

Margarine is a water-in-oil emulsion, in which the oil phase consists of both liquid oil and crystalline fat at room temperature. The semisolid structure is achieved by a three-dimensional, continuous, sheet-like matrix of fat crystals or crystal aggregates which entraps tiny water droplets suspended in oil. Structural integrity is due to irreversible primary chemical bonds and to reversible secondary bonds formed through weak London–van der Waals forces. (*See* **Colloids and Emulsions**.)

The number and size of the fat crystals in a margarine vary with the chemical composition of the oil source(s) and with its processing. Formulations are controlled to encourage the formation of many small β^1 crystals, which are each about 1 μm in length, and to prevent their polymorphic transition, that is, a shift to fewer but larger and more stable β crystals, which are 20–30 μm in length. At a high solids content, a network of β crystals will result in a brittle, hard margarine, while at a low solids content, the large crystals are less able to form a continuous matrix, and the product may become oily. Ideally, the solid crystal particles are so small that the force of gravity is exceeded by the adhesion of the particles, and the spaces between them are small enough to preclude the seepage of the liquid phase. Such a structure confers upon margarine the desirable property of plasticity.

Scanning electron microscopy has shown that the water droplets in a margarine emulsion may be as small as 1 μm in diameter, so that there may be as many as $5–10 \times 10^9$ per milliliter. Emulsifiers such as monoacylglycerols, diacylglycerols, lecithin, and milk proteins are located at the water–oil interface. They assist in dispersing the water as droplets in the oil during the formation of the emulsion and in keeping it dispersed due to their dual, but unbalanced, affinity for both phases. A dominance of nonpolar groups on the emulsifier succeeds in lowering the interfacial tension among oil molecules more than is effected by its polar groups on water, so that oil becomes the continuous phase. The presence of both lipophilic and hydrophilic groups in the emulsifier at the water/oil interface is necessary for emulsion stability. (*See* **Emulsifiers**: Organic Emulsifiers.)

Physical and Sensory Properties

Appearance

Color and gloss are the main determinants of margarine appearance. Both properties may be monitored by instruments such as the Hunter colorimeter or the Lovibond tintometer. β-Carotene, annatto, and tumeric are additives permitted in Canada to match the color intensity and hue of margarine to that of butter, a practice which was often banned in earlier years. In fact, punitive color requirements were imposed on margarine in several Canadian provinces for many years and in one, Ontario, until 1995.

Gloss or sheen, as opposed to a dull, matte surface, is a function of light reflectance from subsurface layers of oil droplets, which is influenced by the tightness of the emulsion. Excessive glossiness develops if the fat crystal network is not sufficiently fine or firm to enmesh the liquid oil. Soft margarines tend to be glossier than the hard type, due to the higher content of liquid oil. In the same context, Finnish scientists have reported that sensory panels perceived significantly less glossiness in reduced fat spreads than in those spreads with normal fat levels. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods; Appearance.)

Texture

Spreadability and rate of mouth melt are two textural properties of table spreads which depend upon the relative amount of solid fat present and its crystalline structure. While both textural characteristics reflect a collective response to temperature and work, their criteria for success are somewhat in opposition. Good spreadability requires that the product retain its plasticity, as it is molded with modest pressure over temperatures ranging from refrigerator to room (4–22 °C). Desirable mouth melt, however, requires rapid melting at mouth temperature (35–37 °C) for prompt flavor release and clearance.

The traditional quality control tool for estimating spreadability has been the solid fat index (SFI) using dilatometry to measure volume changes as solid margarine converts to liquid when equilibrated at three temperatures: 10, 21, and 33.5 °C. Figure 1 illustrates the SFIs for butter and three different margarines. Sensory testing has shown that SFI values between 10 and 20, at the temperature of use, predict good spreadability, while values of 35 and 7 are, respectively, too hard or too soft/oily to spread. Of the SFI curves in Figure 1, the flatter patterns for the soft stick and soft tub margarines illustrate desirable spreadability, even at a temperature of 10 °C, whereas butter

is not spreadable until it reaches 20 °C. More recently, nuclear magnetic resonance (NMR), which depends on differences in the magnetic environment of protons in the solid and liquid phases, is being used to assess the spreadability of table fats. The solid fat content (SFC) values from NMR evaluations are considered more reliable than SFIs, particularly for samples at high solids content at lower temperatures. (*See* **Sensory Evaluation**: Texture; **Spectroscopy**: Nuclear Magnetic Resonance.)

Rapid mouth melt of table spreads provides a cooling sensation due to absorption of the heat of crystallization in melting and is accompanied by prompt flavor release. Figure 1 shows that butter has a steeper SFI slope and therefore more rapid mouth melt than any of the margarines. This provides it with an advantage which is difficult for the processor to duplicate without sacrificing spreadability. Sensory panel measurements of mouth melt time for 1 ml samples of Canadian table spreads on the 1982 market confirmed that butter melted significantly faster than brick margarines whether the starting temperature was 4 °C (18 s vs. 22 s, respectively) or 21 °C (11 s vs. 16 s, respectively). To our knowledge, the extent of the differences in mouth cooling sensations among table spreads as they melt has yet to be documented.

Flavor

Although North Americans have used as much or more margarine than butter since the mid-1970s, a 1986 survey of 4000 US consumers by the dairy industry found that the majority still preferred butter. Europeans echo the same sentiment, even though North Americans usually use salted and sweet cream table spreads, while Europeans favor cultured butter and unsalted spreads. For example, sensory studies in Poland and Finland reported in 1989 that margarines often lacked buttery flavor. In the absence of reports to the contrary, flavor apparently remains a challenge for the margarine processor.

Margarine flavor is a combined response to odorants soluble in the fat phase and tastants dissolved in the water droplets. Permitted flavor additives include compounds which have been identified as important in butter aroma such as diacetyl (1–4 p.p.m.), dimethyl sulfide, lactones, ethyl esters of short-chain fatty acids, ketones, and aldehydes. When ordinary salt is added to table spreads, it is the main tastant, although the lactose from milk solids will add a modest amount of sweetness. In a number of spreads, salt levels have been reduced from 2.0–3.0% by weight to 1.0–1.5%, in the interests of lowering the intake of dietary sodium. Sensory tests on a range of salt concentrations in butter have shown that reductions of this order of magnitude have little effect on perceived saltiness intensity. Sensory tests comparing the perception of salt in water and in butter show in Figure 2 that the high fat content of a water-in-oil

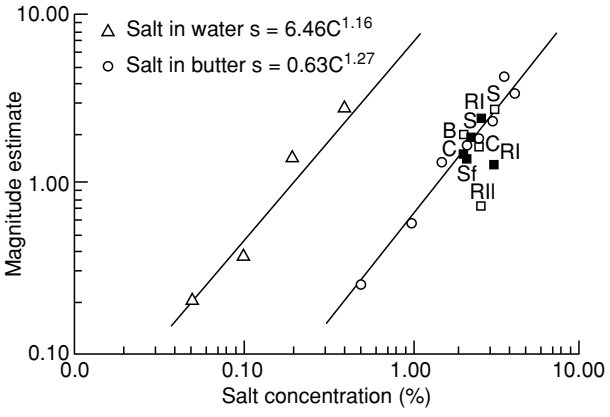

Figure 2 Psychophysical relationships of salty intensity with salt concentration in water and in butter; RI, RII, C, S, and Sf are various retail margarines, and B is butter. From Vaisey-Genser M and Vane BK (1995) Sensory evaluation of margarine. In: Warner K and Eskin NAM (eds) *Methods to Assess Quality and Stability of Oils and Fat-containing Foods*, pp. 76–106. Champaign, IL: AOCS Press, with permission. emulsion like a table spread interferes with the perception of a water-soluble tastant like salt as much as 10-fold. However, altering the salt content may affect the overall flavor balance of margarine because of influences on the partition coefficients of volatile components. (*See* **Sensory Evaluation**: Taste.)

The flavor advantage of rapid mouth melt has been demonstrated with simulated margarines consisting of 0.01% diacetyl and other dairy flavors combined with liquid soybean oil melted with either palm stearin or palm olein and recrystallized at 0 °C. Figure 3 shows the flavor intensity patterns described by trained panelists in time-intensity studies of 2.5-ml samples of these two products. Total flavor intensity peaked after 12 s in the mouth in both products, but flavor was consistently more intense in the more rapidly melting palm olein product. These sensory findings were confirmed by mass-spectrophotometric headspace measurement of diacetyl using the same simulated margarine products agitated at 35 °C with glass beads and artificial saliva.

Stability

Standard 80% fat margarine normally has a shelf life of 6–12 months if the product is refrigerated during marketing, distribution, and home storage. This period is shorter for low-fat, high-moisture products and for those which are salt-free.

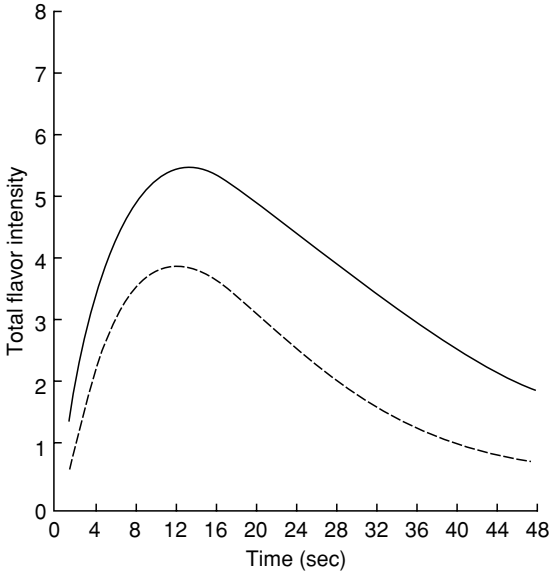

Figure 3 Effect of margarine melting point on the time and intensity of sensory flavor release; — palm olein; --- palm stearin; 0, none; 5, moderate; 10, a great deal. From Lee WE (1986) A suggested instrumental technique for studying dynamic flavor release from food products. *Journal of Food Science* 31: 249–250, with permission.

Microbiological spoilage

The growth of molds and yeasts is limited by controlling the water droplet size and by the addition of salt and other preservatives. Where droplets are smaller than 10 μm and the amount of milk solids is limited, it can be calculated that, per water droplet, there is not enough nutrient to sustain microbial growth. Accordingly, emulsion stability fosters keeping quality. Salt levels of 1.0–1.5% in margarine are considered necessary to avoid microbial hazard. At the level of 1.0% by formula weight, there would be a salt concentration of 6.25% in the serum, assuming 16% water in the margarine formula. Preservatives such as sorbic acid and benzoic acid or their respective sodium or calcium salts add protection by lowering the pH. A pH of 5–6 is recommended for salted margarine and a more acidic pH of 4–5 for unsalted products. (*See* **Preservation of Food; Spoilage**: Bacterial Spoilage.)

Graininess

Margarines prone to poymorphism may exhibit textural instability during storage at refrigerator temperature (4 °C), which is perceived as graininess and is due to crystal growth. This phenomenon is exaggerated by fluctuating storage temperatures. In Figure 4, sensory estimates of the presence or absence of graininess in a margarine during 6 months' refrigerated storage have been plotted against measurements of crystal size from photographs taken under polarized light. These data show a sensory detection threshold of crystal size as 22 μm. It remains likely that the sensation of graininess is a function of both the size

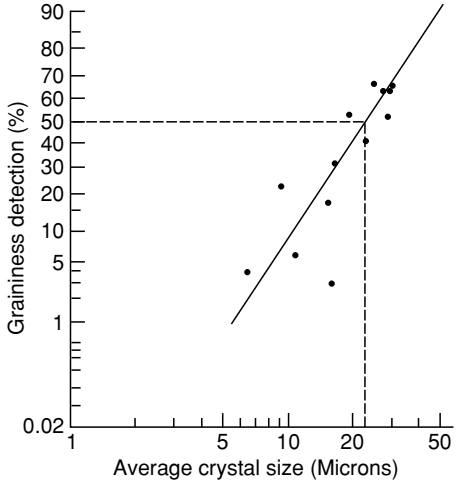

Figure 4 Relationship between fat crystal size in margarine and the percentage of panelists detecting graininess. Adapted from Vaisey-Genser M, Vane BK and Johnson S (1989) Graininess, Crystal size and firmness of stored canola margarines. *Journal of Texture Studies* 20: 347–361.

and the number of crystals. In cases of exaggerated crystal growth, there is the hazard of increased susceptibility to microbial spoilage. The development of extremely coarse fat crystals may squeeze liquid oil from the product and allow partial coalescence of the aqueous phase. Free moisture on the surface may result in mold growth. (*See* **Spoilage**: Molds in Spoilage.)

Flavor

The stability of margarine flavor is enhanced by refrigerated storage to retard autoxidation of the oil and by lightproof packaging to avoid photooxidation. Changes by either mechanism produce off-flavors in oils which are variously described as beany, painty, or fishy. The trend to greater use of soft margarines with higher proportions of liquid oil increases the risk of autoxidation, particularly when the oils used are high in unsaturated fatty acids. The addition of antioxidants is permitted to reduce this hazard. Photochemical oxidation of liquid oils has been shown to be greater at short wavelengths, with a maximum below 455 nm. As fluorescent light in supermarkets may transmit wavelengths between 350 and 750 nm, packaging impervious to low-wavelength light is highly recommended for maximum margarine flavor protection. Methods of Manufacture

R A Carr, Carr & Associates, Burlington, Ontario, Canada
M Vaisey-Genser, The University of Manitoba, Manitoba, Winnipeg, Canada

Background

Consumers have grown to appreciate the margarine products that spread easily at refrigerator temperatures and are enjoyed because of their flavor and texture. To understand the dynamics of the manufacture of these margarines, it is essential to appreciate the relationships between the processing effects, the specific physical properties of the products, and the composition of their oil blends and other components. A major factor in the formulation and control of margarine oils and margarine is the development of desirable solids-to-liquid ratios, achieved by hydrogenation and blending. The types of oils selected for margarine oil formulations are also important in obtaining a stable, uniform crystal structure from specific conditions for processing the oils, as well as the finished margarine products. As a result, margarines as semisolid plastic products in soft tub and wrapped stick forms have been designed to meet consumer demands for health and dietary benefits, as well as performance and convenience.

Physical Properties

A margarine structure is a network of small fat crystals, which acts as a matrix to contain trapped oil and water globules. The degree of finished product spreadability depends considerably upon the proportion and properties of the liquid oil and crystalline fat in the margarine oil component. Butter and stick margarines, for example, are brittle when cold from the refrigerator. They gradually become more spreadable as they approach room temperature, because some of the fat crystals melt as the margarine becomes warmer. Consumers desiring spreadability from the refrigerator may select soft tub margarines, which are designed with lower solids and higher liquid oil contents. Various combinations of hydrogenation, fractionation, interesterification, and blending of diverse oil types and solids contents allow the development of margarines with differing consistencies and properties. (*See* **Colloids and Emulsions**.)

Margarine consumers fall into two main classifications, each with specific quality requirements. The domestic cook requires a product for table use as well as baking and frying. The professional baker demands products that will give a consistent performance for cakes, icings, etc. For the home, a margarine must provide an enjoyable flavor that releases fully and quickly, must melt rapidly in the mouth leaving no gummy or gritty sensation, have sufficient body at room temperature to maintain its form, and must be easy to spread over a broad range of temperatures. Creamability, which is the ability to take up air when beaten, and plasticity are the key priorities required for satisfactory baking. For frying, the fat component must remain stable at high temperatures and contain virtually no free fatty acids, which create a smoking problem during drying.

The physical properties of various margarines depend primarily upon (1) the melting point of the oil component triglycerides, (2) the total solids content present at any given temperature, (3) the distribution of these solid fats over a broad temperature range, and (4) the polymorphic modification of crystal habit of the fat composition. Their combined response to temperature and work applied by external forces is the most characteristic. Margarine is designed to meet flavor, plasticity, and creamability requirements by combining a properly designed margarine basestock with an aqueous phase blend so that the water globules are finely dispersed, but combined loosely enough for the emulsion to break easily upon melting. The aqueous phase generally consists of reconstituted milk powder, brine, and water. Vitamins, coloring, and flavoring agents are included, and emulsifiers, such as monoglycerides and lecithin, are added to the oil phase. (*See* **Triglycerides**: Structures and Properties.)

Formulation

To ensure the development of a proper margarine emulsion prior to the crystallization process, two distinct phases, aqueous and oil, must be prepared individually, prior to blending (**Figure 1**). The composition of the phases is designed for the three basic types of margarines: (1) stick or regular margarine, (2) soft or tub margarine, and (3) diet or calorie-reduced margarine.

Diet margarines contain half as much margarine oil as the stick or tub margarines. Because of their higher water content, they are unsatisfactory for cooking purposes, but are used for spreading on bread by consumers interested in their lower energy content.

Aqueous Phase

The major component in the margarine aqueous phase is either sweet skim milk or water plus reconstituted skim milk powder, or even water without milk if required. Care is taken that the milk is properly pasteurized by rapid heating to 75 °C with sufficient contact time. If desired, cultured milk, which has had some of the lactose content converted to lactic acid, may be used to provide a distinct flavor and acidity to the milk.

Salt, or brine, is then added to the aqueous phase to accentuate the flavor, act as a microbial inhibitor, and reduce splattering during pan frying. Minor components in the aqueous phase include citric acid, ethylenediaminetetraacetic acid (EDTA) and a water-soluble dairy flavor. Citric acid reduces the pH of the liquid phase to approximately 5.3, to enhance the performance of the microbial inhibitor. EDTA acts as a chelating agent by tying up any metal ions picked up either in the equipment or from other components added to the aqueous phase. (*See* **Acids**: Natural Acids and Acidulants.)

Oil Phase

The main component in the oil phase is a margarine oil basestock specifically developed through the refining process to produce a final margarine with the appropriate flavor, keeping quality and melting characteristics necessary to produce a specific margarine with distinctive characteristics demanded by the consumer. Oil basestocks originate from crude oils such as soyabean, palm, corn, cottonseed, sunflower, canola, and rapeseed. Initial processing through refining and bleaching operations removes impurities from the oil. Refined–bleached oils can be modified

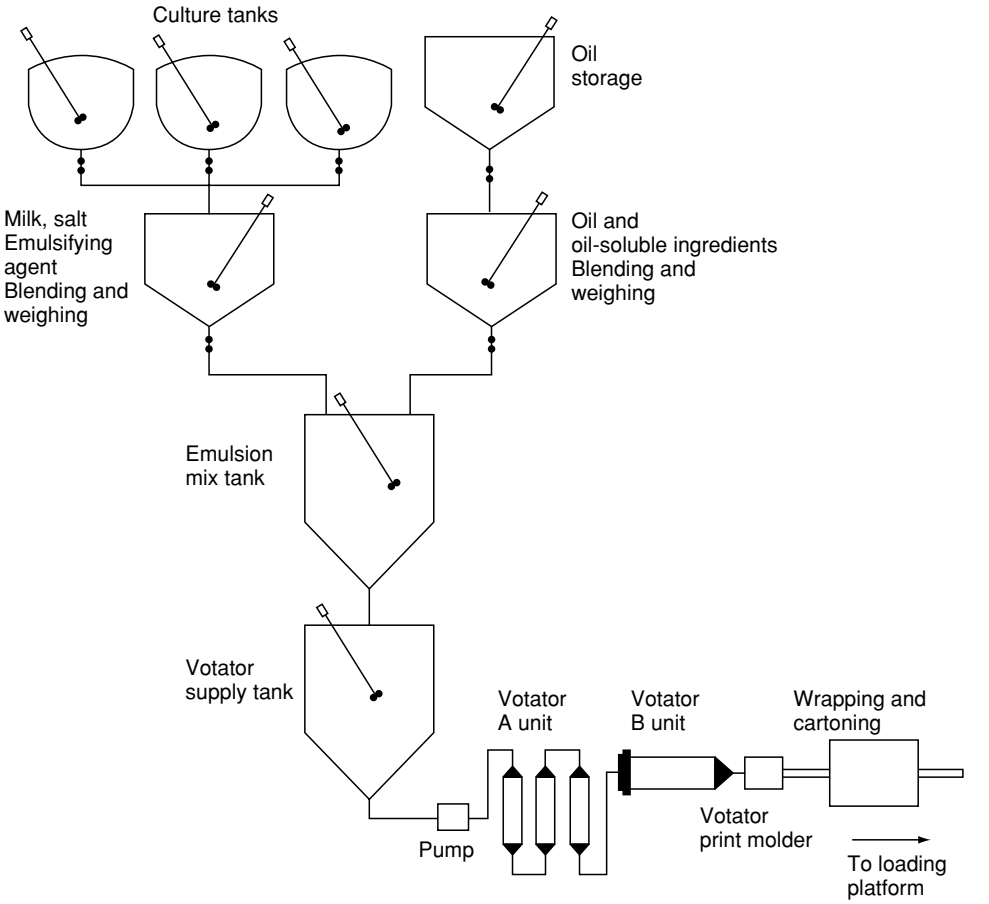

Figure 1 Simplified flow diagram for continuous margarine solidification. Courtesy of the Girdler Co. Reproduced from Margarine: Methods of Manufacture, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press, with permission.

by a hydrogenation process to alter their physical properties, such as melting characteristics and stability. Additional changes in the physical properties can be obtained by blending different oils and interesterification. (*See* **Ground Nut Oil**; **Palm Oil**; **Vegetable Oils**: Oil Production and Processing.)

Changes to the physical properties, or hardness, of a fat can be measured by melting points, dilatometry, and nuclear magnetic resonance (NMR). Dilatometry is based on the difference in specific volume for liquid and solid fats at a specific temperature. Dilatometric curves may be plotted for solid fat indices (SFIs) against the temperature of determination. NMR provides a different approach to the determination of solids in fats and their blends. The results are determined in absolute solids terms and are utilized to provide a relatively simple technique for determining SFI curves, which are somewhat comparable with the dilatometric method. (*See* **Spectroscopy**: Nuclear Magnetic Resonance.)

Most vegetable oils are mainly liquid at room temperature. Therefore, hydrogenation plays a key role in the preparation of basestocks with various SFI melting curves that can be blended for the preparation of margarine basestocks. Other techniques such as fractionation, interesterification, directed interesterification, and corandomization, are also available, but are normally used for specific situations related to oil availability and for products requiring a distinctive melting property, such as bakery margarines.

Liquid unsaturated oils have a relatively high number of double bonds, melt at low temperatures, are more unstable, and are likely to deteriorate over time in terms of odor and flavor. Treatment of the oil in hydrogenation convertors with a nickel catalyst at high temperature with violent agitation, in contact with a flow of tiny hydrogen bubbles, will insert hydrogen into some of the double bonds. Approximately 0.01% catalyst and 200 °C temperature are required for margarine oil basestocks. As the process proceeds, the melting point characteristics of the oil are increased. They are measured by a refractometer in the plant and confirmed precisely in the laboratory by dilatometric or NMR analyses. When the proper

end points are obtained, the oil in the convertor is cooled and then carefully filtered to remove all traces of catalyst.

Hydrogenation is the most flexible single process for producing margarine basestocks. Depending upon the operating conditions selected, the SFI curve can be steepened or flattened by adjustment of hydrogenation temperature, pressure, agitation, catalyst type, and catalyst concentration. For example, selective hydrogenation conditions using a high temperature and lower pressure are utilized to promote high *trans* fatty acid development with a minimum drop in iodine value, to produce steep solids curves. Recently, some nutritionists have expressed concern over the effect of *trans* fatty acids on health. If ultimately confirmed. Other techniques, such as enzymatic reactions, can be utilized to provide basestocks with steep melting curves and low *trans* fatty acid content.

Differing from shortenings, margarine oil blends are formulated to have a sufficient solids content at room temperature to perform as a stick margarine or tub margarine on the table, without slumping. At refrigerator temperature, the solid content should be kept at a minimum to ensure smooth, easy spreadability on bread when used directly from the refrigerator. In addition, margarines should melt very rapidly at body temperature (37 °C) to ensure a 'quick get away' in the mouth with minimum gumminess. This rapid melting characteristic is attained from the development of *trans* fatty acids during hydrogenation, which start to melt rapidly as the temperature is increased above about 25 °C. Opposite to the sharp melting curve required for a margarine, shortenings are formulated to produce flat melting curves, with very little change in solid content, from room temperature to temperatures well above body temperature. (*See* **Fatty Acids**: Properties.)

In addition to the solids content curve, a second important factor in margarine oil blends is their palmitic acid content ($C_{16:0}$), which has a definite effect on the crystal stability of the final margarine. Oil blends with insufficient palmitic acid content tend to revert from the β' crystal state to an undesirable β crystal state during storage of the packaged product. β' crystals produce both margarines and shortenings with a smooth uniform texture, because of the small size of the crystals, from 1 to 3 μm. However, β crystals are larger than 20 μm in size and produce obvious grainy texture and brittleness in margarines and shortenings. β crystal margarines are readily detected by the tongue as an undesirable gritty feel. Oils/fats that are β-tending include canola, cocoa butter, coconut, corn, lard, olive, palm kernel, peanut, safflower, sesame, soya bean and sunflower. β' Types are cotton seed, herring, milk fat, modified lard, palm and tallow. It is normal practice to blend approximately 5–15% of cotton seed or palm oil in margarine oil blends to minimize all possibilities of crystal conversion to the β form. Some margarine manufacturers use a larger number of different hardstock fractions also to minimize the possibilities of β crystal development. A crystal inhibitor such as sorbitan tristearate can add crystal stability insurance more effectively than diglycerides.

Final margarine oil blends are carefully formulated to produce the desired solids melting curve. For example, stick margarine solids contents are approximately 27% at 10 °C, 14.2% at 21.1 °C, and 2.5% at 33.3 °C. Soft or tub margarines, with improved spreadability characteristics, are approximately 13% (SFI) at 10 °C, 7% at 21.1 °C, and 2.3% at 33.3 °C. The stick margarine SFI profile provides sufficient solids at 10 °C to allow satisfactory parchment overwrapping during packaging, satisfactory spreadability at both room temperature and out of the refrigerator, plus a good 'get away' in the mouth. The margarine oil blend is then deodorized at about 250 °C under a vacuum of 6 mmHg for 40 min to remove flavor and odor components, prior to its use in the margarine oil phase.

The oil phase is made up separately from the aqueous phase. Sufficient oil is pumped into the blend tank to ensure that the final product will have an oil content of 80% in the final stick or tub margarine, or 40% for low-energy diet spreads. Approximately 0.2% lecithin is metered into the oil as an emulsifier and antispattering agent during pan frying. Food coloring and oil-soluble butter flavor (0.05% of each) are added, and vitamins A and D are included for nutritional purposes. Margarine flavor release can be affected by the 'tightness' of the final oil/aqueous emulsion. Tight emulsions reduce the flavor impact as compared with loose emulsions. Therefore, phase blending and crystallization practices need to be carefully controlled to ensure uniform flavor release characteristics. (*See* **Cholecalciferol**: Properties and Determination; **Colorants (Colourants)**: Properties and Determination of Natural Pigments; Properties and Determinants of Synthetic Pigments; **Emulsifiers**: Organic Emulsifiers; Uses in Processed Foods; **Retinol**: Properties and Determination.)

Crystallization

Immediately prior to the packaging of margarine, the liquid and oil phases are mixed together in a 1:4 ratio, with gentle agitation, and maintained at about 40 °C. The temperature is selected to develop a stable emulsion and to prevent any precrystallization, which would occur at temperatures below 37 °C. A

proper emulsion will have the water phase droplets finely dispersed in the oil phase, but loosely enough for the emulsion to break easily on melting.

Margarine emulsions can be made by either a batch or continuous system. The batch system has been used for many years and comprises an agitated, temperature-controlled mixing tank to receive the water and oil phases. After the batch has been mixed to form a stable emulsion at the required temperature, the emulsion is then pumped to a scraped-surface heat exchanger for supercooling. The batch system is usually used for operations required to produce many different types of margarines with production runs of relatively short duration.

In lieu of a mixing tank, the continuous system may use a three-headed proportioning pump to meter and mix the oil phase continuously and the water phase simultaneously in the proper proportions into an agitated, temperature-controlled holding tank and then directly to the scraped-surface heat exchanger. The continuous system is designed for plants that run large quantities of similar types of margarines over extended time periods.

A scraped-surface heat exchanger is a unit that adds heat or removes heat from a substance. In the margarine industry, it is used as a closed chilling machine that induces partial crystallization of the fat in the margarine emulsion, all taking place in stainless steel, externally refrigerated cylinders through which the fat is pumped continuously. The cylinders are equipped with fast-revolving scraper blades that work the fat to achieve efficient, even heat transfer to the total mass in the heat exchange tubes. The process, if desired, can be utilized to add air or gas to a margarine, for the production of whipped margarines. In the industry, the process is often called 'votation,' because the original units were produced by the Votator Division of the Chemetron Corporation, Louisville, Kentucky.

The objective of votation is to develop and seed β' crystals throughout the margarine, to ensure their progression to the dominant crystal form in the finished product. If successful, the margarine will then have a smooth textural feel on the tongue, as well as contributing to a smooth-spreading performance on bread. For long-term uniform production, attention must be paid to the sharpness of votator blades and the smooth condition of the chilling cylinders. For margarine, the votator should rapidly reduce the incoming emulsion temperature from about 40 to 7 °C. The votator, also called an 'A unit,' is designed for direct-expansion refrigerants such as ammonia, freon, and propane. Advantage is taken of its high rate of heat transfer due to 'surface boiling.' A considerable proportion of the liquid vaporizes upon contact with the heat-transfer tube, and the velocity of the gas carries a relatively high percentage of liquid ammonia back to the surge drop, thus assuring complete flooding of the heat-transfer surface at all times. As a result, a constant uniform chilling effect is achieved for margarine passing through the chilling cylinder.

The emulsion is worked through the chilling cylinder over a period of about 18 s. Supercooled product leaving the A unit is then pumped to the 'B unit' cylinder, which is considerably smaller in diameter and longer than the B unit used for shortenings. In addition, the margarine B unit is not agitated, so that solidification of the supercooled margarine emulsion takes place under almost static conditions. If desired for whipped margarine, air or preferably an inert gas such as nitrogen can be drawn into the emulsion at the suction side of the product pump in precise amounts regulated by flow meters as it is fed to the chilling unit.

Limiting the amount of work given to the product in the B unit (1) produces a product that is not too soft to be handled in automatic print forming and wrapping equipment, (2) prevents the aqueous phase from being dispersed in a too fine state of suspension, and (3) induces the growth of β' seed crystals from the supercooled mass. Agitation in the B unit would require a long 'dwell period' for the product to become firm enough for packaging. In addition, the resultant tight emulsion and incorrect crystal structure would delay melting of the product in the mouth, producing a waxy impression with the user. Tight emulsions also fail to yield the desirable milk and salt flavors before the product has been swallowed, and contribute to brittleness or hardness, which is reflected in the lack of spreadability at refrigerator temperatures. While the product is in the B unit, the temperature rises by approximately 5 °C, primarily due to the latent heat of crystallization. The supercooled mass solidifies as it is slowly forced through the B unit by the pressure of the feed pump.

After leaving the B unit, the finished stick margarine product is extruded in a rectangular form, shaped, and wrapped. For many print margarines, a combination of vegetable parchment paper and aluminum foil is often used to make a final print product in a unit such as the Benhil. Popular soft margarines are continuously packed in tubs usually made from polyvinylchloride. The filled product is then automatically packed into cases, sealed, and sent to a tempering room. Packaged margarines should be stored at 5–10 °C for 48 h before shipment from the warehouse. This will ensure that the desired β' crystals have sufficient time to multiply and reach a stable state.

Quality Assurance

During production, it is important to carry out an ongoing routine inspection of processing conditions and finished product. The former includes items such as the A unit outlet temperature, which must be frequently checked, adjusted, and recorded by the operator. Product evaluations are usually carried out by the quality control inspectors and laboratory technicians. (*See* **Quality Assurance and Quality Control.**)

Samples from the packing lines are taken every 15–30 min and checked for weight performance versus limits for each product type. Line samples are then checked for package quality, including: carton or container denting or crushing; dirt or oil spots; parchment wrap defects for stick margarine, such as poor folds of the parchment or foil; inadequate gluing of carton inflaps; improper placement of lable.

Packaging materials are then removed, and the product's external appearance is evaluated. Prints are sliced in two or three places for internal examination, and a cone can be cut out of the center of the tub products. The outer texture is checked for slack or overfill, sloshing, product adhering to the lid or wrap, blistered or grainy texture, discoloration, oil separation, dull sheen, etc. After cutting, the inner texture is checked for oil or water separation and streaked, grainy, vacillated, cheesy, or porous texture.

Margarines undergo sensory evaluation to detect any off-quality characteristics, such as lack of flavor, or oil off-flavors such as oxidized, rancid, faulty oil processing, sour, plastic, fruity, artificial, and aged characteristics. If required, quality-rating systems can be established with defect scores assigned by the importance of the defect for the product. For example, a 100-point scale could be used, with 10 points assigned to packaging and 30 points each for outer texture, inner texture, and flavour. The assigned defect points are then subtracted from 100. A grade below an arbitrary level such as 70 would indicate that the related product should be placed on hold for further evaluation and disposition. Composition and Analysis

M Vaisey-Genser, The University of Manitoba, Winnipeg, Manitoba, Canada

Introduction

Margarine is the earliest of the designed food staples. As such, it can be tailored to deliver nutritional and functional advantages in terms of fatty acid composition, the addition of essential micronutrients, spreadability, and performance as a bakery fat. Accurate methods are necessary to guide margarine design and to monitor the legitimacy of claims on margarine labels. This article will describe the required composition of margarine, provide examples of the fatty acid profiles of contemporary products, and comment on the methods for margarine analysis and quality control.

Margarine Composition

The margarine of each country is subject to local standards of identity and regulations, which normally complement the international standard of the Joint FAO/WHO Food Standards Programme as set by the Codex Alimentarius Commission. The existing standard for margarine as set in 1989 (CODEX STAN 32-1981, Rev. 1-1989) is currently under review. Ultimately, it is to be replaced by a general 'Standard for Fat Spreads and Blended Spreads,' a proposal being drafted to address reduced-fat as well as full-fat spreads. The goal is to assure food safety concurrent with the globalization of food trade. As of July 1999, the draft proposal was at Step 3 of what can be

an eight-step Codex approval process. In the interim, the 1989 standard for margarine prevails. The 'essential composition and quality factors' of margarine and its endorsed 'food additives' are set out in Sections 3 and 4, respectively, of the 1989 Codex Standard, as follows:

Essential Composition and Quality Factors

Raw materials (1) Edible fats and/or oils, or mixtures of these, whether or not they have been subjected to a process of modification; (2) water and/or milk and/or milk products.

Minimum fat content 80% m/m of the product.

Maximum water content 16% m/m of the product.

Additions The following substances may be added to margarine: (1) vitamins – vitamin A and its esters, vitamin D, vitamin E and its esters, other vitamins (maximum and minimum levels for vitamins A, D, and E and other vitamins should be laid down by national legislation in accordance with the needs of each individual country, including, where appropriate, the prohibition of the use of particular vitamins); (2) sodium chloride; (3) sugars; (4) suitable edible proteins. (*See* **Cholecalciferol**: Properties and Determination; **Retinol**: Properties and Determination; **Tocopherols**: Properties and Determination.)

Food Additives

Colors (1) β-carotene, 25 mg kg^{-1} (2) annatto extracts, 20 mg kg^{-1} calculated as total bixin or norbixin; (3) curcumin or turmeric, 5 mg kg^{-1} calculated as total curcumin; (4) β-apo-8′-carotenal, 25 mg kg^{-1}; (5) methyl and ethyl esters of β-apo-8′-carotenoic acid, 25 mg kg^{-1}. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments; Properties and Determinants of Synthetic Pigments.)

Flavors Natural flavors and their identical synthetic equivalents, except those that are known to represent a toxic hazard, and other synthetic flavors approved by the Codex Alimentarius Commission are permitted for the purpose of restoring natural flavors lost in processing or for the purpose of standardizing flavor, as long as the added flavor does not deceive or mislead the consumer by concealing damage or inferiority or by making the product appear to be of greater actual value. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Emulsifiers (1) Mono- and diacylglycerols of fatty acids (limited by good manufacturing practice (GMP)) (2) mono- and diacylglycerols of fatty acids esterified with the following fatty acids: acetic, acetyltartaric, citric, lactic, tartaric, and their sodium and calcium salts (10 g kg^{-1} maximum); (3) lecithins and components of commercial lecithin (limited by GMP); (4) polyglycerol esters of fatty acids (5 g kg^{-1} maximum); (5) 1,2 propylene glycol esters of fatty acids (20 g kg^{-1} maximum); (6) esters of fatty acids with polyalcohols other than glycerol: sorbitan monopalmitate, sorbitan monostearate, sorbitan tristearate (10 g kg^{-1} maximum); (7) sucrose esters of fatty acids (including sucroglycerols) (10 g kg^{-1} maximum). (*See* **Emulsifiers**: Organic Emulsifiers; Uses in Processed Foods.)

Preservatives Sorbic acid and its sodium, potassium, and calcium salts and benzoic acid and its sodium and potassium salts (1000 mg kg^{-1} maximum individually or in combination expressed as the acids). (*See* **Preservation of Food**.)

Antioxidants (1) Propyl gallate, 100 mg kg^{-1}; (2) butylated hydroxytoluene (BHT), 75 mg kg^{-1}; (3) butylated hydroxyanisole (BHA), 175 mg kg^{-1}; (4) any combination of propyl gallate, BHA, BHT, 200 mg kg^{-1}, but limits in 4.5.1–4.5.3 not to be exceeded; (5) natural and synthetic tocopherols, 500 mg kg^{-1}; (6) ascorbyl palmitate and (7) ascorbyl stearate, 500 mg kg^{-1} individually or in combination; (8) dilauryl thiopropionate, 200 mg kg^{-1}. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

Antioxidant Synergists (1) Citric acid (limited by GMP); (2) sodium citrate (limited by GMP); (3) isopropyl citrate mixture; (4) phosphoric acid and (5) monoacylglycerol citrate (the maximum for 3, 4, and 5 is 100 mg kg^{-1} individually or in combination).

Acidity Regulators (1) Citric acid and lactic acids and their sodium or potassium salts (GMP); (2) L-tartaric acid and its sodium and sodium/potassium salts (GMP).

Antifoaming agents Dimethylpolysiloxane (dimethyl silicone) singly or in combination with silicon dioxide, 10 mg kg^{-1}.

Vitamin Fortification

As a manufactured food staple that is reasonably homogeneous, margarine is a logical vehicle for fortification with essential fat-soluble vitamins. The addition of preformed vitamin A to margarine is mandatory in several countries including the UK, the USA, and Canada, where the levels specified are

similar. In Canada, not less than 1000 μg of retinol (3300 international units (IU) of vitamin A) per 100 g of margarine are required. This recognizes the necessity for the nutritional equivalence of margarine with butter in respect of dietary vitamin A. Whether or not the vitamin A potential of the carotenoids that may be added to margarine as colorants may be counted as a contribution to the mandatory level of fortification varies among countries.

Although the addition of vitamin A to milk has been known to cause floral and hay-like off-flavors due to photooxidation in the absence of light-proof packaging, no such problems have been reported for vitamin A-fortified margarines. The analytical variability in monitoring the amount of vitamin A present is typically 10–15%. (*See* **Food Fortification**.)

Vitamin D is added to margarine to prevent the deficiency of a nutrient, which is not naturally available in food and is essential to prevent rickets, particularly in climates that limit the exposure of the skin to sunshine. In Canada, it is mandatory to add vitamin D to margarine at a level that will assure not less than 13.25 μg (530 IU) per 100 g in the finished product. Like vitamin A, vitamin D added to margarine is relatively stable; however, the typical analytical variability in monitoring the amount present has been reported as in the order of 30%.

Canadian legislation permits the addition of vitamin E to margarine 'if added in an amount that results in not less than 0.6 mg (0.6 IU) of α-tocopherol per gram of linoleic acid present.' However, the permission has not been widely exercised. Tocopherol isomers, particularly γ and δ, may be added as antioxidants and confer some biological value, though less than the α isomer. The tocopherols occur naturally in vegetable oils but are subject to heat degradation. Table 1 illustrates the content of tocopherol isomers in some margarines on the US market in 1985. It may be noted that the ratio of α-tocopherol equivalents to C18:2 ω-6 is lower in the tub margarines than in the stick form due to the former's higher content of linoleic acid.

Table 1 Tocopherols and linoleic acid in some US margarines

Enrichment with Plant Sterols

Plant sterols, and their hydrogenated counterparts, stanols, have been shown to lower blood cholesterol, which is an advantage in reducing the risk of cardiovascular disease. This prompted the introduction in 1995 of a Finnish margarine (Benecol) enriched with a fat-soluble stanol ester (9%) followed in 1998 by a stanol-enriched low-fat spread (~40% fat). In 1999, the Unilever Research Centre in The Netherlands announced its introduction of a new 'heart-health spread' (Take Control/pro.activ) in both the USA and Europe. This is a reduced-fat spread with 8% plant sterols, so that regular consumption of 20 g per day of the spread would contribute about 1.6 g of plant sterols daily.

Lipid component The total fat in margarine is routinely controlled through metering according to formula specifications and may be monitored in inspection by standard methods. Of most interest, from the perspectives of function and nutrition, is the nature of the triacylglycerols (TAGs) that make up the oils and fats of a margarine basestock. Since each TAG molecule is made up of one molecule of glycerol and three fatty acids, the structure of the constituent fatty acids and their arrangement on the glycerol stem affect its physical properties. These features are dictated by the origin of the oils and fats used in margarine formulation and by their processing prior to blending. The lipid component of margarine is most frequently characterized by its fatty acid composition. Local crops often are dominant constituents such as canola and soybean oils in North American products.

Individual fatty acids, which consist of a carboxyl group and a hydrocarbon chain, are distinguished from one another by chain length and by degree of saturation with hydrogen. Shorter fatty acid chains and greater unsaturation (i.e., less hydrogen, therefore more double bonds) within a TAG mixture favor fluidity and *vice versa*. Unsaturation has the greater softening effect provided that the double bonds are in the natural or *cis* form. This geometric configuration causes the fatty acid chain to double back on itself, resulting in a bend that discourages the secondary association among adjacent molecules, which leads to hardening. Certain processing conditions, such as hydrogenation, convert the natural *cis* isomer to a straighter-chain *trans* isomer that favors hardening. (*See* **Fatty Acids**: Properties.)

Table 2 summarizes the fatty acid composition of some margarines on the Canadian and European Markets between 1995 and 1998. There were some distinct regional differences. Danish margarines had higher levels of saturated fatty acids than those from the United Kingdom and Canada reflecting differences in the sources of the fats and oils which made up their respective basestocks. Canadian spreads were significantly higher in *trans* fatty acids than their European counterparts, likely due to differences in the processing used for hardening.

The data on Canadian spreads shown in Table 2 are drawn from a study by Health Canada of 109 margarine brands (30 print and 79 tub), selected on the basis of their importance in the Canadian market share. The relative amounts (grams per 100 g of total fatty acids) of total *trans* fatty acids (TFA), *t*-18:1, *trans,cis/cis,-trans*-18:2 (*ct*-18:2), *trans,trans*-18:2 (*tt*-18:2), *trans*-18:3 (*t*-18:3), total saturated fatty acids (SFA), *c*-18:1 (all isomers), *cis*-18:2*n*-6 (linoleic acid) and *cis*-18:3*n*-3 (α-linolenic acid), were published in 1998. The trend over time is a positive decrease in TFA from a 'most frequent occurrence' of 30–35% in 1979–1983, 20–25% in 1990, to 15–20% in the 1995 margarines. These changes reflect advances in processing technology and increased use of liquid oil in blends with partially hydrogenated oils in margarine basestocks. However, Table 3 shows that Canadian margarines, like those of Austria and the USA, have average TFA levels substantially higher than those of several European countries and Australia. This is a nutritional disadvantage, considering that dietary TFAs, like saturated fatty acids, adversely affect blood lipid patterns, increasing the risk of cardiovascular disease.

Table 2 Fatty acid composition of some Canadian and European margarines (grams per 100 g of fatty acids)

Source/market form	Total saturates	Total trans	Unsaturates		
			C18:1	C18:2$^{\omega-6}$	C18:3$^{\omega-3}$

[a]As reported by Ratnayake WMN, Pelletier G, Hollywood R, Backer S and Leyte D (1998) *Trans* fatty acids in Canadian margarines: recent trends. *Journal of the American Oil Chemists Society* 75: 1587–1594.

Analytical methods for the fatty acid compositions shown in Table 2 varied among investigators. For the Canadian spreads, a 1 g central plug was taken for each of six samples of the same brand and homogenized. Rather than extract the fat, samples of about 200 mg of the homegenate were converted directly to methyl esters by treatment with 1.5 ml of NaOH in methanol at 100 °C for 5 min followed by mixing with 2 ml of 14% BF_3-methanol at 100 °C for 30 min. The fatty acid methyl esters were recovered with hexane and analyzed using an SP-2560 capillary column in a Hewlett Packard 5890 Series II gas chromatograph (GC) equipped with a HP GC Chemstation. The column oven temperature was held at 165 °C for 75 min, then programmed at 7 °C min^{-1} to a final temperature of 210 °C, which was held for 30 min. While this single-step GC analysis was suitable for samples with less than 5% *trans* 18:1, those with more required the additional step of total *trans* measurement by IR and appropriate corrections. Fatty acids of the UK margarine were analyzed by similar methods in the Netherlands. In the earlier Danish study, fatty acids were extracted from the margarine with isooctane following boiling with methanol and boron trifluoride. The temperature program and column for GC analyses were chosen to provide good separation between cis and trans C18:1. Certified reference materials were used by all

investigators. (*See* **Chromatography**: Thin-layer Chromatography; **Fatty Acids**: Analysis; **Spectroscopy**: Infrared and Raman.)

Hardening

The demand for table fats with the spreadable properties that characterize margarine could not be satisfied without the technology to convert liquid oil into a semisolid product. The two commercial processes used to achieve oil hardening are hydrogenation and interesterification. While hydrogenation is the more common process in North America, interesterification, or transesterification as it may be referred to, is widely used in parts of Europe. (*See* **Vegetable Oils**: Oil Production and Processing.)

The hydrogenation process adds hydrogen at the double bonds of unsaturated fatty acids under conditions of high temperature and high pressure in the presence of a suitable catalyst, usually nickel. As well as increasing the hydrogen content of the unsaturated fatty acids of TAGs, hydrogenation conditions favor a shift in the position of the double bonds along the fatty acid chain and/or a change in geometry to a straighter-chain *trans* form. The *trans* isomers of unsaturates, depending on their frequency, can account substantially for the hardening that results from hydrogenation. However, hydrogenation is a flexible process that may be more or less selective in its effects. By using higher temperatures with lower pressure (e.g., 200 °C, 6 psig) the polyunsaturates are selectively hydrogenated before the monounsaturates but, at the same time, isomerization is encouraged. In contrast, more random hydrogenation occurs under nonselective conditions, which use lower temperatures and higher pressures (e.g., 135 °C, 60 psig), resulting in more saturates and fewer *trans* isomers.

A comparison of the fatty acid profiles in Table 2 for the print and tub forms of Canadian spreads from similar oil sources illustrates the influence of saturates and total *trans* unsaturates on margarine firmness. As the content of total saturates was similar in the two market forms, the greater firmness of the print margarines must be attributed to their higher content of *trans* unsaturates. Because of their novel configuration, *trans* unsaturates cannot be expected to have the unique biological properties of their original *cis* form. For this reason, *trans* fatty acid values are not included in the values for monounsaturated and polyunsaturated fatty acids cited on food labels in North America, although they are included in the total fat values. (*See* **Vegetable Oils**: Composition and Analysis.)

Hardening by interesterification commonly involves combining highly saturated fats and unsaturated oils with a catalyst precursor such as sodium methoxide, alkali metals, or alkyl metal alkylates (about 0.1%) at temperatures ranging from 5 to 135 °C. Hardening depends upon the concentration of saturates because *trans* isomerization does not occur under these relatively mild processing conditions. It is likely that the low level of TFAs shown in Table 2 for the UK spread reflects processing by interesterification. Margarines made by this process have the further advantage of crystal stability. Interesterification conditions cause the fatty acids to trade places within and among the TAGs. As a result of these rearrangements, new and more random TAGs are formed that are less inclined to undergo the degree of TAG packing, which leads to large crystals. Accordingly, interesterification fosters the development of the stable fine β^1 crystals that are desirable for margarine smoothness.

Quality-control procedures

The control of quality in margarines begins with ingredient selection and continues with the monitoring of microbiological and engineering processing conditions, including packaging. The finished product quality is assessed from the packing line for compliance with in-house standards, regulatory requirements, labeling claims, and, where appropriate, trade standards. (*See* **Quality Assurance and Quality Control**.)

Margarine sheen and color are usually judged visually by comparison with a series of color standards using either the Lovibond Tintometer or sets of plastic or enamelled sticks arranged in color gradations from light to dark. Alternatively, the three color dimensions of hue, value, and chroma, may be described by visual comparison with chips in the matte or glossy edition of the '*Munsell Book of Colors*.' In this instance, hue is the color identity, value the lightness or brightness, and chroma the vividness or saturation. The American Society for Testing and Materials has published standards to guide such evaluations. It is important that inspectors who do these assessments be screened for normal color vision, be adapted to daylight and examine the samples when they are illuminated by a controlled source against a gray to white background.

The physical properties of firmness and spreadability are most commonly monitored by the solid fat content (SFC) at temperatures of 10, 21.1, and 33.3 °C, using low-resolution nuclear magnetic resonance under protocols defined by the International Union of Pure and Applied Chemistry (IUPAC). The IUPAC method for SFC provides a convenient and more accurate alternative to the traditional dilatometric determination of the solid fat index. Nuclear magnetic resonance provides the advantage

of accurate SFC readings on margarine 'as processed.' Recent studies have been aimed at relating the macroscopic rheological properties of fat crystal networks to the various levels of structure within the network. This involves not only the TAG structures and the polymorphic and polytypic levels of structure but also the morphology and spatial distribution of the microstructure. For example, fractal scaling theory appears promising to relate spatial distribution within the fat crystal network to the mechanical property of shear elastic modulus.

Sensory properties of spreadability, graininess, flavor release rate, and flavor blend call for analysis by sensory panels that have been trained to recognize typical margarine characteristics and defects as opposed to naïve consumer panels. References that could be useful in training for margarine assessment can be adapted from some of those developed for judging oxidized and sour flavor defects in butter, and for rancid and fruity off-flavors in cheese. It is critical that the preparation and presentation of margarine samples be well controlled to limit changes due to physical handling and temperature. Sampling the spread as cubes, balls, or cylindrical cores is less disruptive to texture than loading it into a container. Temperature changes may be minimized by the use of polystyrene foam blocks as sample holders. (*See* **Sensory Evaluation:** Sensory Characteristics of Human Foods.)

Chemical measurements to control margarine quality normally require monitoring of vitamin additions and fatty acid analyses, depending on the intended label claims. In Canada, '... no statements or representations are permitted for any individual fatty acid other than linoleic acid or for any group of fatty acids other than polyunsaturates, monounsaturates, or saturates. If a statement or claim for linoleic acid is made, a declaration of total fat, the above-mentioned group of fatty acids, and cholesterol is required in addition...' The amounts of these fat components present in a 10 g (two teaspoon) serving must be cited. Currently, negotiations are underway to harmonize North American nutrition recommendations as well as the information that is required and permitted on food labels.

Dietary Importance

D H Morris, Mainstream Nutrition, Toronto, Ontario, Canada
M Vaisey-Genser, University of Manitoba, Winnipeg, Manitoba, Canada

Historical Background

Emperor Napoleon III prompted the invention of margarine in 1869 by calling for a cheap alternate to butter to feed his armies as they marched across Europe. A French chemist, Hippolyte Mège Mouriès, responded with a formula in which an extract from beef tallow

replaced butterfat. Between 1871 and 1874, Mège Mouriès sold his patent to Dutch, British, US, and Prussian companies. Present-day companies based in The Netherlands continue to be world leaders in margarine design and production. This article considers the importance of margarine in the diet from the perspective of its economic, sensory, and nutritional characteristics. In recent years, margarine has emerged as an important functional food. Although both standard butter and margarine are 80%-fat products and hence high in energy, margarine, being a formulated food, can be designed to have nutritional and sensory features that differ from its prototype.

Economic Issues

Price

Margarine is now accepted as a food staple in most countries where table-spread use is habitual. Initially margarine's advantage over butter was chiefly one of price. By the beginning of the twenty-first century, margarines had become available within a range of prices, from lower-cost 'regular' brick- or stick-type products to higher-cost soft 'tub' margarines that could claim a nutritional advantage based on fatty acid composition. This versatility is illustrated in Table 1, which lists the prices of several margarines available in a Canadian superstore in October 2000, together with a summary of the nutrition information presented on the package. The price of Becel margarine, which qualified for the most detailed label claim, was comparable to that of butter. The generic brick margarine was the least expensive, being about a third of the price of butter. Accordingly, consumers may reduce food costs by purchasing their spreads primarily on the basis of price. The irony of the price-based choice among Canadian margarines is that it favors the health prospects of the more affluent. Lower-income consumers, who as a group might have less nutrition knowledge, would be expected to choose the cheaper product. The cost to their families is to miss the opportunity of establishing a healthier eating pattern.

However, economic considerations by the thrifty may explain why a 1982 survey of over 500 western Canadians indicated that margarine was the most commonly used fat for home-baking products such as cookies and cakes. Consumer interest in using margarine as an alternate to shortening is recognized in parts of Europe (e.g., in Switzerland) where 100%-fat 'margarines' are available in grocery stores.

Patterns of Use

North American table-spread consumption patterns, shown in Figure 1, indicate that margarine use in Canada increased to match that of butter by 1975 and has exceeded it ever since. In the USA, the dominance of margarine began more than a decade earlier, following the passage of the Margarine Act enacted by President Truman in 1950 to lift restrictive taxes and laws on margarine production and sales. Concurrent with the increased dominance of margarine, the consumption of table spreads in total has shown a steady decline in both North American countries. This is likely a response to promotional campaigns of health authorities to reduce fat intake in the interest of decreasing the risks of obesity and cardiovascular disease.

Sensory Characteristics

From the sensory perspective, the presence of fat helps make food taste good – smoother, creamier, richer, and more tender. This is so whether the fat is a structural ingredient as in meat or an avocado, as an ingredient in sauces or baked goods, or as a spread on toast or in sandwiches. Consumers surveyed in

Table 1 Examples of table-spread prices (Canada, October, 2000)

Brand	*Market form*	*Price of a 1-lb (0.45 kg) container (Cdn $)*	*Label claim*
Margarine			
Generic	Brick	$1.09	% RDI for vitamins A, D
Generic	Soft	$1.49	% RDI for vitamins A, D; amount of calories, saturated, monounsaturated, and polyunsaturated fatty acids in 10 g (2 tbsp)
Supermarket brand	Soft	$1.69	% RDI for vitamins A, D
Imperial	Soft	$2.29	% RDI for vitamins A, D
Becel	Soft	$2.89	% RDI for vitamins A, D, E; 0 *trans* fatty acids; amount of cholesterol, saturated, monounsaturated and polyunsaturated fatty acids in 10 g (2 tsp); low in saturated fat, nonhydrogenated
Butter			
Supermarket brand	Brick	$2.99	
Beatrice	Brick	$3.99	

RDI, recommended daily intake.

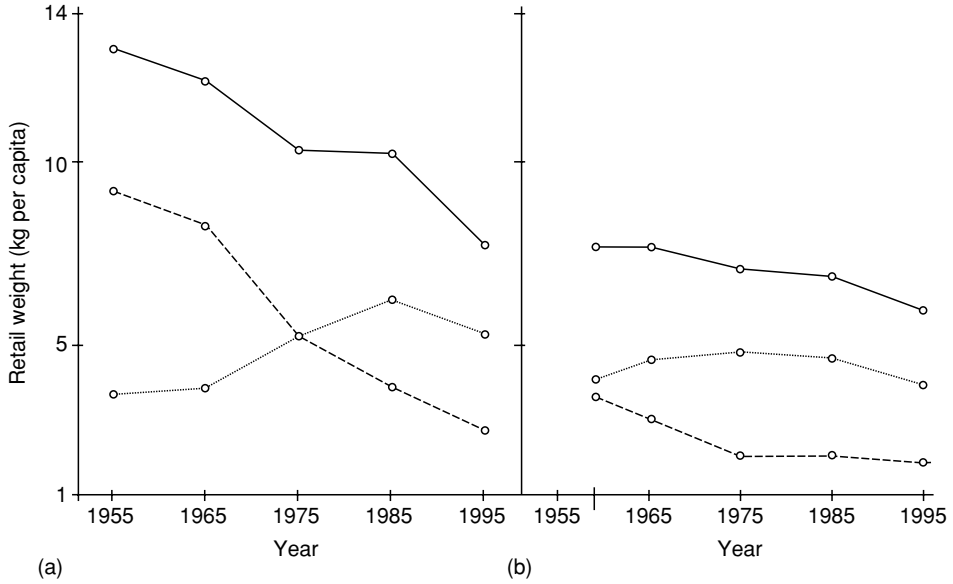

Figure 1 North American patterns of table-spread consumption. (a) Canada; (b) USA. Continuous line, total butter and margarine; dotted line, margarine; dashed line, butter. Data sources: Anonymous (1977) Margarine US per capita consumption may fall this year. *Journal of the American Oil Chemists Society* 54: 840A–841A; Statistics Canada (1998) 32–230-XB; US Department of Agriculture (1966–1998), *Oil Crops Situation and Outlook*, Washington, DC: USDA.

Canada between 1989 and 1997 cited taste as the primary reason for choosing a particular food, one which they were reluctant to forgo, even though 44% agreed that people should be cautious when serving food with fat. Similarly, in a survey of the dietary practices of some 200 aboriginal adults in the northern USA published in 1999, 'taste' was the most frequently mentioned barrier to cutting the intake of high-fat foods. In these cases the term 'taste' apparently was synonymous with how much the respondents liked the food; that is, it expressed their hedonic response to the overall sensory character of the food.

With respect to margarine, experienced sensory consultants, who were enlisted by *Consumer Reports* in 1982 to evaluate 17 different US margarines, described an excellent margarine as one with 'a pale yellow color, a slight hint of dairy flavor and aroma, an appropriate texture for its type, melts readily in the mouth, and has no more than a hint of the parent oil's flavor or aroma.' A later study of US consumer opinion of margarine attributes judged 'good taste' and 'good texture' as the most important features. In this instance, taste might have been more appropriately termed flavor, which embodies both tastes and odors.

Texture

Textural characteristics of margarines include firmness, spreadability, smoothness, and mouthmelt. With each of these, it is critical that the temperature of the margarine samples be rigorously controlled before and during testing. Of the four textural parameters cited above, firmness is the quality that best lends itself to measurement with standard laboratory instruments. For example, 'resistance to shear' can be measured physically with an Instron or other shearing device. What is measured is either the force required to obtain a given deformation or the deformation achieved under a given force. Such instrumental readings can be related to sensory estimates of firmness by the hand pressure required to cut with a knife, again provided that there is strict temperature control of the sample and related implements.

Spreadability represents the ease with which a spread can be applied in a thin, even layer to a controlled surface such as a slice of bread. It is a complex sensory characteristic reflecting the relative amount of solid fat present together with its crystalline structure. For a product to be spreadable, it must be plastic or moldable at the temperature of use, which will normally be between 4 and 22 °C. Fat plasticity depends upon the triacylglycerols involved in the margarine formula and the fineness of the fat crystal matrix which accounts for its structure. The advantage of margarine is that it 'worksoftens' more easily than butter does, even when their initial hardness values are equal. That is why margarines can be spreadable when taken directly from the refrigerator, whereas butter cannot. Easy spreading has a greater advantage than simply the work involved. The thinner layer of spread achievable with margarine contributes to the public health goal in developed countries to decrease fat intake.

Smoothness to the tongue is expected of a good table spread. It reflects a structure of crystals that are small enough to be imperceptible in the mouth, a size that has been estimated to be in the order of 22 μ through controlled storage studies where crystal size was measured under a polarized light microscope and related to sensory tests of smoothness. Margarines with larger crystals or clusters of smaller ones packed together will be perceived as the defect of sandiness or graininess.

Mouthmelt sensation from a table spread is important to both its texture and release of flavor. Margarines will be criticized as waxy or gummy if they fail to melt rapidly and completely in the mouth. Prompt melting has another advantage; it generates a pleasant cooling effect due to absorption of heat of crystallization. Sensory testing using stopwatches has confirmed that butter melts in the mouth faster than the same amount of margarine does, but the degree of temperature change realized in the mouth has not yet been published.

Flavor

Flavor is a combined sensory response by receptors in the mouth and nose to taste and odor stimuli. It is a sensation complicated by individual variations in dentition, breathing rate, and salivary flow.

Of the four basic tastes – sweet, salty, sour, and bitter – saltiness is the most relevant to table spreads, and then only where the use of salted spreads is the norm. In the latter case, salt is added for its value as a preservative as well as for taste, and even then at relatively low levels, usually 1–3%. The high fat content of standard table spreads appears to mask saltiness perception. Sensory tests of butter prepared with a range of salt levels showed that salt intensity in the spread was only one-tenth the magnitude of the same concentrations in water, although the growth of the salty sensation over increasing concentration was similar in both media. Apparently the oil in which the salt/water solution is suspended limited the intensity of salt perception. The eight-member trained panel used in this experiment considered that a level of 1% salt in butter was the most pleasant of eight concentrations ranging from 0.5 to 4.0%.

Odor perception as well as taste can be affected by the composition of the dispersion medium. For example, experimental margarines, containing diacetyl and other dairy flavors dispersed in a lipid mixture of soybean oil melted and recrystallized with either palm stearin or palm olein, differed in perceived flavor intensity. Although the time for flavor intensity to peak for both spreads was similar, total flavor was significantly greater in the spread containing the faster-melting palm olein. Head-space measurement of diacetyl confirmed the results of sensory tests.

Gas chromatography combined with mass spectrophotometry has been used since the 1950s to document volatile compounds in foods using techniques of simultaneous distillation extraction. However, identifying which volatiles in margarine and other foods are crucial to perceived flavor continues to be hampered by several factors. These include the number of compounds released at mouth temperature, the partitioning of flavor compounds between the oil and water phases and between the aqueous phase in the mouth and the gas phase in the nose, and the complexity of their odor impact. Novel tools such as neural networks used with the results of increasingly sophisticated methods for sample head space and oral breath analysis appear promising.

Popular opinion is that butter, in comparison with margarine, still has the better 'buttery' flavor according to studies conducted during the latter part of the 1980s and 1990s in both North America and Europe. Where this is so, it may be a function of the physical characteristics of the margarine emulsion. It has been speculated that 'if the aqueous droplets are uniformly small and heavily stabilized with emulsifiers, the flavor... release will be delayed.'

Nutritional Aspects

Margarine use increased in the 1970s and 1980s when scientists determined that a diet high in fat, especially saturated fat, increased blood levels of low-density lipoprotein (LDL) cholesterol – the so-called 'bad' cholesterol – and decreased blood levels of high-density lipoprotein (HDL) cholesterol – the 'good' cholesterol. High blood levels of total and LDL cholesterol are risk factors for coronary heart disease (CHD). The margarine industry responded to the consumers' demand for 'heart-healthy' food products by formulating margarines that were lower in total fat, saturated fat, and *trans* fatty acids. In some countries, margarine is also a source of one or more essential fat-soluble vitamins.

Vitamin Enrichment

Margarine is a convenient vehicle for the addition of the fat-soluble vitamins A and D. The international standard for margarine issued by the Codex Alimentarius Commission of the Food and Agricultural Organization (FAO) in Rome recommends their addition. In Canada and the UK, the addition of vitamins A and D is mandatory. In the USA, the addition of vitamin A is mandatory, while the addition of vitamin D is optional. Such enrichment gives margarine the edge over butter, in which the vitamin A content varies with the diet of the dairy cow and vitamin D is essentially absent. Vitamin D, which assists in the

absorption of calcium, is naturally produced from the sun's activation of precursors in the skin. However, in cold climates where skin exposure to the sun is precluded by outerwear for many months of the year, foods fortified with vitamin D, including margarines, are an important public health measure.

The addition of vitamin E to margarine is permitted in Canada, if added in an amount that results in not less than 0.6 IU of α-tocopherol per gram of linoleic acid present. However, most Canadian margarine manufacturers do not exercise this option. Fortification of margarine with vitamin E is not permitted in the USA, although tocopherols may be added as antioxidants.

Total Fat, Saturated Fat, and Cholesterol

Dietary patterns low in total fat, saturated fat, and cholesterol are recommended to maintain a healthy weight and reduce CHD risk. Margarine, which contains no cholesterol and is low in saturated fat, is perceived as a healthy alternative to butter. The compositional differences among various margarine products and butter are shown in Table 2. Standard butter and standard margarine both provide the same amount of energy (about 425 kJ or 101 kcal per tbsp or 15-g serving) and fat (11–12 g per tbsp or 15-g serving); reduced-fat margarines provide about half the energy and fat per serving as regular margarine. Butter is a source of dietary cholesterol, whereas margarine is not.

Diets low in saturated fat are considered desirable because saturated fat is the main dietary determinant of blood LDL cholesterol concentrations. Diets providing less than 10% of energy as saturated fat are recommended for the general population; individuals with diagnosed cardiovascular disease and elevated blood LDL cholesterol levels are advised to consume a diet containing less than 7% saturated fats. For an adult consuming 8372 kJ or 2000 kcal day^{-1}, these recommendations amount to a daily intake of only 16 or 22 g of saturated fat from all dietary sources.

One tbsp (15 g) of butter provides about 7.2 g of saturated fat, whereas 1 tbsp (15 g) of hard, brick margarine provides about 2.1 g – a saving of about 5 g day^{-1} of the recommended saturated fat allowance. Soft tub margarines, reduced-fat margarines, and liquid margarines, which are generally recommended over butter and brick margarines, all provide less than 2 g saturated fat per tbsp, allowing for an even greater reduction in saturated fat intake. Thus, substituting soft and liquid margarines for butter and other saturated fats in the daily dietary pattern helps reduce the saturated fat intake but not necessarily the total fat intake.

Trans Fatty Acids

Trans fatty acids are found naturally in butter, milk, beef, and lamb fats and in commercially prepared, partially hydrogenated margarines and solid cooking fats like shortenings. *Trans* fatty acids are produced in the margarine manufacturing process when liquid vegetable oils are hydrogenated to form a semisolid or solid fat with many of the same properties as animal fats and, in some cases, to increase the oxidative and thermal stability of the fat or oil. Indeed, partially hydrogenated vegetable oils were developed in part to take the place of highly saturated animal fats used in spreads and for frying and baking.

During the hydrogenation process, some of the naturally occurring *cis* double bonds in the vegetable oil fatty acids are changed to *trans* double bonds, so that the resulting *trans* fatty acids resemble saturated fats more than unsaturated fats. In Canada, nearly 70% of the vegetable oils consumed by humans are partially hydrogenated.

Table 2 Fatty acid composition of butter and margarines (serving size = 1 tbsp)

Product	*Energy*		*Cholesterol (mg)*	*Total fat (g)*	*Saturated fatty acids (g)*	*Monounsaturated fatty acids (g)*	*Polyunsaturated fatty acids (g)*	Trans *fatty acids (g)*
	kJ	*kcal*						
Butter	426	102	31.1	12	7.2	3.3	0.4	0.3
Margarine, regular, hard, corn and soybean oils	423	101	0.0	11	2.1	5.2	3.5	1.9
Margarine, soft, soybean (hydrogenated and regular)	423	101	0.0	11	1.9	5.1	3.8	0.8
Margarine-like spread (40% fat), soybean (hydrogenated)	208	50	0.0	6	0.9	2.4	2.0	0–2.5
Liquid margarine	428	102	0.0	11	1.9	4.0	5.1	0

One tablespoon = 3 teaspoons or about 15 g. Values for saturated, monounsaturated, and polyunsaturated fatty acids were obtained from the US Department of Agriculture, Agriculture Research Service, USDA Nutrient Database for Standard Reference, Release 13 (1999), Nutrient Data Laboratory Home Page at www.nal.usda.gov/fnic/foodcomp. Values for *trans* fatty acids for all products except liquid margarine were obtained from Jonnalagadda SS, Mustad VA, Champagne C and Kris-Etherton PM (1995) Margarine and plasma cholesterol – a perspective for dietitions on *trans* fatty acids in the diet. *Perspectives in Applied Nutrition* 2: 9–16. The value for *trans* fatty acids in liquid margarine was obtained from the National Association of Margarine Manufacturers (1999), available at www.margarine.org.

The US Department of Agriculture has estimated that biohydrogenation in ruminants accounts for up to 20% of the *trans* fatty acids in the US diet, with the remaining 80% being derived from food products formulated with partially hydrogenated fats like margarine, shortening, shortened baked goods (cake, cookies, pastry) and deep-fried snacks (corn and potato chips, French fries, doughnuts, extruded products). In the USA, the average per capita intake of *trans* fatty acids has been estimated at about 12.5 g day^{-1} or between about 5 and 8% of the total fat in the diet. In Canada, hydrogenated margarine is the main source of *trans* fatty acids, but other foods, particularly cookies, crackers, doughnuts, potato chips, and French fries, also contribute substantially to *trans* fatty acid intake because they are made with hydrogenated shortening.

The primary concern about *trans* fatty acids in the diet is their adverse effects on blood lipids. The results of clinical trials indicate that moderate and high levels of dietary *trans* fatty acids raise blood total and LDL cholesterol; their effect on blood HDL cholesterol concentrations has been variable. Several comprehensive reviews of the literature report an emerging consensus: when substituted for polyunsaturated fats in the diet, *trans* fatty acids tend to act like saturated fatty acids in their effects on blood lipids and thus are likely to increase the risk of CHD. However, when substituted for animal fats and vegetable oils high in saturated fats, *trans* fatty acids have been shown to lower blood total and LDL cholesterol concentrations. Because *trans* fatty acids are typically found in high-fat foods, a prudent approach to reducing CHD risk is to reduce total fat intake in general and saturated fat intake in particular. By choosing foods low in fat and saturated fat, consumers will also reduce their *trans* fatty acid intake.

Plant Sterols and Stanols

It has been known since the 1950s that plant sterols lower blood cholesterol levels. Plant sterols are analogs of cholesterol, differing structurally from cholesterol in their side-chain configuration. Sitosterol, campesterol and stigmasterol are the most important plant sterols from a nutritional standpoint and comprise up to 98% of the total sterols in certain seed and vegetable oils. Plant sterols can be hydrogenated to form plant stanol esters (e.g., sitostanol, campestanol, stigmastanol), a process that improves their solubility in margarine.

In studies conducted in the 1980s and 1990s, margarine was chosen as the vehicle for supplementing the diet with plant sterols because it is widely consumed and easily incorporated into usual dietary patterns. Recent studies show that daily consumption of a margarine enriched with 1–3 g plant sterols or plant stanols is sufficient to lower blood total cholesterol levels by 10% and LDL cholesterol levels by 10–15%. Blood concentrations of HDL cholesterol and triacylglycerols are not affected by plant sterol or plant stanol esters. Consumption of more than about 3 g plant stanol esters per day does not appear to increase its effectiveness.

The strength of these findings led the US Food and Drug Administration to authorize a claim on food labels and in food labeling that plant sterol/stanol esters reduce risk of CHD. The health claim, which became effective in September 2000, was designed to inform the general public that plant sterol/stanol esters should be consumed as part of a diet low in saturated fat and cholesterol. This followed the lead of some European countries, where plant sterol/stanol-enriched margarines were already available. The Raisio Group in Finland, for example, introduced Benecol in 1995; the multinational company Unilever/Lipton introduced a similar product, Take Control, into the US market in 1999.

One potential threat to the widespread adoption of margarines enriched with plant sterols and stanols is the reported adverse effect of these compounds on the absorption of nutrients such as fat-soluble vitamins and carotenoids. In some studies, consumption of about 1–3 g plant sterols daily for 3.5 weeks resulted in 20% reductions in plasma α- and β-carotene, lycopene, and α-tocopherol concentrations. It remains to be determined whether this adverse effect is clinically significant and whether plant sterol- or stanol-enriched margarines should or could be modified to compensate for the effect.

Emerging Health Issues

Although margarine consumption appears to benefit patients with hypercholesterolemia, who are advised to reduce their dietary intake of saturated fat and cholesterol, and may help the general public achieve healthy dietary patterns to reduce the risk of CHD, questions about a possible link between margarine consumption and risk of certain types of cancer have begun to emerge. For example, in a study of 472 women diagnosed with early-stage breast cancer in 1982–84, the reported baseline total consumption of butter, margarine, and lard (measured as times per day) was associated with an increased risk of recurrence of the cancer. Consumption of butter, margarine, and lard appeared to increase the risk of recurrence by 30% for each time they were consumed per day. Unfortunately, the study analysis did not attempt to separate the effects of margarine from butter and lard. In a study of 320 men with

histologically confirmed prostate cancer and 246 men without prostate cancer or a history of the disease, added lipids such as butter on bread, butter for cooking, margarine on bread and for cooking, and seed oils were positively associated with increased risk of prostate cancer. When adjustments were made in the statistical analysis for other food groups, butter, margarine, and seed oils were all positively associated with prostate cancer risk, although the effect was only significant for seed oils.

These findings are suggestive but far from conclusive. Both breast and prostate cancer are hormone-sensitive cancers, meaning that in the early stages of tumor development, tumor growth is influenced by the sex hormones. Thus, hormonal status and lifetime exposure to phytoestrogens (plant compounds that exhibit weak hormone-like activity in the human body) are confounding factors in these studies. Other factors such as family history, age, and diet, particularly the intake of total fat, animal fat, polyunsaturated fatty acids, vitamins, and antioxidants, are known to influence cancer processes. Indeed, the type of dietary pattern adopted over the course of a lifetime appears to be an indicator of cancer risk. Western-type diets high in fat, red meat, protein, fast food, refined grains and sugar, and low in fruits and vegetables are linked with increased risk of cancer, while so-called prudent diets high in fruits, vegetables, and whole-grain cereals and low in fat are associated with low cancer risk. For colon cancer risk, consumers who substitute margarine for butter, whole grains for refined grains, low-fat dairy products for high-fat dairy products, and poultry for red meat have a lower risk than those who eat a typical western diet. In the final analysis, dietary fats have significant effects on cancer processes through their biologic roles in regulating cell growth and immune responses, and a prudent approach to reducing cancer risk is to reduce intake of all fats.

Role of Margarine in the Diet

Margarine is recognized by health professionals and consumers alike as a healthy table spread and a cheaper alternative to butter for use in cooking and in food preparation. Margarine makes an important nutritional contribution to the diet by being a source of one or more essential fat-soluble vitamins such as vitamins A and/or D and by being low in saturated fat. Margarine is cholesterol-free. Newer margarine products are also low in *trans* fatty acids and in some cases are reduced in fat and energy. Some margarines can also be classified as a functional food, because they are enriched with plant sterol or stanol esters that have been shown to lower blood cholesterol levels. Its price, taste, spreadability, and convenience have made margarine a dietary staple in many countries around the world.

Production and Uses of Marine Algae

P A Cordero, Jr., Sultan Qaboos University, Al-Khod, Omen

Background

The introduction and subsequent improvement of mariculture (i.e., managed cultivation for farming of seaweeds) techniques explains the increased production of certain useful green, brown, and red seaweed species. However, the commercial production of seaweeds greatly depends on the demand for certain products and on the pre- and postharvesting and processing costs. The international market obtains its supply of seaweed materials both from natural vegetation and from sites cultivated by humans.

In addition to consuming seaweeds directly as food, humans have found far-reaching uses for its extracts as food additives and as raw materials for making various household products and other biomedical items.

Species of Importance as Food

Edible seaweeds, or sea vegetables, are mainly composed of green (Chlorophyta), brown (Phaeophyta) and red (Rhodophyta) algae. The predominance of pigments manifested externally has been the basis for their conventional classification. However, in the case of the red alga, e.g., *Eucheuma* growing in the shallower intertidal zone, overlying green coloration is visible owing to the destruction of the characteristic red pigment, phycoerythrin.

Some sea vegetables simulate the gross morphology of terrestrial plants in having leaf-like, stem-like, and root-like parts. The latter part, however, is mainly for anchorage, while the functions of nutrition extraction and the assimilation and conversion of inorganic substances into organic ones are performed by the leaf-like fronds or blades.

The species composition of seaweeds eaten as food varies according to the consumer groups. Thus, the orientals such as the Chinese, Japanese, Malays, and Filipinos include the following species among the common sea vegetables: the green algae, *Enteromorpha*, *Ulva*, *Monostroma*, *Codium*, and *Caulerpa*; the brown algae, *Hydroclathrus*, *Hizikia*, *Cladosiphon*, *Sargassum*, and *Laminaria*; and the red algae, *Porphyra*, *Gelidiella*, *Gracilaria*, *Halymenia*, *Hypnea*, and *Laurencia*. Popular among the occidentals are the green alga, *Ulva*, the brown algae, *Macrocystis*, *Ascophyllum*, *Laminaria*, and *Undaria*, and the red algae, *Porphyra*, *Gelidium*, *Palmaria palmata* (*Rhodymenia palmata*), and *Chondrus crispus*.

In an attempt to popularize the eating of sea vegetables, several seaweed recipes were developed, catering to the South-east Asian cuisine. Of the 80 sea vegetable recipes developed by Cordero and his research team, 63 proved to be acceptable to selected food tasters using the Hedonic Rating Scale, a measurement to determine the acceptability of food, in which a rating of 9 means highly acceptable and 1 least acceptable.

Harvesting and Use of Natural Floras

The methods of harvesting seaweeds have been revolutionized through the years. The more primitive method involved grabbing the seaweed with bare hands, or cutting it with sharp knife or sickle while wading in the shallow intertidal zone. This method, while still considered economical, defies the principle of conservation as the standing crop of wild seaweeds in a given area is easily depleted. An improved version finds a gatherer on-board a paddle-driven banca (boat), later to be substituted with motorized ones, from which the gatherer uses a 'grabber' pole with curved knife on one end to cut the seaweeds from the stem.

In northern Luzon, the Philippines, natural stands of *Porphyra marcosii* and *P. suborbiculata* are scraped from the rough surfaces of infratidal rocky ledges.

Two of the more recent methods of harvesting naturally grown seaweeds are an air-lift vacuum cleaner system, and a mechanized harvester device used in Europe and the USA. The former system was

developed to collect drift *Chondrus crispus* materials, and the latter for harvesting *Macrocystis pyrifera* off the coast of California. The latter device is mounted on a specially crafted boat so that the machine mechanically cuts, gathers, and loads the seaweed materials into the vessel.

Farming Techniques

The history of seaweed farming or mariculture is well recorded among oriental farmers. The technology has advanced considerably from the use of 'Hibi' (see below) to the present culture nets made popular for *Porphyra*, *Monostroma*, and *Ulva*. For *Eucheuma* farming, the use of the monoline system, in which ropes are tied to poles on both ends, has been adopted in Asia.

The use of Hibi was introduced by the Japanese fishermen long before any other farming methods were known. It utilized an artificial substrate composed of cut bundles of bamboo or brushwood, affixed in shallow areas where spores of wild *Porphyra*, once released, became attached to the Hibi. After sometime, the Hibi setups were gathered and transported to a 0.9–1.5 m deep growing area where the spores germinated into sporelings and then into harvestable plants. An innovation of the Hibi method is the use of rope or synthetic twine as an artificial substrate. A rope or synthetic twine is knitted to form a culture net with a 15×15 cm mesh size. In autumn, nets measuring 20–40 m by 1–2 m are set up in the natural habitats of *Porphyra*. The nets are suspended afloat by ropes moored on the sea bottom, or the ends of the nets are tied to wooden poles. *Porphyra* spores, once released, settle on the nets and are allowed to grow until harvest time.

The Taiwanese experience of mariculture adopts the polyculture system, whereby seaweed cuttings, e.g., *Eucheuma* and *Gracilaria*, are stocked in floating and moored cages together with other fish and shellfish stocks.

Other conventional, usually broadcast methods are actually modified systems of vegetative propagation. They can involve tying stocks of *Eucheuma*, *Gracilaria*, or *Gelidiella* to pieces of rock and then randomly broadcasting them in the rocky or corally bottom of the intertidal zone. Similarly, *Caulerpa* cuttings are scattered inside abandoned fishponds and allowed to grow under the prevailing natural conditions as seen in Mactan Island, Central Phillippines.

Marketing and/or Preservation

Seaweeds are marketed either in semiprocessed or processed forms. Fresh materials, after being cleaned of dirt, epiphytes, and invertebrates adhered to or mixed with them, are sun- or kiln-dried, or pickled for export or for household consumption. Those intended for export may be dried, or they may be processed in the form of algal extracts, such as carrageenan, agar, alginate, and algin. These and other phycocolloidal extracts are used as components in the manufacture of industrial products from dairy, pharmaceutical, and surgical items to plastic wares and paints, among others. The papery *Porphyra* and *Monostroma* are dried on bamboo slats so that the seaweeds can be molded into circular and rectangular shapes as sold in Philippine markets. In Japan, the same dried seaweeds are mechanically cut into desired strips and marketed in polythene packs.

In the Americas and parts of Europe, live *Palmaria* and *Chondrus* are impounded for days in specially designed tanks allowing water movement, sufficient nutrient exchange and entrance of sunlight. This method of preservation and storage helps to prolong the palatability of the sea vegetables. These are then dried using a mechanically operated dehydrating device and marketed. Indeed, the seaweed industry, a potential dollar-earning enterprise, faces a bright future. The world market needs a steady supply of seaweeds for its wide spectrum of industrial products. The Third World nations located within the Pacific Basin are favored with a rich variety of tropical seaweed species, which, if judiciously tapped, could plough back much-needed money to improve their economy.

The recently relaxed seaweed importation scheme by the USA, specially for *Eucheuma*, is a boost for the Asian sea-farmers. The Philippines ranks seaweeds such as *Eucheuma* among its top five fishery export items. The high production of the carrageenan-yielding *Eucheuma* in the Philippines is attributed to the simplified and less capital-intensive mariculture method introduced to the Filipino sea-farmers living along the coastal areas of the Visayas and Mindanao Islands. Moreover, this has given birth to the small-scale family business in *Eucheuma* farming. Similarly, Cordero (1982) has found the mariculture of *Porphyra* to be financially feasible for the Philippines, and this author has projected a modest increase in net income of 38% per hectare per year for the first 5 years using *P. marcosii* stock.

Role of Some Species in the Diet of Selected Societies

Edible seaweeds come from the green, brown, and red groups of algae. These protein- and iodine-rich marine plants, found in both cold and warm seas, have been known for their contemporary food

preparations as salad, soup, pickles, jam, etc. The Chinese and Japanese are among the prolific seaweed-eating people, and are accredited with recognizing its food value. The Hawaiians were known to keep 'Limu' gardens containing choice edible seaweeds for the consumption of their noble families.

Green Sea Vegetables

Species of *Caulerpa* and *Codium*, known in the Philippines as 'lato' (Visayan) and 'pok-poklo' (Ilokano), respectively, are the most common edible green algae among the South-east Asians. These, like the other brown and red seaweeds, are simply prepared as a salad with vinegar and a dash of salt. Some people add slices of green unripe mango and crushed tomatoes to enhance the salad preparation.

The low incidence of goiter cases among the coastal dwellers in Asia is attributed to the high iodine intake derived from the edible seaweeds.

Brown Sea Vegetables

Representing the more popular edible brown seaweeds are *Hizikia*, *Hydroclathrus*, *Laminaria*, and *Undaria*. Aside from their food use, the Japanese have made and marketed 'Kombu-Cha' – a kind of tea made out of processed *Laminaria*. The tender tops of *Sargassum* and *Hormophysa* are cooked with vegetables; *Cladosiphon* and *Laminaria* are relished as soup preparations.

Red Sea Vegetables

The red sea vegetables include the greatest number of known edible species. The orientals prefer *Porphyra*, *Gracilaria*, and *Eucheuma*; the occidentals have *Palmaria* or 'Dulse,' *Chondrus* or 'Irish Moss,' and *Porphyra* or 'Laver,' to cite the more popular ones. Their food preparations vary among European and American consumers, although salads, soups, pickles, jellies, etc. are among the favored ones.

It is no wonder that sea vegetable is now known as the poor man's source of cheap protein and iodine, and has an export potential for tropical countries.

Edible Animals Found in the Sea

R D M Nash and J P Thorpe, University of Liverpool, Isle of Man, UK

Current consumption

In western society the main marine invertebrates consumed are those groups conventionally termed shellfish; that is, various crustaceans (mainly decapods) and bivalve and gastropod molluscs. However other marine invertebrates are widely, if not extensively, consumed in Europe and North America, whilst elsewhere in the world patterns of consumption vary considerably. In various areas, particularly in the tropics, artisanal fisheries for unusual invertebrates can be locally important and in the Far East there is a great demand for food species not commonly eaten in the west. One group in particular, the cephalopod molluscs (octopus, squid, and cuttlefish), are currently important in terms of world catches and also offer potentially highly important fisheries if the technology to exploit them can be developed.

Cephalopods

Of the two extant subclasses of cephalopods (phylum Mollusca, class Cephalopoda), only the Coleoidea are important as food for humans. The other subclass, the Nautiloidea, contains a small number of species, all in the single genus *Nautilus* and all confined to the tropical Indo-Pacific. These support local artisanal food fisheries only, although the very attractive shells are more widely traded. The Coleoidea include the three orders Sepioidea (cuttlefish), Teuthoidea (squids), and Octopoda (octopuses), all of which include species eaten by humans.

Sepioidea (Cuttlefish)

Cuttlefish are almost absent from the Americas, although a few species of *Semirossia* occur along

the west Atlantic coast and are fished off Argentina and in the Gulf of Mexico. Elsewhere both large (mainly *Sepia*) and small (Sepiolidae) cuttlefish are fished in the coastal waters of most temperate and tropical latitudes. Total world annual catch is around 200 000 tonnes, with the most important areas being the eastern central Atlantic (Spain, Morocco), north-west Pacific (Korea, Taiwan, Japan), and western central Pacific (Thailand, Vietnam, Malaysia). Cuttlefish are caught in most areas as a bycatch of other fisheries, but in some areas they are specifically fished with trawls or other nets, dredges, pots, or jigs (lures). The major species fished are *Sepia officionalis* (which occurs down the eastern Atlantic from northern Europe to South Africa and throughout the Mediterranean and Baltic seas), *S. pharoensis* (found from the Red Sea to Japan and south to Australia), *Sepiella inermis* (which occurs from the Persian Gulf to eastern Asia, fished mainly in India and Sri Lanka) and *S. japonica* (Japan and China), but numerous other species are caught in smaller quantities. The tiny *Sepiola rondeleti*, which occurs from northern Europe to west Africa, is extensively eaten in many Mediterranean countries.

In the larger species the muscular mantle and tentacles are mainly eaten, but in many areas sepiolids are consumed whole. Major markets, even for Atlantic- and Mediterranean-caught cuttlefish, are in Japan and Korea and large quantities are exported frozen. In Japan larger cuttlefish are commonly eaten raw, cut into thin strips (sashimi) and smaller animals are packed and frozen ready for cooking. Some species are mainly eaten dried (surume).

Teuthoidea (Squids)

There are two suborders of squids, the Myopsida which are inshore, mainly demersal, squids, generally confined to shallower waters near shores or on continental shelves, and the Oegopsida, which are mainly pelagic offshore squids of deep oceanic waters, although these may come on to the continental shelves to spawn.

All the myopsid squids currently eaten are confined to the family Loliginidae and most are from the very large genus *Loligo*, species of which are found on continental shelves worldwide. Inaccurate and inadequate statistical data make it difficult to assess annual world catches, but the total for all loliginid species may be around 200 000 tonnes. Major fishery species are *Loligo bleekeri* (fished in the Sea of Japan), *L. chinensis* (which occurs from China south to eastern Australia), *L. duvauceli* (fished extensively in coastal waters throughout most of Asia and north-east Africa), *L. edulis* (China to northern Australia), *L. forbesi* (coastal waters from Sweden to Senegal, Mediterranean, Red Sea, south-east Africa), *L. gahi* (southern South America, Falkland Islands), *L. japonica* (Japan, China), *L. opalescens* (Pacific coast of North America), *L. pealii* (Newfoundland to northern Brazil), *L. reynaudi* (South Africa), *L. vulgaris* (northern Europe to South Africa, Mediterranean), *Sepioteuthis lessoniana* (Red Sea to Japan and Australia), *Alloteuthis media* (occurs from the UK to North Africa and Mediterranean, trawled in western Mediterranean). Capture methods for loliginid squids are mainly with nets (purse seines, otter trawls, pair trawls) and at night with lights. Some occur as bycatches in finfish fisheries.

Oceanic (oegopsid) squids form well over half of the total world cephalopod catch, with an annual total of perhaps 1 500 000 tonnes. A few species are demersal at least at some stage of the life cycle, but most are found in the water column, although this may be at great depths. For obvious reasons the species presently exploited commercially are generally only those occurring comparatively close to the surface. Currently only about nine (Enoploteuthidae, Octopoteuthidae, Onychoteuthidae, Gonatidae, Psychroteuthidae, Lepidoteuthidae, Histioteuthidae, Ommastrephidae, Thysanoteuthidae) of 32 recognized families have any species fished by humans, although many others have potential as food. Exploited species of major commercial significance are confined to only four families:

1. Enoploteuthidae, *Watasenia scintillans* (China, Japan).
2. Onychoteuthidae, *Onychoteuthis borealijaponica* (occurs in the northern Pacific from Japan and USA to about 55 °N, fished off Japan and north-west USA).
3. Gonatidae, *Berryteuthis magister* (found in the northern Pacific, from Japan to Canada, fished off Japan and north-eastern Russia).
4. Ommastrephidae *Illex argentinus* (south-eastern South America, Falkland Islands), *I. coindetii* (eastern Atlantic, Sweden to South Africa, and Mediterranean: fished in the western Mediterranean and Atlantic, off Spain and North Africa), *I. illecebrosus* (north Atlantic from USA to northern Europe, north to Arctic: fished north-west Atlantic), *Todaropsis eblanae* (continental shelves Europe, Africa, Asia to Australia: fished Mediterranean and north-west Africa), *Todarodes pacificus* (northern Pacific, China to Alaska, fished by Japanese), *T. sagittatus* (eastern half of Atlantic north of 20 °S to Greenland, Mediterranean, Arctic Ocean from Greenland east to northern central Russia: fished Norway, Italy), *Nototodarus gouldi* (Australia), *N. sloani* (New Zealand),

Ommastrephes bartrami (circumglobal, subtropical to temperate, northern and southern hemispheres, fished northern and southern Pacific), *Dosidicus gigas* (eastern Pacific, Chile to Mexico).

The exploitation of oegopsid squid is largely to satisfy the demands of the Japanese and, to a lesser extent, the Taiwanese market. Thus several of the major fishery species are those occurring in the northern Pacific, whilst others (for example *Nototodarus gouldi* off Australia, *N. sloani* off New Zealand and *I. argentinus* off the Falkland Islands) are exploited largely or almost entirely by Japanese, Korean, and Taiwanese vessels. Capture of oceanic squids is mainly by special ships equipped for jigging; squid are attracted towards the surface at night by the use of bright lights and are caught on barbless hooks attached to lures. The whole process of capture, unhooking, and processing and freezing of the catch is automated. In a few fisheries some of the catch is taken by drift nets in a manner similar to the gill netting of fish.

In Japan the way in which squids are sold varies between species, but the main methods are fresh and raw as sashimi, cooked and processed as saliika, dried as surume, canned, and frozen.

Octopoda (Octopuses)

Only octopods of the suborder Incirrata are fished commercially. Of these, only one (Octopodidae) of the eight families is at all important, although small numbers of the circumglobally distributed *Argonauta argo* (Argonautidae) are occasionally marketed from bycatches. Total world annual landings of octopods probably vary around 200 000 tonnes. All the main species caught are in the widely distributed genus *Octopus: O. briareus* (Caribbean and northern South America), *O. conispadiceus* (Japan), *O. cyaneus* (widespread from East Africa to India and Australia, throughout the Indian Ocean and western and central Pacific), *O. dofleini* (coastal from China to south-western USA), *O. globosus* (India), *O. maya* (Gulf of Mexico), *O. membranaceus* (coastal waters from India to Japan and Australia, important fishery species in Japan and China), *O. variabilis* (Japan, China), *O. vulgaris* (coastal distribution from northern Europe around Africa, including Mediterranean and Red Sea, and Asia east to Japan, also western Atlantic from USA to Brazil: fished over most of this huge range; of major importance in Japan, north-west Africa).

As with other cephalopods, much of the world market for octopus species is in Japan, where they are highly esteemed and are marketed fresh, frozen, dried, and/or salted.

Barnacles (Crustacea, Cirripedia)

There are a variety of barnacles exploited and eaten throughout the world. The large stalked barnacle *Polliceps polliceps* is eaten particularly by the Basque people, but is also consumed throughout Iberia and the Atlantic Island groups (Canaries, Madeira, and Azores). The acorn barnacles (*Megabalanus* spp.) are consumed in Chile (*M. psittacus*) and in the Azores (*M. tintabulum*). The goose barnacle *Mytella mytella* is eaten in Japan.

Jellyfish (Scyphozoa)

At least three species of jellyfish, of which *Rhopilema esculenta* is the most important, are consumed in Japan. These are usually served raw in a vinaigrette or similar dressing.

Sea Anemones (Anthozoa)

A variety of species are eaten in various countries, including Japan, Samoa, and France. The intertidal *Actinia equina* is eaten in Italy. All are usually eaten fried.

Tunicates (Urochordata, Ascidiacea)

The Japanese eat at least two species of sea squirts (*Halocynthis roretzi* and *H. aurantium*) and the French primarily utilize just one species (*Microcosmus claudicans*). All three species are from the same family (Cynthiidae).

Sea Urchins and Sea Cucumbers (Echinodermata)

Sea urchins are increasingly becoming subject to commercial fisheries, primarily to satisfy the Japanese market. Two species (*Paracentrotus lividus* and *Echinus esculentus*) are traditionally eaten in some Mediterranean countries and on the west coast of Ireland. Similar species are eaten in the Far East, particularly Japan. Sea urchins are also eaten by Maoris in New Zealand, who eat the complete contents out of the shell. Some North Atlantic species are exported to Japan and Japanese boats fish sea urchins commercially in Australian waters. In general only the roe (gonad) is eaten and this is consumed raw. In Japan the roe is only considered top-grade if it is a pale yellow color and the skeins are unbroken. Darker brown or damaged roes do not command such a high price. For prime roes prices are very high, around £30 per kg.

The market for sea cucumbers is also mainly in Japan. The very large black species *Stichopus japonicus* is taken locally, whilst several other species are

exported to Japan from various Pacific Islands (where they are locally known as bêche de mer).

Bristle Worms (Polychaeta)

The main type of polychete consumed is what are known as palolo worms, several species of which occur in various parts of the world. A common feature of these worms is that they swarm to the surface in very large numbers at predictable times of the year. The large swarms are primarily for reproduction, and are of a stage in the life cycle known as a sexual epitoke. A number of species are eaten: the Pacific palolo (*Eunice viridis*) from the areas surrounding Fiji and Samoa, wawo (*Lysidice oele*) from the Ambonia area, and the Atlantic palolo (*Eunice schemacephala*) in the Dry Tortugas. The Japanese palolo (*Tylorrhynchus heterochaetus*) is known by a number of different names in Japan.

Other Exploited Marine Invertebrates

Many more species and other marine invertebrate groups are, or are likely to be, eaten or otherwise exploited on a limited scale somewhere in the world, but to find and list them all is beyond the scope of this article. Those outlined above give some indication of the diversity of marine invertebrates consumed by humans.

However, one further area which should be mentioned is the recent and expanding exploitation of species of certain phyla (e.g., sponges, bryozoans, coelenterates, ascidians, nemerteans) which contain allelopathic (usually antipredator or anticompetitor) or otherwise 'useful' biologically active chemicals of value to the pharmaceutical industry. Many of these biologically active natural products have been studied and a number are likely to become medically and commercially important. One such product is what has been termed bryostatin, a biologically active compound, which has been found to have a potent action against various types of cancer cells. Bryostatin is obtained from the North American bryozoan *Bugula neritina*, but huge quantities of the bryozoan are needed; for example, one group studying this compound based its synthesis on a sample of 10 000 gallons (about 45 000 kg) of the bryozoan. With collection on such a large scale, any small invertebrate in pharmaceutical demand may become overexploited unless aquaculture can take over.

Possibilities for Future Exploitation of Marine Invertebrates as Food

Many of the world's conventional shellfish fisheries, like those for finfish, are being overfished and are in decline. It is unlikely therefore that there is much potential for future expansion of fisheries for decapod crustaceans or shelled molluscs, but as fish stocks, which provide the great bulk of wild caught marine animals, appear certain to continue to decline, other resources are needed.

Future demand for other invertebrate food species will presumably depend partly on the success of aquaculture in providing fish and shellfish and whether untapped sources (e.g., deep-sea species) can be exploited. Marine invertebrates of many groups are eaten little or not at all in most parts of the world. Thus there is apparent scope for the development or expansion of fisheries. However, most of the species within these groups are either inedible or present in only relatively small biomasses and therefore have little potential. Abundant marine invertebrates for future exploitation could be Antarctic krill (mainly *Euphausia superba*) and oceanic squid, particularly some of the deeper-living species.

Krill stocks are thought to be unnaturally high, because the near elimination of their major predators, the large whales, and the huge biomasses present in the Antarctic Ocean offer a potentially very great fishery resource, although of low value and palatability. They have been used for human consumption in Russia, but their commercial exploitation to date has been mainly as fish meal. Large-scale exploitation of krill could lead to ecological problems because they are generally considered the 'cornerstone' species for the whole vast Antarctic marine ecosystem and hence major exploitation could be serious, and overfishing a disaster.

Currently cephalopods and in particular squids make a useful contribution (about 2–3%) to fisheries on a global scale and in some areas (e.g., Japan) they are of great importance. Squids collectively rate as the sixth most commercially important fish species in world fishery statistics. Their significance as food is, for various reasons, greater than catch figures would suggest. They have little skeletal tissue and are highly muscular and hence, compared to most fish species, a relatively greater proportion of the catch is edible. Several of the fish species making the greatest contribution to world catches are used for fish meal (for fertilizer or animal feeds) and thus are not directly eaten by humans. Consequently the amount of fish eaten is considerably less than that caught. However, from the human viewpoint, the most important feature of cephalopods is probably their potential to increase world food supply.

Currently total world landings of fish are approximately static, at about 80 million metric tonnes (Mmt), despite continual increases in fishing efficiency and effort. This is occurring because many

fish stocks are being overfished and are declining, and overall the prospects for improvement do not look good. Since about 1970 world catches of cephalopods (mainly squids) have increased annually by an average of about 6% and even among coastal octopus species (probably the group with the least capacity for expansion) there is considered to be the potential to increase world catches greatly. Among oceanic squids the potential is enormous. Estimates of stock sizes are necessarily very approximate because there has been little or no relevant scientific study of the stocks of most squid species. Indeed, it is likely that there are still many species which are as yet unknown.

Evidence pointing to massive untapped squid populations comes from several sources. For a few species there are adequate scientific data for stocks to be estimated. For example, the large (up to 150 kg) cranchid squid *Mesonychoteuthis hamiltoni* is abundant in Antarctic waters and the flesh is considered to be of excellent quality and flavor. This species is not caught commercially at all, but the stock is estimated at about 90 Mmt (i.e., larger than the total annual catch of fish by humans). A second example is the very large species *Architeuthis* (Architeuthidae) which is thought to be distributed throughout all the oceans apart from continental shelves and close to the poles. Very few have been caught by humans, but its frequent consumption by whales (identified mainly from the beaks, which remain undigested in whale stomachs) and occasional stranding in shallow water suggest it is not rare. As individuals weigh up to about 1000 kg, the total biomass is likely to be huge. Current direct estimates by fishery biologists of total world squid stocks vary considerably, up to about 500 Mmt, but indirect estimates from other sources indicate that even this figure may be conservative.

Studies of the squid consumed by various predators suggest very large populations. In the Antarctic, penguins and elephant seals, for example, are thought to take annually about 13 and 4.5 Mmt respectively (neither of these, incidentally, eats any of the estimated 90 Mmt of *Mesonychoteuthis hamiltoni*). Sperm whales eat mainly squid found on or near the bottom in depths restricted by their diving capabilities. Sperm whale populations have been seriously depleted by overexploitation, but even so they probably eat annually a weight of squid equivalent to about twice the entire world catch of fish by humans.

From recent research it is also becoming clear that there are great biomasses of largely unknown squid at mesopelagic and bathypelagic depths throughout much of the world's oceans. Over 70% of the world surface consists of sea deeper then 2000 m and by volume more than 98% of the sea is off the continental shelves, with an average depth of several thousand meters. Over many years the work of research ships towing midwater trawls at these depths had indicated that throughout most of this vast volume of water, animal life was rather scarce. However, recent studies using television cameras attached to the net frames reveal considerable numbers of often quite large (up to tens of kilos) squids present at a wide range of depths and over huge areas. These are not generally caught simply because, as large and highly mobile visual predators, they easily avoid nets. Since they are distributed through such huge volumes of the deep ocean the biomass of these squid is likely to be immense.

Thus various sources of evidence indicate that oceanic squids may be present in biomasses which dwarf known stocks of exploited fish species. Since most squid are thought to be annual and semelparous (they grow for a year, spawn, and die) they 'turn over' faster than most fish species and thus, if well managed, should be able to sustain higher relative rates of exploitation. If fished in the later stages of the annual life cycle and as long as enough adults survive to spawn, the entire stock can be exploited because there are no juveniles which need to be preserved for future breeding. However, for many of the oceanic squids, the depths at which they live present major barriers to the development of commercial exploitation. Our knowledge of their biology and behavior is at best minimal and technological advances will be necessary before most can be utilized.

Marine Reptiles as Food

Marine reptiles (turtles, saltwater crocodiles, iguanas, and sea snakes) occur in many areas of the tropics and subtropics and various species are exploited on a small scale by local human populations. Turtles were formerly exported on some scale for consumption, particularly in Europe, but many of the wild populations are now endangered and their import is banned in most countries. Most species are, however, good to eat and are still netted or harpooned on a small scale by native fishermen. Turtle eggs are also considered a delicacy in many parts of the world. Saltwater crocodiles can grow to a length of about 10 m and are the world's largest living reptiles. These are occasionally killed in the Far East, although their food value is considerably less than that of the hide.

There are six widespread species of marine turtle:, loggerhead (*Caretta caretta*), leatherback (*Dermochelys coriacea*), hawksbill (*Eretmochelys imbricata*), Kemp's Ridley (*Lepidochelys kempii*), olive Ridley (*Lepidochelys olivacea*), and the green turtle (*Chelonia mydas*). The only one currently commercially exploited on a large scale for food is the green turtle. This is a medium-sized species growing up to about 1 m and

occurs naturally in the tropical Atlantic, Caribbean, and elsewhere. The species has been severely overexploited and is now scarce and heavily protected in the wild, but is the subject of a large aquaculture enterprise in the Caribbean. Captive broodstock adults, kept in large saltwater ponds, lay their eggs 'naturally' on an artificial sandy beach and the eggs are then dug up and incubated artificially. This method is highly successful, with nearly 90% survival of the newly hatched young (compared with about 0.2% in the wild). The young turtles are then reared in large tanks of sea water for 3 years before harvesting. The meat is highly prized and has almost no fat content, but more protein than prime beef or chicken.

M Hanusardóttir, Home Rule Government, Faroe Islands

Introduction

From the earliest times, humans have, wherever possible, included a wide range of wild terrestrial and aquatic animals in their diet as sources of animal protein and fat. Seals and whales have long constituted a natural part of the diet of the inhabitants in those regions of the world where these marine resources occur.

For example, in the Faroe Islands, a tiny archipelago in the eastern north Atlantic, the economy is dependent almost exclusively on marine resources. The long-finned pilot whale, *Globicephala melas*, and other whales have been caught for food in the Faroes ever since people first settled in the islands (around the year 675). Detailed statistical records of whale hunts date back to 1584, and from 1709 to the present these are unbroken. For this reason the following description of marine mammals as a food source is based largely on the example of the long-finned pilot whale off the Faroe Islands. In addition to these historical records, from 1986 to 1988 an international research project examined the long-finned pilot whale off the Faroe Islands in detail, and this research resulted in studies of, among other things, the percentage of whales used for human consumption, as well as their content of nutrients and contaminants. An earlier study examined the significance of the pilot whale in the everyday diet of Faroe Islanders.

The use of seals is also significant for human consumption in many coastal communities.

Classification of Whales

Whales, which are cetaceans, are divided into two main groups – baleen whales (Mysticeti), and toothed whales (Odontoceti).

According to the North Atlantic Marine Mammal Commission (NAMMCO) and the International Whaling Commission (IWC), the following baleen whales are currently used for human consumption: bowhead, gray, fin, humpback, and minke whales. Of the toothed whales, the following are used for human consumption: Baird's beaked whale, narwhal, white whale, false killer whale, long-finned pilot whale, short-finned pilot whale, Atlantic white-sided dolphin, bottlenose dolphin, pantropical spotted dolphin, striped dolphin, common dolphin, Risso's dolphin, harbour porpoise, and Dall's porpoise.

Annual catches are listed by NAMMCO and the IWC and published in their annual reports; the number taken in 1997, directly and indirectly as bycatches, was around 33 500 whales worldwide.

Hunting Methods and the Use of Whales

The ban on the use of the cold grenade (i.e., nonexplosive grenade) harpoon in commercial whaling was

extended to include minke whales from the beginning of the 1982–83 pelagic and 1983 coastal seasons.

In the fishery of small cetaceans, harpoons, rifles, nets, and driving methods are used. In the drive fishery in the Faroe Islands, entire schools are driven into an authorized whaling bay and killed by severing the jugulars and arteries supporting the brain with special knives. All stages in this organized hunt are regulated by law. It is worth mentioning that there are no professional whalers or whaleboats involved in this whale drive, and the shares are distributed free to all local inhabitants. No factory processing of the catch occurs. For indepth descriptions of the various stages of driving, beaching, killing, and butchering, see Further Reading.

The size of the driven schools varies and it can be seen from the statistics that pilot whales occur in Faroese waters with a cyclic periodicity of about 120 years. In the period from 1709 to 1999, the school size was on average 139.8 whales (range 1–1200), with an average of 7.1 schools beached a year (range 0–23), giving an annual average catch of 850 whales (range 0–4448).

Regulations state that pilot whales must be butchered and the shares removed within 1 h after the shares have been allotted. According to the regulations, the shares are given to the participants in the drive and to local households in the district.

The whales are butchered on the quay by those receiving shares. The section of the whale which is used is cut behind the head to the anus. First the blubber is peeled off in transversal strips and placed on the quay with the skin down so as not to soil the blubber side. After that, the meat is removed and placed on top of the blubber, and when the whole whale has been butchered in this way, the shares are then divided between those who have a share in the same whale.

Food Uses and Products: Significance in National Diets

The different parts of the whale used for human consumption in different parts of the world are listed in Table 1. In general, the meat is used by all the whaling countries, either raw or, more commonly, prepared in some way. Some of these countries, where edible fat has been in short supply, have also developed national dishes using the blubber in different ways. Finally, especially in Japan, national dishes have been developed for nearly all parts of the whales, except the backbone.

In the Faroes both the meat and blubber of pilot whales are utilized for human consumption. On average, 54% in weight of the animals is used, with the amount of meat and blubber used being nearly equal. On the beach, kidneys are taken, free, as anyone's share. The kidney is boiled fresh in salted water and eaten at once. The share of meat and blubber is prepared in different ways in the home. The traditional and still the most common method for conserving the household share is by salting or wind-drying. In the last 25 years this method has been supplemented by deep-freezing the products fresh or after some wind-drying. Normally, however, very little of the meat and blubber is frozen fresh, partly owing to limited freezer space, and partly because the traditional methods are thought to provide the most delicious result.

The different methods used to prepare the whale products are discussed in the following two sections.

Table 1 Preparation methods of the various parts of whales used today for human consumption

Preparation method	*Part of whale*	*Country*
Raw	Meat	Japan[a]
	Gum meat	Japan
	Lung	Japan
	Skin with blubber	Greenland[b]
Boiled or fried in oil or water	Meat	Worldwide use
	Blubber	Japan, Faroe Islands[c], Greenland
	Tongue	Japan
	Ventral groove	Japan
	Kidney	Faroe Islands
	Internal organs	Japan
	Lung	Japan
Smoked	Ventral groove	Japan
	Meat	Japan
Salted dry or pickled	Meat	Japan, Faroe Islands
	Blubber	Faroe Islands
	Fin	Japan
	Ventral groove	Japan
Dried by sun/wind	Meat	Japan, Faroe Islands
Lactic acid	Meat	Iceland[d]
	Ventral groove	Iceland
Wine-preserved	Cartilage	Japan

Whale Meat

In general, most of the whale meat is eaten fresh (worldwide), salted, wind-dried (Faroe Islands), or sun-dried after being thinly sliced (Japan). In Iceland, the ventral grooves and meat of baleen whales were conserved in containers with lactic acid. (*See* **Drying**: Drying Using Natural Radiation.)

In the salting process, pieces of meat or blubber are placed in dark containers, pressed together, and covered in a brine of boiled water with a salt solution in which a potato can float. After salting for at least 1 month, the meat is washed in water for 24–48 h before being boiled in water, and the blubber is eaten boiled or raw, unwashed (Iceland and the Faroe Islands).

When drying, whale meat undergoes a process of fermentation combined with drying (the Faroe Islands). The pieces of meat are sprinkled with salt (12–24 h) after being cut into thinner pieces of about 50 cm in length and 10 cm in diameter. The surface is smoothed, resulting in a quick stiffening of the surface in the wind which prevents flies from laying eggs. The pieces are hung up outside on the northern side of the house, and are ready for boiling in salted water after 3–4 weeks. Alternatively, when dried quite hard after about 3 months it is eaten raw in thin slices. (*See* **Preservation of Food**.)

The above-mentioned means of food preservation is only possible in the north Atlantic where the climatic conditions are cold and windy. Moreover, in the Faroes it is a means still commonly used for preserving local sheep, fish, and geese.

Whale meat and blubber are also smoked in both Iceland and Japan.

Blubber

Very little blubber is frozen fresh. Nearly everything is salted, either dry or in brine, as described above (the Faroe Islands, Iceland) or wind-dried (Iceland). After lying in salt for at least 1 month, preferably up to 3 months, the blubber is edible and conserved for years. The skin and outermost layer of blubber is eaten raw (Greenland), and elsewhere the blubber is boiled or fried (Japan, the Faroe Islands, Greenland).

Significance in National Diet

For many years, pilot whaling has been essential to the survival of the Faroese community. In modern Faroese society an annual catch of approximately 2500 whales still represents 50% of the Faroese meat production (equal to sheep and cow production) and 25% of the Faroese meat consumption.

In former times, and still today, salted whale meat and blubber has been used as food on board ships, especially on smaller boats without freezers (the Faroe Islands, Japan).

Furthermore, marine mammals are virtually the only reserve for some Inuit communities in the Arctic.

Chemical Composition and Nutritional Value

Whale meat and blubber, most commonly used for human consumption (Table 1), have a very high nutritional value. The meat is an excellent source of protein (Table 2), with a low fat content. Thus it agrees well with western health recommendations. (Refer to individual nutrients.)

Table 2 The chemical composition of whale meat, expressed per 100 g of meat

Component[a]	*n (number of samples)*	*Mean value*	*Standard deviation*	*Species*
Protein (g)	20	25.0	0.7	Pilot whale

Vitamin C, ascorbic acid (μg)		1		Narwhal

[a]Data for protein-selenium from Poulsen (1995). Data for vitamins B and C from Jepsen (1983): Jepsen O (1983) *Kostvurderinger over Grønlandske fødevarer*. FDB's centrallaboratorium. Copenhagen: Forenede Danske Brugsbutikker's Centrallab.

Whale Meat

Compared with other mammals and various fish species, whale meat has a very high content of practically all types of macro- and microminerals. Of particular note is the high content of selenium and iron (Table 2). Selenium has an important role because it seems to prevent carcinogenic reactions, and iron is required to meet the needs for growth, maintenance, and repair of tissues. The estimated safe and adequate daily dietary intake of selenium for adults is 0.05–0.2 mg, and the recommended dietary allowances (RDA) for iron for adults is 18 mg. Thus 100 g of pilot whale meat a day will provide enough of these two minerals. (*See* **Fish Oils**: Dietary Importance; **Fish**: Dietary Importance of Fish and Shellfish; **Meat**: Nutritional Value; **Offal**: Types of Offal.)

Little information is available about the content of different vitamins in pilot whales, but the meat from narwhals is a good source of vitamins B_1, B_2, and A.

Blubber

Blubber is composed of practically pure fat (70–80%) and water. However, the fatty acid composition is very good (Table 3). Blubber has a high ratio of polyunsaturated to saturated fatty acids (P:S value), and the amount of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) is high, compared with various fish species, which are the main natural sources of these fatty acids. EPA and DHA are probably the most important fatty acids in preventing coronary heart disease. (*See* **Fatty Acids**: Dietary Importance.)

Table 3 Fatty acid composition in blubber from long-finned pilot whales off the Faroe Islands

	Fatty acid content (%)
Saturated fatty acids (S)[a]	16.34
Monounsaturated fatty acids	60.45
Polyunsaturated fatty acids (P)[a]	14.90
Polyunsaturated fatty acid fraction	
Eicosapentaenoic acid (EPA)	1.20
Docosahexaenoic acid (DHA)	5.41

[a]P/S is 0.91.

Data from Poulsen (1995): Poulsen M (1995) øFroyskar Fødslutalvur (Faroese Food Composition Tables.) Heilsufrøðiliga Starvstovan, pp.1–25. Tœrshavn: Food and Environmental Agency.

Chemical and Microbiological Hazards

Despite the fact that whales are of extremely high nutritional value, there are reasons for caution. The meat can contain large amounts of heavy metals, such as mercury and cadmium, and the blubber can be contaminated with persistent, lipid-soluble synthetic compounds such as pesticides and polychlorinated biphenyls (PCBs) and halogenated aromatic hydrocarbons in general. It is sometimes found that individuals carry a muscle mercury concentration of $6\,mg\,kg^{-1}$. The normal level is however one-third of this – about $2\,mg\,kg^{-1}$ (Table 4). The proportion of the total mercury which is present as the most potent toxic species methylmercury is highly variable among the individuals in the school, varying from 24% to 86% in one school in 1978; the average methylmercury component in samples from two schools were however approximately 50%. Also cadmium may pose a threat to both individual whales and also to consumers of pilot-whale livers and kidneys. The concentration of the metals in the liver are severalfold higher than in the muscle where in individual instances concentrations approaching $250\,mg\,kg^{-1}$ of cadmium and $600\,mg\,kg^{-1}$ of mercury have been detected. The content of mercury in different parts of the pilot whale (Table 4) and examinations of Faroe Islanders indicate that the estimated long-term intake of mercury and cadmium from eating whales may reach or exceed the recognized critical level for negative or toxic effects in humans. (*See* **Cadmium**: Toxicology; **Mercury**: Toxicology.)

Inspecting the mean values of total dichlorodiphenyltrichloroethane (DDT) and PCB in blubber from pilot whale schools in the Faroes in 1987 and 1997 (Table 5) reveals the frequently observed

Table 4 The total mercury concentration in various tissues of long-finned pilot whales off the Faroe Islands

[a]tDDt = *p,p′*-DDT + *p,p′*-DDE + *p,p′*-DDD + *o,p′*-DDT.

Polychlorinated biphenyls (PCB) are given with reference to the commercial product; the 1987 data were quantified with a 1:1 mixture of Aroclor 1254 and 1260. The 1997 data were quantified as single congeners; however, for reasons of comparision with the 1987 data, these were expressed as Aroclor 1260 units. The calculation of Aroclor 1260 units is based on regression analysis in human samples which had been analyzed for PCBs both with an Aroclor standard and with a single congener standard. For reasons of

feature of mature females to excrete persistent organic pollutants and thus carry a lower body burden than immature whales and mature males. A recent study of the group of polybrominated diethylethers (PBDE), also known as flame retardants, in blubber samples revealed a widespread distribution of these compounds also in pilot whales, and the same pattern of elevated concentrations in the young as is seen with PCBs and pesticides in general. The concentrations of PBDE as well as PCBs, both the nonortho congeners which are also known as the coplanar ones, as well as the bulk of PCBs, are high (Table 6). In addition, the concentration of polychlorinated dibenzo-*p*-dioxines and -*p*-furanes, often referred to simply as dioxins, are given for the adult whales sampled in Vestmanna in 1996. Due to the scarcity of data, the distribution of contaminants between the groups of adults in this particular school should not be considered as typical. What can cause changes in the relative distribution is that the adult males are more transient members of the school, and the males and females need therefore not have common history regarding food and foraging area, which are both important parameters in determining pollutant body burden. What may be compared, regardless of the uncertainty between the sexes, is the distribution of pollutants within the groups. We note that the common PCBs, although each one less toxic than the coplanar ones and the dioxins in general, are still responsible for the highest toxic load, expressed in toxic equivalents, and this is due to the much higher concentrations. The toxic equivalents are defined with reference to the most toxic dioxin compound, 2,3,7,8-TCDD. It is apparent that although this seveso-dioxin is assigned a toxic equivalent value of 1, the 2,3,7,8-TCDD is only accounting for less than 10% of the toxic effect

Table 6 Concentrations of polybrominated diethylethers (BDE), polychlorinated biphenyls (PCB), also of the non-ortho congeners, polychlorodibenzo-*para*-dioxin (PCDD), and polychlorodibenzo-*para*-furanes (PBDF) in pilot whale blubber

Lipid %	*ad ♀♀ 79 % (ng g^{-1} lipid)*	*ad ♂♂ 83 % (ng g^{-1} lipid)*
Te-BDE #47	529	862

TEQ sum PCDD/PCDF	12.9	10.0
TEQ, 2,3,7,8-TCDD	0.86	0.58

[a]Sum BDE is the sum of 19 individual tetra, penta and hexa bromodiethylethers.

[b]Sum PCB is the sum of 61 congeners quantified using single congener standards.

[c]Sum of the three nonortho-substituted PCB congeners CB 77, 126, and 169.

The samples were taken in Vestmanna 27 June 1996; the analyses were done on pooled samples of adult females (ad ♀♀) and males (ad ♂♂), each representing 19 and 8 animals respectively. The results are given in units of ng g^{-1} lipid and pg g^{-1} lipid, depending on the range of concentrations detected. The chlorinated compounds are also presented in toxic equivalents (TEQs), using the conversion factors of the World Health Organization.

of the dioxins. (*See* **Heavy Metal Toxicology; Pesticides and Herbicides**: Toxicology.)

Based on different research work and the recommended acceptable daily intake, Faroese health authorities issued the following recommended intake levels for the Faroese population in 1989:

1. On average, adults should eat no more than 150–200 g of whale meat per week. Pregnant women should eat much less or, preferably, not eat whale meat at all.
2. Adults should eat no more than 100–200 g of blubber per month.
3. People should not eat entrails (liver, kidney, etc.) from pilot whales.

In 1998 the dietary advice was revised according to new data on toxicity and contamination load and the recommendations given were:

Diet Recommendation Concerning Pilot Whale Meat and Blubber – Faroe Islands August 1998

Blubber High PCBs contents in blubber lead us to recommend that adults eat pilot whale blubber at most once to twice a month.

However, the best way to protect fetuses against the potential harmful effects of PCBs is for pregnant women not to eat blubber until they have given birth.

Meat The mercury content of pilot whale meat is high and is one of our main mercury sources. Therefore we recommend that adults eat no more than one to two pilot whale meals a month.

Women who plan to become pregnant within 3 months, pregnant women, and nursing women should abstain from eating pilot whale meat.

Organs Pilot whale liver and kidneys should not be eaten at all.

The above recommendations are considered the most advisable for the present. When new information is acquired, this diet recommendation will be revised accordingly.

This recommendation is given by the following Faroese authorities: Food and Environmental Agency, Department of Occupational and Public Health, and Chief Medical Officer.

After the killing and before the butchering of the carcasses, it is important that the beach is clean and away from sewer outlets or the like. This is important to avoid contamination by pathogenic bacteria. Most often the meat is heated before eating, except for wind-dried meat which is eaten raw (see above). When eaten raw it is of utmost importance that the meat does not contain pathogenic bacteria. The drying circumstances must be suitable to avoid the growth of such bacteria. (*See* **Spoilage**: Bacterial Spoilage.)

Waste Product Utilization

According to Faroese law, all remains after a whale drive must be removed within 24 h after the killing, and the quay cleaned again. The remaining 46% of pilot whales in the Faroes not used for consumption consists of the skeleton, head, tail, and intestines. Before the introduction of electric lighting in homes, the heads were boiled down for lamp oil, and the bones were used as fertilizer in the fields, a method which is still used in Japan. In the Faroe Islands today, the intestines are used by some as bait in line fishery, and production of fertilizer from whale remains is being considered.

MASS SPECTROMETRY

Contents

Principles and Instrumentation

F A Mellon, AFRC Institute of Food Research, Norwich, UK

Principles

Mass spectrometry is an extremely sensitive and specific analytical technique, capable of providing qualitative and quantitative analytical data on nanomolar to attomolar amounts of analyte. It has been applied successfully to a very wide range of analytical problems in the food and nutrition sciences. Mass spectrometers have become far more accessible, cheaper to purchase and operate, and easier to use, especially over the last decade. This is mainly a consequence of the advent of compact, bench-top instruments, usually coupled to gas or liquid chromatographs. The following article describes the basic theory of mass spectrometry and the principal types of mass spectrometric equipment relevant to food and nutrition analysis and research. Applications of mass spectrometry and techniques of combined chromatography mass spectrometry are covered in separate articles.

Mass Spectrometer

All mass spectrometers comprise four main components. First, an ion source, where sample molecules may be ionized by a variety of means, second, a mass analyzer that separates ions according to their mass-to-charge ratio, *m/z*, third, a detector that measures the abundances of the separated ions as an electrical signal, and fourth, a recording device that converts the detector signal into a form suitable for further study and processing.

Ionization Techniques – Organic Mass Spectrometry

Ionization of organic molecules may be accomplished by a variety of techniques. The most common practical methods are described below.

Formation of Ions

Organic mass spectrometry

Electron ionization (EI) The analyte is vaporized into the EI source and bombarded with 70-eV electrons. The ion source chamber is maintained at a vacuum of 10^{-3} Pa. A proportion of the energy of the electron beam is transferred to the molecule, ejecting an electron to generate a *molecular ion* ($M^{+\bullet}$), the most important ion in the mass spectrum (eqn (**1**)).

$$M + e^- \rightarrow M^{+\bullet} + 2e. \qquad (1)$$

Excess electronic energy is also transferred to the molecule during the ionization process and is rapidly converted to internal vibrational energy. This energy may be sufficient to induce bond cleavage in some ions, generating fragment ions that may also decompose. This is shown in the sequence of decompositions of a hypothetical molecule ABCD (eqn (**2**)).

$$ABCD^{+\bullet} \rightarrow ABC^+ + D^\bullet \rightarrow AB^+ + C \rightarrow A^+ + B. \qquad (2)$$

Rearrangement processes may also occur (eqn (**3**)).

$$ABCD^{+\bullet} \rightarrow AD^{+\bullet} + CB. \qquad (3)$$

Most ions formed by EI have a single positive charge ($z = 1$), and m/z is then equivalent to the mass of the ion. The way in which a molecule fragment is determined by a number of factors that will not be discussed here. Semiempirical rules for predicting or rationalizing bond cleavages and rearrangements can be found in several textbooks. The most important consequence of the fragmentation process is that it generates a characteristic, reproducible mass spectrum that serves as a spectrometric 'fingerprint' of the analyte.

Mass spectra are generally recorded in the form of a line diagram (bar graph). Ion intensities are normalized so that the largest peak in the mass spectrum, the *base peak*, has an intensity of 100 units, and all other ion abundances are expressed as a percentage of this value. The low-resolution mass spectrum of caffeine is shown in Figure 1.

A molecular ion can be seen at m/z 194, and a number of abundant fragment ions are also present. In this example, the molecular ion is also the base peak, although this is not always the case; strongly favored fragmentations may yield abundant fragment ions that are more intense than the molecular ion.

Some molecules are difficult to analyze by EI mass spectrometry for either or both of two main reasons. They may fragment very readily, so that the molecular ion is of very low abundance and therefore (in the case of an unknown) difficult to assign. Alternatively, the molecules may be involatile or thermally labile and difficult or impossible to vaporize without inducing thermolytic decomposition. Several 'soft' ionization methods are available for analyzing molecules that fall into this category. These techniques are used to transfer analytes from the liquid or solid phase to the gas phase and ionize them by mechanisms that impart minimal amounts of energy.

Chemical ionization (CI) CI is based on the reactions of gaseous analyte molecules with an excess of ions formed by electron bombardment of a reagent gas. These reactions take place at high (relative to EI) ion source pressures, typically in the range 10–150 Pa. Typical reagent gases include methane and ammonia: these generate CH_5^+ and NH_4^+ ions, respectively under CI conditions. The reagent ions are present in large excess (10^4:1) relative to analyte molecules. The reagent ions generally react with analyte molecules M by protonation (eqn (**4**)),

$$M + NH_4^+ \rightarrow MH^+ + NH_3. \qquad (4)$$

Negative ion chemical ionization is also possible. Negative ion reagent gases include water. This generates OH^- ions and reacts by proton abstraction (eqn (**5**)),

$$M + OH^- \rightarrow [M - H]^- + H_2O. \qquad (5)$$

A special case of negative ionization, electron capture negative chemical ionization (ECNCI) is not strictly CI. It is an electron capture process where low-energy electrons generate radical anions (eqn (**6**)),

$$M + e(\text{thermal}) \rightarrow M^{-\bullet}. \qquad (6)$$

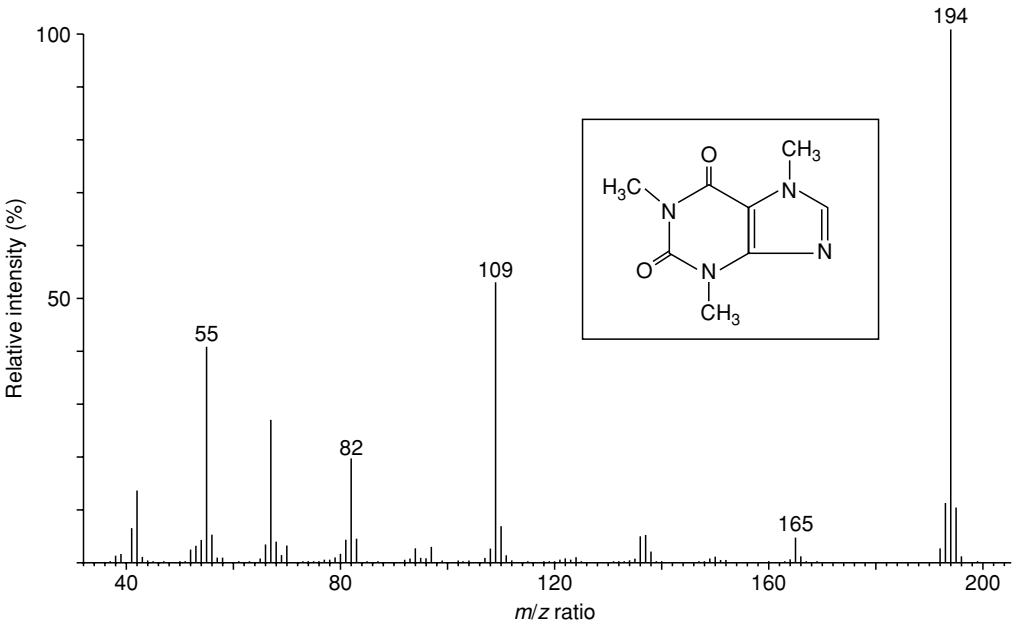

Figure 1 Low-resolution electron ionization mass spectrum of caffeine in bar graph format.

In this case, the 'reagent' gas acts as a moderator, slowing the electrons to the thermal energies where the electron capture process become efficient. ECNCI is particularly useful for determining analytes with strong electron capturing properties, for example, halogenated molecules such as dioxins. ECNCI can yield much greater sensitivities and lower detection limits in these cases.

Positive and negative reagent ions may also react in other ways. A range of gases are available for specific applications. CI spectra usually contain intense protonated or negatively charged molecules and fewer fragment ions than EI.

Desorption EI and CI In conventional EI and CI, analyte molecules are typically introduced into the ion source via a heated probe or GC inlet. Desorption EI and desorption CI provide techniques for obtaining mass spectra of less volatile, thermally labile molecules by rapid heating whilst the samples are very close to the electron beam or are immersed in the CI plasma. These techniques are still used occasionally but have largely been superseded by more robust and efficient methods for analyzing involatile molecules, as described below.

Fast atom bombardment (FAB) and liquid secondary ionization mass spectrometry FAB and liquid secondary ionization mass spectrometry essentially describe the same technique, and the terms can be used interchangeably. FAB was the first ionization technique to enjoy widespread success in analyzing polar, labile, and large molecules, including peptides and polysaccharides. The analyte in a viscous, low-boiling liquid matrix, typically glycerol that is bombarded with a stream of atoms or ions, typically Xe atoms or Cs^+ ions that have average translational energies in the keV range. Abundant protonated or cationized molecules, for example $[M+H]^+$ or $[M+Na]^+$ and deprotonated ions, $[M-H]^-$, are formed and detected in positive and negative ion modes, respectively. Characteristic fragment ions may also be formed.

FAB enjoyed great and deserved popularity in the 1980s and helped to establish mass spectrometry very strongly in the biological sciences. However, it has generally been superseded by the more powerful, versatile techniques of electrospray and matrix-assisted laser desorption ionization.

Electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) In ESI, the analyte is dissolved in a suitable solvent, for example a 50:50 mixture of acetonitrile and water, and is pumped through a narrow diameter stainless steel capillary tube that is maintained at a voltage in the range of 1–4 kV. This process generates a plume of charged liquid droplets in atmosphere (the Taylor cone). A heated (usually nitrogen) gas aids evaporation of the charged droplets and helps break up clusters of analyte and solvent ions. Analyte ions are generated from the charged droplets by an evaporation mechanism. The ions are conducted into the mass spectrometer vacuum via a pumped nozzle-skimmer system (**Figure 2**).

A curtain of nitrogen gas, which also aids evaporation of the charged droplets, prevents cluster ion formation. The ions are sampled through an orifice and enter the mass analyzer. ESI has revolutionized mass spectrometry by enabling mass spectra to be obtained routinely on polar, involatile molecules. Even high-molecular-weight biomolecules can be analyzed by ESI. Proteins, for example, yield a series of multiply charged ions well within the mass range of conventional mass spectrometers such as quadrupoles or magnetic sector instruments. These signals can be transformed mathematically to yield the molecular weight of the sample (**Figure 3**).

APCI is closely related to ESI and often employs an almost identical ion source. The only changes are the addition of a discharge electrode and replacement of the ESI spray probe with an APCI probe. In APCI, flowing liquid, typically an HPLC eluent, that contains the dissolved analyte(s) is conducted to a pneumatic nebulizer, where it forms a spray. As with ESI, the spray is generated in atmosphere and is directed towards a discharge electrode that is maintained at 1–4 kV. This is placed close to a small-diameter orifice that leads to the high-vacuum mass analyzer region. A pumped nozzle and skimmer arrangement removes excess solvent molecules, and desolvated ions are admitted to the mass analyzer, in a similar manner to an ESI source. Reagent ions are generated from solvent molecules in the electrical discharge near the corona pin. These react with analyte molecules to generate protonated or deprotonated molecules ($[M+H]^+$ or $[M-H]^-$), in a similar manner to conventional CI.

APCI is more robust (being less prone to solvent or solvent modifier effects) than ESI but is usually too vigorous and energetic to yield useful data on fragile biomolecules. However, it is very useful for determining molecules of low to intermediate polarity and is capable of producing useful data on some quite polar molecules, for example monoglycosides.

Matrix-assisted laser desorption Ionization (MALDI) MALDI is one of the best techniques for obtaining analytical data, including molecular weight information, on medium and large biomolecules. The sample, in low concentration, is mixed

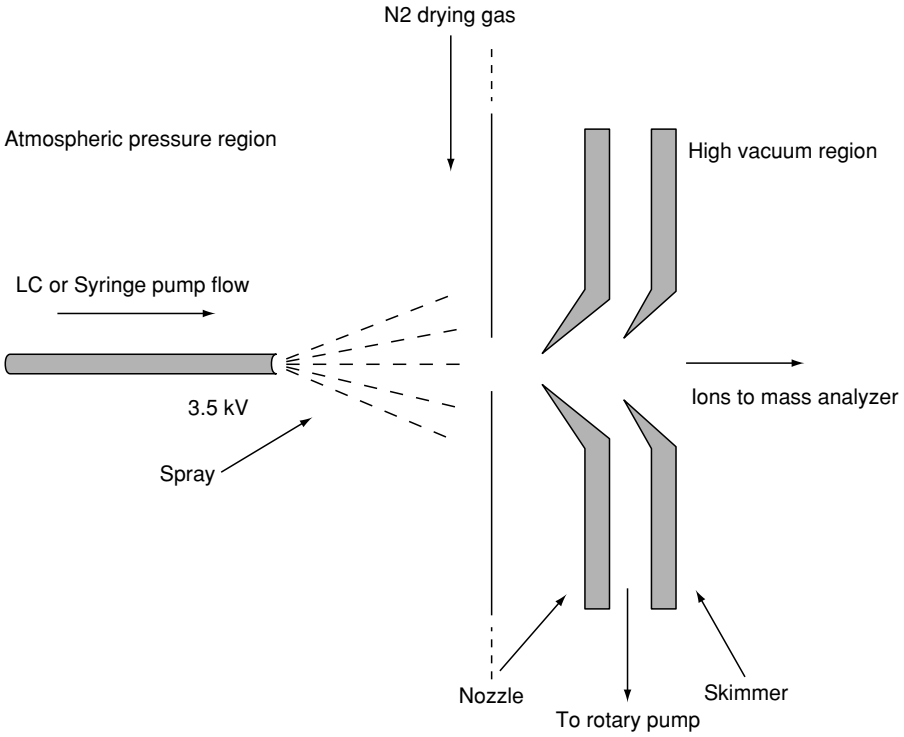

Figure 2 Schematic diagram of an electrospray ionization source.

with a concentrated solution of, for example, sinapinic acid, on a metal target. The solution is dried, and the target is introduced into the mass spectrometer ion source vacuum. The sample plus matrix is irradiated with a pulsed laser (typically a 327-nm nitrogen laser). The matrix chosen should be sublimable and be able to absorb and transfer energy at the laser wavelength. The mechanism of desorption and ionization is complex. It is thought that the matrix then transfers sufficient transverse vibrational energy to the sample molecules to desorb some of them with very little excess energy for fragmentation. The technique is particularly useful for mass measuring large and medium-sized biomolecules, especially peptides, proteins, and DNA fragments, and generates $[M+H]^+$, $[M-H]^-$ or adduct ions, $[M+Na]^+$.

Other ionization methods Several other methods have been used to ionize organic molecules in the past. For example, field ionization, field desorption, and ^{252}Cf plasma desorption were once popular techniques for analyzing otherwise intractable molecules, such as biopolymers. These techniques are now mainly of historical interest and have generally been superseded by more practical, reliable and robust methods, particularly ESI and MALDI.

Inductively coupled plasma ion source (ICP-MS) Inorganic mass spectrometry has increased in importance in food and nutrition science through applications in authentication, nutrient mineral metabolism and toxicology. One of the principle techniques of inorganic mass spectrometry, ICP-MS, is based on the production of ions in a high-temperature (6000–8000 K) atmospheric-pressure argon plasma formed by a self-sustaining electrical discharge that is induced by a high-frequency induction coil. This plasma is capable of ionizing most elements in the periodic table very efficiently. Samples are introduced into the ion source in nebulized solutions flowing at rates of 0.1 –1 ml min^{-1}. They are then ionized efficiently by the high-temperature plasma. Alternative sample introduction techniques, including electrothermal vaporization, laser desorption, hydride generation, electrospray, and combined chromatography/mass spectrometry, are also available.

The ionization efficiency is generally very high for most nutrient and toxic elements. The plasma forms a supersonic jet in the differentially pumped region behind the sampling cone. Ions are introduced into the vacuum of the mass analyzer via a series of differentially pumped stages. A schematic diagram of an ICP-MS ion source is shown in Figure 4.

Most ICP-MS instruments are based on quadrupole mass analyzers. However, high-resolution magnetic sector instruments are also available. These are capable of resolving polyatomic interferences generated in the argon plasma that may have the same mass

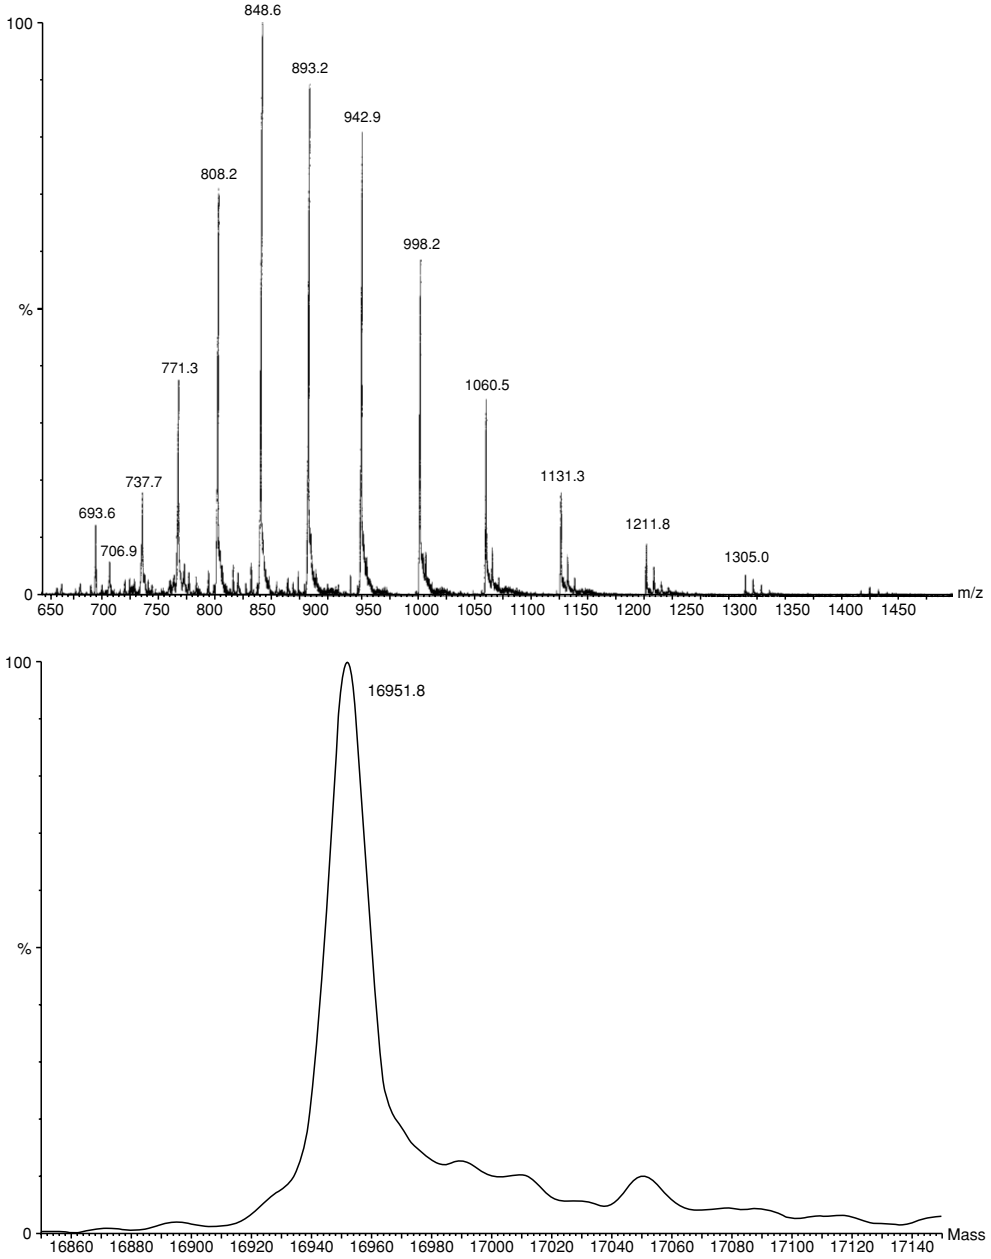

Figure 3 Electrospray mass spectrum of horse heart myoglobin, showing the raw, multiply charged data (upper trace) and the transformed spectrum (lower trace) showing the measured molecular weight of the sample.

as isotopes of interest, for example $^{40}Ar\ ^{16}O^{+}$ and $^{56}Fe^{+}$. High-precision isotope ratio measurements may also be conducted if multicollector magnetic sector mass analyzers are employed.

A major step forward has been the introduction of collision cell technology to eliminate polyatomic interference ions. These cells have been used with quadrupole and magnetic sector instruments. The important nutritional element selenium suffers from an abundant interference peak from $^{40}Ar_2^{+}$ in the ^{80}Se mass channel. This interference can be attenuated considerably by charge exchange with H_2 in the collision cell.

ICP-MS is a rapid and useful multielement analysis technique that is also capable of determining isotope ratios in studies of trace element metabolism in humans.

Thermal ionization mass spectrometry (TIMS) TIMS is a well-established technique in inorganic mass

spectrometry with a much longer pedigree than ICP-MS. It is based on the production of positive or negative atomic or molecular ions at the surface of a resistively heated metal filament. It has been used to conduct stable studies of nutrient mineral metabolism and is a 'gold standard' analytical technique for quantitative analysis of nutrients and toxicants in foods by isotope dilution mass spectrometry, in which measurements are conducted by adding a predetermined quantity (the 'spike') of an enriched stable isotope (of known isotopic composition) to the target analyte. Isotope ratio measurement of the mineral of interest then yields the amount of analyte precisely and accurately.

Mass analyzer The mass analyzer of the mass spectrometer separates ionized atoms and molecules according to their mass-to-charge ratio, m/z. Several different types of mass analyzer are available. The main types of relevance to food and nutrition research are described below.

The maximum practical resolving power, R, of a mass spectrometer is an important instrumental characteristic. It is effectively a measure of the instrument's ability to separate ions. Several different methods can be used to define R, but the two most common are the '10% valley' definition (eqn (7)), which is based on the separation between two peaks of equal height and mass m and $m + \Delta m$,

$$R = \frac{m}{m + \Delta m}, \qquad (7)$$

when the peaks are separated by a valley of 10% peak height, and the full width at half height definition (eqn (8)),

$$R = \frac{m}{\Delta m}, \qquad (8)$$

where Δm is the width of a peak of mass m at 50% of its height.

Some instruments, magnetic sector-based mass spectrometers, for example, yield constant resolution over the entire mass range (i.e., $m/\Delta m$ is constant). In contrast, quadrupole mass analyzers yield a constant Δm over the entire mass range. In this case, resolution is mass-dependent, usually some multiple of the mass, e.g., twice the mass.

Magnetic sector mass spectrometers Ions formed in the ion source region are accelerated through a potential and are injected into a sector magnetic field (*See* **Figure 8**). The motion of the ions in the magnetic field is described by eqn (**9**),

$$m/z = \frac{B^2 r^2 e}{2V}, \qquad (9)$$

where z is the number of charges on an ion of mass m, e is the electronic charge, B is the magnetic field strength, and r is the radius of the ion path. The mass scale is generally scanned by varying, B rather than V, as this yields the most sensitive and reproducible data. Voltage scanning is used to perform selected ion monitoring measurements, in which a small number of mass channels are monitored consecutively and repetitively. This mode is used to record quantitative data with high sensitivity (selected ion monitoring measurements may also be performed using other types of mass analyzer).

Single-focusing magnetic sector mass spectrometers (now something of a rarity) are capable of a maximum resolution of about 5000. Increased resolving power is attainable by adding an energy resolving sector, a pair of curved plates held at a defined electrical potential, to yield a 'double-focusing' instrument. These help to increase resolving power by

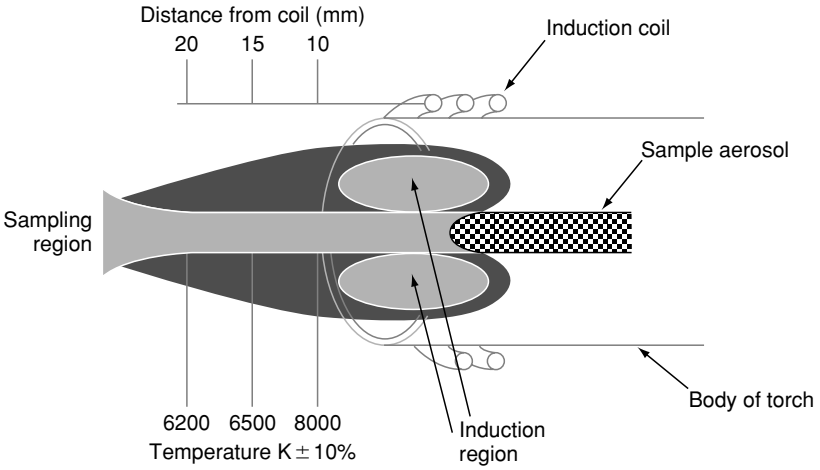

Figure 4 Schematic diagram of an ICP-MS ion source. Redrawn from a diagram supplied by VG Elemental, with permission.

correcting for the spread in ion velocities that most ionization techniques produce. The electric sector can be placed before or after the magnetic sector. Figure 5 shows a design of 'Nier–Johnson' geometry, in which an electric sector deflects the ion beam through $\pi/2$ radians, before it enters a magnetic sector with a deflection of $\pi/3$ radians.

Double focusing mass spectrometers are available in a number of designs and can attain maximum resolving powers from 10 000 to over 200 000, depending on their design.

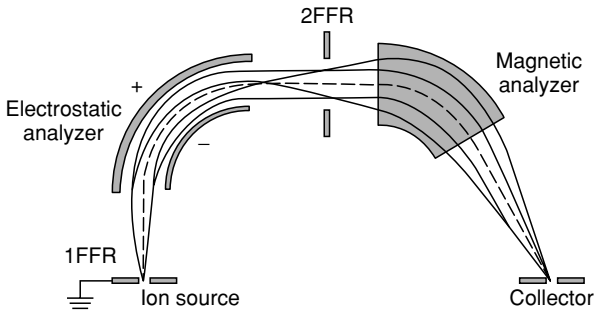

Figure 5 Schematic diagram of double-focusing magnetic sector ion optics of Nier–Johnson geometry. FFR, first field-free region. From Chapman JR (1985) *Practical Organic Mass Spectrometry*, 2nd edn. Chichester, UK: Wiley-Interscience with permission.

High-resolution mass spectrometry is commonly used to measure 'accurate masses', i.e., masses determined to three or four decimal places. These data may then be converted into the empirical formulae of ions in the mass spectrum. High-resolution mass spectrometry may also be used to increase the specificity of quantitative measurements, or to resolve isotopic clusters of multiply charged peaks formed by electrospray so that the charge state can be measured unambiguously.

Isotope ratio mass spectrometers Although isotope ratios may be measured successfully using conventional mass spectrometers, some applications much require higher precision measurements than can be attained by using scanning instruments. In such cases, specialized high precision isotope ratio mass spectrometers are available. An example of this type of instrument is the gas isotope ratio mass spectrometer (GIRMS), used to determine the isotope ratios of gases such as CO_2, N_2, SO_2, and H_2 to a very high degree of precision and accuracy.

The analyte is combusted or reduced to generate the gases that are ionized in a gas tight EI source. A magnetic sector separates the ion beam, with the difference (from a conventional scanning instrument) that each mass channel is collected simultaneously, i.e., the mass spectrometer uses a *multicollector* ion detection system. This yields high-precision isotope ratios because any fluctuations in ion beam

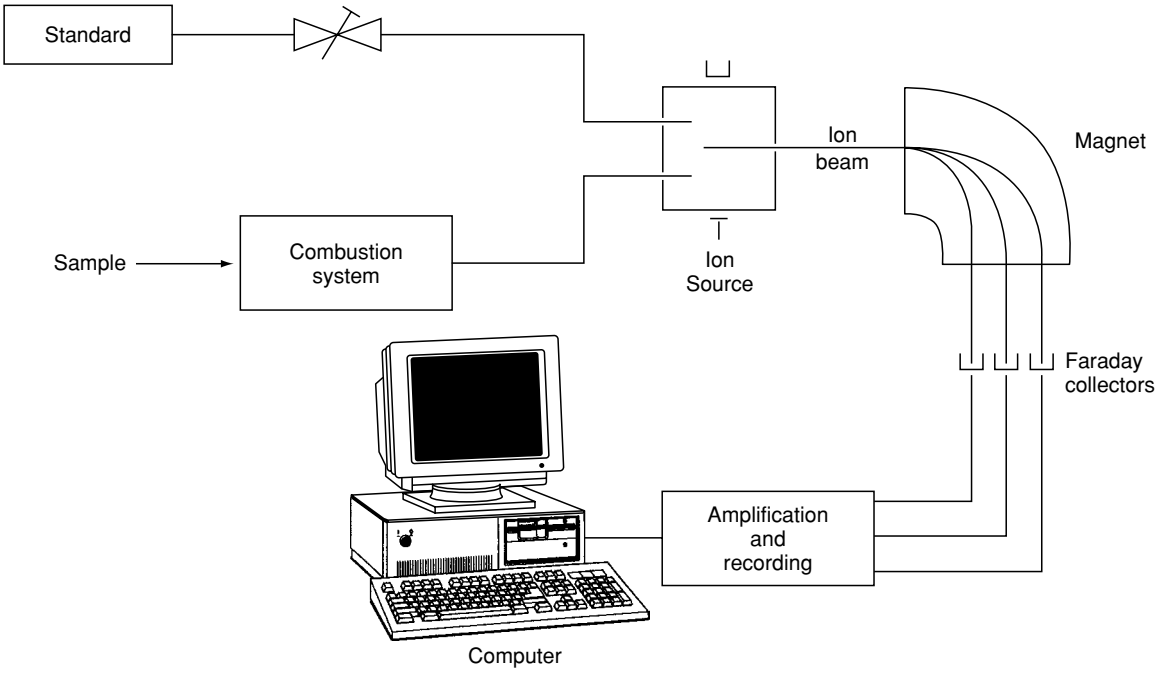

Figure 6 Schematic diagram of a gas isotope ratio mass spectrometer. From Mellon F, Self R and Startin JR (2000) *Mass Spectrometry of Natural Substances in Food*. London: The Royal Society of Chemistry with permission.

intensity occur simultaneously at each detector. A diagram of a GIRMS instrument is shown in Figure 6.

The main uses of GIRMS in food and nutrition science are in determining the authenticity of foods and in human studies of nutrient metabolism. High-precision multicollector mass spectrometers are also available for use with TIMS or ICP-MS.

Quadrupole mass analyzers Quadrupole mass analyzers comprise four parallel rods of circular or hyperbolic cross-section. These are connected to radio-frequency (V_0 *cos* ωt) and direct-current (U) power supplies, as shown in Figure 7.

The equations of motion governing the path of ions between the rods describe a complex series of oscillations and will not be discussed here. These oscillations are stable for particular values of the equations and unstable for other values. By operating the quadrupole in a stable region, the ions will be constrained to follow a path between the rods until they reach the detector. The mass spectrum is scanned by varying V_0 and U so that the ratio U/V_0 remains constant. The quadrupole mass analyzer acts as a mass filter, allowing one mass channel at a time to reach the detector as the mass range is scanned. Quadrupole mass spectrometers are intrinsically low-resolving-power instruments but are relatively cheap and robust.

Ion traps The Paul ion trap is related to quadrupole mass analyzers. The term 'Ion Trap' is, strictly speaking, generic and can encompass the Penning ion traps used in Fourier transform ion cyclotron resonance (FTICR) instruments (see below). However, ion traps are generally used in the scientific literature to refer to Paul ion traps, thanks to the great success of these instruments in compact, bench-top designs of mass spectrometer.

An ion trap may be described as a quadrupole that has undergone a solid of rotation. A typical ion trap comprises two endcap electrodes and a ring electrode, all of hyperbolic or hemispherical cross-section (Figure 8).

The end-cap electrodes contain small-diameter holes for allowing ions to enter and leave the trap. Ions are confined inside the trap by a radio-frequency field of constant frequency but variable power. The ions may be detected, according to their m/z ratio, by applying voltages sufficient to eject them from the trapping field. Ion traps, despite their simplicity and cheapness of construction, can be used to perform sophisticated tandem mass spectrometry experiments in addition to fulfilling a role as conventional scanning mass spectrometers.

FTICR mass spectrometry FTICR (sometimes simply known as Fourier transform mass spectrometry) is a Penning trap in which ions confined by a strong magnetic field, B, move in circular orbits of characteristic frequency, ω (Figure 9).

The motion of the ions is governed by the cyclotron equation (eqn. (**10**)),

$$\omega = z\frac{B}{m}. \qquad (10)$$

A broad-band 'chirp' of electromagnetic radiation is applied to excite all ions in the trapping cell to their cyclotron frequency. The orbiting ions induce an alternating 'image current' in the walls of the cell

receiver plates. This signal is complex because each *m/z* value generates its own characteristic frequency. A Fourier transform of this complex signal yields the masses of all ions in the spectrum. Frequencies can be measured with great accuracy, and so very high resolving powers, over 1 000 000 in some cases, are attainable. However, resolution does fall off with increasing *m/z*.

FTICR instruments can be used to perform sequential tandem mass spectrometry experiments and are compatible with pulse ionization techniques. Although they are expensive to purchase, and running costs are high, they have undergone something of a renaissance in recent years. This is partly due to their compatibility with newer pulse ionisation techniques like MALDI. Perhaps more importantly, the multiple charging observed in ESI of proteins yields a mass envelope in the region where full advantage can be taken of FTICR's high-resolution performance (i.e., 600–2000 Th). This allows unambiguous determination of the charge state of product ions formed in tandem mass spectrometry experiments.

Time of flight (ToF) mass analyzers The ToF mass analyzer is now becoming widespread for several reasons. First, it is compatible with MALDI, a pulsed ionization technique that is a perfect match for ToF. Second, improvements in design and performance have yielded major advances in performance, particularly resolution and sensitivity. Third, ToF mass analyzers have, theoretically, an unlimited mass range.

ToF analyzers are based on the property that the drift velocities of ions are dependent on their *m/z* ratio. Ions formed in the source region are accelerated through a potential, *V*, and then enter a field-free drift region (Figure 10).

According to eqn (**11**), the ions will all have the same kinetic energy.

$$\frac{1}{2}mv^2 = zeV, \qquad (11)$$

where v is the ion velocity. The ToF, t, of the ions is governed by eqn (**12**),

$$t = \left(\frac{m}{2zeV}\right)^{\frac{1}{2}} L. \qquad (12)$$

Early ToF instruments had limited mass resolution, but 'delayed extraction' techniques and the introduction of electrostatic mirrors (reflectrons) have increased their resolution dramatically. ToF instruments are capable of a very high sensitivity because they record all the ions generated in a single ionization pulse.

Ion detection and recording The most common detector in mass spectrometry is the *electron multiplier*; this amplifies the weak ion beam signal greatly, yielding gains of up to the order of 10^6. Multipliers can be either a *discrete dynode* type or a *continuous dynode*, generally known as a *channel electron multiplier* or *channeltron*. The discrete dynode electron multiplier comprises a series of Be–Cu alloy dynodes arranged as shown in Figure 11.

The first dynode is held at a negative potential of several kilovolts relative to the (positive ion) beam. The beam strikes the first dynode and generates a shower of secondary electrons. These electrons are then attracted to the second dynode, generating more electrons, and so on, in a cascade through the device. Negative ions may be detected by using a conversion dynode held at a high positive potential. Channeltron detectors operate according to similar

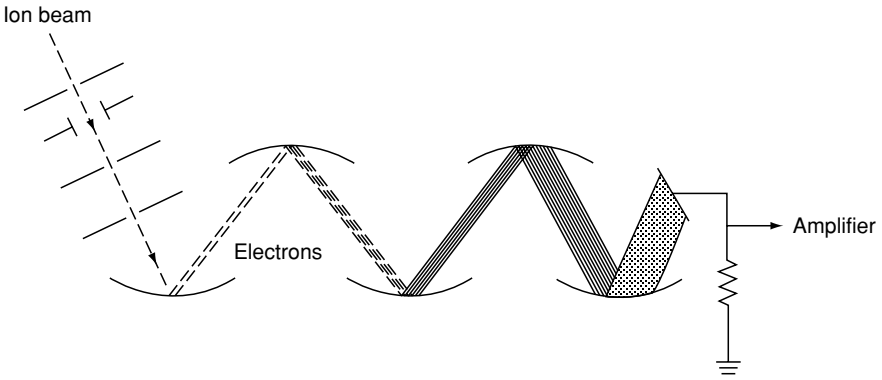

Figure 11 Schematic of a discrete dynode electron multiplier ion detector. From McFadden WH (1973) *Techniques of Combined Gas Chromatography/Mass Spectrometry*. Chichester, UK: Wiley-Interscience with permission.

principles as discrete dynode electron multipliers. The main difference is that individual dynodes are replaced by a tapered, coiled tube, and electrons bounce from along the tube towards the earthed terminus. *Array detectors* comprise a series of miniaturized channeltrons that are arranged adjacent to each other. They can be used to detect ions simultaneously over a range of masses and are used to increase sensitivity in some types of magnetic sector mass spectrometer.

The *scintillation detector* is an alternative ion beam amplification device in quite widespread use. The ion beam strikes a surface that emits electrons towards a phosphor screen, generating photons. The photons are amplified using a device akin to the image intensifiers used in night-vision binoculars and similar devices. Scintillation-based photomultiplier arrays are also available.

Faraday cup detectors are used mainly in isotope ratio mass spectrometers. The Faraday detector is a very simple device, comprising a conducting 'bucket' that collects the ion beam, yielding an electrical signal. The minute electrical signal generated is then amplified and recorded. Faraday cups are used in applications where accurate measurement is more important than sensitivity, for example in high-precision isotope ratio measurements conducted by GIRMS, ICP-MS, or TIMS.

Tandem mass spectrometry (mass spectrometry/mass spectrometry (MS/MS)) Tandem mass spectrometry, or mass spectrometry/mass spectrometry (MS/MS), experiments are conducted classically by combining two mass analyzers in a single instrument. For example, two double focusing magnetic sector or two quadrupole mass analyzers may be combined in series. Tandem quadrupole mass spectrometers are generally known as 'triple quadrupoles.' However, only two of the quadrupoles are involved in mass analysis: the third (middle) quadrupole transmits all ions and is used to 'activate,' i.e., transfer energy to, the ions of interest.

MS/MS has been described as 'taking the mass spectrum of an ion in a mass spectrum.' The principle of MS/MS is that a sample is ionized and mass-analyzed in the first mass analyzer. A particular *m/z* value of interest is selected from the mass spectrum and is directed into a *collision cell* that contains a neutral gas (argon, for example). The ion is vibrationally excited by collision with the target gas, a process known as *collision induced dissociation*. This generates fragment ions that are separated and recorded by the second mass analyzer. The process is shown schematically in Figure 12.

The example given is of a *product ion scan* and is used as a general technique for analyzing target components in a mixture, or for generating characteristic fragment ions from a sample that yields stable molecular ions under the ionization conditions used. Other scan modes are available, including *precursor ion scans, constant neutral loss*, and *selected reaction monitoring*.

Tandem mass spectrometers are available in several different configurations. 'Hybrid' instruments, for example magnetic sector/quadrupole or quadrupole ToF, are also found in many laboratories. ToF mass spectrometers may also be used in MS/MS mode. MS/MS experiments may also be performed using ion trap or FTICR instruments. In this case, MS/MS is conducted by temporal, rather than spatial, separation of ions. For example, an ensemble of ions in an ion trap is 'swept' using a scan function that expels all ions from the trap except the *m/z* value of interest. These ions are activated by collision with a gas admitted to the ion trap, and the ionic products of

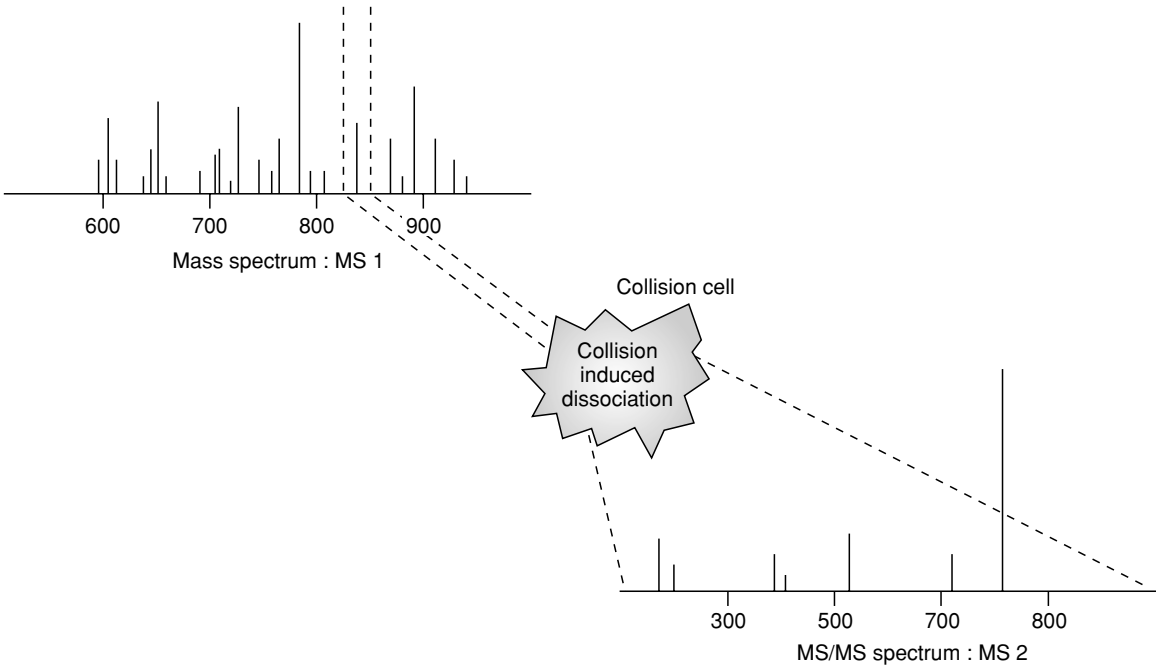

Figure 12 Schematic representation of tandem mass spectrometry (product ion analysis).

this activation are measured by a conventional mass scan. This process of isolation can be repeated, i.e., a particular product ion can, in turn, be isolated and activated, and so on in a sequence of reactions. This allows MS/MS/MS or MS^n experiments to be carried out.

MS/MS has many analytical applications. These include the analysis of complex mixtures without any chromatographic separation, generation of characteristic fragment ions from molecular ions, and improving the selectivity of quantitative measurements.

Data acquisition and processing Computers, typically PCs, are now used routinely both to control mass spectrometers and to acquire and process mass-spectrometric data. Parameters such as focusing, resolution, and scan speed may be adjusted and set via a computer. The same computer may be used to control mass spectrometer inlet systems such as gas chromatography, high-performance liquid chromatography, or automated direct insertion probes. The computer is also the final link in the signal-recording chain. It forms part of the system used to digitize the mass spectrum, calibrate the mass scale, enhance the quality of data, and, ultimately, to aid in the interpretation of data. All these functions may be carried out by a single computer coupled to a sophisticated data digitization device.

Library searching of a large database of the mass spectra of known compounds is now routine as an aid to interpreting EI spectra and identifying components in (for example) a complex gas chromatography – mass spectrometry chromatogram. More sophisticated, compound class-specific algorithms are available for particular types of analysis, such as identification of proteins in proteomics experiments. Computer systems are now an integral component of mass spectrometers and have greatly simplified the process of instrument control, data acquisition, and interpretation.

Applications

F A Mellon, AFRC Institute of Food Research, Norwich, UK

Background

Food science, food technology, and nutrition present the scientist with a very wide range of analytical problems. Consequently, many different mass spectrometric techniques, alone or in combination with chromatographic or other methods, have been used to address specific analytical problems in food and nutrition research. It is impossible to give a comprehensive account of applications of mass spectrometry in food science in a short article. Instead, some representative examples are chosen from a range of topics that illustrate the diversity of techniques and applications in selected areas.

Major Food Components

Carbohydrates

Carbohydrate analysis has a long history in the food sciences because of the importance of carbohydrates as macronutrients, as major constituents of dietary fiber, and as food structure components and food additives. A classic, still widely used, method for determining the composition and linkages of polysaccharides involves gas chromatography/mass spectrometry (GC/MS) analysis of partially methylated alditol acetates (PMAAs). The polysaccharides are methylated, hydrolyzed, and reduced to *O*-methyl alditols. These are acetylated and analyzed (both qualitatively and quantitatively) by GC/MS. Partially methylated alditol acetates yield characteristic mass spectra that allow determination of the nature and linkage position of the monosaccharides comprising the polysaccharide. This technique has been used to analyze cell wall polysaccharides in many fruits, vegetables, and cereals.

The molecular weights of large polysaccharides can be measured with the aid of electrospray ionization (ESI) (in liquid chromatography/mass spectrometry (LC/MS) or direct injection modes) and matrix-assisted laser desorption ionization (MALDI) mass spectrometry (MS). Both techniques may also be used to obtain partial or (for smaller polysaccharides) complete sequence information in MS/MS mode. Pectins, for example, are widely used in the food industry as stabilizers or to form gels. Nanospray MS/MS of an unseparated digest of partially methyl-esterified (DE (degrees of esterification) 31%) pectin has been used to obtain useful structural information. The tandem mass spectrum of the doubly deprotonated decamer with two methyl esterified residues is shown in Figure 1. ^{18}O labeling is used to distinguish the reducing and nonreducing ends of the molecule.

Complete Foods

Many mass-spectrometric methods used in food analysis and research focus on the determination of specific components or of mixtures of structurally related compounds. However, pyrolysis mass spectrometry (Py/MS) is capable of yielding analytical information on microgram or submicrogram amounts of whole foodstuffs. Py/MS is based on the rapid, controlled thermal degradation of samples in an inert atmosphere. This produces mixtures of volatile compounds whose electron ionization (EI) or chemical ionization (CI) mass spectra are recorded. This generates a complex 'fingerprint' of the sample under investigation. Py/MS data are generally processed by chemometric methods to obtain optimal information from the analyte. The technique has been used in the quality assurance of foods and drinks, in the study of food plants, and in the identification of food pathogens.

Flavors and Taints

Because most flavor components are highly volatile, combined GC/MS (using EI and/or CI) has been a primary technique in flavor analysis and research since the early 1960s. For example, almost 1000 discrete compounds have been identified in coffee volatiles.

Direct injection of headspace samples on to a GC column reflects flavor composition more accurately than extraction or trapping methods and is less likely to generate artefacts. However, the ease with which solid-phase microextraction GC/MS studies may be conducted has made this an important and useful technique for sampling flavors and taints. GC/MS has been supplemented by LC/MS techniques for studying involatile flavor precursors (glucosinolates, for example) or semivolatile or involatile food components that have important flavor characteristics.

The availability of a large knowledge base of flavor profiles (largely defined by GC/MS analysis) and recent instrumental advances have resulted in a recent shift in emphasis of mass spectrometric applications. Instead of characterizing complex mixtures of volatiles, several

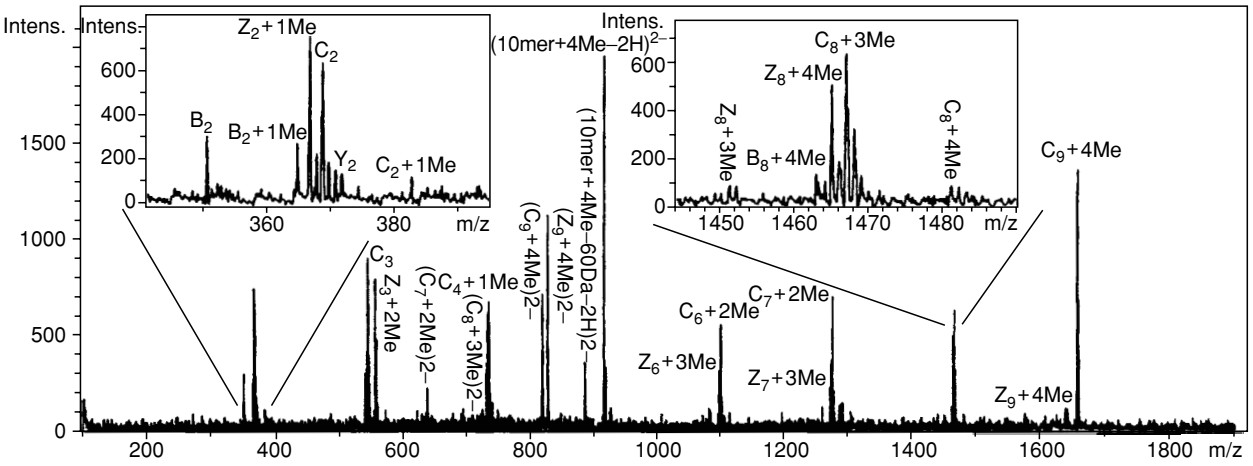

Figure 1 Negative ion MS/MS spectrum of the doubly deprotonated decamer with two methyl esterified residues and ^{18}O-labeled reducing end from an unseparated PG II digest of 31% methyl esterified pectin. Figure 2 Average volatile release curves for menthol, menthone, and limonene released while eating mint-flavored sweets. From Linforth RST, Ingham KE and Taylor AJ (1996) *Flavour Science: Recent Developments*, pp. 361–368. Cambridge: Royal Society of Chemistry with permission.

researchers are now focusing on flavor release and, more specifically, on sampling volatiles released into the mouth and nose. By using a special atmospheric-pressure chemical-ionization (APCI) probe coupled to a mouth or nose piece, it is possible to conduct dynamic, breath-by-breath analyses of air expired during eating. An example of the type of data that can be acquired is illustrated in Figure 2, which shows volatile release curves for menthol, menthone, and limonene released while eating a mint-flavored sweet. The APCI technique represents the 'state of the art' in modern flavor-release studies.

Mass-spectrometric methods are also useful for authenticating flavor components. Flavor concentrates from natural sources are usually sold at a premium price compared with their synthetic analogs. Mass spectrometry has an important role in detecting fraudulent representation of synthetic flavor compounds as natural. Microcombustion of flavor samples yields CO_2 that is then swept into the ion source of an isotope ratio mass spectrometer where $^{13}CO_2/^{12}CO_2$ ratios are measured to a very high precision. These isotope ratios are characteristic of the source of the sample and can be used to authenticate the material. The technique can be used directly on the sample without prior pretreatment. If a more sophisticated analysis is required, GC/combustion/isotope ratio mass spectrometry will yield accurate isotope ratios on the individual components of a flavor sample.

Lipids

Although complex mixtures of lipids cannot be characterized by any single analytical technique, mass spectrometry is very useful in the qualitative and quantitative analysis of many different lipid types, including long-chain fatty acids and their esters, mono-, di-, and triacylglycerols, and phospholipids.

Branched-chain fatty acids and their esters exhibit characteristic bond scissions adjacent to the branching point. The degree of unsaturation of fatty acids esters can be determined readily from EI mass spectra. However, double-bond *location* presents considerable difficulties because long-chain unsaturated compounds rearrange extensively under EI, and consequently, fragment ions do not generally supply reliable information about double-bond position. A number of strategies have been devised to overcome these problems: one of the most popular is derivatization, followed by GC/MS. Several different procedures are available, including oxidation followed by silylation, epoxidation and the analysis of methoxy or dimethyldisulfide derivatives. An alternative strategy is to generate chemical derivatives that localize

charge, preventing charge-induced double-bond migration. Pyrrolidide derivatives have been used for this purpose but are insufficiently volatile for GC/MS. A useful alternative that generates derivatives suitable for GC/MS is provided by 2-substituted 4,4-dimethyloxazoline formed by condensation of the fatty acid with 2-amino-2-methylpropanol. The 'charge-localizing' derivatives yield clusters of ions 14 mass units apart, reducing to 12 mass units when a double bond interrupts the chain. MS/MS techniques for locating double bonds include 'charge-remote' fragmentation of molecules ionized by negative ion CI. If high collision energies are used, free fatty acids yield ions characteristic of the double-bond position.

Capillary GC/MS is useful for identifying the carbon and unsaturation number of acylglycerols. However, APCI LC/MS has the ability to analyze less volatile acylglycerols (particularly-triacylglycerols) that may be unsuitable for GC/MS. It is fast becoming the technique of choice for qualitative and quantitative analysis of acylglycerols and, when combined with MS/MS, is capable of distinguishing fatty acid chains in the *sn*-2 position from those in the *sn*-1/3 positions.

The sensitivity, selectivity, and convenience of positive and negative ion ES LC/MS make this the current benchmark technique for analyzing phospholipid mixtures. Additional structural information can be obtained by MS/MS. Where these advanced techniques are unavailable, a more laborious approach of chromatographic class separation, chemical degradation, and GC/MS analysis of fatty acid can be used to generate useful structural information.

Proteins, Oligopeptides, and Amino Acids

Amino acids, peptides, and proteins are of interest in several areas of food and nutrition science, and only a small sample of current applications can be described here. For example, GC/MS, and LC/MS are particularly useful for analyzing the products of amino acid/sugar reactions (Maillard or Amadori products) that have important flavor characteristics. Free amino acids themselves may be analyzed by electrospray ionization (ESI) LC/MS. However, alternative (and cheaper) techniques to mass spectrometry are available, and mass spectrometric methods are generally confined to specialist applications (for example, metabolic studies or the identification of unusual amino acids).

The mass-spectrometric study of proteins and oligopeptides was once largely conducted by fast-atom bombardment (FAB) MS, but this methodology has now been supplanted by the more robust and sensitive methods of ESI and MALDI time of flight (ToF). An instructive example is provided by a rapid screening system, based on MALDI-ToF, developed to determine the presence of gliadins in food samples. Direct observation of the characteristic gliadin mass pattern in processed and unprocessed gluten-containing foods has yielded an nonimmunological alternative for the quantitative estimation of gluten gliadins in foods. Figure 3 shows the MALDI-ToF spectrum of an unfractionated ethanol extract of wheat gliadins.

Tandem mass spectrometry of oligopeptides, usually following ESI ionization, yields characteristic ions that allow full or partial amino acid sequencing of the analyte molecule. These techniques can be used to confirm the structures of individual oligopeptides, for example the food preservative nisin and genetically engineered analogs of this molecule.

One of the most powerful applications of mass-spectrometric peptide sequencing methodology is in the rapidly developing field of proteomics. Two main mass-spectrometric techniques have been developed for proteomic studies. The first involves enzymatic digestion of individual spots excised from a two-dimensional gel. The resulting peptide mixture is analyzed, without prior separation, by MALDI-ToF mass spectrometry. This yields a unique pattern of molecular weights that are searchable against protein databases. If this fails to yield a positive identification, a backup technique, involving ultrasensitive MS/MS sequencing of peptides generated by specific digestion of a protein two-dimentional spot, yields a 'sequence tag,' again searchable against a database to identify the unknown protein. Finally, a third level in this hierarchy of mass spectrometric techniques may be used to identify posttranslational modifications of proteins, where required. Proteomics has considerable potential in food and nutrition research, for example in the investigation of environmental responses in food-poisoning microorganisms, in the study of diet–health relationships, and in the assessment of genetically modified food safety.

Nutritional Studies

Stable Isotope Methods

Interest in the use of stable-isotope mass spectrometry for studying the nutritional value of foods and diets has increased considerably. Enriched stable isotopes, in contrast to radioisotope methods, provide safe, scientifically rigorous techniques for determining nutrient bioavailability and metabolism in all human population groups.

The only major drawbacks of stable isotope studies are associated with the presence of endogenous isotopes of the elements under investigation. Sufficient label must be administered to generate a measurable increase in isotope ratio above natural

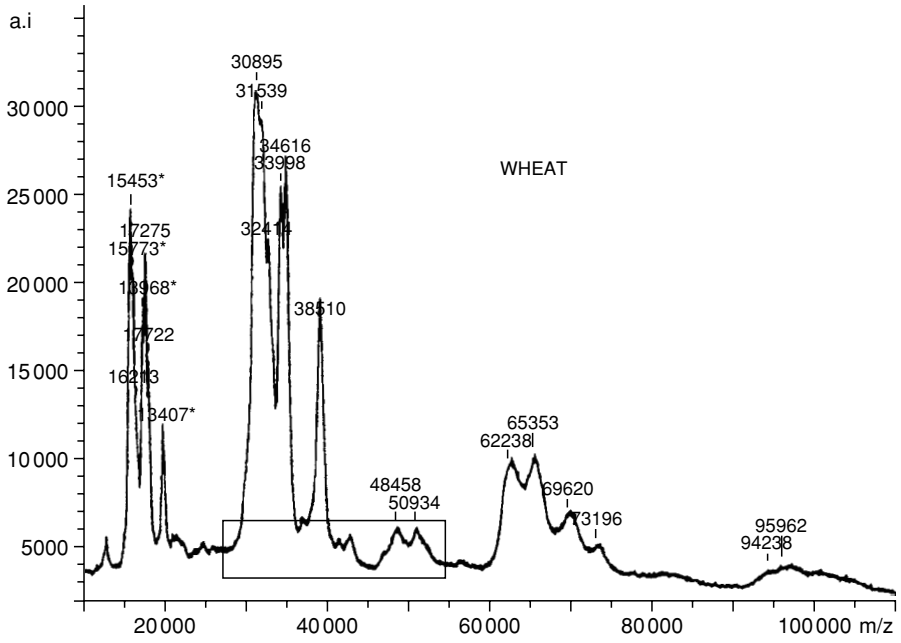

Figure 3 MALDI-ToF spectrum of the unfractionated 70% ethanol extract of wheat endosperm. A box indicates the characteristic gliadin region. Asterisked peaks are doubly charged ions. From Mendez E, Camfieta E, Sansebastian J *et al*. (1995) Direct identification of wheat gliadins and related cereal prolamins by matrix assisted laser desorption ionization mass spectrometry. *Journal of Mass Spectrometry and Rapid Communications in Mass Spectrometry (Combined Issue)* S123 with permission.

abundance. However, care is needed to prevent administration of excessive amounts of label, as this would yield unrepresentative data and might even have toxic effects. However, administration of small quantities of label requires very accurate measurement of isotope ratios because the enriched material is diluted by the endogenous nutrients already present in the body. In the case of mineral metabolism studies, additional precautions are necessary when studying trace elements because of the possibility of contamination with environmental minerals during sample processing.

Stable isotope nutritional studies usually involve administration of the enriched stable isotope of an element or isotopically labeled compound in, or with, a meal. The method of labeling depends on the type of study undertaken. For elements such as selenium, where absorption and metabolism are highly dependent on chemical form, an intrinsic label (i.e., one incorporated biosynthetically in the food) should be used in most cases. However, minerals believed to form a 'common pool' in the digestive system may be mixed directly with the food and administered following equilibration (extrinsic labeling). In some cases, a second isotope is injected or infused intravenously to correct for endogenous losses. Samples of breath, blood, urine, saliva, or feces are then collected for an appropriate period and subjected to isotopic analysis. Isotope ratio measurement often requires specialized instrumentation such as high-precision gas isotope ratio mass spectrometers or specialized inorganic mass spectrometers (e.g., thermal ionization mass spectrometry (TIMS)) or inductively coupled plasma mass spectrometry (ICP-MS).

Mineral Nutrients

Although GC/MS, FAB TIMS, and ICP-MS have all been used to measure enriched stable isotopes of nutrient minerals (in the case of GC/MS, after derivatization to generate volatile metal–chelate complexes), the dedicated inorganic methods of TIMS and, especially, ICP-MS are now used almost exclusively. ICP-MS has distinct advantages over alternative techniques because it is rapid and sensitive, and sample preparation can be minimized. Furthermore, because ICP-MS can be used with continuous flow sample introduction methods, it is suitable for coupling directly to separation techniques such as size-exclusion chromatography or HPLC. This means that speciation studies, i.e., determination of the chemical form of particular elements (oxidation state, protein binding, etc.) and the effect of this on metabolism may also be studied. The two major drawbacks of ICP-MS, low precision relative to TIMS and interference effects from polyatomic ions in the argon plasma, have largely been overcome by new generations of instruments equipped with multiple collectors and collision cells, respectively.

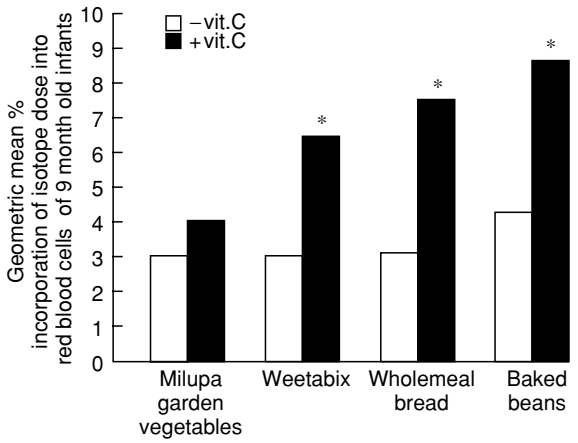

Figure 4 Bioavailability (percentage incorporation into red blood cells, measured by TIMS mass spectrometry) of iron in selected weaning foods given to 9-month-old infants, with and without a vitamin C drink. From Fairweather-Tait SJ, Fox T, Wharf SG and Eagles J (1995) The bioavailability of iron in different weaning foods and the enhancing effect of a fruit drink containing ascorbic acid. *Pediatric Research* 37: 389 with permission.

A wide range of human studies have been conducted, using enriched stable isotopes of nutrient minerals, including determination of the absorption and metabolism of iron, zinc, calcium, copper, selenium, and molybdenum. An example of the type of information that can be obtained is provided by a study of iron absorption from different weaning foods, and the effects of vitamin C on iron absorption (Figure 4). These measurements, conducted using enriched stable isotopes of ^{57}Fe and ^{58}Fe, demonstrated a doubling of iron absorption when a drink containing 50 mg of vitamin C was administered with the food.

A recent development, especially useful for conducting very long-term studies of the effect of diet on metabolism, is to administer extremely low levels of long-lived radioisotopes, e.g., ^{41}Ca, that are then measured by the ultrasensitive, highly specific technique of accelerator mass spectrometry. Because the activity of the radioisotope is extremely low (typically $< 10^{-6}$ of annual background radiation dose), it is safe for human use. Accelerator mass spectrometry is required to determine these radioisotopes because the activity is too low to measure by counting decay particles.

Vitamins

Mass spectrometry has always had considerable, though until recently unrealized, potential in the study of vitamins and their metabolism. The newer LC/MS techniques of APCI and ESI are particularly useful, as many vitamins are too thermally labile or unstable for conventional (EI and CI) mass-spectrometric measurement. The current range of mass-spectrometric techniques can be used to determine all vitamins in foods, biological tissues and fluids. Mass spectrometry is not generally a cost-effective technique for determining vitamins, as alternative, cheaper techniques are usually available. However, mass spectrometry can be used as a 'gold standard' method to validate alternative techniques and is also the method of choice for measuring isotope ratios in human studies of vitamin absorption and metabolism.

Vitamins D_2 and D_3 and their major metabolites have been studied extensively by GC/MS of volatile derivatives; these studies include quantitative determination by isotope dilution. More recently, ESI and particle-beam LC/MS and LC/MS/MS have been used in the qualitative and quantitative measurement of vitamin D and vitamin D analogs.

Recent trends include studies of the metabolism of isotopically labeled folates and carotenoids by GC/MS and LC/MS. There is evidence that folates are associated with a reduced risk of chronic disease (particularly cardiovascular disease) and with prevention of neural-tube defects. Improved mass-spectrometric methods determining these B-group vitamins are desirable, and there is evidence that ESI LC/MS fulfills this requirement, without the necessity for preparing volatile derivatives (a necessity in GC/MS studies). Figure 5 shows the negative ion ESI spectrum of 5-methyltetrahydrofolic acid at low and high cone voltage.

Carotenoid metabolism is also undergoing study by LC/MS techniques because of epidemiological evidence of their putative role in cancer prevention. Although ESI LC/MS has shown promise in preliminary mass-spectrometric studies, APCI LC/MS now appears to be the method of choice because of its robustness and tolerance of a wider range of organic solvents.

Trace Components of Foods

Food Additives

Food additives comprise a wide variety of compounds that are generally monitored by techniques other than mass spectrometry; however, occasional quantitative applications do occur, exemplified by GC/MS determination of antioxidants in stored products.

Biologically Active Naturally Occurring Nonnutrients

Biologically active (bioactive) nonnutrients in foods encompass natural substances that may have deleterious or beneficial effects. This wide-ranging category of food components has not been studied as much as

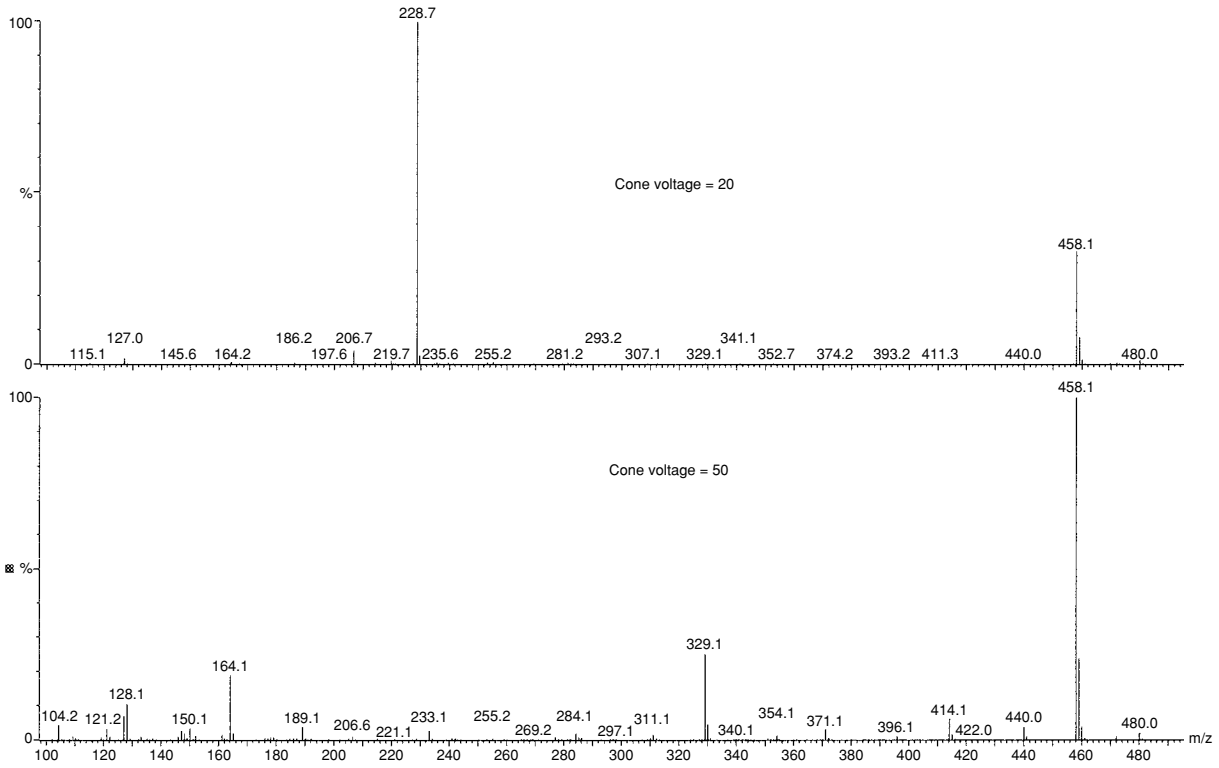

Figure 5 Negative ion ESI spectrum of 5-methyl tetrahydrofolic acid at low (upper trace) and high (lower trace) cone voltages. Fragment ions (e.g., *m/z* 329 and 164) are more intense, and the doubly charged ion at 228.7 is considerably reduced at the higher cone voltage (copyright Institute of Food Research, redrawn with permission).

anthropogenic compounds (e.g., pesticide or veterinary drug residues). However, this situation is now changing for a variety of reasons. These include the amounts present in the diet (e.g., natural pesticides in foods may be found at concentrations 10 000 times higher than synthetic pesticide residues) and the potential health benefits or toxicity of these substances. Because such a wide range of bioactive natural substances are found in foods, it is only possible here to discuss mass-spectrometric analysis of a small range of these compounds.

Glucosinolates (Figure 6) and their biologically active breakdown products are found in many plant foods. More than 100 different types of glucosinolate have been isolated from plants. Although some glucosinolates may have toxic (e.g., goitrogenic) properties, they are known to be potent inducers of Phase II enzymes that protect against carcinogens and other potentially toxic electrophiles.

The structural variability is in the aglycone, R, that may comprise linear or branched alkyl and alkenyl side-chains, alcohols, methylthioalkyl, methylsulfinyl, aralkyl or heterocyclic groups. GC/MS is the most useful mass-spectrometric technique for analyzing *volatile* glucosinolate breakdown products. Negative ion ESI LC/MS is now the method of choice for

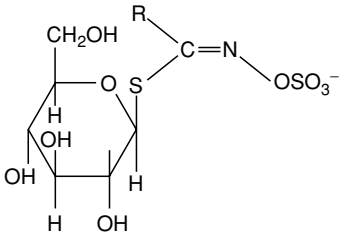

Figure 6 General structure of the glucosinolates.

determining intact glucosinolates and positive ion APCI LC/MS for analyzing the more thermally labile breakdown products (e.g., sulforaphane). ESI LC/MS and MS/MS are also useful for conducting metabolic studies, for example, by detecting and determining glutathione conjugates of isothiocyanate breakdown products of glucosinolates. Figure 7 shows a positive ion ESI mass spectrum of the glutathione conjugate of allyl isothiocyanate, a metabolite of the glucosinolate sinigrin, under low and high cone voltage and MS/MS conditions. These data are useful in developing qualitative and quantitative methods for analyzing glucosinolate metabolites *in vivo* and *in vitro*.

Phenolics are a distinctive feature of all plant tissues and are of interest because they can affect

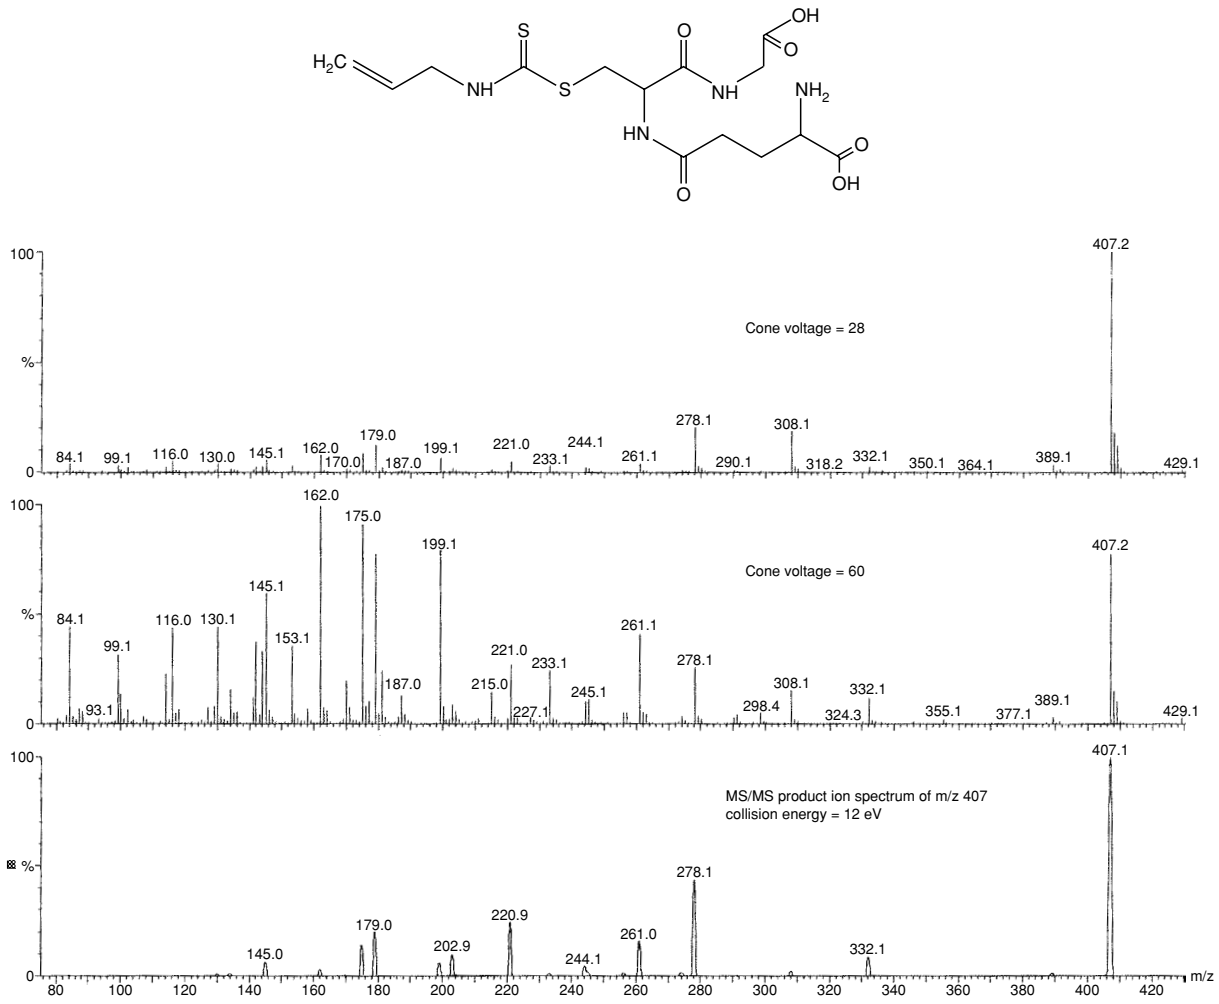

Figure 7 Positive ion ESI spectrum at low cone voltage (upper trace), high cone voltage (middle trace), and the MS/MS product ion spectrum of the $[M+H]^+$ ion (*m/z* 407) of the glutathione conjugate of allyl isothiocyanate, a metabolite of the breakdown products of the glucosinolate sinigrin (copyright Institute of Food Research, redrawn with permission).

the palatability, taste, nutritional value, and particularly the health properties of foods. For example, the flavonoids and isoflavonoids occur very widely in plants, and there is great interest in their role as protective factors in the diet. More recently, the modern methods of LC/MS analysis APCI and electrospray have been applied to the detection and quantification of flavonoids and isoflavonoids. Although early mass-spectrometric techniques for analyzing these molecules focused on GC/MS methods (after appropriate derivatization), the newer LC/MS methods are now coming to the fore. For example, isoflavones and their conjugates have been determined in soy foods (including soy beans and soy flour) by positive and negative ion APCI LC/MS. These methods also offer great potential for conducting metabolic studies.

Mycotoxic secondary metabolites produced by *Aspergillus* (aflatoxins) and *Fusarium* (tricothecenes, etc.) food-spoilage molds comprise two of the most notorious groups of natural toxicants. Many different mass-spectrometric techniques, including EI, positive and negative ion CI, GC/MS, LC/MS, supercritical fluid MS, and MS/MS have been devised to monitor the levels of mycotoxins in foods, body fluids, and tissues. The most recent developments include ESI LC/MS determination of aflatoxins down to low picogram levels. Additional selectivity (at the cost of loss of sensitivity) is provided by MS/MS selected reaction monitoring.

Anthropogenic Toxicants

Many examples of mass-spectrometric methods for determining toxic or potentially deleterious anthropogenic compounds in foods can be found in the scientific literature. The range of compounds analyzed is wide and includes dioxins, polyaromatic hydrocarbons, pesticide and veterinary drug residues,

plasticizers from packaging materials, and environmental contaminants. GC/MS and GC/MS/MS techniques are used widely for determining these compounds down to p.p.b. or even p.p.t. levels.

Isotope dilution mass spectrometry is an accurate and sensitive technique for determining toxic trace elements in food matrices. Lead, cadmium, and thallium have been analyzed down to very low levels by TIMS and ICP-MS. The latter technique is particularly useful for simultaneous measurement of a wide range of elements. Because the toxicity of an element can be highly dependent on its chemical form (for example, organomercury compounds are more toxic than inorganic mercury), ICP-MS is also useful in the speciation of toxic minerals in foodstuffs by combination with HPLC or size-exclusion chromatography.

Meat Species

Meat is defined as the flesh of animals used as food. In practice this definition is restricted to a few dozen of the 3000 mammalian species, but it is often widened to include, as well as the flesh, organs such as liver and kidney, brains, and other edible tissues. A major part of the meat consumed in the world is derived from pigs and cattle (**Table 1**). Mutton and lamb and goat meat also make a significant contribution. Poultry meat is important and growing rapidly, at the rate of 4% per annum. Refer to individual sources.

In addition, substantial quantities of horse meat, buffalo meat, and venison are consumed; and various other mammalian species are eaten in different parts of the world according to their availability or because of local custom. Thus, for example, the seal and polar bear are important in the diet of Eskimos, and a wide

Table 1 World meat production (1989)

	Million head	*Million tonnes*	*Change in weight produced over 1980 (%)*
Beef and veal	237	49.0	+12
Buffalo meat	11	1.5	+68
Mutton and lamb	443	6.5	+13
Goat meat	204	2.4	+31
Pig meat	882	67.2	+30

range of species in that of tribes of Central Africa: the kangaroo is eaten by aborigines and the whale is eaten in Norway and Japan. (*See* **Marine Foods**: Marine Mammals as Meat Sources.)

The vast majority of meat derives from domesticated animals. Domestication of cattle followed the establishment of settled agriculture about 5000 BC. Domesticated hump-backed cattle (*Bos indicus* Zebu) existed in Mesopotamia by 4500 BC. Major developments of breeds have taken place, with important differences in characteristics between parts of the world.

Pigs were not domesticated before the permanent settlements of Neolithic agriculture. They are descendants of wild pigs, of which the European representative is *Sus scrofa* and the eastern Asiatic representative is *S. vittatus*. There is definite evidence for their domesticity by about 2500 BC in Europe.

Domestic sheep belong to the group *Ovis aries* and appear to have originated in eastern Asia. By 3000 BC several breeds of domestic sheep were well established in Mesopotamia. The domestic goat derives from the wild goat, *Capra aegagrus*, and was probably the first ruminant to be domesticated, some time before 7000 BC in Iran.

Several other bovine species and bison have been domesticated and make a small contribution, together with camels, llamas and alpacas, rabbits, reindeer, and some rodents.

In order to classify meat further, consideration has to be given to the carcass from which it comes. This has a major impact on the size and composition of prepared cuts. The next sections will, therefore, be concerned with carcass composition and evaluation.

Selection for Meat Production

Over the centuries, the domesticated species have been selected to produce carcasses with high meat content, using visual appearance and tactile assessments. Historically, carcass evaluation has been dominated by considerations of size and shape. Carcass shape has been considered very important, its influence stemming from the esthetic appeal of certain types of stock. For example, in the last century, the traditional British beef breeds, Hereford, Aberdeen Angus, and beef shorthorn, were all altered in shape to fit a human idea of what a 'good' beef animal should look like. In making this change to blocky, rectangular animals, breed producers and meat traders have come to believe that these shapes are associated with more meat and better-quality meat. More recently, selection has focused on producing larger, leaner animals to meet consumer demand. This has been particularly successful with the pig in producing a dramatic increase in leanness in the European and North American pig populations.

Detailed compositional studies of carcass composition, involving tissue separation, are a relatively new phenomenon. About 70 years ago, Hammond and coworkers at Cambridge University began to examine the influence of stage of growth and level of feeding on proportions of lean (muscle), fat, and bone in the carcass. Some 40 years ago, Butterfield in Australia demonstrated that differences in shape between breeds are not reflected in important differences in the way total muscle weight (of a particular species) is distributed between different joints of the carcass.

Today, the principal trend in the western world is to reduce the proportion of fat in the carcass because of concern about the effects of high fat consumption, especially of saturated fat on health. However, there is a conflict here with the need to maintain sufficient fat in the meat to insure good eating quality, and a minimum fatness level is often required.

Carcass Structure and Composition

The type of meat from a carcass is influenced by the carcass from which it comes, in particular its (1) weight, (2) proportions of the main tissues (muscle, fat, and bone), (3) distribution of these tissues through the carcass, (4) muscle thickness, (5) chemical composition, and (6) meat quality.

Weight

The weight and size of a carcass have a major influence, not only on the quantity of the various tissues, but also on the size of the muscles exposed on cutting and of the individual joints prepared from it. This is of importance particularly in relation to a retailer's ability to provide cuts of suitable size for customer requirements. Over generations, the meat industries in different countries and the different regions of the same country have become accustomed to handle

certain weight ranges of carcasses; abattoir practices and cutting methods have been developed accordingly. Most wholesalers state desired weight ranges in buying schedules for their producers and apply discounts to carcasses falling outside these ranges. For example, in the UK pork has traditionally been produced from pigs of relatively light carcass weights; in the USA, lamb has been produced from relatively heavy carcasses.

Proportions of the Tissues

Among carcasses of similar weight, the percentage formed by each tissue varies considerably depending on breed type and growth rate. The proportion of lean meat in the carcass is of major importance since this is the principal determinant of meat yield and commercial value. Certainly, among western consumers, leanness is the criterion by which most consumers judge quality and value for money. Taken as a generalized ideal, the best carcasses should have a maximum lean content, an optimum level of fatness and minimum bone. The meat from the carcass should follow the same ideal but with most bone removed before sale. There are many different commercial techniques for assessing carcass composition.

Distribution of Tissues

The distribution of tissues through the carcass is potentially important because there are wide differences in the quality and retail value of meat from different regions of the carcass, largely influenced by the degree of tenderness and the type of cooking normally required. For example, beef fillet steak (the psoas muscle) is worth nearly three times as much as stewing steak at present in the UK. However, muscle weight distribution is a fairly constant characteristic and there is little variation to exploit commercially. On the other hand, the distribution of fat between different depots in the carcass varies considerably. The general distribution of fat is important because it influences the overall efficiency of meat production: fat in the body cavity or excess fat trimmed during retail preparation is of little commercial value in comparison with that sold as part of retail cuts. The position of fat in the carcass is also important because subcutaneous fat can be trimmed more easily than intermuscular fat and is, therefore, preferable in carcasses containing fat in excess of consumer requirements. Indeed, excess intermuscular fat cannot be trimmed from some joints, especially from lamb carcasses, without mutilating them. The evenness of fat distribution is also important because wedges or bulges of fat in some joints can lead to excessive trimming or devaluation. Intramuscular fat (that within the muscles) is important in insuring that the meat is juicy and tender.

Muscle Thickness

While this characteristic appears to vary considerably from carcass to carcass, much of this variation can be attributed to weight and fat content variations. Among carcasses of similar weight and fatness, 'blockier' carcasses will tend to have thicker muscles, but this remaining variation has little impact on retail realization values. Retailers tend to favor carcasses with good meat thickness, however, as this is thought to be associated with a higher yield of saleable meat and to improve the appearance of joints. There may also be advantages in terms of tenderness and reduced weight losses in the preparation and cooking of cuts, but the commercial significance of these advantages is not clear.

Carcass Classification

The above characteristics influence the commercial value of carcasses and national and international carcass classification schemes have been developed to describe carcasses. These have been used for grading purposes (encouraging the production of meat most suited to consumer requirements) and to facilitate trade at a distance. Techniques range from simple visual assessments of fat cover and shape to much more sophisticated objective measurement devices.

Carcass Anatomical Structure and Different Cuts of Meat

The carcass is composed of hard and soft tissues. Bones, and to some degree cartilage, form the hard tissues, while muscle, fat, and connective tissue form the soft tissues. Important differences exist between the main meat-producing species in size and bone structure which influence the types of cut produced.

The largest component of the carcass is muscle. Excluding the head, there are over 100 different muscles, which can be grouped in a variety of ways and in different degrees of detail. The distribution and structure of muscles have a major impact on the cuts of meat produced. Approaches to commercial cutting differ markedly between countries. In many countries, and especially the English-speaking world, particular joints are made by cutting across muscles, so joints as sold will consist of a mixture of muscles differing markedly in expected eating quality. In other countries, notably France and Belgium, commercial cutting is more anatomically based, the muscles are trimmed of fat and often individually

separated, allowing cuts as sold to consist of more homogeneous groupings of muscles.

In commercial practice, muscle or lean is usually sold with some adhering fat. This mixture of lean and fat is referred to as 'saleable meat' or 'trimmed deboned cuts,' although, depending on the species, cut, and country, saleable meat may contain some bone. For example, lamb cuts in the UK are commonly sold bone-in. In developed countries, there is a general trend for meat to be sold deboned as prepared retail cuts or in more processed forms.

The ratio of lean to fat in the meat sold depends on the fat content of the carcass from which the cuts are derived, the nature of the cut, and the preferences of retailers and their customers. When customers self-select their purchases from retail display cabinets, there is a worldwide tendency for those cuts with high lean-to-fat ratios to be preferred, other things being equal; but there is still much variation in the fat content of the carcasses that butchers select and in the amount of fat they trim in the preparation of retail cuts. Consumer attitude studies show that many consumers in developed countries do not like fat and that the preference for lean meat and products is growing. Fat requires extra labor for trimming and, in any case, fat is extremely expensive to produce. There can be little doubt that market forces will filter back to producers and economics will favor the production of leaner-meat animals.

In less-developed countries where meat consumption is low, all parts of the animal are often considered to be of equal value (certainly as far as boneless meat is concerned), and the degree of processing is relatively low. There is also a greater tolerance for fat.

Structure

C R Calkins and K M Killinger, University of Nebraska Lincoln, Lincoln, NE, USA

Introduction

Meat is the flesh of animals used for food. The primary components of meat include muscle, fat, and connective tissue. Of these, muscle is the major food component. The unique composition and structure of muscle allow it to perform a variety of physiological functions and give rise to the characteristic properties of meat.

Composition

Moisture (water), protein, and lipid (fats) are the primary constituents of muscle. Their proportions can be quite variable, as are their functions. Additional trace minerals, carbohydrates, and inorganic compounds are located within the tissue, but contribute little to the gross structure.

Water makes up 68–80% of muscle weight; much of this is located within the individual muscle cell. There it functions as the liquid medium (sarcoplasm), as a coolant, and as a transporter of nutrients and waste products. Water-soluble compounds essential for life are distributed throughout the sarcoplasm.

Proteins contribute 15–22% of muscle weight. The numerous and varied types of protein provide critical features to muscle. Proteins are frequently classified on the basis of solubility. Sarcoplasmic proteins are water-soluble. Myofibrillar proteins are salt-soluble and contribute to the contractile machinery (located within the myofibril). In contrast, stromal proteins create a fibrous, structural element within the tissue and are relatively insoluble. Another nomenclature reflects the specific function of proteins. Under this system, proteins are classified as contractile, regulatory, or cytoskeletal (**Table 1**).

Lipid content is the most variable of all meat constituents, making up 0.5–20% (or more) of the weight. Lipids are located within cell membranes, adipose

Table 1 Location and function of muscle proteins

Protein	*Location in sarcomere*	*Proposed function*[a]
Major contractile proteins		
Myosin	Thick filaments	Contraction
Actin	Thin filaments	Contraction
Regulatory proteins		
Tropomyosin	Thin filaments	Regulates contraction
Troponin	Thin filaments	Regulates contraction
α-Actinin	Z-line	Anchors thin filaments from opposing sarcomeres in the Z-line
Cytoskeletal proteins		
Titin	Extends from M-line to Z-line	Protects sarcomere from overstretch
C-protein	Thick filaments	Inhibits skeletal muscle myosin adenosine triphosphatase (ATPase)
H-protein	Thick filaments	Inhibits skeletal muscle myosin ATPase
F-protein	Thick filaments	Binds to thick filaments, inhibited by C-protein
I-protein	Thick filaments	Inhibits Mg^{2+}-ATPase activity of actomyosin in the absence of Ca^{2+}
Nebulin	Thin filaments	Controls thin filament length
Tropomodulin	Thin filaments	Blocks depolymerization of actin filaments
β-Actinin/CapZ	Thin filaments	Anchors thin filaments in Z-line
M-protein	M-line	Forms the transverse portion of the M-line in fast-twitch fibers
Creatine kinase	M-line	Binds to M-protein
Myomesin	M-line	Anchors titin in the M-line and binds myosin
Skelemin	M-line	Attaches M-lines of adjacent myofibrils
Cypher	Z-line	Binds at Z-line
Telethonin/T-cap	Z-line	Binds titin in Z-line
Desmin	Z-line periphery	Transversely links myofibrils at Z-line
Filamin	Z-line periphery	Transversely links myofibrils at Z-line
Vimentin	Z-line periphery	Transversely links myofibrils at Z-line
Synemin	Z-line periphery	Links desmin to Z-line, modulates assembly/disassembly of intermediate filaments
Dystrophin	Near the sarcolemma	Stabilizes sarcolemma and binds actin
Utrophin	Neuromuscular junction	Immobilizes acetylcholine receptor clusters
Dystrophin-associated proteins	Sarcolemma	Family of proteins involved in anchorage of dystrophin in the sarcolemma
Vinculin	Near the sarcolemma	Attachment of actin to the sarcolemma
Talin	Near the sarcolemma	Attachment of actin to the sarcolemma
Paxillin	Near the sarcolemma	Adapter molecule for signal transduction
Tensin	Near the sarcolemma	Anchors actin and maintains tension
Integrin	Sarcolemma	Family of mechanoreceptors, anchors some cytoskeletal proteins in the sarcolemma
Spectrin	Near the sarcolemma	Binds to actin and stabilizes the sarcolemma
Ankyrin	Near the sarcolemma	Attachment of spectrin to the sarcolemma

[a]Some proteins listed have several functions, while some functions have not been fully characterized.

cells, or the sarcoplasm of muscle cells. Lipids are a source of energy in living muscle and also serve a vital role in cell membrane structure.

Muscle Structure

Contraction must be translated from the cellular level to gross muscle movement. This is accomplished through the integration of skeletal muscle contraction with a connective tissue harness that traverses the entire muscle down to the individual muscle cells (Figure 1). The connective tissue harness is primarily composed of the protein collagen. The epimysium, the outermost connective tissue layer, surrounds the individual muscles themselves. Individual muscles contain large groups of muscle cells (called bundles) which are surrounded by the perimysium, the middle connective tissue layer. Finally, the individual muscle cells or myofibers are surrounded by the endomysium, the innermost layer of connective tissue. Myofibers, which are usually several centimeters in length, rarely transverse the entire length of a muscle.

Muscle cells contain the organelles typically associated with eukaryotic cells; however, some muscle cell structures merit attention. The prefix 'sarco' is derived from the Greek word for flesh and is often used to denote certain muscle cell structures, including the sarcolemma (cell membrane), sarcoplasm

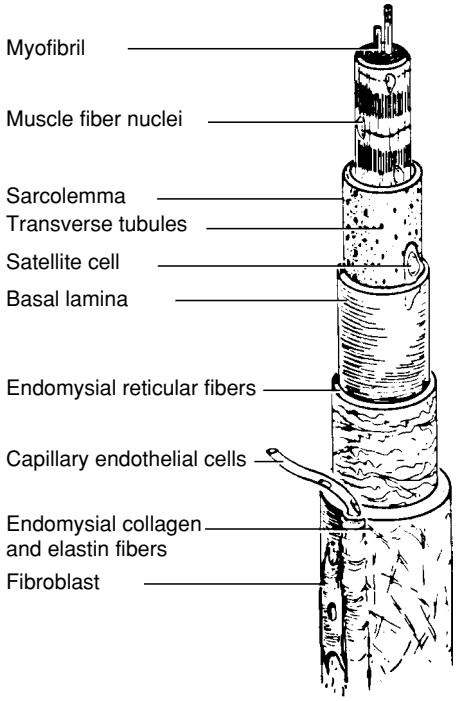

Figure 2 Organization of a muscle cell. Courtesy of Dr JE Novakofski, University of Illinois Urbana-Champaign.

(cytoplasm), and sarcoplasmic reticulum (endoplasmic reticulum).

The structure of the sarcolemma is unique in that it has two sturdy outer layers, the reticular lamina and the basal lamina, in addition to the lipid bilayer (Figure 2). The sarcolemma also has invaginations which reach deep into the muscle cell. These invaginations are known as the transverse tubules or t-tubules. In mammalian, striated skeletal muscle, the t-tubules are located at the junction of the dark and light bands, thus each sarcomere is associated with two t-tubules. The terminal cisternae of the sarcoplasmic reticulum is connected to the t-tubules via protein bridges called ryanodine receptors (Figure 3). The sarcoplasmic reticulum regulates the dynamic pool of calcium within the muscle cell.

Skeletal muscles are unique because they are multinucleated, with the nuclei typically located between the sarcolemma and the underlying myofibrils. Nuclei contain the genetic material that regulates protein synthesis within the muscle. Numerous mitochondria are also found in muscle cells and are located just beneath the sarcolemma as well as between myofibrils. Mitochondria, the powerhouse of the cell, synthesize energy compounds necessary for cellular functions. Muscle cells that perform more aerobic metabolism tend to contain more mitochondria. The sarcoplasm and the myofibrils make up most of the muscle cell volume.

When viewed under a light microscope, skeletal muscle exhibits a characteristic pattern of alternating dark and light bands that are parallel to the long axis of the myofiber. This pattern gives rise to the term 'striated, skeletal muscle.' The dark bands, called A-bands, are dense, birefringent, and anisotropic, which means they do not allow the passage of light. The light bands, called I-bands, are less dense and are isotropic (allow the passage of light). The I-bands are bisected by a dark line perpendicular to the long axis of the myofiber, which is called the Z-line.

Within a myofiber, the aggregation of contractile proteins into long filaments creates myofibrils (Figure 2), which contain sarcomeres, the functional contractile unit of the muscle cell. Each sarcomere is approximately 2–2.5 μm and spans from Z-line to Z-line (Figure 4). The sarcomere is composed of a series of overlapping protein filaments. The thick myofilaments, located within the A-band, contain myosin as the predominant protein. The thin myofilaments, predominantly located within the I-bands, are composed mostly of actin. When a myofiber is at rest, the thin and thick myofilaments overlap slightly in the sarcomere. The H-zone spans the central portion of the sarcomere where the thin and thick myofilaments do not overlap. Within the H-zone, the pseudo-H-zone lies over the portion of the thick myofilament which does not contain the globular heads of myosin. Additional structural and regulatory proteins are also found in the center of the A-band in the centrally located M-line, which serves to maintain the three-dimensional alignment of the thick myofilaments.

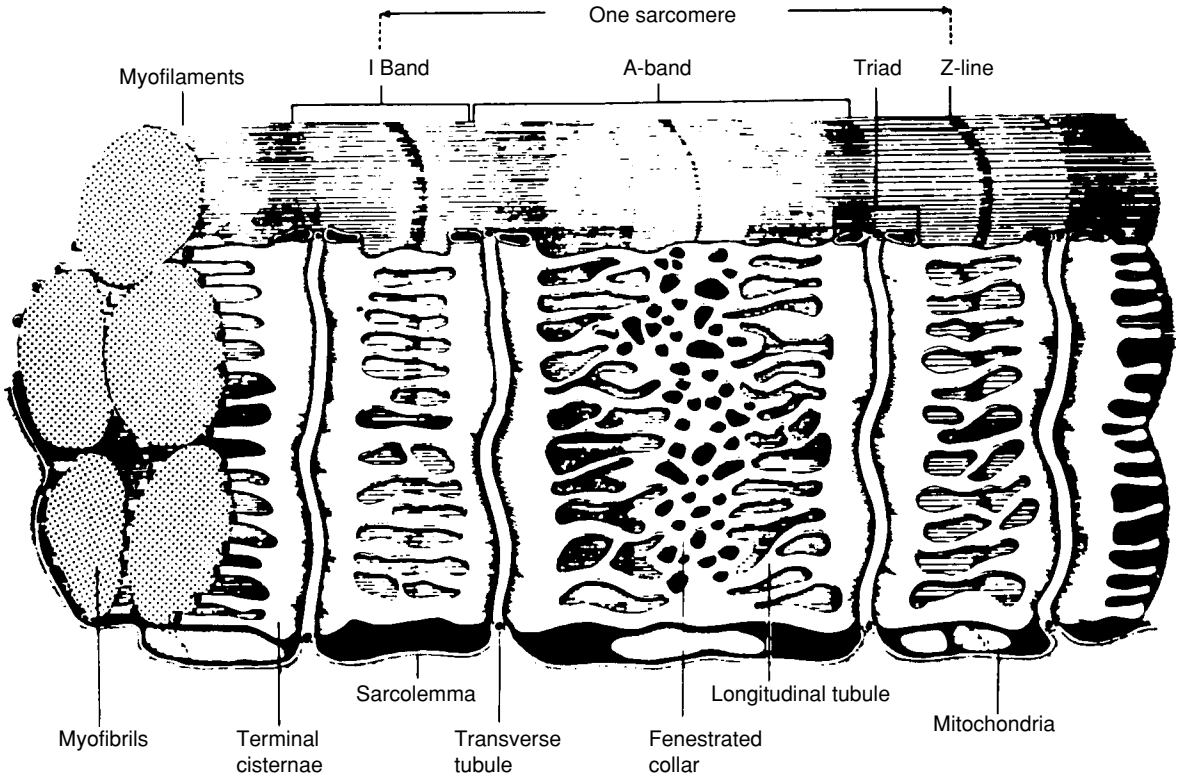

Figure 3 Diagram of t-tubules and sarcoplasmic reticulum in longitudinal view of skeletal muscle. From Pearson AM and Young RB (1989) *Meat and Muscle Biochemistry*. San Diego, CA: Academic Press, with permission.

Myofibril cross-sections have different appearances depending on the location within a sarcomere (Figure 4). In the I-band, the thin myofilaments (smaller in diameter) form off-set rows, with every other row being aligned. In the H-zone, the thick myofilaments (larger in diameter) form a similar pattern of off-set rows, with every other row being aligned. Within the area where the A- and I-bands overlap, the thin myofilaments surround the thick myofilaments. Each thick myofilament has access to six thin myofilaments, and each thin myofilament is accessible to three thick myofilaments.

Function

The proteins associated with the M-line are believed to provide support to the thick myofilaments and to help maintain the structural integrity of the sarcomere. The proteins in the Z-line interior are believed to help anchor the thin myofilaments, while the proteins at the periphery of the Z-line are believed to play a role in attaching adjacent myofibrils.

The costameres are rib-like structures encircling the myofiber. They overlie the I-bands on each side of the Z-line (Figure 5). The costamere structure is comprised of several proteins (like vinculin, dystrophin, and spectrin), some of which are closely associated with the sarcolemma and others which are filamentous strands that appear to associate with the Z-line. Some of the proteins found in costameres also appear to connect the M-line to the sarcolemma, although this connection has not been fully characterized. Costameres are integral in the attachment of the sarcolemma to underlying myofibrils. In addition, they help transmit the force of contraction to the extracellular matrix and laterally along the myofiber.

The thin myofilament is predominantly composed of actin. Actin monomers, called globular actin or G-actin, are almost spherical in shape and polymerize to form two strands of actin that wrap around each other in a helical fashion to form the bulk of the thin myofilament. The strands of polymerized actin are called filamentous actin or F-actin. Each G-actin molecule contains a myosin-binding site that is critical for contraction to occur. A rod-shaped protein, tropomyosin, winds around the strands of actin and blocks the myosin-binding site on the actin molecules in muscle at rest. Troponin, a second regulatory protein, is located at regular intervals along the thin myofilament. Troponin is composed of 3 subunits. Troponin T (TnT) binds to tropomyosin and to

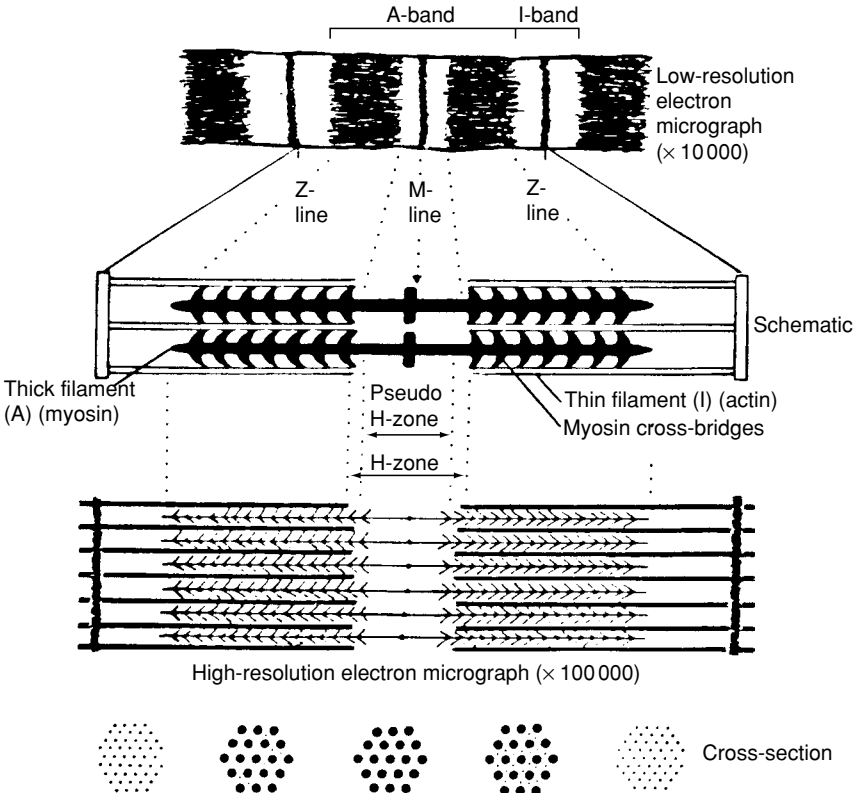

Figure 4 Fine structure of a sarcomere along with portions of two adjacent sarcomeres. From Pearson AM and Young RB (1989) *Meat and Muscle Biochemistry*. San Diego, CA: Academic Press, with permission.

troponin C (TnC), which is the calcium-binding subunit. Troponin I (TnI), the inhibitory subunit, connects TnC to the thin myofilament. At sufficient levels of calcium, the interaction between the troponin, tropomyosin, and actin exposes the myosin-binding site of actin.

In the thick myofilament, the best-characterized protein is myosin. Myosin has been called a mechanoenzyme as it not only plays a structural role in the thick myofilament, but also acts as an adenosine triphosphatase (ATPase). Myosin's globular head has both enzymatic and structural roles. It breaks down adenosine triphosphate (ATP) to provide the energy necessary for contraction, while it also interacts with actin to form a cross-bridge between the two proteins. The tail portion of the myosin molecule plays a structural role, and is involved in the formation of the thick myofilament. Other proteins in the thick myofilament help maintain the structure of the myofiber and also play regulatory roles.

During contraction, the globular head of myosin breaks down ATP to adenosine diphosphate (ADP) and inorganic phosphate, binds to actin, and subsequently changes the angle of the actomyosin cross-bridge from 90° to 45°. When another molecule of ATP binds to actomyosin, myosin detaches from actin. This process is cyclical and results in the thin myofilament sliding inward past the thick myofilament. Contraction ceases when calcium ions are sequestered back into the sarcoplasmic reticulum. Contraction of an antagonist muscle is required to return the original muscle to resting length.

The signal for muscle to contract begins as a wave of depolarization, or action potential, that sweeps down a nerve cell. When the action potential reaches the neuromuscular junction (the connection between a nerve cell and a muscle fiber), acetylcholine is released from the nerve cell, crosses the synapse (the gap between the nerve and muscle cell), and attaches to receptors located on the sarcolemma. The sarcolemma depolarizes in a similar manner to the nerve cell, and the message is carried into the t-tubule system in order to carry the message deep into the myofiber. The sarcoplasmic reticulum is stimulated by the t-tubules to release calcium which interacts with regulatory proteins to initiate contraction.

All myofibrils within a muscle cell contract in concert. By moderating the number of muscle cells recruited for contraction, the strength of a particular muscle can be controlled. Thus, fine motor movements and considerable physical strength can both be demonstrated by the same muscle.

Postmortem Changes in Meat

In the conversion of muscle to meat, several changes occur that impact meat quality. During slaughter and processing, the muscle cell environment undergoes changes like: declining energy levels, pH, and temperature, increasing ionic strength, and changes in redox potential. The pH declines as lactic acid is produced as a byproduct of anaerobic metabolism. Lower muscle pH results in reduced water-holding capacity and influences meat color.

An important contributor to the increase in ionic strength is calcium. As energy sources are depleted, the sarcoplasmic reticulum loses its ability to sequester calcium. With increased calcium levels in the sarcoplasm, conditions for contraction exist (as long as sufficient energy is available). Eventually, the cross-links between the thick and thin myofilaments (myosin and actin) are sustained. These attachments (rigor bonds) cause muscle rigidity (rigor mortis) and reduce meat tenderness. Shorter sarcomeres have a greater number of rigor bonds and create less tender meat.

Meat is usually held at refrigeration temperatures for a time postmortem to modify meat palatability (flavor and tenderness). This storage period is called aging. Meat undergoes several structural changes during this period which lead to an increased fragility of the myofibrils (as measured by an increase in meat tenderness). The decrease in the intensity of the Z-line and subsequent loss of Z-line integrity is the most notable change in structure. Additionally, the sarcolemma separates from the underlying myofibrils. Adjacent myofibrils also separate from each other, and some researchers have observed discontinuities in the I-band.

Despite considerable research, a unified theory on the mechanism of postmortem tenderization in meat has not been embraced. Tenderness increases most rapidly and to the greatest extent during the first 3–4 days postmortem. Changes in tenderness are believed to be associated with the degradation of structural proteins in the myofibers. Early researchers attributed postmortem tenderization to the cathepsins, a group of hydrolytic proteins found in the lysosomes, while other researchers have suggested that the change in ionic strength within the cell is the cause of postmortem tenderization. More recently, the calpain system has been implicated as a link in postmortem tenderization. This group of proteases

requires calcium for activation. They maintain activity in the cellular environment that predominates in meat. There are three calpain isoforms: m-calpain, μ-calpain and skm-calpain. All three forms have been identified in skeletal muscle; however, skm-calpain (also called p94) is only found in skeletal muscle. skm-calpain is difficult to purify, and therefore has not been fully characterized. The other two isoforms are activated at different calcium levels, and the typical conditions during postmortem aging favor μ-calpain. The calpain system is subject to control by a powerful inhibitor, calpastatin. It is believed that one molecule of calpastatin can inhibit multiple calpain molecules. The calpains have been shown to degrade several proteins like titin, nebulin, desmin, and TnT, which may influence postmortem tenderization.

Collagen is another contributor to meat tenderness. Collagen molecules are cross-linked in order to stabilize the molecule and to impart the strength associated with connective tissue. In young animals, collagen cross-links are reducible, and therefore less stable. Collagen containing reducible cross-links will hydrolyze to form gelatin if heated in the presence of moisture. The conversion to gelatin, a softer material, results in more tender meat. However, in older animals, the collagen cross-links become heat-stable and nonreducible, thus contributing to tougher meat. Pyridinoline appears to be one of the more significant nonreducible cross-links.

The flavor of meat is determined by two major components: the meaty flavor is associated with protein, while the species flavor is associated with fat. During aging, proteins are altered to impart the characteristic flavor of aged meat. The breakdown of protein and fat produces flavor compounds, including hypoxanthine, xanthine, hydrogen sulfide, ammonia, acetylaldehyde, and acetone. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

The structure of living muscle is inexorably linked to the structure and characteristics of meat; therefore, an appreciation of all three is required to understand meat-based food products.

Slaughter

K Troeger, Bundesanstak f■r Fleischforschung, Kulmbach, Germany

Introduction

Meat consumers, especially young people in largely urbanized regions of developed countries, are increasingly demanding that animals be reared, handled, transported, and slaughtered using humane practices. At slaughter, this means that stunning should render animals insensible to pain to insure that they do not suffer needlessly during slaughter. Because of animal welfare considerations in European law, all animals must be stunned before they are slaughtered. The second aspect of slaughtering is the quality of the final product. This article describes technical parameters of the slaughter process in relation to both meat quality and aspects of animal welfare.

Animal Handling

The moving, handling, and unloading of animals within a slaughterhouse should be carried out with care. Good handling procedures will reduce pale, soft, exudative (PSE) meat, bloodsplash, and injury losses. Animals should be unloaded as soon as possible after arrival at the slaughterhouse. The unloading facilities (ramp, bridge, gangway) should be fitted with siderails and the slope should not exceed 20°.

While cattle should if possible be slaughtered immediately after unloading to avoid poorer meat quality (dark-cutting beef or DCB), lairage times for pigs of at least 2 h and at most 4 h have proved to be successful. The shape and construction of the pens

should permit most of the animals to lie against a wall. Holding pens should therefore be long and narrow rather than square. The following conditions of lairaging have proved to work well:

- Group penning: groups of animals should be kept together, not mixed with 'strangers'
- Number of animals per pen: each animal must have enough space to lie down and turn around
- Sprinkling: showering, at least during hot weather, is particularly recommended for pigs
- Water: drinking water must always be available

Cattle and pigs are driven to the stunning place along passageways and races. Sticks and electric prods are used commonly as guiding instruments. According to European law, personnel involved in preslaughter handling must be trained and certified. Suitable passageways allow the use of gates on rollers or guiding boards, so a more gentle driving of pigs is possible. Races should be short, straight, horizontal, and wide enough to enable two animals to walk side by side for as long as possible. Shadows and sparkling reflections should be eliminated. Animals tend to move from a darker area towards a lighter one, but they will avoid blinding light. Animal welfare-relevant problems mostly occur if it is necessary to line up pigs in a single race. A new Danish carbon dioxide (CO_2) stunning system (Backloader) makes it possible to handle pigs in a group into and through the stunning unit. The principle of the new concept is that 15 pigs are driven forward using a series of push-hoist gates or, alternatively, manually driven to the area in groups of 15. There are three main elements to this concept: first, there is an area where the group of 15 hogs is divided into smaller groups (e.g., five); second, there is automatic transfer of these smaller groups to and through the stunning equipment; and third, there is a system for presenting the stunned hogs for shackling and sticking. As the hogs are stunned in groups, the concept assumes that CO_2 stunning will be used and this has several advantages. Hogs do not like to be isolated away from one another and stunning in groups eliminates this problem. Moreover, hogs find restraint stressful and in modern CO_2 systems hogs are not restrained at all during the stunning itself (Figure 1).

Stunning

General Aspects

Stunning aims to bring the animal immediately to a state of insensibility that lasts until it is dead. Another aim is to produce sufficient immobility to facilitate exsanguination. These two aims are not necessarily complementary. Some methods of stunning result in violent reactions by the animals after they have been rendered insensible. Conversely, certain procedures, such as low-voltage application, may produce total-body immobility without causing insensibility. In the light of present scientific and practical knowledge, acceptable stunning methods, if applied properly, are electrical stunning, CO_2 stunning or stunning with alternative gas mixtures (e.g., argon), and percussive stunning (penetrative; nonpenetrative with restriction). Irreversible stunning methods, such as cardiac arrest stunning, induced by an electrical current or longer exposure to gas mixtures, is preferred from the animal welfare point of view as well as for meat quality reasons.

Electrical Stunning

Electrical stunning is important first for slaughtering pigs and poultry; sheep and cattle are also stunned electrically in some countries. The electrodes must be placed so that they span the brain. Effective electrical stunning results in immediate insensibility, which is exhibited as an epileptiform seizure. The effectiveness of electrical stunning depends on a minimum current level passing through the brain. Using a constant stunning current of 1.3 A, for pigs effective stun can be induced within a minimum current flow time of 0.3 s. This time requirement seems to be appropriate

for animal welfare-conforming electrical stunning. There are two main types of electrical stunning: head-only and head-to-body. In head-only systems electrodes are applied only to the head, whereas in head-to-body stunners an (additional) electrode is placed elsewhere on the animal's body (back, breast) so that the flow of current passing through the body should additionally cause cardiac ventricular fibrillation. With this method, all species will be rendered immediately and permanently insensible.

Besides manual stunning with a pair of tongs or single-handed prods, fully automated electrical stunners are available for use on both sheep and pigs. With older systems, animals are fixed and conveyed in a v-conveyor (restrainer) to the point of stunning (bilateral electrode contact on the head). The stunning voltages used in these systems are about 450–1000 V (high-voltage systems). Recent developments have led to improvements in automatic electrical stunning devices. The Midas system (Stork, Netherlands) incorporated a new conveyor belt transport system; the pig rides on this belt with its feet hanging down on both sides and becomes relatively relaxed in this position. This is a good condition for an effective stun. The system has the capacity for 200–600 hogs per hour. It is not a high-voltage system. The induction of cardiac ventricular fibrillation is carried out by an automatic breast electrode, so the animals show little or no convulsions. After a current flow through the head, the third electrode is contacted pneumatically with the left side of the breast and an additional current flows head-to-body.

The current flow through the brain leads to depolarization of neurons, with subsequent repolarization, which causes uncoordinated motor activity (tonic–clonic spasms). These muscle contractions stimulate glycolysis, with production of lactic acid in the musculature. The consequence is an accelerated pH drop postmortem, which favors the incidence of PSE meat. Fewer muscle spasms occur after cardiac arrest stunning. Other adverse effects of electrical stunning can be fractures of bones or bloodsplash (intramuscular hemorrhages) and speckling (petechial hemorrhages in subcutaneous tissues). Factors important for a careful slaughter process including electrical stunning are summarized in Table 1.

Gas Stunning

Gas stunning with high concentrations of CO_2 in air is used primarily for pigs; turkeys and chickens are also sometimes stunned or killed with CO_2. CO_2 is colorless and heavier than air, so stunning can be done in a pit. The gas atmosphere for stunning consists of about 70–95% CO_2 and air. CO_2 has the general effect of depressing neuronal function by both hypoxia and lowering tissue pH < 7.0. There are two main types of CO_2 stunning or killing systems: a dip-lift system, where pigs are lowered continuously into the gas, and the paternoster system, where pigs are lowered successively into the gas with stops as pigs enter or leave the equipment. The paternoster system is most commonly used. The latest development is an automatic Danish system for group CO_2 stunning of up to 800 hogs per hour. This system has the advantage that lining up and restraint of animals are no longer necessary. Up to five pigs enter the stunning box simultaneously. Adequate stunning can be achieved using high CO_2 concentrations (> 90%) and a long exposure time (> 150 s).

The welfare implications of CO_2 stunning are still under debate. Some studies have shown that most pigs will avoid an atmosphere of high concentrations of CO_2. This aversion was found to be greater than the motivation to obtain a reward in the CO_2 atmosphere, even after 24 h fasting. On the other hand, exposure to CO_2 was less aversive than electrical shocks. Scientists have also interpreted the increase in rate and depth of respiration that occurs during inhalation of CO_2 as respiratory discomfort. In contrast to stunning of pigs with CO_2, the animals show no aversive reactions when exposed to gas mixtures of either 90% argon in air or 60% argon and 30%

Table 1 Electrical stunning: important factors for animal welfare and meat quality

Factors	*Criteria*
Minimum of excitement and physical strain	Internal muscle temperature (ham) 45 min post mortem $\leq$ 40.5 °C
Immediate unconsciousness	No vocalization (squealing) if the stunning current is interrupted after 0.3 s
Two-step cardiac arrest system:	Little or no convulsions
1. Constant current ($\geq$ 1.3 A) through the head, followed by	Death within 60 s (no eye reactions, dilatation of the pupils)
2. Head-to-body current	Insignificant bloodsplash
Horizontal bleeding table	Conveying till muscles are relaxed (1.5–2 min)
Short stun-to-stick interval	Horizontal bleeding < 10 s after stunning
Effective sticking	Amount of blood > 3 l per pig

CO_2 in air. The phase before unconsciousness happens without stress. The practicability of these gas mixtures under commercial conditions was tested in the UK.

CO_2 anesthesia results in fewer carcass defects than electrical stunning. The incidence of bloodsplashes, fractures, and PSE meat is lower.

Percussive Stunning

Percussive stunning methods can be divided into two categories: penetrative and nonpenetrative. The first category includes free bullets, captive bolts, and high-pressure water jets. Nonpenetrative methods deliver a controlled obtuse blow to the head (mushroom head, manual blow). In all cases kinetic energy is transferred to the brain, which causes neuronal dysfunction and subsequent unconsciousness. While penetrative methods, which produce a trauma of brain tissue, cause permanent insensibility, unconsciousness after the use of nonpenetrative methods is only temporary.

For penetrative stunning – in general of cattle, sheep, goats, and horses – captive bolt apparatus and pistols are mostly used. These consist of a steel rod with a collar and piston (bolt) at one end contained in a chamber. On activation the bolt is propelled forward by the energy of a cartridge or by compressed air and penetrates the head of the animal. Water jet stunning is the use of a high-pressure water jet with 2500–4000 bar and an injection time of 20–100 ms for stunning or killing slaughter pigs. This method is in an experimental phase. The only method of nonpenetrative percussive stunning commonly used is the 'mushroom head' fitted to a captive bolt and used almost exclusively on cattle, especially in cases of ritual slaughter. The 'mushroom' is a metal convex disk approximately 4 cm in diameter and the impact is applied to the frontal region of the head.

After the correct use of a captive bolt, corneal reflexes cannot be evoked and respiration ceases. The effect of a nonpenetrative percussive technique depends on the size of impulse delivered. Studies have shown that only about 80% of animals are being stunned effectively by such methods.

Percussive stunning, like other stunning methods, causes an increase in blood pressure, violent muscular contractions, and elevated levels of catecholamines. These factors can result in bloodsplash and the occurrence of PSE in pigs. In some European countries, where cases of bovine spongioform encephalopathy (BSE) have occurred, the use of captive bolts for stunning cattle is under debate. There is a clear risk, because of the destruction of brain tissue, including blood vessels, with this method, that in the case of BSE infectious brain tissue might be dispersed into the blood stream, and especially to the lungs.

Killing

Killing of slaughter animals is usually done by exsanguination (bleeding). An incision (sticking) which severs the major arteries of the neck or anterior thoracic cavity causes a rapid loss of blood, resulting in a lack of oxygen to the brain. Irreversible cellular changes occur and the animal dies. Because most stunning methods are reversible as a rule, prompt and accurate (effective) sticking is of high importance from the animal welfare point of view.

Bleeding can be done with the animal in a vertical or horizontal position. The most common technique is to shackle a hind leg and to elevate the stunned animal on the bleeding rail, where sticking is done in a hanging position. There is a significant positive effect on pork quality (reduction of PSE), if prone bleeding is practiced. Sticking is done immediately after electrical stunning on a movable conveyor. For a bleeding time of about 2 min, the pigs are conveyed in a horizontal position. As a result, muscle spasms have a less detrimental effect on meat quality, and internal ham bruising and bloodsplashing are obviated.

Severing of the common carotid arteries or the vessels from which they arise during sticking can be done in different ways. A transverse incision of the neck is a common method of bleeding sheep. This method is also used for ritual slaughtering of sheep and cattle.

Ritual slaughter is performed by a throat cut, which severs all soft tissues of the throat (muscles, blood vessels, esophagus, trachea, nerves) without preslaughter stunning. It is necessary to distinguish between kosher (Jewish) slaughter and halal (Muslim) slaughter. For kosher slaughter, there exist exact rules for the slaughter process, the instruments used, and the qualifications of the slaughterman. A straight, razor-sharp knife (chalaf) that is twice the width of the throat is required, and the cut must be made in a single continuous motion. For halal slaughter, no special knife design is required.

Another sticking method, lateral stab incision of the neck, avoids incision of the trachea and esophagus, because this may result in aspiration of blood and pollution of the blood by stomach contents. Finally, thoracic sticking is commonly used for cattle and pigs. The knife is inserted in the midline, cranial of the sternum bone, so that the bicarotid trunk and anterior vena cava are incised.

Skinning, Scalding/Dehairing, Evisceration, and Splitting

In industrial slaughterhouses skinning, including scalding and dehairing (hogs), evisceration and splitting of carcasses occurs continuously within a slaughter conveyor (Figure 2). The capacities of slaughter lines in Europe may be up to about 80 cattle and 800 pigs per hour. There is a great deal of mechanization, automatization, and robotization in slaughterhouses worldwide.

Skinning (Cattle, Sheep)

After bleeding, the free hanging leg is skinned; this leg is then used temporarily for hanging, so that the slaughter chain can be taken away from the other leg. This leg is skinned too. The gambrel is provided and the belly, chest, and neck part are skinned. Further skinning is done mechanically by means of a skinning machine. For this, the front legs are fixed and the skin is drawn off from the lower to the upper side. This is the traditional method of depelting sheep. A lower carcass microbial level can be achieved if the sheep are depelted from the shoulder to the hind leg; this process is most easily done by suspending the animal from the front legs (inverted system). For cattle, with a roller-mounted hide stripper, skinning is possible either from top to bottom or from bottom to top. If the head remains on the carcass and is skinned too, the carcass has to be stabilized by an electrical current (electrical stimulation with about 150 V, electrodes on the back). A disadvantage of this method is that the force needed for dehiding is so high that overstretching of the hide can happen, which lowers its value for processing.

Scalding, Dehairing, Singeing, Polishing (Pigs)

The conventional process of hair removal from slaughtered hogs utilizes hot water for scalding and a gas flame for singeing. The traditional scalding method is vat scalding. Using a water temperature of 58–62 °C, the scalding process requires 4–6 min. On economic grounds, many hogs are scalded in the same hot water; this results in rapid pollution of the scalding water. From a bacteriological point of view, therefore, it is important that the scalding temperature exceeds 60 °C, but it should not exceed 62 °C because of the coagulating effect on pig skin, which results in damage to the skin by the dehairing machine. A disadvantage of vat scalding is the possibility that scalding water can enter the lungs and, via the sticking wound, into deeper tissues of the carcass. Investigations have revealed that the risk of bacterial internal contamination of lung, liver, heart, and muscles depends on the scalding and dehairing technology. From a hygienic point of view, vat scalding with simultaneous dehairing (mechanical treatment by dehairing implements with pressing and pumping effects on the thorax) was the most dubious method.

An alternative to vat scalding is the scalding tunnel. The pigs are brought through the tunnel by means of

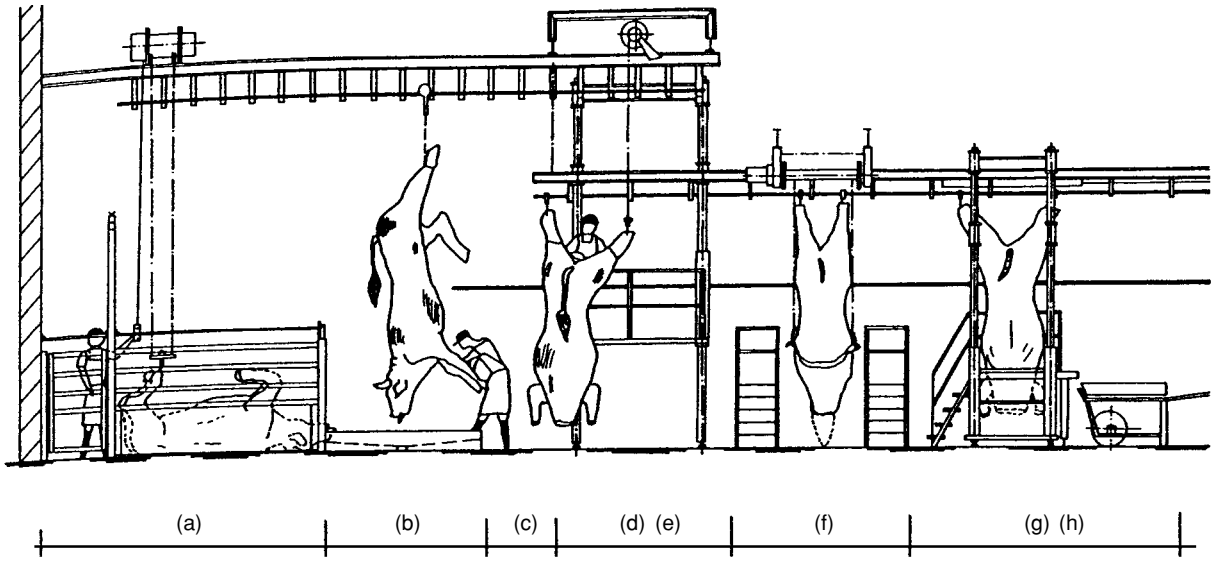

Figure 2 Slaughter line for cattle with hanging up to bleed. (a) Stunning; (b) sticking; (c) decapitation; (d), (e) transfer to slaughter line, removal of hind legs, and preliminary skinning; (f) removal of remaining skin and opening of breast bone by sawing; (g), (h) removal of paunch and breast organs, and cleaving. Reproduced from Meat: Slaughter. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

a chain-conveyor in a hanging position. Scalding is done either by spraying carcasses with hot water that is pumped around the system or by condensed steam. To obtain a low bacterial count on the carcass surface, it is still necessary that the pigs pass through a prewashing machine prior to the scalding tunnel.

After scalding, the next process in a pig slaughter line is dehairing. Dehairing (scraping) machines are constructed from heavy U-shaped bars, a steel frame, and one or two shafts to which belt scrapers are attached. The hogs are sprayed with water as they pass lying and rotating through the dehairer. If the water in the machine circulates, the water temperature should be at least 55–58 °C for hygienic reasons. After dehairing, the pigs are conveyed to the prepolisher. The prepolish machine is needed to remove any remaining hair and to dry the surface of the pig. In this way the effect of the singeing furnace will be optimal and gas consumption is reduced. The singeing furnace is intended to reduce surface bacteria and to singe hair stubble. The surface bacterial count can be reduced by 1–2 powers of 10 by the heat effect. This is not the case if the carcasses are still very moist after singeing. This is followed by the polishing machine, which cleans the singed pigs by brushing. Here the mechanical treatment of the pig skin comes to an end. The washing and polishing process usually causes recontamination of the carcass surface. This is due to the whips inside the washing machine, which are hard to clean.

Evisceration

This follows the 'clean' side of the slaughter line where, when working hygienically, the surface bacterial count of the carcasses is no longer greatly affected. Opening and evisceration of the slaughtered animals take place on the slaughter conveyor manually by means of knife, axe, or saw. First the aitch-bone is split at its midpoint. The next step is loosening the anus and the reproductive tract. For this step, mechanical rectum looseners are frequently used. After splitting the sternum and opening the belly cavity, the gut set and the stomach are taken out once the esophagus has been cut approximately 2 cm from the stomach (in pigs). In the USA and the Far East, the guts and the pluck (contents of the thoracic cavity) are taken out together.

To avoid the hygiene risk of an outflow of rumen content in cattle, the esophagus should not be cut but rather it should be separated from the trachea and shut with a special instrument (rodding). Removing the pluck is the last step of evisceration.

Hog opening can also be done by a robotic system that adapts itself to the physical shape of the hog. The slaughtering robot cuts loose the rectum, splits the aitch-bone, and separates the ham. The front unit cleaves the sternum and opens the abdominal wall of the hog.

Splitting

Splitting of carcasses (cattle, pigs, horses) can be executed manually by axe or saw or in automatic carcass-splitting systems. The automatic systems work within the continuous dressing conveyor. The carcasses are split by a circular saw. Backbone guides and holding jaws on each side stabilize the carcass and thus prevent miscuts. During the cutting operation the saw blade is cooled with cold water. After splitting, the saw blade as well as the holding jaws are sterilized with hot water (82 °C). For pig carcasses, automatic chopper machines are also in use.

Waste Product Handling

Waste products are those parts of a slaughter animal that are not suitable for direct utilization. This includes condemned meat and offals, obligatorily confiscated tissues, e.g., meat of the sticking cut, eyes, tonsils and gut, stomach and rumen contents, glands, hair, inedible fat and blood. As a result of the BSE epidemic in some European countries, in the European Union the so-called specific risk material (SRM) has to be extirpated. This includes the following tissues of cattle, sheep, and goats greater than 12 months old: skull, including brain and eyes, tonsils, and spinal cord; the spleen of sheep and goats and the ileum (part of the small intestine) of cattle greater than 12 months old. In comparison to live weight, waste material accounts for about 20% for sheep (live waste weight 45 kg), 14% for bulls (live weight 450 kg) and 10% for pigs (live weight 90 kg).

With modern technologies, nearly all the slaughter waste can be economically transferred to useful products (Table 2). (*See* **Offal**: Types of Offal.)

Precleaning of waste water is frequently done within the plants. With mechanical methods such as rotating filter tubes or paternoster filter grids, up to 60% of sedimentable particles can be separated. More complete cleaning can be achieved by a flotation process, whereby suspended substances (colloids) are coupled with microgas bubbles so that they come to the surface by flotation and can be removed. (*See* **Effluents from Food Processing**: On-Site Processing of Waste; Composition and Analysis.

Effect on Meat Quality

There is a close relationship between meat quality and the treatment of animals before slaughter. Rough handling of pigs and fighting between animals

Table 2 Waste product handling

Waste material	*Processing*	*Final product*
Condemned meat, condemned offal		Liquefied, sterilized material
Obligatorily confiscated tissue (eyes, reproductive tract, etc.)	Rendering	Meat meals, animal feeds, inedible fats (oils, soaps, fatty acids for cleaners, cosmetics, etc.)
Inedible blood		
Inedible fat		
Blood, not for human consumption	Drying	Blood meal, animal feeds
Stomach and gut contents, inedible blood	Fermentation (anaerobic)	Biogas (methane)
Rumen contents	Fermentation (aerobic)	Fertilizer
Horns, toe nails	Drying, chopping	Horn chippings (fertilizer)
Hair	Physical/chemical treatment	Brushes, upholstery, animal feeds
Endocrine glands	Extraction	Hormones (e.g., insulin), enzymes (e.g., heparin), bile acids (e.g., chenodeoxycholic acid)

prior to stunning both increase the incidence of PSE meat. When the glycogen level in a stressed pig is high, much lactic acid is produced after killing, while muscle temperature is still high (about 40 °C). The combination of high lactic acid level and high temperature leads to denaturation of muscle proteins and thus produces PSE meat. The next severe stress factor is stunning. Many stunning methods cause vigorous clonic spasms (with stimulation of glycolysis and accelerated pH drop) and high release of stress hormones such as epinephrine (adrenaline) and norepinephrine (noradrenaline). By activating enzyme systems, epinephrine causes increased breakdown of muscle glycogen to lactic acid. If sticking of the stunned animal is delayed, the glycolytic effect of stress hormones is more pronounced and the incidence of PSE meat is higher.

The treatment of the carcass can influence the postmortem biochemical reactions in the musculature. It has been found that pigs that had been dehided instead of scalded had musculature that was darker, with better water-binding properties and greater tenderness. The reason is that scalding and singeing of pig carcasses produce muscle temperatures that are about 1 °C above those that apply during dehiding. This results in a quicker pH drop postmortem. Also, the intensive mechanical treatment of the carcasses from hair scrapers and other mechanical machines may contribute to the production of PSE meat.

Long times of stress, long fasting times (transport, lairage), and mixing animals from different farms produce dark, firm, dry (DFD) meat. In these cases, at the time of slaughter most of the muscle glycogen reserves are already exhausted. The remaining glycogen is therefore at a much lower level, so that the amount of lactic acid, which is produced via glycolysis, is also low. Consequently, the ultimate pH value in DFD musculature is relatively high (> 6.2). Refer to individual meats.

Preservation

D A Ledward, University of Reading, Whiteknights, Reading, UK

Introduction

The principles of meat preservation are mainly associated with preventing or delaying microbial spoilage and chemical action, and avoiding as far as possible weight loss and any change in taste or texture. Methods of preservation are based on control by low or high temperature, reducing available water (water activity), or by the application of chemical additives. In developed countries the shelf-life of meat and meat products is, in the main, controlled by refrigeration or by a combination of refrigeration and

other methods of preservation, such as modified-atmosphere packaging, curing or high pressure. Whereas other techniques result in some changes to color, taste, and texture, refrigeration and high pressure are distinct in that their effect on appearance and taste is minimal. (*See* **Legislation**: Additives; **Preservation of Food**; **Spoilage**: Chemical and Enzymatic Spoilage; **Spoilage**: Bacterial Spoilage; Molds in Spoilage; Yeasts in Spoilage.)

Refrigeration

Product Cooling

Refrigerated meats are generally classified as chilled or frozen. However, there may be several steps involved in reducing a hot product to chill or frozen storage temperature, with several additional links before final consumption. The design and operation of equipment to perform these functions require an understanding of the thermal properties of foods and an appreciation of their complexity and that of prevailing legislation.

Immediately after heat treatment or cooking, it will be necessary to commence cooling under controlled conditions. Filtered ambient air or mains water are suitable media for cooling the product temperature to about 35°C. Naturally, the latter would only be used where there is a hermetically sealed skin packaging. These represent cheaper energy sources than mechanical refrigeration or expendable refrigerants, which are required for achieving the statutory temperatures, which lie below 10°C.

Chilling

The rate of evaporation of moisture from an exposed surface is a function of the temperature difference between the surface and the air and is influenced, to a lesser extent, by its relative humidity. The air velocity over the surface has a marked effect, at least in the initial stages of cooling. A similar set of conditions prevails if the cooling medium is a gas other than air, e.g., carbon dioxide or nitrogen.

By lowering the applied temperature and increasing the velocity, the initially high rate of evaporation is offset by a reduced surface cooling time. This results, overall, in reduced weight loss. Hence different modes of refrigerated chilling may be employed:

1. Rapid chilling in which chilling is applied at the maximum rate possible (without freezing the surface of the product) with the objective of minimizing evaporative loss. Where air is the cooling medium, the applied temperature would be below 0 °C at a velocity of 2.0–3.5 m s^{-1}. However, rapid chilling introduces the risk of toughening due to 'cold shortening' of carcasses chilled to < 10 °C before the pH has decreased to below 6.0. In beef carcasses this would normally be in less than 10 h.
2. Conventional chilling at a rate sufficient to meet production requirements without undue regard to evaporative weight loss. In this case the applied temperature and velocity would be greater than 0 °C and in the range 0.25–0.50 m s^{-1}, respectively. Even at this rate of chilling there is a risk of 'cold shortening' causing irreversible toughening in areas close to the surface.

Freezing

In exceptional circumstances, the product may be frozen from an initial temperature of about 35 °C ('hot' freezing), but is more likely to have already been chilled to 4 °C for pork and lamb or to 7 °C for beef carcasses. Since lean meat begins to freeze at a temperature of −1 °C, there is initially a sensible heat load until this temperature is reached, followed by the removal of latent heat. Conventions for freezing time are not clearly defined as freezing may not be entirely complete, even at temperatures below −20 °C, owing to the depression of freezing point by remaining concentrated solutes. One convention quotes the 'nominal freezing time' as the time required to achieve a temperature 10 °C below that at which freezing commences. This is distinct from the 'effective freezing time', being the elapsed time interval from product initial temperature to low-temperature storage. (*See* **Freezing**: Principles.)

Tempering

The heat capacity of foods containing water is virtually halved once the temperature is reduced below −2.0 °C. At the same time, the thermal conductivity is doubled. Hence, meat which has been taken through most of the latent heat phase will respond much more rapidly to changes in external temperature, e.g., if storage is to be at −25 °C a final core temperature of −15 °C may be satisfactory for the freezing stage, allowing the product to equalize and stabilize at the holding temperature in the cold store.

Cold Storage

The low-temperature store will be designed to accommodate the maximum quantity of a product within a given volume. The store will maintain a temperature of about 1 °C if the product is to be kept chilled or less than −20 °C if frozen. In the former case it will be more critical that the product has been chilled to the design storage temperature, whereas for frozen products a small proportion of residual heat, as already

outlined, may be removed during the holding period. Packaging assists in preventing weight loss, freezer burn, and the onset of rancidity. (*See* **Freezing**: Storage of Frozen Foods.)

Refrigerated Transport

In theory there should be few problems in the storage or transport of chilled or frozen products, especially in the case of meat or meat-based products, since:

1. Cooling, chilling and, where applicable, freezing and tempering have been completed so that refrigerated transport equipment has merely to insulate the product from sources of ambient heat
2. The product is insulated by primary and secondary packaging
3. There is no respiratory heat load such as occurs with some fruits and vegetables.

Retail Display

With the introduction of the European Community (EC) Food Hygiene Regulations, the temperature of chilled foods in the EC has to be kept at or below 5 °C. This requires much more stringent control than bulk storage since the displayed products have to be accessible and hence are potentially exposed to a warm atmosphere. A high intensity of lighting can lead to a further rise in temperature due to a 'greenhouse' effect inside transparent packaging.

Similar conditions apply to frozen foods, but these are more likely to be cartoned in opaque material with entrapped air, which acts as an insulator. It is also a fact that it is much more difficult to check and hence legislate on the temperature of frozen foods.

Domestic Storage

As with retail display cabinets, domestic refrigerators have minimal reserve capacity for chilling, freezing, or tempering. Therefore the addition of substantial amounts of a product which is above the set storage temperature will affect that of the existing contents. An awareness of the necessity to maintain the cold chain from the retailer to domestic refrigerator is paramount. While it has been demonstrated that meat which has been repeatedly frozen and thawed under controlled conditions suffers minimal deterioration, such a practice cannot be recommended wherever precise control cannot be guaranteed.

Refrigeration Plant Selection

The first priority in plant selection is to quantify the refrigeration duty. To do so requires a knowledge of the thermal properties of the product under consideration, such as: (1) initial and final temperatures; (2) heat capacity above and below freezing; (3) latent heat of freezing; and (4) effective chilling or freezing time between specified initial and final temperatures. (*See* **Freezing**: Operations.)

Recognition has to be taken of the fact that the maximum rate of product heat output (which occurs in the early stage of chilling or freezing) may be two or three times the average. To the load is added the heat due to: (1) leakage through insulation into the refrigerated space; (2) leakage of ambient air through door openings; (3) electrical input such as lights, fans, or fork-lift trucks; (4) metabolic heat from personnel.

Having estimated the total refrigeration load, a decision is taken on the type of refrigeration equipment to be installed. In the majority of cases this will be mechanical refrigeration using ammonia or a fluorocarbon as the refrigerant. Where production is seasonal, it may be more economical to use an expendable refrigerant such as liquid nitrogen or carbon dioxide.

Moisture Control

Freezing *per se* is an effective means of preservation as it makes moisture unavailable for microbial growth by its conversion to ice. However, other means of moisture control have been devised that enable products to be stored at temperatures above the freezing point of water. These include curing, several methods of dehydration, including freeze-drying, intermediate-moisture technology, and high-pressure processing.

Curing

Salting as a means of meat preservation has been practiced for 3000 years and contamination of salt by potassium nitrate probably led to the development of modern cured meats, since it led to characteristic and acceptable effects on color and flavor. Thus, although heavily salted products are not now available, having been supplanted by more acceptable preservation procedures, cured pork and to some extent poultry, beef, and fish products have established niches in the marketplace, though the relatively low levels of salt now present (usually < 4%) are more for flavor than preservation.

To cure meat, salt (sodium chloride) and nitrite must be present and other ingredients may be used during processing to accelerate curing, stabilize color (e.g., ascorbic acid), modify flavor (e.g., sugars) and texture, and reduce shrinkage (e.g., polyphosphates).

Several methods may be used to incorporate the curing ingredients into the meat, the object being to achieve uniform distribution. In comminuted

products, such as sausages, the cure ingredients (in the dry form or as a concentrated solution) are incorporated into the product during mixing or comminution.

For whole sides or muscles the oldest technique is dry-curing. Here, the dry-curing agents (salts) were rubbed over the surface of the meat, the meat then being placed on a shelf or in a box to cure. For large muscles or cuts the process needed to be repeated several times and it may have taken up to 80 days to get uniform distribution in, for example, the top of the hind leg.

Another method which is still practiced for a few specialty products involves immersing the cuts or sides in concentrated brine, usually at 3–7 °C, and allowing the brine slowly to diffuse through the meat. This method is also very time-consuming and care must be taken to insure microbial spoilage does not occur during curing.

The curing procedure can be considerably shortened by injection of brine into the meat to achieve rapid, uniform distribution. Three such methods are: (1) artery pumping, in which brine is pumped directly into the intact vascular system; (2) stitch pumping, in which brine is injected (through a hollow needle) into various parts of the meat, especially the thickest parts and those near to joints; and (3) multiple injection, in which brine is injected simultaneously and automatically through a series of hollow needles which have a number of evenly spaced holes along their length. Another modern method is the 'tumbling' or 'massaging' of meat pieces in rotating drums. In the presence of about 0–6% of their weight of salt the physical interactions of the meat pieces draw out salt-soluble protein which, on subsequent heating, gels to bind the pieces together in 'reformed' hams. Tumbling can shorten the curing period to 24 h or less. Tumbling may be carried out under vacuum to eliminate problems caused by dissolved air.

A typical traditional brine contains 25–30% sodium chloride and 3–4% sodium or potassium nitrate and specific salt-tolerant bacteria capable of reducing the nitrate to nitrite. In modern cures, nitrite may be added directly at a concentration of 200 p.p.m. or less. In most countries there are strict limits on the level of nitrite permitted in meats (usually 200 p.p.m.) and addition of nitrite directly, rather than relying on nitrate reduction *in situ*, insures such limits are not breached.

Dehydration

That dehydration can preserve meat has been known for over 5000 years and simple drying procedures are still used today in some parts of the world. In these processes, strips of lean meat are exposed to the sun, e.g. pemmican manufactured by North American Indians, or a combination of light salting and drying is used as in the preparation of charqui (South America) or biltong (South Africa). (*See* **Drying**: Theory of Air-drying; **Drying**: Drying Using Natural Radiation.)

Hot-air drying has been used in the past to prepare dehydrated meat for the armed forces, but has not been manufactured successfully for domestic consumption. Due to case hardening, raw meat cannot be successfully dehydrated and the need for a high surface-area-to-volume ratio has limited its use to cooked, minced meat. A typical procedure involves cooking the meat in thin slices, mincing (0.3–0.8 cm in diameter) and drying under controlled conditions. The temperatures that can be tolerated without causing unacceptable damage to the meat depend on both the residual water and fat contents. A typical regime that lowers the moisture content to about 5% in about 5 h involves an air speed of 3 m s^{-1}, a temperature of 60 °C, a relative humidity of 40%, and a tray loading of about 10 kg m^{-2}. Vacuum drying has been unsuccessfully tried to improve the quality of dehydrated meat. A successful technique for both raw and cooked meat is freeze dehydration. In this process the product remains frozen throughout the drying cycle and thus the water (ice) is sublimed from the meat. At a vacuum pressure of 1.0–1.5 mmHg, temperatures up to 43 °C can be tolerated with no thawing. The rate of freeze-drying is limited by the rate of heat transfer to the product for sublimation and several methods have been developed to increase the rate, including the use of microwave or radiant (infrared) energy. Freeze-drying is an expensive processing procedure and freeze-dried meats (containing about 2% moisture) are usually only used in such foods as dehydrated soup mixes and specialty products for campers, the military, and space agencies. (*See* **Freeze-drying**: The Basic Process.)

Dehydrated meats need to be rehydrated prior to consumption and, to address this step, with all its attendant problems, and evolve a technology suitable for developing countries, intermediate-moisture meats have been formulated. With intermediate-moisture foods the object is to lower the water activity to a level at which bacteria will not grow, but without lowering the water content to a point where the product becomes unpalatable. This involves mixing the meat with suitable humectants, such as sugars, salts, polyols, and amino acids, to lower the water activity to about 0.85 whilst keeping the moisture content at 20–50%. Under these conditions bacteria will be inhibited, but molds and yeasts may proliferate and thus an antimycotic such as sorbate or propionate is often incorporated at a concentration

of 0.1–0.3%. (*See* **Intermediate-moisture Foods; Water Activity.**)

For minced products, such as semimoist pet foods and Chinese pork, the equilibration is easily achieved by batch-mixing. In the production of semimoist pet food, the mixture is subsequently shaped and formed in a cooker-extruder. For whole meats two techniques are available: (1) desorption processing, in which the meat pieces are soaked in an infusing solution of high osmotic pressure so that, after equilibration, the meat has the desired water activity (equilibration is normally aided by heating, which has the additional benefit of inactivating enzymes); and (2) absorption processing, in which freeze-dried meat is equilibrated with the infusing solution to the appropriate water activity. Though this latter method allows close control of water activity, the cost is prohibitive for all but the most specialized uses (e.g., space flights).

Other Preservation Techniques

Although temperature reduction and moisture control are the most commercially important methods of meat preservation, other techniques may have important niches in the marketplace. For example, fermented meat products, in which specific bacteria, such as selected *Lactobacillus* strains, are encouraged to grow and reduce the pH of the meat to levels inhibitory to the growth of spoilage organisms, are well established in many parts of the world. This technology is often combined with partial dehydration to enhance shelf-life. Though not commonly made in the UK, European varieties include French saucisson sec, German Dauerwurst and Rohwurst and Italian crudi stagionati. In modern processes a starter culture is used to initiate two fermentations – the conversion of nitrate to nitrite (by micrococci) and of carbohydrates to lactic acid by lactobacilli. Fermentation ceases after 3–7 days under high (e.g., 26 °C) temperatures and humidities (e.g., 95%). The product is then dried at lower temperatures and humidities to moisture contents in the range 30–35%. This takes several weeks (usually 3–7) and the product is then matured for several months. The combination of low pH (about 4.5), lactic acid, low water activity, and residual nitrite gives a shelf-life from 6 months to over 2 years, provided the whole process has been controlled and managed correctly. (*See* **Lactic Acid Bacteria.**)

The use of chemical preservatives in meat is not widely practiced (except for cured/fermented products), but sulfur dioxide is permitted in some countries for certain products. Thus 'English'-style sausages may contain up to 450 p.p.m. of this compound, usually added in the form of a salt such as metabisulfite.

High-temperature preservation (canning) of meat and meat products is also well established and, although certain cured products may only require a pasteurization regime, others are heated under the more severe regimes necessary for low-acid foods. (*See* **Canning:** Principles.)

In the 1940s, ionizing radiation was advocated as a method of meat preservation and after very extensive trials it was permitted in most countries under certain conditions. Thus, in 1991 in the EC pasteurizing doses of γ-rays up to 5 kGy were permitted for poultry. (*See* **Irradiation of Foods**: Basic Principles; Legal and Consumer Aspects.) More recently, high pressures (≥ 400 MPa) have been used to extend the shelf-life of cured meats. However, this technology has less potential for uncured products, although the technology is developing rapidly.

Chemical, Physical, and Microbiological Implications of Preservation

Chilling and Freezing

The physical dimensions of postrigor meat are unaffected by both chilling and freezing but fluid (drip) is exuded from both chilled and frozen products. The amount expressed is far greater in frozen-thawed meat and some evidence suggests the amount increases as the freezing rate decreases.

In frozen meat, bacterial growth usually ceases, but yeasts and molds may continue to grow down to about $-5\,^{\circ}C$. In chilled meat, psychrotrophic bacteria become the dominant species, mainly *Pseudomonas, Achromobacter, Micrococcus, Lactobacillus, Streptococcus, Leuconostoc, Pediococcus, Flavobacterium*, and *Proteus* spp. Of these, during storage in air, *Pseudomonas* spp. are the most important since they give rise to slime and off-odor formation at levels of 10^7–$10^8\,cm^{-2}$. The time for this to occur depends on several factors (especially temperature, relative humidity, and initial load) but meat kept in retail packs at a relative humidity of 99.3% usually spoils after 5–10 days at 1 °C. If meat is stored under elevated levels of carbon dioxide the growth of *Pseudomonas* spp. is inhibited and *Lactobacillus* spp. become dominant. Such meat can be kept for several weeks at chill temperatures with little evidence of spoilage.

Chemical changes take place during storage of fresh meat and some, such as those due to enzymatic proteolysis, may be favorable, leading as they do to increased tenderness. The major deteriorative changes are oxidative in nature, leading to the formation of the undesirable brown methemoproteins and rancidity. The formation of methemoproteins is

important in both chilled and frozen meat but lipid oxidation leading to rancidity is usually only important in frozen meats. This oxidation is responsible for recommending maximum shelf-lives of 4 months for pork and poultry and 6 months for beef and lamb at −18 °C. (*See* **Oxidation of Food Components**.)

Cured Products

Nitrite is essential for the development of the pink-red color of cured meats and has the further important attribute of being a very effective inhibitor of *Clostridium botulinum*. The pink-red color is due to nitric oxide, from nitrite, binding to the iron atom of hemoprotein (myoglobin and hemoglobin) at the sixth coordination site; there is still controversy regarding the mechanism involved in the formation of this nitrosyl pigment. In the presence of light and oxygen (air), nitric oxide can be liberated from the hematin and the color fades as the oxidized methemoprotein forms. Thus, cured meats should be stored in the absence of oxygen and/or light if an extended shelf-life is required. Although cured meats are eaten uncooked (e.g., Parma Iberian ham), many are cooked prior to consumption, either by the consumer, e.g., bacon, or by the manufacturer to be sold as cooked, ready-to-eat meats (e.g., boiled or roast ham). The red pigment formed on heating is relatively stable in the presence of light and oxygen and is believed to be a complex of free hematin and either one (pentacoordinated) or, less likely, two (hexacoordinated) molecules of nitric oxide.

Dehydrated Meats

Hot-air-dried meats are invariably shriveled and are virtually impossible to rehydrate to typical 'full-moisture' products. Freeze-dried meats retain the shape and color of the original meat pieces and the porous structure does rehydrate more satisfactorily than hot-air-dried products. Intermediate-moisture meats have the physical characteristics of their fresh-meat counterparts.

Unless partial rehydration inadvertently occurs, dehydrated meats are not susceptible to microbial spoilage and can be kept for several weeks at elevated temperatures. The factors limiting their shelf-life are chemical in nature, mainly lipid (or sorbate) oxidation, and/or nonenzymatic browning. With freeze-dried meats, nonenzymatic browning involving glucose and glucose-6-phosphate (with protein) occurs, as also, in the presence of oxygen, does oxidation of the hemoproteins to yellow bile pigments. Some fat oxidation due to residual lipolytic activity may also occur. In intermediate-moisture meats, browning involving reactions between sorbate or lipid oxidation products and protein occurs, as also does oxidation of the hemoproteins. However, a reaction occurring in intermediate-moisture meats, but not fully dried meats, is hydrolytic degradation of collagen. Anaerobic storage of intermediate-moisture meats inhibits all these reactions, except for the breakdown (hydrolysis) of collagen. (*See* **Browning: Nonenzymatic**.)

Eating Quality

I Lebert, S Rousset, A Lebert and R Talon, National Institute of Agronomic Research, France

Background

Meat eating quality refers to microbiological safety, shelf-life, sensory properties, nutritive values, and healthiness. Safety is the priority, but sensory qualities must also satisfy the consumer. The acceptability of the final product is often influenced by the processing of the raw material. The hygienic and sensory

Table 1 Beef chilling: effect of increasing time, temperature, air velocity, and humidity on quality

	Time	*Temperature*	*Air velocity*	*Humidity*
Microbiological quality	−	−	+	−

Appearance	−	−	−	+
Weight loss	+	+	+	−

+, increase; −, decrease; 0, no effect.

qualities (texture, juiciness, flavor, and color) are particularly important. The control of the quality must therefore be implemented from the entry of the live animal into the meat chain. Initial carcass chilling is particularly important, and its effects on beef quality are listed in Table 1.

Consumers are becoming more sensitive to issues of safety, hygienic, and sensory qualities, and these issues are discussed in this article.

Microbiology of Meat

The microbiological quality of meat carcasses is highly dependent on the processing conditions: most important are the temperature and time of storage and distribution, which largely determine the number and spread of contamination during slaughter and processing (Figure 1).

During slaughter and dressing, the three major sources of contamination are: (1) the skin of the animal, which is mainly contaminated by spoilage flora such as staphylococci, micrococci, pseudomonads, yeasts, and molds; (2) fecal contamination during evisceration, which, if little care is taken, could happen by bursting of the intestinal tract; then *Salmonella, Escherichia coli*, enterococci, and *Clostridium perfringens* can be detected in meat; (3) contamination by direct contact or cross-contamination between dirty and clean surfaces. Staphylococci are the main concern, since they are widely distributed, and contamination may arise from both animal and human sources. Airborne particles and aerosols also contribute to the dissemination of microorganisms.

Under good hygienic conditions, dressed carcasses may have typical surface aerobic bacterial counts of 10^2–10^4 cm^{-2} for beef, 10^2–10^5 bacteria cm^{-2} for sheep, and 10^4–10^5 bacteria cm^{-2} for pig carcasses.

Once the temperature at the surface of the carcass has fallen below 10 °C, growth of mesophilic bacteria no longer occurs, and a psychrotrophic flora (*Pseudomonas, Acinetobacter, Psychrobacter, Lactobacillus, Brochothrix thermosphacta, Shewanella putrefaciens*, some genera in the family Enterobacteriaceae) gradually displaces the micrococci and coliforms, which are commonly found on freshly dressed carcasses.

Two bacterial flora can be found on meat products: a pathogenic flora (*Salmonella* spp., *Clostridium* spp., *Yersinia enterocolitica, Staphylococcus aureus, Listeria monocytogenes*) that causes foodborne diseases and a spoilage flora (*Pseudomonas* spp., lactobacilli, staphylococci, micrococci, *B. thermosphacta*) that limits the storage of the product.

Pathogenic Flora

Epidemiology Public health authorities need to be informed about the nature and magnitude of foodborne illnesses and their epidemiology for the early detection of outbreaks, planning, evaluation of any disease, and policy implementation. Foodborne disease cases are significantly underestimated because of the weakness in foodborne disease surveillance and of the variation in reporting systems between countries. As a consequence, it has been estimated that the reported incidence of foodborne diseases represents less than 10%, perhaps even less than 1%, of the actual incidence.

Foodborne outbreaks occur in most, if not all, countries (Table 2). *Salmonella* spp. cause 84.5% of all outbreaks (*Salmonella enteritidis*, 50.9%); *S. aureus*, 3.5%; *Clostridium botulinum*, 1.1%; *Bacillus cereus*, 1.0%; and unknown agents, 9.5%. Sporadic cases have been associated with *Escherichia coli, Campylobacter jejuni, L. monocytogenes, Y. enterocolitica, Aeromonas hydrophila, Shigella, Vibrio parahaemolyticus*. The main factors affecting the growth of these pathogenic bacteria are the temperature, pH, and water activity (Table 3).

The most frequently identified foods associated with outbreaks are eggs and egg products (25.4%), meat and meat products (23.4%), and confectionery, cakes, pastries, puddings, desserts, and icecream (17%). Fish and shellfish, milk and dairy products, and poultry and poultry products were each implicated in less than 5% of the outbreaks.

Main pathogenic bacteria As mentioned above, *Salmonella* spp. cause 84.5% of all outbreaks, and many foods of animal origin, particularly beef and pork, have often been identified as vehicles in outbreaks of salmonellosis. *Salmonella* are transferred to meat surfaces from the intestinal contents and from feces contaminating hair, skin, and feet of animals. Considerable contamination of pig carcasses occurs during scalding and dehairing. Later, bacteria can be transferred from carcass to carcass and from contaminated carcasses to knives, work surfaces, and the hands of meat handlers. Minced pork and sausages, as well as

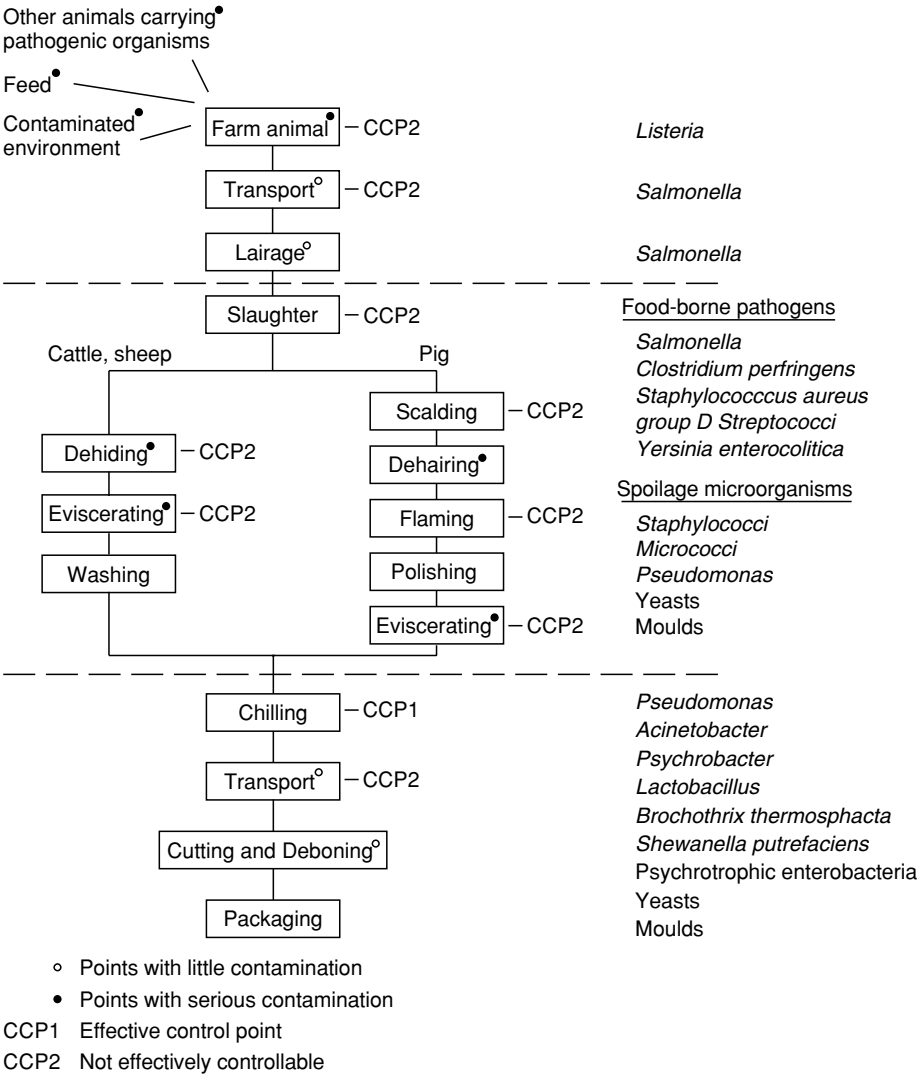

Figure 1 Causes of contamination from live animal to store.

Table 2 Cases of foodborne diseases in 1997 and 1998

Date	*Locations*	*Number of cases*	*Bacteria*	*Associated foods*
1997	Australia	650 (three deaths)	*Salmonella*	Different food in many foodborne outbreaks
	Russia	12 (one death)	*C. botulinum*	Fish
	Finland	200	*Salmonella*	Pig
	USA	745 (one death)	*Salmonella*	Stuffed ham
1998	Argentina	9	*C. botulinum*	Matambre (meat specialty from Argentina)
	Japan	1142	*Salmonella*	Unknown origin
	USA	316	*V. parahaemolyticus*	Oysters
	Algeria	1400 (17 deaths)	*C. botulinum*	Spoiled chicken
	USA	100 (20 deaths)	*L. monocytogenes*	Hot dogs
	USA	165	*Shigella*	Interhuman?
	Canada	130	*Salmonella*	Turkey meat
	France	300	*Salmonella*	Egg/egg product 52%, meat/meat product/chicken 24%, other foods 24%
	France	68	*C. perfringens*	meat/meat product/chicken 40%, other foods 60%
	France	155	*S. aureus*	Meat/meat product/chicken 15%, milk/milk product 24%, other foods 61%
	France	139	*Unidentified*	Meat/meat product/chicken 14%, other foods 86%

Table 3 Minimal and maximal temperature (T), pH and water activity (a_w) values for the growth of some pathogenic bacteria (ICMSF, 1996)

Organisms	*T (°C)*	*pH*	a_w
Bacillus cereus	4–55	5–8.8	> 0.93
Vibrio parahaemolyticus	5–43	4.8–11	> 0.94
Escherichia coli	7–45	4.4–9.0	> 0.95
Campylobacter jejuni	32–45	4.9–9	> 0.987
Yersinia enterocolitica	1–42	4.2–9;6	> 0.97
Listeria monocytogenes	0–45	4.4–9.4	> 0.92
Aeromonas hydrophila	0–45	4.5–NR	> 0.97
Salmonella spp.	5.2–46.2	3.8–9.5	> 0.94
Shigella spp.	7.9–45	5–9.2	> 0.978
Staphylococcus aureus	7–48	4–10	> 0.83
Clostridium perfringens	12–50	5.5–9	> 0.93
Clostridium botulinum			
A & B	10–50	4.7–9	> 0.93
Non proteolytic, C & D	5–NR	4.7–9	> 0.95
E	3.3–15–30	4.7–9	> 0.97
F	4–NR	4.7–9	> 0.95

NR: not reported.

inadequately cooked meat, are frequently implicated in salmonellosis. *Salmonella* are widespread in poultry, especially turkey and chicken carcasses, and are transferred to the meat from the intestinal tract or from fecal material on feet and feathers. Cross-contamination is a particular problem in which the critical steps include defeathering, evisceration, and chilling. The major recent change in the epidemiology of *Salmonella* concerns the emergence of *S. enteritidis* and *S. typhimurium*. These bacteria, first studied in the USA and UK, are now reported in many industrialized countries. The factors that may contribute to their emergence are the microbial adaptation and dissemination of the pathogen through increasing global distribution of food and international travel, the increasing susceptible populations as well as lifestyle changes leading to an increase in food-service establishments and food outlets combined with inadequate knowledge of food-handling.

S. aureus is ubiquitous and occurs on the skin of most warm-blooded animals, including all food animals. The organism is resistant to drying and may colonize food-processing equipment that may be wet and difficult to clean. Meat and meat products are frequently incriminated in staphylococcal food poisoning, but cases have arisen in egg products, sandwich fillings, milk, and dairy products. Foods that require considerable handling during preparation and that are kept at slightly elevated temperatures after preparation (20–40 °C) are frequently involved in staphylococcal food poisoning. Human intoxication is caused by ingesting the enterotoxins produced in the food by some strains of *S. aureus*, usually because the food has not been kept hot enough (60 °C or above) or cold enough (7.2 °C or below). The toxin is a highly heat-stable protein. The toxin is produced when *S. aureus* populations exceed 10^5 per gram. A toxin dose of about 1.0 μm produces symptoms of intoxication.

The incidence of *C. botulinum* in meats appears to be low, but its presence has been demonstrated in sufficient large surveys of pork. Botulism in man results most often from eating improperly stored foods in which *C. botulinum* has multiplied and produced toxin.

C. perfringens is part of the normal flora of the intestinal tract of animals, including man, and is found in a large variety of foods. In raw meat, a few vegetative cells may be found deep in muscle tissue after slaughter, and more cells are found in meat from fatigued animals. The presence of spores on the surface of recently slaughtered carcasses is the result of fecal contamination. Care is needed with foods made of several ingredients such as meat pies, cooked meats, and poultry products, because spores may survive cooking.

Other pathogenic bacteria causing sporadic cases

Undercooked or raw ground beef has been implicated in nearly all documented outbreaks of *E. coli* O157:H7 and in other sporadic cases. *E. coli* is a normal inhabitant of the intestine of all animals, including humans. Currently, there are four recognized classes of enterovirulent *E. coli* that cause gastroenteritis in humans. The enterohemorrhagic strain, designated *E. coli* serotype O157:H7, is a rare variety of *E. coli* that produces large quantities of one or two toxins that cause severe damage to the lining of the intestine. These toxins are closely related to the toxin produced by *Shigella dysenteriae*.

C. jejuni frequently contaminates raw chicken. Surveys show that 20–100% of retail chickens are contaminated. This is not entirely surprising, since many healthy chickens have these bacteria in their intestinal tracts. Raw milk is also a source of infections. The bacteria are often carried by healthy cattle and by flies on farms. However, properly cooking chicken or pasteurizing milk kills the bacteria. Campylobacters can be isolated from freshly slaughtered red-meat carcasses, but in smaller numbers than on poultry. This bacterium is recognized as an important enteric pathogen. Recent surveys have shown that *C. jejuni* is the leading cause of bacterial diarrhea in the USA, causing more illness than *Shigella* spp. and *Salmonella* spp. combined.

L. monocytogenes has been associated with foods such as raw milk, cheeses (particularly soft-ripened varieties), raw vegetables, but also fermented raw-meat sausages, raw and cooked poultry, all types of

raw meats, and raw and smoked fish. Its ability to grow at temperatures as low as 3 °C permits multiplication in refrigerated foods. The contamination of meat and meat products can be due to fecal contamination during slaughter, presence on clean and unclean sections in slaughterhouses, and contaminated ground and processed meats: 10–80% of contaminated samples contain less than 10–100 CFU g^{-1}. *L. monocytogenes* is a ubiquitous bacteria found in soil, silage, and other environmental sources, and is present in the intestines of 1–10% of humans. *L. monocytogenes* is quite hardy and resists the deleterious effects of freezing, drying, and heat.

Y. enterocolitica has been recovered from a wide variety of animals, foods, and water. Pigs seem to be the principal reservoir of bioserotypes pathogenic to humans, but the exact cause of the food contamination is unknown.

Aeromonas spp. are ubiquitous and are also associated with foods of animal origin (raw meats, poultry, and milk). *A. hydrophila* grows rapidly in a refrigerated environment and can increase its number 10–1000-fold in meat and fish samples over 1 week of refrigerated storage.

Among several environments (Table 4), the home is where the pathogens are frequently identified (13%), with 46% of the outbreaks occurring in people eating at home largely due to mishandling of food products (Table 4). The consumer must take care when handling food at home, and recommendations have been given by The National Advisory Committee on Microbiological Criteria for Foods to prevent the contamination of food products by foodborne pathogens (Table 5).

Spoilage Flora

Without exception, there is a loss in microbial quality in meat products following slaughter and manufacture (Table 6). Microorganisms cause deterioration in appearance, texture, flavor, odor, or safety of the product. The first detectable sign of spoilage is usually an off-odor, which is slightly sour or putrid. The odors are caused by bacterial metabolic end products, as they accumulate, the color of meat may change to a gray or green color, while the texture changes due to the destruction of proteins and lipids. Spoilage may occur slowly in the refrigerator and more rapidly at higher temperatures.

On meat held under aerobic conditions, spoilage is often related to the growth of *Pseudomonas* and occurs when the *Pseudomonas* counts exceed about 10^6 CFU cm^{-2}. Because of their psychotrophic characteristics, *Pseudomonas* species have a marked advantage in growth rate compared with other genera, and this advantage tends to increase with decreasing temperature. *Pseudomonas* is less tolerant to reduced water activity than lactobacilli and *B. thermosphacta*, so these organisms may become dominant in the drier parts of the carcass. *Acinetobacter* may become dominant in high pH meat.

Vacuum packaging is used to prolong the storage life of fresh meat (for 21–28 days at 0–1 °C) and

Table 4 Results of foodborne disease surveillance

Place of contamination or mishandling	*Identified outbreaks when people eat food products*	*Factors contributing to outbreaks*
Entering the food chain at the farm (50%)	Homes (46%)	Temperature abuse, inadequate cooling, and improper cooking (44%)
	Restaurants/hotels (15%)	
Mishandling	Catered events (8%)	Contaminated or toxic raw products (16%)
Restaurants (22%)	Medical-care facilities (6%)	Contamination by personnel or equipment (15%)
Homes (13%)	Canteens (6%)	Lack of hygiene in processing, preparing, and handling (10%)
Catering establishments (7%)	Schools (5%)	Cross-contamination (4%)

Table 5 Recommendations of safe food preparation

Wash hands and utensils before handling food, especially after handling raw foods
Reheat all foods thoroughly (above an internal temperature of 74 °C)
Keep hot food hot (above 63 °C)
Keep cold foods cold (below 4 °C)
Thoroughly cook meat, poultry, and seafood, and adequately heat frozen or refrigerated foods
Chill foods rapidly in shallow containers
Keep raw and cooked foods separate, especially when shopping, preparing, cooking, and storing these products
Wrap and cover foods in the refrigerator
Keep the refrigerator temperature between 1 and 4 °C

Table 6 Type of spoilage caused by spoilage bacteria in meat

Frequency	*Bacteria*	*Spoilage*
High	*Pseudomonas*	Green color, slimy
	Acinetobacter	Putrid
	Enterobacteria	Gas, green color (*Proteus*)
	Flavobacterium	Putrid
	Brochothrix	Green color, cheesy odor
	Lactobacilli	Green color, sour
Medium	*Bacillus*	Putrid odor, brown color
	Alcaligenes	Putrid
	Streptococcus	Sour
	Aeromonas	Putrid, gas
	Clostridium	Putrid, gas, green color
	Shewanella	Putrid, green color
Rare	*Pediococcus*	Green color, sour
	Kurthia	Putrid

restricts the growth of *Pseudomonas* so that *Lactobacillus* or *B. thermosphacta* becomes the dominant flora. In most cases, *Lactobacillus* can grow more rapidly than *B. thermosphacta*, but *B. thermosphacta* dominates in fatty meat with a high pH.

The deterioration of the food occurs progressively during the storage and results from the activity of the microorganism in the food. To avoid these changes, preservative techniques can be applied to inactivate the microorganism: by heat or irradiation; and to inhibit growth: by chilling or freezing, drying, curing with salt, vacuum or gas packaging, acidifying, or by adding preservatives. Consequently, in dried cured meat product, the pathogenic and spoilage flora are inhibited by drying and salting, whereas in dried sausage, the main inhibiting factors are drying and acidification. Eventually, the cumulative effects of the changes reach a point of consumer rejection due to unacceptable quality expectations and perception.

Acceptability and Sensory Properties of Meat

In order to determine the characteristics of food products and their acceptability, food manufacturers need two kinds of information: how much people like their products overall and the sensory characteristics of the products. Hedonic liking tests are carried out by consumer panels and usually ask a question of overall acceptability and ask for comments about the characteristics which consumers like or dislike. At least 60 consumers are generally included in such surveys because of the large range of their hedonic responses. Retailed sensory characteristics are not asked of consumers because they usually use only a limited vocabulary to describe the food. Qualitative and quantitative sensory descriptions are reserved for a trained panel composed of 12 assessors. Their work is to generate sensory attributes, to give accurate definition of these terms, and to assess the intensity of each attribute for each product. Sensory and hedonic guidelines which are reviewed regularly and published by standards organizations include: ISO (International Organization for Standardization), AFNOR (Association Française de Normalisation), AMSA (American Meat Science Association), DIN (Deutsches Institut für Normung), BSI (British Standards Institution), UNI (Ente Nazionale Italiano di Unificazione), AENOR (Asociación Española de Normalización y Certificación), and ASTM (American Society for Testing and Materials). Data are analyzed using multivariate statistical techniques, such as preference mapping, which are used to relate sensory and acceptability data in order to understand the acceptance or rejection criteria.

Factors Affecting Consumer Acceptability for Meat

Many experiments have shown that acceptability varies widely among consumers. A large number of factors can influence meat acceptability (Table 7), which is related to the product sensory characteristics: flavor, toughness, and appearance. For most consumers, food flavor seems to be the most important acceptability criterion before texture and appearance. However, in beef, tenderness is probably the most studied characteristic because its variation is wider than that in flavor. If beef is tough, other sensory properties become less important, and as meat tenderness increases, the overall acceptability to the consumer generally increases. For beef, tenderness is a major criterion of acceptability and toughness a criterion of reject. However, for poultry, firm meat may be preferred. Appreciation of the right level of tenderness thus depends on the product and on the individual or groups of consumers. This fact suggests that the sensory expectancies are variable for various meat products.

Table 7 Factors influencing the acceptability of meat products

Sensory characteristics of meat	*Type of meat products*	*Sensitivity of consumer*	*Food habits of consumer*
Flavor	Species	Olfactory	Gender
Texture	Cut	Gustatory	Age
Appearance	Fat		Custom

Appearance of meat also determines acceptance. Many consumers do not want to eat meat with too much visible fat because they consider it harmful to health that dominates over any contribution to flavor. Exudates or off-colors serve as indicators of unsafe products to consumers. Consumers also use color to determine when meat has been cooked sufficiently, essentially as a predictor of flavor and texture.

Acceptability depends on the product and the context, and consumers' preferences may be based on different sensory characteristics: for example, some for its tenderness and some for its grilled meat aroma. Some individuals are very much taste- and smell-oriented, while others divide their attention among multiple sensory inputs. Moreover, what one person likes, another may dislike. Some consumers prefer higher-salt/higher-fat restructured steaks, and others prefer and actively seek out lower-salt/lower-fat steaks. Olfactory and gustatory sensitivity can also play a role in interindividual differences in liking.

Meat acceptability depends strongly on the food habits of consumers. Consumers generally like what they know. For example, in New Zealand, consumers eat much lamb and find the specific flavor of lamb attractive, whereas American people appear not to because they are more used to consuming pork and beef. In an inter-European country study on consumer preferences for dry-cured hams, most of the French and Italian consumers preferred Italian home-style Parma and Bayonne hams, whereas Spanish people preferred Iberian hams. These differences in liking are attributed to the different sensory traits among the different types of ham. Parma and Bayonne have a pink red color, salty taste, and fresh meat flavor, whereas the Iberian hams are generally soft, purplish, slightly sweet, and bitter with a strong, rancid, blue cheese and mushroom aroma.

Most consumers eat meat because it has desirable sensory properties. Many of the sensory attributes depend on the species and cut of meat, which determines to a large extent the cooking method.

Main Factors Affecting the Sensory Characteristics of Meat

Sensory properties have been used to study meats from different origins (species, age, sex, rearing conditions of animals), to monitor processes (aging duration, electrical stimulation, mincing), and to compare products. Such qualitative and quantitative descriptions, without any hedonic connotation, are carried out by a panel of trained panelists.

Texture Sensory profiles of texture describe in detail the different stages of its perception (Table 8). The surface texture is evaluated, followed by an impression of the first bite or mastication stage and then the characteristics of the residual or swallowing stage. Surface properties are smoothness/roughness, surface moisture, or a granular appearance. During the mastication stage, the degree to which the sample returns to its original form (springiness/elasticity), the tenderness/hardness, the fatty perception, and the moisture release (juiciness) can be evaluated.

Table 8 Texture attributes at different stages of mastication

Stage of perception	*Attribute*
First stage: surface perception	Granular
	Rough
	Moist
Mid stage: during mastication	Tender/hard
	Springy/elastic
	Cohesive
	Moisture release
	Moisture absorption
	Juicy
	Gristle
	Stringy
	Fibrous
	Particle size and shape
	Sticky
	Greasy
Final stage: residual perception	Number of chews
	Mouth coating
	Ease of swallowing
	Residual particles

Source: Bett KB (1993) Measuring sensory properties of meat in the laboratory. *Food Technology* 47: 121–127.

Tenderness is the opposite of toughness or resistance to rupture during chewing. Meat tenderness depends largely on the amount and status of the connective tissue and myofibers. The connective tissue is composed mainly by collagen, of which its quantity, quality, and distribution in muscle contribute to the specific character of meat tenderness. The extent of aging (chill storage) increases, whilst a contracted state of the myofibrils decreases tenderness. Collagen content imposes the cooking method of muscles. When the collagen content is low, the muscle can be grilled quickly at high temperature to avoid myofibrillar toughness. However, if meat is rich in collagen, a long cooking in a wet atmosphere and at a moderate temperature is essential to solubilize the collagen and to reduce mechanical resistance.

Juiciness is related to the perception of water released from meat during chewing and to the intramuscle fat content, which has a stimulant effect on salivation.

The residual texture stage depends on the number of chews to prepare the sample for swallowing, the fibrousness of the connective tissue, the denseness, the bolus formation, the ease of swallowing, and how much and what is remaining in the mouth

(Table 8). It includes the description of remaining particles and any residual coating. The essential components of the qualitative description of texture are the same for all meats from different species.

Flavor Flavor refers to the taste and olfactory properties that are perceived by the gustatory receptors of tongue and the olfactory mucous membrane in the nasal cavity. The four basic tastes of sweet, salty, acid, and bitter can be found at low to moderate intensities in the various muscle foods. Sweet and salty have naturally low intensities in fresh meat but can be more intense in cured meats. Astringent and metallic perceptions, which result from the presence of metal ions, are two mouth feel descriptors commonly found in meats. Umami is another taste common to meats; it is given by the presence of monosodium glutamate and nucleotides.

Meat flavor has been shown to be affected by several *ante-mortem* (age, sex, species, nutritional status, stress level, muscle type, fat level and composition) and *post-mortem* (slaughter, carcass handing, aging, cooking, and storage after cooking) factors. Animal age is an important factor; flavor intensity is higher in meats from older animals. Meat contains nonvolatile flavor precursors such as lipids, fatty acids, sugars, organic acids, nucleotides, peptides, vitamins, and volatile components such as products of reactions of oxidation. The flavor of cooked meat is developed by the application of heat that induces Maillard reactions and the degradation of lipids. The Maillard reaction products are formed by reactions between sugars and amino acids or peptides. Heterocyclic compounds produced by the Maillard reaction, especially those containing sulfur, are important and provide meaty, roast, and boiled aroma. Most cooked meats have characteristics brothy, browned, and meat flavor. The accurate determination of flavor is cumbersome because of the multitude of sensory terms and has not been fully elucidated.

The flavor characteristics of meat from different species are listed in Table 9. The lipid fraction probably contains the specific odorant tracers of each species, while the aqueous fraction holds the common nonvolatile meat taste. The main beef flavor attributes developed are the serum/bloody aroma associated with raw beef lean, the brothy/meaty aroma associated with cooked lean meat, the aroma associated with cooked beef fat, and the browned aroma associated with the outside of grilled or broiled beef. The beef flavor note is due to the presence of many compounds: methyl-branched aldehydes, ketones, nitrogenated heterocycles, and other compounds. Lamb exhibits the strongest and the most variable flavor: animal, cabbage, rancid odor, and meaty flavors. The branched fatty acids (4-methyloctanoic and 4-ethyloctanoic acids) are found in abundant quantities in lamb fat and are responsible for the mutton flavor. Abnormal flavors androstenone (boar taints) or other metabolites (skatole) contained in the fatty tissue of male pigs. Cured pork meats have more aroma than fresh meat. The fermentation process used in dry sausage with bacterial starters or the drying process of dry-cured ham leads to the formation of flavor such as buttery, vinegar, nutty, and cheese aroma. Poultry skin contains fat and sulfur compounds responsible for the characteristic chicken aroma. Moreover, inosinic acid, inosine, and guanylic acid may also react with other components of meat

Table 9 Flavor attributes for various species of meat

Beef	*Lamb*	*Pork*	*Poultry*
Cooked beef lean	Gamey/muttony	Porky	Boiled chicken
Brothy/meaty	Fatty	Sex taint/boar odor	Meaty
Cooked beef fat	Bloody/serum	Fatty	Brothy
Serum/bloody	Browned/caramel	Bloody	Browned
Browned	Livery/organ meat	Browned	Liver/organ-like
Grainy/cow-like	Meaty		
Livery/organ meat	Sheep meat		
	Boiled meat		
	Poultry		
	Animal		
	Rancid		
	Oily		
	Buttery		
	Cabbage		
	Roast		
	Rubbery

during the Maillard reaction and add complexity to the chicken flavor.

Conclusion

Good manufacturing practices, developed in the past 20 years, have introduced new hygienic rules that limit contamination by pathogenic and spoilage bacteria. Consumers are more aware of the quality and storage of meat and of the safety measures taken during its preparation. Consumer preferences are considered by the food industry in order to provide meat products with the desired sensory and nutritional qualities. However, several criteria other than eating quality play an important role in meat acceptability, e.g., price of meat, attitudes and knowledge of consumers towards meat, and convenience in preparing meat. Multidisciplinary studies should be useful in understanding the complexity of eating behavior.

Sausages and Comminuted Products

J G Sebranek, Iowa State University, Ames, IA, USA

General Information

Sausages and comminuted (ground, chopped, or otherwise subdivided) meats are processed-meat products which offer consumers a wide range of alternatives to the standard fare of steaks, chops, and roasts. These products not only offer meat with different flavors and textures but also allow processors to improve the keepability and safety of meat products. Spices and other ingredients are used to create unique flavors while processes such as curing and drying improve product color and textural properties. The use of ingredients, such as salt and nitrite, and processes, such as cooking, together serve to kill microorganisms and consequently improve keepability and safety of sausage products.

Comminuted meats can be as simple as ground beef, an immensely popular consumer product, or as complex as fermented, smoked, dried hard salami. The flavor, color, texture, and storage stability of ground beef compared with hard salami provide a good example of the extremes which can be achieved with this group of food products. Ground beef is an inexpensive product, popular by itself but also frequently used in combination with other ingredients (vegetables, mushrooms, cheese, pasta, etc.) to increase menu flexibility and eating variety. The hard salami, in contrast, is a relatively expensive, gourmet product that provides a unique gustatory experience by itself. Sausage products also offer consumers a high degree of convenience since many are cooked and may be eaten cold or simply reheated using a microwave. There is little or no waste from these products.

Sausages and comminuted meats are good examples of 'value-added' processing by the food industry whereby relatively low-value meat cuts and

trimmings are dramatically improved for eating enjoyment. Chopping and grinding, for example, can greatly improve the tenderness of tough meat cuts; spices, smoking, and cooking can create unique textures, flavors, and aromas which increase eating pleasure. Each processing step can be achieved in a number of different ways (different comminution methods, spice blends, smoking and cooking processes, etc.) which means there are hundreds of varieties of sausages and comminuted meats available. In addition, the meat industry is constantly striving to create new products in order to remain competitive with the rest of the food industry. This means that consumers can expect to see more new varieties of sausages and comminuted products in the future.

The preparation and processing of sausage products was once considered exclusively an art, with secrets handed down through generations of sausage makers. However, scientific research in the twentieth century has provided the understanding necessary to make this field a sophisticated science.

Historical Background

Sausage products are believed to have been developed well before written history. The word 'sausage' has been described as originating from the Latin word *salsus*, which means salted. This would imply that sausage processing, in the form of adding salt to meat, existed at least several hundred years BC.

It is likely that most sausage-processing techniques were discovered by accident. People who used salt for flavoring purposes eventually noticed that salted meat did not spoil as quickly as unsalted meat. Likewise, smoking was probably discovered as a side-effect of cooking over an open fire, and drying for preservation may have resulted from observing meat exposed to the sun during warm, dry days. The discovery of spices resulted in a tremendous increase in meat product variety as people experimented with different spice combinations and blends. The need for convenience in handling led to the use of sausage casings derived from the gastrointestinal tract of animals slaughtered for meat. Thus, allied industries developed to supply meat processors with spices, casings, and equipment necessary to manufacture sausage products.

The development of cured sausage probably originated with salt-preserved meat where the salt used contained saltpeter. Saltpeter (potassium nitrate) is a relatively common contaminant in crude salt which will result in a unique pink-red cured color when used in meat. Additional effects from saltpeter include a marked resistance to spoilage. Such observations would have greatly encouraged use of this compound for cured meat processing. By the late 1800s, scientific studies had shown that the nitrate ion from saltpeter was the source of meat-curing reactions and, by the 1920s, scientists determined that nitrite rather than nitrate was the active curing agent. Consequently, direct addition of sodium nitrite is the most common means today of producing cured meats. Cured products include not only many sausages and comminuted meats but also intact muscle products such as hams, bacon, and corned beef.

Many of the sausage products common in the USA can be traced to their origins in Europe and other parts of the world. In most cases, the type of product is related to environmental conditions within the geographical region in which they originated. Dry sausage, for example, was largely developed in southern Europe where such products are unlikely to spoil in the warm climate. On the other hand, northern Europe gave rise to cooked sausage where a cold climate permitted longer storage. It has been suggested that the development of highly spiced foods, often typical of warm climates, was encouraged by the ability of spices to prevent and mask off-flavors which are likely to develop at warm temperatures. Many meat products also have names which suggest origin from a specific region or city; examples include Frankfurt (frankfurters) and Bologna (bologna). The development of mechanical refrigeration, modern packaging, and rapid transportation systems has allowed widespread distribution of traditional sausage products all over the world.

Classification of Sausages and Comminuted Meats

Because sausages and comminuted meats are characterized both by processing procedures and by ingredients used, classification of these products largely reflects their processing history. Of course, this also means that classification becomes somewhat arbitrary in cases where several processing techniques may be combined to produce a specific product. Nevertheless, most sausages and comminuted meats can be placed in one of seven general classes (**Table 1**).

Close review of **Table 1** shows that products can be distinguished by five fundamental treatments: seasoning, cooking, curing, smoking, and drying. For example, fresh comminuted meats such as ground beef or restructured nuggets are not cured (do not contain nitrite), usually contain little seasoning, and are not smoked. While 'fresh' may be defined as 'raw, uncooked' meat, it is more specifically understood in the sausage industry to mean 'uncured.' This category of products is becoming increasingly popular as cooked products ready for quick reheating. This popularity has been facilitated by use of batters, breadings,

Table 1 Classification of sausages and comminuted meats

Product group	*Examples*	*General characteristics*
Fresh comminuted meats	Ground beef Ground pork Ground poultry Nuggets Restructured patties, steaks, chops	Uncured, typically uncooked and unseasoned but may include limited seasoning and/or binders; nuggets and restructured products may also be coated with batter or breading. Increasingly, this category of products is found as fully cooked and ready for microwave reheating
Fresh sausage	Pork sausage Bratwurst Italian sausage	Uncured, well-seasoned with salt and spices, usually stuffed into casings but not smoked or cooked; may be found as patties or in bulk quantities besides the traditional sausage links
Uncooked, smoked sausage	Kielbasa Mettwurst	Cured or uncured, seasoned, stuffed into casings and cold-smoked; must be fully cooked before serving
Cooked, smoked sausage	Frankfurters Bologna	Cured, seasoned, stuffed into casings, smoked and fully cooked; may be served cold or reheated. Casings are usually removed prior to sale
Cooked sausage	Braunschweiger Liver sausage	Cured or uncured, seasoned, stuffed into casings and cooked; may or may not include smoke flavorings
Cooked luncheon meats and loaves	Pickle and pimiento loaf Ham and cheese loaf Sandwich spread Scrapple	Cured or uncured, seasoned, cooked, not smoked. Products in this category show wide variety of nonmeat (cheese, olives, pickles, honey, etc.) ingredient use
Dry and semidry sausage	Pepperoni Hard salami Summer sausage Lebanon bologna	Cured, seasoned, stuffed into casings; usually fermented; usually smoked and cooked. Controlled air-drying utilized for dry sausage, with most products characterized by final moisture-to-protein ratio

and other coatings which add new flavors, improve mouth feel, and increase retention of meat flavor and juiciness in these products. Fresh sausage, in contrast to fresh comminuted meats, is well-seasoned with salt and spices and is usually stuffed into casings or formed into patties. Uncooked, smoked sausage, which is relatively uncommon in the USA, is smoked for flavor enhancement but remains uncooked.

Cooked and smoked sausage makes up by far the largest sausage category in the USA and is typically cured, seasoned, smoked, and fully cooked. Because these products are considered ready-to-eat (RTE), they are very convenient and easy to use. This group makes up about 40% of all sausage products in the US, with the most common being frankfurters and bologna. The cooked-sausage category includes products which may be cured or uncured but will usually be stuffed into a cylindrical casing. Because smoke is not usually applied to these products, cooking, when done, is often carried out in hot water instead of hot air, as is typically done for combined smoking/cooking processes. Cooked loaves and luncheon meats is a category of processed meats which includes extensive use of unique nonmeat ingredients such as pickles, pimientos, cheese, olives, honey, and corn meal. These nonmeat ingredients offer a tremendous variety of flavors and appearance characteristics for these products. The dry and semidry sausages may be the most distinctive group of processed meats because, in addition to curing, seasoning, and stuffing into a casing, these products are usually fermented with a microbial culture to acidify the product and facilitate subsequent drying. Semidry products such as summer sausage are not further dried and are ready for distribution after fermentation and cooking. With an appropriate pH (acidity) from fermentation, and adequate vacuum packaging, these products will be shelf-stable and may not require refrigeration. Dry sausage, such as pepperoni, is dried after the fermentation/cooking process to reach a characteristic moisture:protein (M:P) ratio as required by regulation. In the USA, for example, the required M:P ratio for pepperoni is 1.6:1 or less; for Genoa salami, it is 2.3:1, and for beef jerky, it is 0.75:1. For comparison, fresh meat has an M:P ratio of about 3.7:1. The overall result of drying processes for dry and semidry sausage is a product with distinctive flavor, unique texture, and very high resistance to spoilage. The high resistance to microbial growth and spoilage which characterizes this category of sausage products also contributes to improved product safety.

Ingredients Used for Sausages and Comminuted Meats

The ingredients chosen to manufacture sausages and comminuted meats not only determine product identity but are also critical to the quality of the finished

product. Ingredients include both meat ingredients and nonmeat ingredients, both of which play a major role in creating product identity and eating quality.

Meat Ingredients

The selection of meat ingredients to be used for manufacturing sausages and comminuted meats is one of the first, and most important, decisions made by meat processors. The first requirement is that the meat be of high quality and as fresh as possible. It is sometimes assumed that meat quality is not critical to final product quality because spices and other ingredients will overwhelm and mask small quality differences in meat ingredients. It has been clearly shown by research, however, that the subtle chemical changes which occur in meat before processing, such as the beginning of lipid oxidation, can have major effects on finished product quality.

The second requirement for meat ingredients to be used for sausages and comminuted meats is information on composition and color of each ingredient. The various meat ingredients available are highly variable in color, composition, and ability to retain moisture and fat when cooked. Consequently, sausage processors must choose and combine meat ingredients in the proportions that will create the finished product qualities desired. The meat ingredients are not only the source of the fat, water, and protein content of the finished product, but also affect the texture, juiciness, flavor, and appearance of the product. When the desired product qualities have been achieved, it becomes important to reproduce the same product consistently every time it is manufactured.

The differences in meat ingredients are the basis for the use of least-cost computer formulations by the meat industry. For these computerized calculations, all meat ingredients are first chemically analyzed for input data to be used in the program. The computer program then determines the proportions of each ingredient needed to achieve the desired product characteristics at the lowest possible cost. Because there are dozens of different meat ingredients available and each will vary from day to day, computerized least-cost formulation programs are very useful. An additional advantage to cost control, however, is the improvement in product consistency and uniformity that is achieved at the same time.

Nonmeat Ingredients

After selecting the meat ingredients, a sausage manufacturer is faced with decisions on nonmeat ingredients. Many of the nonmeat ingredients are essential to product characteristics; salt for most sausages is one such example and the only decision to be made concerns the amount of salt to be used. Other nonmeat ingredients such as spices offer the opportunity to create unique products by using different blends and combinations.

Table 2 includes the most important nonmeat ingredients with the major functions and typical use levels of each. In many cases, nonmeat ingredients are restricted by regulations which may vary in different countries of the world. When trying to determine the limits of nonmeat ingredient use, it is important to check the regulations appropriate to where the product is being manufactured and/or sold. Awareness of the specific functions of each nonmeat ingredient is important because each contributes specific product characteristics that often cannot be produced any other way.

Salt, for example, is responsible for several different characteristics essential to sausage products and is much more than a simple flavoring ingredient. While the flavor from salt is important, salt is even more critical to microbial control (both for spoilage and food safety), product texture, and binding of fat and water. Because there has been concern about human dietary sodium intake and the potential relationship of sodium to hypertension, considerable research has been conducted on the reduction of salt levels in processed meats. While the research has shown that salt can often be reduced to some degree, it has also become clear that microbial problems and cooking losses quickly increase as salt is reduced, especially below 2%. Salt is also necessary for typical texture and binding qualities of meat because the meat proteins responsible for these characteristics are solubilized by salt. The proteins must be at least partially solubilized to be effective. Protein solubility and binding is one of the main reasons a small (0.5–1.0%) amount of salt is used in restructured meats and nuggets. Recent developments with enzyme technology, such as the use of transglutaminase to achieve meat protein cross-linking, may offer an alternative to the use of salt for binding in restructured meats.

While salt is used for every sausage product and most comminuted meats (except ground beef, pork, lamb, or poultry), one ingredient that differentiates product classes very clearly is sodium (or potassium) nitrite, which separates cured and fresh products. Nitrite is responsible for cured meat color and flavor, as well as being a strong microbial inhibitor. Sodium (or potassium) nitrate is often described as a curing ingredient but is ineffective by itself. The only function of nitrate in processed meats is to form nitrite which then contributes all the cured meat characteristics. The use of nitrite (and nitrate) is strictly regulated. The most common limitation, and that which applies in the USA, is a maximum of 156 mg sodium nitrite per kilogram (156 p.p.m.) of meat. One exception to

Table 2 Nonmeat ingredients used for sausages and comminuted meats

Ingredient	*Function*	*Level of use and applications*
Salt (sodium chloride)	Flavoring, microbial inhibition, protein solubilization (which controls fat and water retention in cooking), product texture, and product adhesion	0–5% in all sausages and many comminuted meats Dry sausage may be as high as 5%, other sausages 1.5–2.5%, restructured comminuted meats 0.5–1.0% and ground beef 0%. There are no regulatory limits
Sodium or potassium nitrite	Curing agent responsible for cured color, flavor, and microbial control, particularly for *Clostridium botulinum*	Limited to 156 p.p.m. in most products. Used in all cured meats. Maximum levels established by regulation
Sodium ascorbate or erythorbate	Accelerates the curing reaction of nitrite, contributes antioxidant (protection from off-flavor) function	Limited by regulation to 550 p.p.m. when used Usually included with nitrite in meat curing
Phosphates (sodium tripolyphosphates; sodium polyphosphate, glassy; tetrasodium pyrophosphate; sodium hexametaphosphate)	Increase protein solubility (with related fat and water binding) and product adhesion, increase meat pH, chelate metal ions that encourage rancidity, contribute to microbial inhibition	0.2–0.5% in both cured and fresh products Maximum level of 0.5% is controlled by regulation
Sweeteners (sucrose, dextrose, lactose, corn syrups, sorbitol)	Provide sweetness, improve water retention, substrate for fermentation	Usually used at 0.5–1.0%. Sucrose and dextrose are unlimited but corn syrups and sorbitol are restricted to 2.0% by regulation
Starter cultures	Produce lactic acid from sugars and lower product pH	Limited to 0.5% (with water) for fermented sausage
Binders and extenders (milk proteins, soy proteins, cereal products, starches, carrageenans, hydrocolliods)	Improve water binding, product slicing, cooking yields, reduce product costs	May be used in any product. Generally limited (in USA) to 3.5% except soy isolate (2%), with some exceptions
Antioxidants (BHA, BHT, TBHQ, propyl gallate) and synergists (citric acid, sodium citrate, monoisopropyl citrate, monoglyceride citrate)	Inhibit rancid flavors; synergists are used to chelate metal catalysts, making the antioxidants more effective	Used in fresh sausage and dry sausage. Limited by regulations (in USA) to 0.01% of the fat in fresh sausage (0.02% in combination) and to 0.003% of product weight in dry sausage (0.006% in combination)
Antimicrobial agents (sodium or potassium lactate, sodium diacetate, potassium benzoate, potassium sorbate, microbial fermentation products such as pediocins)	Inhibit microbial growth, especially pathogenic bacteria	Limited by regulation with amounts ranging from 0.1 to 3.5% depending on product and specific use

BHA, butylated hydroxyanisole; BHT, butylated hydroxy toluene; TBHQ, tertiary butylhydroquinone.

this is pumped bacon which is limited to 120 p.p.m. Nitrite is a remarkable ingredient in that it performs its functions at extremely low concentrations and no other ingredient has been found that will produce the same effects. Nitrite is also important because, in addition to preventing spoilage, it is a highly effective inhibitor of *Clostridium botulinum*, thus providing food safety assurance. Cured, cooked meat in vacuum-sealed cans or packages, an environment where *C. botulinum* is most likely to grow, is very well protected against the likelihood of causing botulism. Most modern curing processes also include sodium ascorbate or erythorbate as accelerators to speed up the nitrite curing reactions and facilitate more rapid production systems. These two ingredients differ only in that ascorbate is biologically active as vitamin C while erythorbate is not. Both are equally effective when used to accelerate meat curing reactions. Interestingly, there is a persistent rumor which circulates among consumers that erythorbate means earthworms and products with erythorbate are to be avoided. Because this unfounded rumor has persisted, some meat-processing companies have begun indicating on product labels the true source of erythorbate, that is, 'made from sugar.'

Other multifunctional nonmeat ingredients include the polyphosphates. These compounds, of which there are several, interact strongly with salt for protein solubilization. Consequently, the phosphates are major contributors to product texture and binding characteristics. The importance of the phosphates becomes more marked in meat products with reduced

salt content and, in practice, one of the roles of phosphates is to permit lower concentrations of salt to be used. Restructured, comminuted meat products and nuggets which usually contain only 0.5–1.0% salt depend greatly on the presence of phosphates to achieve protein solubility and binding. Most of the approved phosphates are good chelating agents and will bind (chelate) contaminants such as metal ions which commonly initiate rancid flavor production. Thus, phosphates also function as flavor protectors.

Spices are ingredients traditionally used for flavoring of sausage products. More recently, spices have been found to have other important functions as well. For example, pepper, ginger, cloves, sage, and rosemary are effective antioxidants and serve to protect product flavor. Other spices have been noted to contribute to inhibitory effects on bacterial growth. However, because spices are dried plant products, they are often a source of microbial contamination which can be a significant problem in processed meats. Spices are usually treated with ethylene oxide or irradiation to reduce the microbial contamination. Spice extractives or liquid spices may also be used to avoid the microbial problem. Flavoring agents such as nucleotides, monosodium glutamate, and hydrolyzed proteins are sometimes used to increase meat and/or spice flavor intensity.

Sweeteners, which are most often sugars, might also be considered flavoring agents but, in addition to contributing sweetness, these ingredients also help bind water because they are hygroscopic. Sucrose or cane sugar may be used but dextrose or corn sugar is more common. Dextrose is also utilized for fermented sausage as the carbohydrate of choice for fermentation. The amount of lactic acid produced by the fermentation and the product tanginess it produces can be controlled by the amounts of dextrose used. Dextrose is also well-recognized as a reducing sugar which will result in caramel-colored surfaces when heated in the presence of protein, a color desired for some meat products.

Starter cultures are another nonmeat ingredient developed for use in fermented sausage. The use of starter cultures has given fermented sausage processors immensely improved control over fermentation processes. By using pure strains of desired bacteria, processors have avoided many of the problems which were caused by 'wild' cultures inherent to the meat ingredients used. There are several types of bacteria used for sausage starter cultures, with specific strains of *Pediococcus, Lactobacillus*, and *Micrococcus* being most common in the USA. In addition to lactic acid, starter cultures may also produce a variety of other fermentation end products, some of which contribute to flavor. Thus, the specific culture used may create a unique flavor and product as a result of the fermentation process.

A wide variety of extenders or binders may be used to improve water and fat retention, slicing or cooking yields of processed meats. These compounds differ greatly and range from milk and plant proteins to starches and hydrocolloids. This category of nonmeat ingredients is closely regulated, with limits for most being 3.5% or less.

A unique group of nonmeat ingredients permitted only in fresh sausage or dry sausage is the antioxidants and synergists. These compounds are used to retard the development of rancidity and thus protect flavor. Included are butylated hydroxyanisole (BHA), butylated hydroxy toluene (BHT), tertiary butylhydroquinone (TBHQ), and propyl gallate. These compounds are frequently used in combinations to gain improved effectiveness. While very effective in meat systems, these antioxidants are considered synthetics and are not normally found in meat products unless they are added. Some questions have been raised concerning the use of these antioxidants and natural antioxidants have been sought as alternatives. Most natural antioxidants have been found to be less effective, though some show enough antioxidant activity to be useful. One such compound is rosemary extract, which has significant antioxidant activity and is widely accepted because it is derived from the spice.

Sausages and Comminuted Meats in the Human Diet

Consumers are sometimes critical of the dietary value of sausages and comminuted meats despite the fact that these products provide high-quality protein, B vitamins, and several minerals such as iron. Dietary concerns are usually based on fat and caloric content, salt (sodium) concentrations, and presence of additives such as nitrite and synthetic antioxidants.

Concern for fat and caloric content has been most significant for traditional sausage products which have been formulated with 30% or more fat. A limitation to fat reduction in the past has been the tough rubbery texture that occurs in low-fat, high-protein products if other adjustments are not made. Recent technology developments with nonmeat ingredients have permitted meat processors to offer reduced-fat and fat-free products with very acceptable textural characteristics. Thus, consumers are given a choice and can seek out low-fat products by reviewing the product labels. Salt (sodium) content has also been reduced in many products, though sausage products will always contain higher sodium levels than fresh meat. Sodium content of processed meats may remain

a concern to individuals who are hypersensitive to dietary sodium. Product labels provide information on sodium content so that consumers can make educated choices. Nitrite and synthetic antioxidants have both been controversial because of concern that these compounds may be potential carcinogens. Nitrite, however, is not, by itself, a carcinogen, though it can react with other components in meat systems to form carcinogenic nitrosamines. Past research has improved curing procedures to the point where virtually all nitrite is utilized in meat curing reactions with none available for formation of carcinogens. Recent research has shown that residual nitrite in commercial processed meats has declined dramatically from that found a few years ago. Total nitrite consumption from processed meat is presently less than 5% of the total dietary intake. Concerns for the synthetic antioxidants have not been investigated as thoroughly as for nitrite. However, in this case, other antioxidants may be used to replace the synthetics if necessary – an alternative that does not exist for nitrite.

Analysis

B D McLean, Chemistry and Biochemistry Dept, Chipping Campden, UK

Introduction

Meat consists essentially of water, protein, fat, and mineral salts (ash) and it is these proximate analyses that are carried out routinely in many laboratories. This is often to identify the data which can be used for labeling purposes, or to calculate the apparent meat content. This in turn can be used to calculate the added-water content of products such as ham and bacon that contain added curing solutions. Meat products such as bacon, sausages, and burgers often also contain ingredients such as wheat rusk, sugar, and soya and hence also contain carbohydrates. The level of carbohydrates needs to be known when calculating energy content and possibly meat content and is routinely estimated 'by difference' using the formula in **Table 1**. This carbohydrate 'by difference' value is usually sufficient for routine work; however, if necessary the carbohydrate can be analyzed directly from the analysis of sugar, starch, and dietary fiber which makes up the bulk of the carbohydrate in meat products. **Table 1** also lists the most common analyses carried out on meat and meat products.

Sampling

Meat, being a natural product, is very variable in its composition. Raw meat consists essentially of muscle

Table 1 Common analyses on meat and meat products

Analyte or test	*Commonly used methods*
Nitrogen	Kjeldahl or Dumas method
Fat	Acid hydrolysis and ether extraction or Soxhlet-type extraction of 'free fat'
Ash	Incineration at 450–550 °C
Water/moisture	Oven drying at 101–105 °C (with or without use of sand)
Carbohydrate	Calculation by difference from analytes above using the formula Carbohydrate (by difference) = 100 − (% fat + % water + % protein + % ash)
Qualitative identification of meat, cereal, soya, onion, heart, kidney, MRM, etc.	Microscopic examination
Soya protein	Soya immunoassay
Connective tissue content (collagen)	Hydroxyproline determination by colorimetric method
Indication of previous freezing	β-HADH enzyme test
Species of meat present	Species immunoassays and DNA techniques

β-HADH, β-hydroxyacyl-coenzyme A-dehydrogenase; MRM, mechanically recovered meat.

and fatty tissues held together by tough connective tissue. It is somewhat difficult therefore to obtain a homogeneous sample from such a mixture that is suitable for analysis. Prior to the analysis of meat and meat products, it is almost always necessary to chop and blend the samples. It is also necessary to consider the amount of sample to take, for example, the number of entities such as pies and sausages to include, and what part is to be included (e.g., should the rind be removed from bacon? Should the pastry be separated from pies?). The presence of pieces of rind in the final sample makes it difficult to blend evenly and it may be preferred to remove the rind prior to blending. The more uniform the final mix, the easier it will be to obtain good-quality repeatable analytical results. Once blended, the samples must be stored in airtight containers with the minimum amount of air space to avoid loss of moisture. If they are not to be analyzed immediately (the preferred option) then they must be deep-frozen to prevent chemical changes to the proteins and fat.

Quality of Results

To show that analytical results are under control it is necessary to carry out quality control procedures. These may involve the analysis of reference materials (prepared in-house or purchased with precertification), replicate analysis, or participation in proficiency testing schemes. One proficiency scheme which has a meat test series called 'nutritional components' is the UK Food Analysis Performance Assessment Scheme (FAPAS). This includes the analysis of fat, water, ash, protein, hydroxyproline, and salt (sodium and chloride) in meat and meat products and it is a useful way to show the quality of these analyses. Other series are available which are suitable for meat analyses including those covering the composition of fats, presence of veterinary medicines, and levels of trace elements.

Nitrogen and Protein

This is an important analysis in determining the composition and meat content of meat and meat products. For many years the protein content has been determined by the Kjeldahl procedure, often in one of its semi-automated forms. This assumes that the proportion of non-protein nitrogen in a food material is too small to be significant and that a determination of total nitrogen (excluding that present as nitrate and nitrite, which is not measured by Kjeldahl anyway) will therefore be an accurate reflection of the total protein content. In the Kjeldahl procedure, the entire food sample is digested at high temperatures (420 °C) with boiling sulfuric acid under reflux. Essentially, the protein is converted to ammonium ions by digestion with superheated sulfuric acid. The digestion includes potassium sulfate and a catalyst of copper, mercury, or titanium, although the use of mercury is frowned upon these days due to its environmental pollution problems. The nitrogen content is then determined by making the digest alkaline and distillation of the resulting ammonia into boric acid or standardized acid solution. The ammonia is then titrated with standard acid or alkali respectively. The nitrogen content is converted into a protein content using a factor of 6.25, which assumes 16% of nitrogen is present in meat proteins.

There is now increasing use of the Dumas analysis technique to determine the nitrogen content of foods. In this procedure, the nitrogen-containing constituents of the sample are combusted at high temperature in the presence of oxygen and helium. This produces oxides of nitrogen which are then reduced over copper to gaseous nitrogen and measured by thermal conductivity. The

Table 2 Comparison of the nitrogen content of chicken as determined by the Dumas and Kjeldahl methods

Sample	*% Nitrogen*	
	Kjeldahl	*Dumas*
1	3.14	3.28
2	3.18	3.26
3	3.19	3.27
4	3.22	3.27
5	3.25	3.28
Mean	3.196	3.271
Calculated protein	19.98%	20.44%

level of nitrogen is then converted to protein content by the conventional factors mentioned above. Modern developments in instrumentation have allowed the Dumas procedure to be automated to a far greater extent than the digestion and steam distillation stages of the Kjeldahl approach.

It should be noted that the Dumas technique does not necessarily measure the same substances in meat as the more traditional Kjeldahl technique. Table 2 shows some details of the results obtained on five samples of chicken by both of these methods. It has been shown that the means of the Dumas results are statistically significantly higher than the Kjeldahl method and would give rise to a calculated apparent meat content approximately 2% higher than the latter method. This difference may not normally be a problem but it may be of significance in calculations of added water content.

The other meat species tested in the work were not significantly different. It must also be noted that the official nitrogen factors used to convert nitrogen levels into a meat content have so far been determined only by the Kjeldahl procedure. The British Standard quotes a level of 0.1 g per 100 g for the repeatability of the nitrogen determination using the Kjeldahl procedure. In practice, a repeatability of 0.07% absolute (95% confidence) is achievable.

Ash

The ash content of foods is the least important value and is relatively easy to determine. The method for ash is well-documented, with the food normally being incinerated at a temperature of between 525 and 575 °C. The ash content of meat is normally about 1%, but when salt is added (e.g., cured meats), then this level increases proportionally. The ash consists of minerals such as sodium (especially if salt is present), calcium, potassium, magnesium and iron and zinc, with chloride and phosphates. The presence of bone particles in meat and meat products will obviously also increase the ash content.

Where the ash is to be used for the determination of the salt content or trace metals analysis, then the lower end of the quoted temperature range for ashing is recommended as chloride and some metals can volatilize above 550 °C. In general, the repeatability (95% confidence) of the ash determination should be 0.1% absolute or less.

Fat

The fat present in meat may be considered as consisting of free fat and bound fat. The free fat can be extracted by less polar solvents such as petroleum spirit or diethyl ether. The bound lipids need to be released from the protein matrix by the use of acid or alkaline hydrolysis. This allows all of the fat present in the food to be extracted and measured gravimetrically.

Problems are sometimes encountered when laboratories achieve low-fat-content results due to the use of analytical methods that do not remove all of the bound fat. These are normally based on modifications of the traditional Soxhlet solvent extraction process determined on commercially available equipment. When such fat results are declared on the label of the food, the data have been found to be low by enforcement laboratories that frequently use acid hydrolysis methods to remove all of the fat present from the food. On some occasions, laboratories have used 'correction factors' to increase the free fat to the expected level of total fat. The use of such correction factors is not good practice.

The Werner-Schmid and Weibbull-Stoldt methods are particularly good methods for the determination of fat in meat as they involve an acid hydrolysis step that releases the bound fat prior to extraction. The repeatability level quoted in the British Standard of 0.5% is achievable at low level but is very difficult for laboratories to achieve consistently at levels above 30% fat.

Moisture

Moisture or water is normally determined in meat by drying at temperatures between 101 and 105 °C. This is achieved by weighing a few grams of the blended food with a small amount of sand in a dish. The inclusion of a rod assists in mixing the meat with the sand. The meat–sand mixture in the dish is then partly dried on a water bath and mixed further to form a friable mass before further drying in an oven at around 103 °C. Using this procedure it should be noted that any substance that is volatile at 103 °C would be measured as water. Alcohol or acetic acid, which may be present in some meat products (e.g.,

pâté with spirits), would also be lost using this procedure. The repeatability (95% confidence) of this method is generally of the order of 0.6% absolute, and laboratories are normally able to achieve this level of precision.

It is becoming increasingly common to use microwave drying to determine the moisture content of foods. It is essential when using this procedure to insure that the microwave heating does not burn the food and the settings on the microwave must be determined with care. This can be achieved by comparing the results of microwave drying with the more traditional oven-drying reference method and adjusting the drying time accordingly.

For rapid results, instruments are available which consist of a balance which has an infrared heater above it. Samples are weighed on to the balance and then immediately dried using the heating element to a constant weight.

Connective Tissue Content

Enforcement authorities are increasingly interested in the connective tissue content (rind, skin, gristle, etc.) of meat and meat products. Connective tissue content is also used as a measure of the quality of exported meat products within the EC. The amino acid hydroxyproline is present in animal protein collagen at a relatively high and consistent level compared with muscle proteins. The determination of hydroxyproline content of meat and meat products therefore allows an assessment of the level of connective tissue. This in turn allows a decision to be made on whether the amount of connective tissue in a product is acceptable.

The method of analysis used for the determination of hydroxyproline is essentially a colorimetric procedure. After hydrolysis of a test portion of the meat in sulfuric acid at 105 °C, the hydrolysate is filtered and diluted. This is followed by an oxidation step with chloramine T.

The resulting solution is then treated with *p*-dimethylaminobenzaldehyde, which produces a red compound, the amount of which is measured using a spectrophotometer.

In order to calculate the amount of connective tissue that is present in foods, a number of factors have been derived (Table 3). The procedure documented by Lord and Swan is commonly used by enforcement authorities to determine the connective tissue content of meat and meat products.

Table 3 Factors used to convert hydroxyproline data into useful parameters

1. Hydroxyproline × 37 = % Wet fat-free connective tissue
2. Hydroxyproline × 1.28 = % Connective-tissue nitrogen
3. Hydroxyproline × 8 = % Collagen

Calculation of Meat Content and Added Water Content

Analytical data can be used to calculate the apparent total meat content of meat and meat products. This is achieved by measuring the amount of nitrogen present and applying standard factors to determine the apparent fat-free meat content and, with a further allowance for fat, the apparent total meat content. This is the basic method described by Stubbs and More, which has changed little since its publication in 1919. This approach to calculating apparent total meat content can be modified to allow for the presence of the more complex ingredients now used – such as soya – which contribute protein (and so nitrogen), but not meat. Also, the lean meat content can be estimated by further calculation allowing for the level of fat deemed to be appropriate for lean meat.

The principle of the Stubbs and More method involves the estimation of the apparent fat-free meat content, from the amount of nitrogen originating from the meat. Factors are used for the conversion of the nitrogen content to meat content. An allowance is then made for the amount of meat fat to determine the apparent total meat content. 'Nitrogen factors' are available for the conversion of the nitrogen content to raw meat equivalent for many meats. The average nitrogen factors used for meat content calculation have been the subject of much debate; however, the Nitrogen Factors Sub-Committee of the Analytical Methods Committee of the Royal Society of Chemistry publish the most widely accepted values (Table 4). It should be remembered that a nitrogen factor is the average nitrogen content of the fat-free meat and represents a range of values and not a single exact value. A worked example, applying this approach to roast lamb, and including the relationship between nitrogen content and protein content, is given in Table 5.

The above basically holds true for meat and meat products which consist essentially of meat. However, for more complex products (e.g., sausages, burgers), further corrections must be applied for any sources of non-meat nitrogen. If these corrections are not applied, the calculation would give an artificially elevated meat content result.

Lean meat content is often referred to by legislation. It is not possible to determine the lean meat content of a food due to the variability of the fat content of lean meat (e.g., the lean meat from pork can naturally contain from less than 5% to

[a]Includes hydroxyproline data.

Table 5 Example calculation to determine the meat content of roast lamb from analytical data

Fat	17.9%
Water	55.3%
Ash	0.7%
Nitrogen	4.18% (equivalent to 26.1% protein (4.18 × 6.25))
Carbohydrate	0
The appropriate nitrogen factor for lamb is 3.50	
Apparent fat-free meat content $=\frac{4.18}{3.50}\times 100 = 119\%$	
and adding the fat content gives:	
Apparent (or raw equivalent) total meat content $= 119.4 + 17.9\%$ (fat) $= 137\%$	

Note: Meat contents can exceed 100% because on cooking the moisture reduces and the nitrogen increases above the level naturally present in meat. This gives a raw equivalent meat content of over 100%.

over 12% fat). However, it is usual to estimate the lean meat content by adding 10% of the fat-free meat on to the fat-free meat content. This assumes that lean meat contains 10% fat. Therefore, a food with an apparent fat-free meat content of 67% would have an apparent lean meat content of 74% (viz. $67 \times 100/90$). Where the actual fat content of the food is less than the 10% allowance being added, then it is usual to add all of the fat content of the food on to the apparent fat-free meat content to give an estimation of the apparent lean meat content. This will also equal the apparent total meat content.

Added water is present in some whole-meat products such as ham and bacon due to the use of curing solutions. Such added water is often subject to maximum limits or must be declared in the labeling.

The amount of added water can be estimated, by calculation, in various ways. The most widely used formula for calculating the added-water content of cured meat products is based on the Stubbs and More approach. Using this method, the added water is calculated by subtracting the total meat content and all of the added ingredients from 100 (Table 6). This is therefore an indirect method and the result would be in error if any of the analytical parameters or the meat content were incorrectly determined.

Species Testing

It is often necessary to check the species of meat present in meat mixtures and, in some instances, of individual pieces of meat. Over the last 30 years

Table 6

Added water (%) = 100 − (% Apparent total meat content + % salt + % carbohydrate + % other ingredients)
As an example, a sweet cured bacon containing salt (3%), sugar (2%), and with an apparent total meat content of 88%, would contain, for example:
Added water (%) = 100 − (88 + 3 + 2) = 7%

methods have progressed from assessment of the composition of the fat present in the meat, and electrophoretic methods of protein separation and identification, through to the use of serological techniques. Current procedures are based on immunological techniques in the form of enzyme-linked immunosorbent assays and dipstick tests to the newer polymerase chain reaction methods which use the sample's DNA to identify the species present. As yet, the methods do not offer sufficient quantitative precision for it to be possible to determine precisely (with certainty) the amount of the individual species present.

The immunological test takes the form of kits for both raw and cooked meats. As an example, the kit for cooked meat is a noncompetitive sandwich-type enzyme immunoassay that uses a biotin-avidin enhancement process. The antibody is designed to recognize antigens in the cooked meat. Raw or uncooked meat may be tested by heating prior to the extraction of the target antigen. This kit is widely used within the meat industry for routine meat species analysis. However, it does not differentiate between poultry species and hence results can only be reported as poultry. A raw species kit, which is also available, will differentiate between chicken and turkey meat.

The relatively new methods use the analysis of the DNA from the species concerned. These are gaining popularity and are currently the subject of extensive method development. In the cleaved amplified polymorphic sequences (CAPS) method, DNA is first extracted from the meat sample. A specific region of the mitochondrial cytochrome *b* gene is then amplified using the polymerase chain reaction and the amplified product is subject to digestion using a range of restriction endonucleases. The products generated by the restriction endonucleases are subject to electrophoresis on an agarose gel and stained with ethidium bromide dye. The gel is visualized under ultraviolet light and a photographic record of the resulting patterns is obtained.

Spoilage

During spoilage, the proteins present in meat break down and the fat can become rancid. The assessment of the freshness of meat can normally be easily assessed from the odor of the food. It also often includes a microbiological assessment and measures to assess the breakdown of proteins and fat. With respect to the microbiological aspects of meat spoilage, there are wide ranges of microorganisms that can grow on meats and result in spoilage, including *Pseudomonas*, Enterobacteriaceae and lactic acid bacteria. The particular group of organisms responsible for meat spoilage will vary from product to product, depending on the chemical characteristics such as pH, water activity, and storage conditions used, i.e., temperature and atmosphere.

The protein breakdown can be assessed by using the traditional total volatile nitrogen determination, otherwise known as total volatile bases. This measures the protein breakdown products and is carried out by distillation of a portion of the meat from slightly alkaline conditions and titration of the ammoniacal distillate with standard acid. As an example, beef is normally considered to be acceptable if the total volatile nitrogen value does not exceed 16.5 mg nitrogen per 100 g food.

During breakdown of meat, the fat may become rancid and the measures of this rancidity which are often used are those of free fatty acid content and peroxide value of the fat. The free fatty acids are derived from the breakdown of the triglycerides, and the results of the free fatty acid determination is generally expressed as oleic acid. The fat is extracted from the food, and the acidity of a measured amount of the fat is determined by titration. In order to carry out this titration, the fat is dissolved in neutral alcohol and the solution is titrated with standard sodium hydroxide solution using phenolphthalein indicator. A preferred option, to avoid the need to evaporate down the fat extract and hence incur further fat breakdown, is to extract the fat from the meat with chloroform and carry out the titration directly on this extract. A portion of the filtrate can be evaporated to determine the amount of fat present. It is generally accepted that most fresh beef samples would not have a free fatty acid content (calculated as oleic acid) above 1.2%. The peroxide value is a measure of the peroxides contained in the fat. During storage, peroxide formation is slow at first during an induction period, which may vary from a few weeks to several months, depending on the fat involved. It is usually determined volumetrically from the reaction of the bound oxygen with potassium iodide in acid

Table 7 Changes in chicken meat stored in a fridge at 4 °C

Number of days after purchase	*Appearance and odor*	*Total volatile bases (mg·100 g^{-1})*	*Acidity of fat (%) (oleic)*
0	Normal	12.8	0.54
2[a]	Normal	12.0	0.51
5	Some off-odor; appearance normal	30.1	1.5
7	Off-odor; green/yellow discoloration	31.0	1.3
9	Increasing odor and color; slimy	39.7	1.3
12	Unpleasant odor, green color and slimy consistency	46.4	1.7

[a]Best before date.

solutions. The liberated iodine is then titrated with sodium thiosulfate. Fresh oils normally have a peroxide value of well below 10 mmol kg^{-1}.

As rancidity is a complex matter, it is advisable to carry out as many tests as possible on doubtful samples. Other tests that are used to evaluate the oxidation of lipids include the Kreis test, the anisidine value, and the thiobarbituric acid number.

Data on the total volatile nitrogen and free fatty acid values of individual chicken legs removed from storage in a domestic refrigerator are shown in Table 7. The literature available on the normal values for these parameters is inadequate and often data have to be derived from small surveys undertaken when data are needed.

Differentiation of Fresh and Frozen-Thawed Meat

Legislation prohibits the sale of previously frozen meat as 'fresh' and thawing and refreezing are improper treatments of meat. Such treatment can enhance the possibility of the increase of the populations of microorganisms, such as *Salmonella*, and thus pose a serious health risk. Furthermore, the consumer may be disadvantaged because fresh meat normally commands a higher price than frozen meat and it is therefore important that it can be differentiated. The usual means of determining whether meat has been previously frozen and thawed is from the use of the β-hydroxyl-coenzyme A dehydrogenase (β-HADH) enzyme test. This test involves measuring the activity of mitochondrial enzymes that are released when the meat is frozen and thawed. The freezing and thawing of meat damages the muscle mitochondria, which results in the partial release of the mitochondrial enzymes into the sarcoplasm or muscle juices. The enzyme that has most commonly been used is β-HADH. The biochemical method was developed by Gottesmann and Hamm in meat press juice by means of a relatively simple spectrophotometric enzyme assay and has been the subject of research and validation. The activity of β-HADH is measured by determining the rate at which nicotinamide-adenine-dinucleotide (reduced NADH) is converted to nicotinamide-adenine-dinucleotide (NAD^+). This conversion is dependent on the level of β-HADH activity and can be measured by the decrease of absorption of the reaction solution at 340 nm. Work carried out on chicken indicates that the test will give an indication that it has been frozen where the meat has been stored below − 12 °C. The method has also been collaboratively tested.

Nutritional Value

J Higgs and J Pratt, Meat & Livestock Commission, Milton Keynes, UK

Background

This article considers the different animal species available for human consumption and the significance of the nutritional value of meat as a whole. Increased awareness of animals as sentient beings, and the option to elect to avoid eating meat in affluent societies, influences discussion of the role of meat in the modern human diet.

In theory, it is possible to construct both omnivorous and vegetarian diets that meet dietary recommendations, although allowing for the differences in bioavailability of some micronutrients and practical issues relevant to modern society (preparation time and cooking); this task is easier for an omnivorous diet. It is unknown whether or not there would be any significant differences between two such diets that would influence public health advice.

Of all foods, meat provides one of the widest ranges of nutrients in useful amounts. This may be one of the reasons for its importance throughout history as the central focus of the diet, included particularly within celebratory meals. It is perhaps the fact that meat has been eaten as much for enjoyment as for its nutritional qualities that allows any offending aspect of meat production to affect its consumption by affluent nations.

Types of Meat

The types of meat commonly consumed in different countries are dependent on eating habits and the ability to rear the animals successfully, which is influenced by local climate, geography, and economy. Sheep and goat meat are more popular in developing countries, while native llama, buffalo, and antelope are important parts of the local ecosystems in many areas, especially Bolivia, Peru, Ecuador, Asia, and Africa.

Beef, lamb, pork, and chicken are the major meats consumed in Western societies, with beef predominating. Although the total meat consumption in the UK has remained fairly steady since the 1980s, consumption of chicken, pork, and meat products has increased, while that of beef and lamb has declined. Major influences include increasing demand for convenience, a trend towards eating out of the home, and a superior health image for poultry during this period. Veal, horse meat, hare, rabbit, and game birds such as duck and pheasant also contribute to meat intake. With the establishment of farmed deer in recent years, venison has become more popular and affordable, promoted for its low fat content. Commercial rearing of ostrich meat is new to Europe and, like emu, has grown rapidly in the USA. Both ostrich and emu meat are promoted for their favorable fat profile, which is similar to that of poultry and pork, although the iron content of ostrich is closer to that of beef and lamb.

Meat includes carcass meat and edible offals (organ meats, e.g., liver, kidney, tongue, heart, sweetbreads (thymus and pancreas), and tripe (stomach)). Meat products is a term that includes the result of any type of processing ranging from composite dishes such as pies and ready-made meals to the addition of other ingredients such as water to increase succulence, curing, fermentation, and preparations such as brawn, black pudding, meat bars (pemmican), etc.

Consumption

Meat consumption increases with affluence. Japanese intake has increased to half that in the USA, and in China, meat intake is also increasing dramatically (**Table 1**).

Table 1 Meat consumption 1980s and 1990s (g per person per day)

Country	*1980s*	*1990s*
USA	310	231
Australia	296	290
UK	201	204
France	290	305
Germany	269	261
Japan	100	123
China	26	108

The values quoted are from the OECD for the years 1982–84 and 1992, respectively. The exception is China; these values are taken from *Asia Pacific Food Industry* (1995) 7(11): 14, using the years 1979 and 1994. The figures include bone weight.
Reproduced from Meat, Poultry and Meat Products: Nutritional Value, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Macronutrient Content

Protein

Meat is a significant source of protein, which is of high biological value. Within developed nations, meat provides around 60% of protein intake compared with only 15% in poorer nations. The protein content of different meats and cuts varies inversely with fat content. Meat is a rich source of the amino acid taurine; this is essential in newborn infants as they are unable to synthesize this amino acid from cysteine in sufficient quantities. The significance of lower levels of taurine in the breast milk of vegan mothers is unknown.

Fat

The total fat content varies with species and across the carcass. Although the fat content of lean muscle from most species is around 2–5%, the total fat content depends on rearing practices, feeding regimes, and age. The level of fat trim sold with the meat provides opportunities to affect the fat content as-consumed further, through cooking and trimming by the end user. This is illustrated by looking at the changes seen in the fat content of pork since the 1970s (Figure 1). Trimming visible fat (subcutaneous and intermuscular) has the most influence on the final fat content, since the invisible (intramuscular) fat makes a relatively small contribution to the total. Table 2 provides UK data showing the range of trimmable fat on specific red meat cuts.

Fat is lost on cooking meat, assuming that it is allowed to escape, for example. The amount lost depends on the initial fat content, and fully trimmed lean meat loses little fat. The concurrent loss of moisture on cooking meat obscures fat losses, as viewed in composition tables.

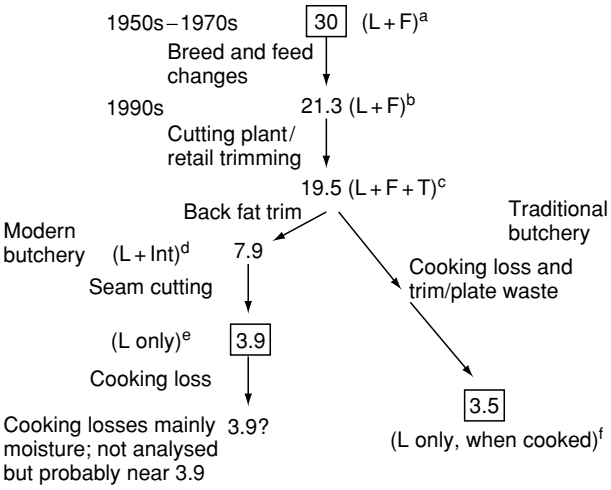

Figure 1 Change in fat content of pork loin for 100 g of raw edible tissue. Key: (L + F), lean + fat, untrimmed; (L + F + T), lean + fat, some trimming; (L + Int), lean + intermuscular fat; (L only), lean only. Meat	*Means and ranges (%)*
Beef	
Braising steak	7 (0–18)
Fore-rib	21 (10–35)
Sirloin steak	18 (6–34)
Lamb	
Chump chops	21 (11–32)
Breast	33 (20–48)
Rack of lamb	22 (18–25)
Pork	
Leg	18 (12–28)
Loin chops	25 (16–34)
Steaks	11 (3–35)

From Chan W, Brown J, Lee SM and Buss DH (1995) Meat, poultry and game. Supplement to *McCance and Widdowson's The Composition of Foods*. Cambridge: Royal Society of Chemistry and the Controller of Her Majesty's Stationery Office.

During the years following World War II, the emphasis for meat production was on maximizing its energy (fat) content and minimizing cost in an attempt to produce enough nutrient-dense food to improve the nutritional well-being of the whole population. Thus, in the 1970s, red meat and meat products contributed 27.4% to the total daily UK fat intake, and little of this was trimmed away. In the early 1980s, diet and health reports identified meat as a major contributor to fat intake, and so started the negative health association with red meat. Poultry meat was recognized as being significantly lower in fat and was recommended in preference by health experts. The red meat industry responded by reducing the fat content of red meat once again. Selective breeding and feeding practices, carcass classification changes to favor leaner production, as well as butchery techniques (seaming out whole muscles and trimming away all intermuscular fat) have meant that the meat on sale in the 1990s is much leaner than it was in the 1970s. The fat content of the carcass has been reduced in the UK by over 30% for pork (making British pork virtually the leanest in the world), by 15% for beef, and by 10% for lamb. Further reductions are anticipated for beef and lamb in the future. Overall, little change has occurred in poultry meat; most of the fat is in the skin, which is 48% fat.

Minced meat, predominantly beef, has become more popular in recent years, reflecting a move to convenience and a more cosmopolitan approach to meals. Although viewed as a fattier product, fat levels have dropped to typically 15%, with some extra-lean mince as low as 5%.

Since food-composition tables throughout the world have not kept pace with these changes, the health image of red meat has suffered disproportionately to the nutritional benefits it offers. Food-composition tables from different countries (e.g., the UK, USA, and Germany) vary due to the analysis of different cuts, different consumer demands, and how upto date the tables are. Data on the composition of red meat are shown in Table 3, and a 1995 fat audit for the UK to trace all fat in the human food chain provides useful information to illustrate the reduction in fat intake since 1982 from meat, compared with other foods (Table 4).

The fat content of meat products can vary considerably, depending on the proportion of lean and fat from meat as well as the other ingredients. Traditional types such as sausages, pastry-covered pies, and salami were high in fat, up to 50%, but modern products include ready-made meals and prepared meats, which can be low in fat (5%). The trend downwards in fat of red meat is reflected in the reduced fat content of a number of meat products, such as hams and sausages. Reduced fat versions of popular hamburgers and sausages continue to enter the market, and utilization of fat replacers will enable this trend to continue (Table 5).

Fatty Acids

As with other foods, meat contains a mixture of fatty acids. As the fat content of red meat has reduced, so the fatty acid mix has changed with the percentage of saturated fat than in the past. Poultry fat is 30% saturated, while pork, beef, and lamb are less than 50% saturated. The contribution made by meat to dietary saturated fat is given for the UK (Table 6). The principal saturated fatty acids are palmitic acid (C16:0 and stearic acid C18:0, which are thought not to raise blood cholesterol levels. There are only minor amounts of myristic acid, the most atherogenic.

Meat is one of the main contributors to the monounsaturated fat content of the British diet, principally oleic acid (C18:1) from red meat. Around 40% of the fat in meat is monounsaturated. Ruminant meats also contain *trans* fatty acids, contributing around 18% of British intakes.

Recent international analyses of beef, lamb, and pork demonstrate useful levels of long-chain polyunsaturated fatty acids in pasture- and grain-fed animals, specifically eicosatrienoic acid (20:3*n*-6), arachidonic acid (20:4*n*-6), eicosapentaenoic acid (20:5*n*-3), and docosapentaenoic acid (22:5*n*-3). Significant losses of some fatty acids, particularly the more highly unsaturated fatty acids (C20 and C22) that are more susceptible to oxidation, occur in cooking. The small amount of docosahexaenoic acid (22:6*n*-3) present in raw samples is lost on cooking. The richest dietary sources of 20:4*n*-6 include liver, kidney, and turkey, while smaller quantities are found in beef, lamb, pork, and chicken (Table 7). Grass-fed animals have higher concentrations of α-linolenic acid compared with grain-fed animals, and beef and lamb have favorable *n*-6:*n*-3 ratios. Meat, along with fish, provides the only significant dietary sources of C20 and C22 *n*-3 fatty acids, and for countries like the UK, where fish intakes remain low, the contribution to the diet from meat is significant, despite absolute levels in meat being low relative to those in fish (Table 8).

It is possible to manipulate the fatty acid profile of meat to satisfy human nutritional concerns more easily in monogastrics (pigs and poultry) than in ruminants (cattle and sheep), where polyunsaturated fatty acids are hydrogenated in the rumen. The fatty acid profiles of meats will continue to change as knowledge of their significance to human health improves, such that food composition data for meat can only represent a single point in time.

Table 3 Nutrient composition of different meats per 100 g

Micronutrient Content

The micronutrient content of meat can make a significant positive contribution to nutritional intakes, since it is a relatively concentrated source of a large number of vitamins, minerals, and trace elements, and the bioavailability of several such as iron, copper, and zinc is greater from meat than from plant foods.

Iron

Meat, especially red meat and offal, is a rich source of iron, a 100-g serving of beef rump steak providing 3 mg. Red meat contains 50–60% of its iron in the heme form (from hemoglobin and myoglobin), and this is absorbed by a more efficient mechanism than nonheme iron, the sole source of iron in plant foods. Moreover, heme iron is unaffected by the numerous inhibitors of iron absorption such as phytate. Thus, the absorption of iron from meat is typically 15–25%, twice that from plant sources. Meat also plays a valuable role as an enhancer of iron absorption from plant foods, so the presence of meat in a meal can double the amount of iron absorbed from the other components of the meal. The exact mechanism for this, although not confirmed, is believed to be due to the iron-binding capacity of cysteine within peptides following proteolysis of meat muscle. Although the absolute iron content of white meats, e.g., chicken, and meat products may appear low compared with some plant food sources, this enhancing function and better iron availability make these foods useful contributors to iron intakes. Cooking in iron or steel utensils can increase the iron content of the meal owing to this enhancing effect of meat. Meat is thus a particularly important influence on iron intake and iron status. Serum ferritin levels, which indicate iron stores in the body, are strongly correlated with heme iron intake. Meat can have a major impact in groups vulnerable to iron deficiency, specifically toddlers, adolescents, and women of child-bearing age.

Table 4 Total UK dietary fat[a], per person, contributed from all foods groups in 1982 and 1992

Food group	*Dietary fat (kg per person per year)*	
	1982	*1992*
Beef and veal	2.09	1.93
Lamb	0.66	0.51
Pork and products (1981, 1992)	6.54	4.36
Poultry meat	9.29	6.80
Fats and oils	17.40	21.98
Dairy fat (1983, 1992)	12.91	11.04
Fish and fish oil	4.40	2.20
Eggs	1.56	1.09
Chocolate	1.54	1.92
Cereals	0.92	1.05
Nuts	0.27	0.34

[a]Contribution of fat from primary food source rather than the end product, e.g., 'Fats and oils' includes fat used ultimately in such products as bakery goods, meat products, and confectionery.

Zinc

The best sources of zinc are meat, especially beef, lamb, pork, poultry, and seafood. As with nonheme iron, the bioavailability of zinc is reduced by inhibitors in the diet such as phytate and oxalate, and is enhanced when consumed with animal protein. In metabolic studies, zinc absorption and retention are greater on diets with a high meat content compared with those on a low meat content. Lower plasma zinc levels in vegetarians and vegans, despite higher intakes, suggest that meat has a major influence on zinc status. Approximately 20–40% of zinc is absorbed from meat, which is the major contributor to zinc intakes in Western countries (Table 6).

Table 5 Nutrient content for a range[a] of meat products per 100 g

Product	*Fat content (g; range)*	*Energy (kJ; range)*	*Energy (kcal; range)*	*Iron (mg; range)*
Bacon, all types	11.7–26.6	727–1388	174–332	0.4–1.1
Beefburgers, raw	6.2–25.4	472–1258	113–301	1.7–2.7
Chicken nuggets/fingers	1.5–17.1	552–1212	132–290	0.6–1.1
Cornish pasties	16.3–24.3	1066–1496	255–358	1.0–1.1

Selenium

Selenium is added to animal feeds to prevent deficiency. Concerns of excess build-up of selenium in soil and water supplies as a consequence of this are difficult to substantiate. The bioavailability of selenium from plant foods was thought to be greater than that from animal foods, but recent data demonstrate that meat, both raw and cooked, provides selenium in a form which is as bioavailable as that in cereals. Meat provides on average 10 μg of selenium per 100 g and contributes around a quarter of daily needs.

Vitamins

Meat can make a significant contribution to intakes of all B vitamins except folate and biotin. Pork and pork products, such as bacon and ham, are particularly rich sources of thiamin, typical servings providing the daily requirement. Liver and kidney provide more than the daily requirement of riboflavin in less than 100 g. Meat also provides the richest source of niacin (half of which is derived from the amino acid tryptophan) and vitamin B_6. Per 100 g portion, veal liver provides half the daily B_6 needs, and other meats provide around a third. Organ meats are particularly rich sources of folate and vitamin A (Table 9). Currently in the UK, liver is not recommended during pregnancy, despite being an excellent provider of iron and folate, owing to the very high levels of retinol it contains, which may potentially cause malformation of the developing fetus. Vitamin A in its active form, retinol, is found only in foods of animal origin, so meat provides a preformed source of this vitamin.

Vitamin B_{12} merits particular attention, since foods of animal origin provide the only significant dietary source. It is recommended that where meat and dairy products are avoided, supplements should be taken. In the past, some B_{12} was provided from the soil on poorly cleaned foods, which may in part explain the apparent absence of deficiency in some vegan groups.

Pantothenic acid is universal in all living matter, and rich sources include liver and kidney. Most of the vitamin is leached into the drip loss associated with frozen meat.

Table 9 Nutrient content of a range of offal meats

	Energy (kJ)	Fat (g)	Iron (mg)	Zinc (mg)	Vitamin A (μg)	Vitamin D (μg)	Vitamin B_{12} (μg)	Cholesterol (mg)	Folate (μg)

Vitamin D

Meat, apart from liver, was thought to be a poor source of vitamin D. New analytical data for meat and liver include significant amounts of 25-hydroxycholecalciferol, assumed to have a biological activity five times that of cholecalciferol. Previous work on the British diet and nutrition surveys using updated food composition data of adults and young children has shown that, rather than contributing as little as 4% of dietary vitamin D intakes, meat and meat products appear to provide 21 and 18%, respectively, becoming the major contributor of natural dietary vitamin D intakes.

Role of Meat in the Diet

Meat has played a significant role in human evolution. Early herbivorous hominids did not survive, whereas those that developed the ability to hunt became our ancestors (*Homo erectus*).

Anthropological research shows that the length of the gut in primates and humans became shorter with the introduction of animal-derived food. Smaller quantities of food of high digestibility required relatively smaller guts, characterized by simple stomachs and proportionately long small intestines, emphasizing absorption. Furthermore, it has recently been suggested that selection for relatively large brains in humans over the last 2 million years could not have been achieved without a move to a high-quality diet, based on animal products, since the energy saved with a shorter gut allowed an increase in brain mass. It is believed that better nutrition, specifically increased animal protein and fat intake together with improved public health, has allowed us to move towards attaining our genetic optimum.

Meat has traditionally been considered an essential component of the diet to ensure optimal growth and development. With a limited range of foods available in primitive societies throughout history, meat was important as a concentrated source of a wide range of nutrients. With the range and abundance of foods now available to developed societies, the nutritional significance of any one food is reduced. Where meat is excluded, the missing nutrients can be supplied from a combination of other foods, and within traditional vegetarian cultures, this appears at least adequate. Concern arises when meat is excluded with insufficient attention given to selecting appropriate combinations of foods to ensure that nutrients are supplied in adequate quantities. There is no doubt that in modern Western societies where less time is devoted to planning and preparing meals, and an increasing proportion of daily food intake is consumed outside the home as snacks and quick meals, the inclusion of meat in the diet minimizes the risk of micronutrient deficiencies, especially iron, albeit subclinical.

Meat and Health: Addressing the Concerns

Traditionally, meat intake was associated with improved health, but as a consequence of its association with dietary fat, this role has been marginalized. To assess the role played by meat, numerous studies have compared the health status and mortality of vegetarians with those of omnivores. Simplistic conclusions from such work can be flawed, since interpretation of the results must take into account the many other influential differences between such groups. In particular, lifestyle factors must be

considered: vegetarians traditionally smoke less, consume less alcohol, tea, and coffee, and, being generally more health conscious, tend to exercise more. Typically, the meat-eating groups tend to be dominated by sedentary, physically inactive subjects with little interest in diet. Since the 1950s, omnivorous diets have been relatively high in animal protein and fat with insufficient dietary fiber, fruit and vegetables, such that meat intake may have acted as a marker for a generally 'unhealthy' diet.

Regular consumption of red meat is associated, epidemiologically, with increased risk of coronary heart disease (CHD), owing to its fat composition. There is, however, a growing bank of evidence that a healthy diet which includes lean red meat can produce positive changes in lipid biochemistry. Blood cholesterol levels are increased by inclusion of beef fat, not by lean beef in an otherwise low-fat diet. Equal amounts of lean beef, chicken, and fish added to low-fat, low-saturated-fat diets similarly reduce plasma cholesterol and low-density lipoprotein cholesterol levels in hypercholesterolemic and normocholesterolemic men and women.

The association between the arachidonic acid content of meat and increased thrombotic tendencies has recently been challenged. The presence of large amounts of linoleic acid in current diets results in plasma increases of linoleic and arachidonic acids only, but in the absence of linoleic acid, the long-chain *n*-6 and *n*-3 polyunsaturated fatty acids present in lean meat can influence the plasma pool, increasing plasma 20:3*n*-6, 20:4*n*-6, and 20:5*n*-3 fatty acids and probably reducing thrombotic tendencies.

Meat has been associated with various cancers, particularly colon cancer. However, meat-eating is strongly inversely correlated with gastric cancer, which makes any public-health recommendations difficult to determine, based on meat-eating alone. Epidemiologically it is difficult to distinguish the influence of animal fat, protein, and meat.

There does appear to be an independent role for protein as a source of cooked food mutagens. Heterocyclic amines produced on overcooking meat have been shown to be carcinogenic in rats, although at normal cooking temperatures and average cooking times, the level of these compounds produced is not excessive, compared with the amounts required for carcinogenicity.

Nitrates are added to meat products to prevent microbial proliferation. However, the levels used now are much reduced such that the nitrosocompounds (NOC) produced from these additives are present at very low levels in meat products. Contrary to public perception, their carcinogenic potential is likely to be minor. In humans, high-protein (meat) diets increase fecal NOC levels, although the significance of this for normal healthy diets remains unclear.

Table 10 Paradoxical associations between meat and health

- Generally, in countries where meat consumption is high, intake of protective fruit and vegetables tends to be low, and vice versa.
- There is a lower risk of colon cancer among South Asian immigrants to the UK, than in the general population, and this is equally true of vegetarian and meat-eating Asians.
- Mormons who abstain from alcohol, tea, coffee, and smoking but consume meat have death rates from cancer and CHD similar to those of vegetarian groups, indicating that meat is not the major determinant. Blood pressure is reduced on switching from a meat-based diet to a vegetarian diet, but adding meat to a vegetarian diet is not associated with an increase in blood pressure, suggesting that the potassium-to-sodium ratio is more influential than the presence of meat *per se*.
- Consumption of meat has almost doubled in Japan since the 1970s, yet CHD morbidity has reduced from an already low level. Meat consumption in the USA remains higher than in the UK, yet, unlike the UK, morbidity from CHD has been falling steadily since the 1970s.

Daily consumption of green and yellow vegetables with meat is associated with a reduced risk of cancer at many sites, whereas daily meat consumption with less frequent vegetable consumption has been associated with increased risk. The significance of meat's role as a risk factor in cancer causation remains the subject of much debate, and results of more informative long-term cohort studies are required to elucidate the full picture.

There are many paradoxes concerning the apparent associations between meat consumption and both CHD and cancer. Some of these are listed in Table 10. They serve to demonstrate that the diet and health story, at least as far as meat is concerned, is both complex and incomplete. Two reasons for this are, first, that meat is but one influential aspect of the diet. Its effects are modified by other foods (e.g., fruit and vegetables) such that the net effect may be quite different. Second, the changing lipid composition of meat, in response to increased knowledge of lipids in relation to health, will continue to alter the role played by meat in this context. Fortunately, since most of the valuable nutrients in meat are within the lean component, reducing the visible fat has little bearing on its contribution to micronutrient status (Table 11).

Hygiene and Safety Aspects

The wholesomeness of meat and meat products is dependent on a variety of factors, some of which act in the period prior to arrival of the animal or bird at the slaughterhouse. The health status of the herd or

Table 11 Nutrient variability across the carcass – values given for lowest and highest fat cuts for different species

flock is in turn influenced by the method of husbandry practiced on the farm, the health prevention measures applied, the conscientiousness of monitoring, and the level of prompt and necessary action taken, e.g., the isolation and treatment of veal calves infected with one or more species of salmonellae. However, calves may be carriers of infections such as *Escherichia coli* and *Listeria monocytogenes*, and display no symptoms of disease but may prove a hazard to public health when meat and offal are prepared from the carcasses. Similarly, campylobacteria may be present in a mild form in a batch of broilers which appear perfectly healthy in life but may prove a hazard to the consumer. Close monitoring of farm health records and scrutiny by the herd/flock veterinarian and collaboration with the supervising official veterinary surgeon in the slaughterhouse and poultry plant will help prevent subsequent potential consumer health hazards.

The raising of stock in dirty conditions allows the hides, fleeces and feathers to contaminate the environment during the slaughter and dressing of carcasses. Cross-contamination of the carcasses from feces and soil in addition to the soiling of plant, equipment, and the protective clothing of slaughterhouse operatives can markedly reduce the general hygiene in the meat plant with levels of bacteria, bacterial spores, parasites, viruses, and fungi exceeding acceptable levels. *Staphylococcus aureus* is a normal commensal of skin and hair, and can produce toxins in food. A highly successful recent campaign has highlighted the necessity for only clean livestock to be presented for slaughter.

Transport of animals, especially loading, unloading, and lairaging, can lead to stress conditions, particularly if groups are mixed. In some countries, two-tier lorries are used to transport cattle, and three-tier sheep transporters are common worldwide, resulting in gross contamination with urine and feces. Again, stress from loading and unloading can occur. Stressed animals, particularly carriers of disease, are known to demonstrate clinical disease and excrete pathogenic organisms. Welfare and hygiene regulations governing animals during transport minimize such occurrences.

The slaughterhouse itself may not be free from external vectors of disease – insects, vermin, and birds must be excluded from the curtilage of the meat plant. Measures are in place and reviewed regularly so that the environment of the meat plant suffers minimum contamination from the animals consigned to the plant, from the lorries and staff transporting the stock, and from all other potential vectors of pathogenic and spoilage agents into and throughout the plant.

Procedures within the meat or poultry plant itself dictate the standard of hygiene and safety of the product. The training and continuing professional development of staff in handling of and caring for the animals, in stunning and slaughter techniques, and in the dressing procedures of the carcasses are significant contributors to the overall standards pertaining through the plant. The operative has the potential to contaminate the carcass, and vice versa, but training and legislation obviate this from occurring.

Management must be aware of the likely points of entry of pathogenic agents and where they may have maximum impact on the meat and meat products. Recognition of these critical points where hazards are potentially most dangerous is now enshrined in the Hazard Analysis and Critical Control Point principle. Checking regularly and acting on findings at these areas in the meat plant allow a structured approach to the maintenance of hygiene and safety aspects of meat and poultry and their products. Increasing rates of throughput on the slaughterline must be accompanied by even more vigilant monitoring of hygiene standards.

The proper dressing of the carcass is fundamental to good hygiene. The hide, fleece, or feathers constitute a dirty coat to the sterile muscle and organs. The alimentary tract extending from the mouth to the anus is also a source of microbes and parasites. Therefore, the exterior coat and the complete intestinal tract must both be removed carefully so that the absolute minimum of contamination occurs. The surface of meat or muscle is an excellent medium on which pathogens and spoilage organisms grow, so the separation of edible and inedible tissues must be carried out expertly and completely. For this reason, the movement of these two elements follows an agreed flow chart implicitly within the plant so that 'clean' and 'dirty' areas are entirely separate. No crossover of staff, equipment, and tools is allowed; however, in the case of supervising officers moving between areas, a strict regime of changing protective clothing must be followed.

Water used within the meat plant must be of a quality that does not present a risk to the meat or meat product. Potable water is routinely checked in the slaughterhouse and meat processing plant so that pathogenic and spoilage organisms are not allowed entry. The monitoring is supervised by the official veterinary surgeon of the plant, as are the antemortem examinations, post-mortem inspections of the animals or birds and carcasses to check for pathological change, residues of veterinary medicines, and other substances, and the storage temperature control for meat and meat products. In many countries, veterinarians are helped in their duties by assistants/meat-hygiene inspectors to ensure that only healthy carcasses and their offals are deemed fit for human consumption.

These duties are delineated in national meat hygiene and inspection legislation, which is harmonized throughout the European Community. Other meat-producing countries, e.g., the USA, Australia, and New Zealand, adhere to their own similar legislative controls.

Meat products may undergo little processing, e.g., steak tartare, when no cooking takes place, or undercooking may unwittingly allow pathogenic agents to survive, e.g., lightly barbecued beef burgers being the source of an outbreak of hemolytic *Escherichia coli* O157. The increase in the number of chilled ready-made meals supplementing some frozen products may also be conducive to poisoning with organisms or toxins surviving in the meat if proper procedures in storage, preparation, and cooking are neglected.

The integrity of properly prepared meat and poultry and their products can be – and often is – undermined by contamination by a food handler who has neglected proper personal hygiene procedures or who is a carrier of a food-poisoning organism. The mishandler or carrier could, of course, be the consumer in their own home.

In conclusion, therefore, the arrival of meat and poultry and their products on the table from the farm can be hazardous if neglect occurs at any of the steps of the journey. Legislation, guidelines, and well-recognized proven routines ensure safe and healthy products, provided these are properly understood and implemented. However, one significant area of concern to the consumer, in the UK in particular, is the catastrophic bovine spongiform encephalopathy (BSE) epidemic that has devastated the livestock and meat industry.

Control measures introduced early on in the epidemic reduced the incidence of BSE markedly after its peak in 1992 and 1993, although the long incubation period (4–5 years) meant that any preventative legislation took the same time for its effects to be realized. Much research has been carried out in the UK and around the world on BSE, with consequent benefits accuring to other transmissible spongiform encephalopathies, including scrapie in sheep and Creutzfeldt–Jakob disease (CJD) in humans.

Some young consumers of beef contaminated by the BSE agent have contracted a new variant of CJD. However, this contamination occurred prior to the controls introduced in the late 1980s. It will be some years before it is known how many victims will succumb to this new form of CJD on account of the unknown length of the incubation period in humans.

Hygiene

J F Gracey, Brookvale Hornsby, Carlisle, Cumbria, UK

Introduction

Traditional meat inspection procedures have remained virtually unchanged for over 100 years in many countries. They were mainly based on the work of the German veterinarian, Robert von Ostertag, who in 1872 published his textbook *Handbuch der Fleischbeschau fr Tierärzte, Arzte und Richter*, and on the pathogenesis of bovine tuberculosis and are thus solely concerned with postmortem gross pathology.

However, with the elimination of bovine tuberculosis and other notifiable diseases in many areas, the change in disease type to the so-called diseases of production, many of which are associated with outbreaks of food poisoning, and the new systems of intensive husbandry, especially of pigs and poultry, attention is now beginning to be focused on the live animal. Consumer concern about intensivism, animal welfare, and residues in foods of all forms, has also served to influence authorities about the safety of the food we eat.

In addition, there has been concern about some of the techniques used in meat inspection, notably the number of routine incisions made in meat and offal, for each incision results in varying degrees of contamination. Indeed, it has been advocated by some experts that the incision of lymph nodes should be abandoned and replaced by inspection only. The cost-effectiveness of traditional methods has also come under adverse criticism, but the complete absence of proper veterinary antemortem (AM) examination and laboratory procedures in many quarters has probably been the main reasons for a more scientific approach to the inspection of meat.

Although public health is the main consideration, much can also be achieved with regard to the promotion of animal health and welfare, which also demand attention when cost-effectiveness is under inquiry.

Demands of the Consumer

The consumer demands and is entitled to the following safeguards:

1. Meat free from all zoonotic bacterial and viral diseases and their toxins, e.g., tuberculosis, salmonellosis, listeriosis, campylobacteriosis, yersiniosis, giardiasis, vibriosis, colibacillosis, botulism, and ornithosis, and also free from parasitic diseases such as cysticercosis, trichinosis, hydatidosis. (*See* ***Campylobacter***: Campylobacteriosis; ***Listeria***: Listeriosis; **Parasites**: Illness and Treatment; **Viruses**; **Zoonoses**.)
2. Meat free from residues of drugs, hormones, antibiotics, heavy metals, pesticides, and tranquilizers. (*See* **Heavy Metal Toxicology**; **Pesticides and Herbicides**: Toxicology.)
3. Meat produced in a hygienic manner from livestock handled humanely.
4. Meat which is wholesome, palatable in flavor and tenderness and of the nature, substance, and quality demanded.

Efficient Meat Inspection

In order to achieve the foregoing desiderata, three important investigations are required:

1. AM examination of the live animal or bird with reference to its previous husbandry.
2. Postmortem (PM) examination of the carcass and its viscera.
3. Microbiological, pathological, and chemical tests, where required.

Should any of these fundamental requirements be omitted or performed at suboptimal levels, efficient meat inspection can be said to be lacking and the consumer possibly put at risk. While PM examination is still required to eliminate lesions of gross pathology, modern meat inspection must be concerned with the nontangible agents of *Salmonella, Listeria*, and *Campylobacter* which are related to the increasingly common human foodborne diseases. The vital importance of laboratory procedures is illustrated in the diagnosis of bovine spongiform encephalopathy (BSE). First identified in England in 1986, the condition, because of its long incubation period, only affects adult bovines, has a long clinical course with neurological and behavioral symptoms, and is invariably fatal. Diagnosis can only be made by demonstrating spongiform changes and the presence of scrapie-associated fibrils (SAF) in fixed brain tissue by light microscopy. (*See* **Bovine Spongiform Encephalopathy (BSE)**.)

It is necessary to remember that many conditions can only be recognized or suspected in the live animal; PM examination may reveal nothing or at the most only minor lesions which are easily overlooked. Among these are tetanus and neurological diseases such as listeriosis, BSE, Aujeszky's disease and rabies, and many subclinical conditions. The bovine which shows only slight loss of condition and mild diarrhea may well be a case of salmonellosis, but in the absence of significant PM findings may be passed as fit for human consumption and in addition contaminate other meat as well as personnel.

Legislative Authority

In England and Wales, legislative authority is contained in the Fresh Meat Export (Hygiene and Inspection) Regulations 1987 for export purposes; AM inspection is not required for the home market under the 1987 Meat Inspection Regulations. The equivalent European Community (EC) law is the 91/497/EC Directive which amends and consolidates Directive 64/433/EC on health problems affecting intra-EC trade in fresh meat to extend it to the production and marketing of fresh meat.

General provisions are made concerning the time of inspection – day of arrival at abattoir with reinspection if held overnight; facilities to be provided; need for adherence to animal welfare rules; resting for 24 h of tired and agitated animals; prohibition of slaughter of animals whose meat is likely to be unfit; and a detailed PM examination of certain categories of diseased animals.

Less than one page is devoted to AM, compared with four on PM. A further anomaly in EC law relating to AM inspection is given in the Council Regulation COM(89) 668 laying down health rules for the production and placing on the market of fresh poultry meat, which indicates that AM inspection can be carried out by lay assistants. One of the cardinal rules in the diagnosis of disease, in bird or beast, is that it be accurate, otherwise both public and animal health may well be jeopardized. The diagnosis of poultry disease is no less difficult and important than that in the larger farm animals.

Legal Controls in Milk and Meat Production

Apart from the Zoonoses Order 1989, which requires the State Veterinary Service (SVS) to be notified when *Salmonella* or *Brucella* organisms are isolated from samples taken from farm animals and their carcasses, products, and surroundings, and similar legislation relating to residues, the law associated with meat production is sparse compared with that for milk.

In England and Wales the Milk and Dairies (General) Regulations 1959 stipulate the following requirements: premises to be of registered basic structural standards; a safe and adequate water supply; effective hygiene and milking routines; prohibition on the sale of milk from diseased cows, with periodic inspections of premises and stock. In addition, the Milk (Special Designation) Regulations 1989 require the registration of licenced processing dairies (pasteurization; sterilization and ultrahigh-temperature (UHT) milk); registration of heat treatment plants with special reference to temperature recorders and flow diversion valves; microbiological standards for raw and heat-treated milk; prescribed heat-treatment processes and special conditions of sale for untreated milk. (*See* **Heat Treatment**: Ultra-high Temperature (UHT) Treatments; **Pasteurization**: Principles; **Sterilization of Foods**.)

Now that the new Food Safety Act of 1990 has defined 'food source' as 'any growing crop or live animal, bird or fish from which food is intended to be derived (whether by harvesting, slaughtering, milking, collecting eggs or otherwise),' it is to be

expected that comparable legislation will be enacted for meat production.

Purposes of Antemortem Inspection

Since AM and PM procedures are intimately linked, some of the following also apply to the latter:

1. Protection of the public health against bacterial, viral, parasitic and chemical hazards.
2. Protection of livestock against the spread of infectious diseases, especially notifiable diseases.
3. Protection of animal and food handlers against zoonoses.
4. Reduction of certain conditions and injuries causing unnecessary losses in livestock through disease data retrieval and feedback to producers.
5. Assurance of the meat industry and the public against meat of inferior quality, with avoidance of wastage of a valuable commodity.
6. Prevention of contamination of meat, premises, equipment, and personnel by dirty animals.
7. Efficient handling of livestock before and at slaughter to insure high standards of animal welfare and subsequent good meat quality and shelf-life.
8. The area of PM examination rendered more straightforward with fewer condemnations.
9. 'One of the most important functions of antemortem inspection is to ensure that animals are rested sufficiently so that signs important to inspection disposition are not masked. It also ensures that signs that are important to inspection disposition but that may be less readily observed (or not evident) at postmortem examination can be taken into account in reaching a decision as to safety and wholesomeness of meat' (Codex Alimentarius 1991).

Preslaughter Livestock Handling

Although AM inspection is usually taken to represent the clinical examination immediately before slaughter (AM immediatum), its full scope embraces preslaughter livestock handling and extends to the husbandry of the animal on the farm.

Factors such as the length of journey, time of year, environmental temperature, climatic conditions, food and water availability, species/age/sex of animal and its source, e.g., market or farm, influence the lairage holding time. It is important to keep farm social groups intact, to segregate horned and aggressive animals, to isolate the female in estrus, and the sick or injured beast (for further examination). Young bulls and spring lambs are best slaughtered early, as is the cow in good condition in cold conditions since she may succumb to hypomagnesemic tetany. Stress is the evil which must be controlled at all costs through efficient handling by trained stockmen. Much can also be achieved by providing straw and fine tepid-water sprays for pigs in lairage pens to prevent fighting.

Preslaughter lairage periods can therefore vary. But excessively long periods are contraindicated since they can result in deaths, injuries, loss of condition, cross contamination, difficulties in lairage cleansing, and problems with carcass dressing, e.g., excess ruminal/intestinal fluid in cattle.

To be humane to animals is to handle them in a manner least distressing to them and with full consideration for their normal species-specific behavior requirements.

Decisions on Antemortem Inspection

UK and EC law in the main deal with the system of AM inspection. The only legislation in the UK governing the admission of animals to meat plants is contained in the Slaughterhouses Hygiene Regulations 1977 (Amendment 1987), which deal only with casualty animals, i.e., those which are affected with certain diseases or injuries or represent culls from herds due to infertility or old age.

Since the aim of meat inspection is to produce a safe and wholesome product for the consumer, the conditions governing the admission of animals for slaughter must be extremely stringent in order that only apparently normal livestock and genuine casualty animals are accepted.

The following categories of decisions constitute the ideal rather than that specified by law:

1. Refusal or admission under special control.
2. Release for slaughter of all apparently normal animals.
3. Delayed slaughter, e.g., because of inadequate drug withdrawal period or temporary illness.
4. Slaughter under special circumstances, e.g., casualty animals at the end of the kill or in emergency slaughter unit.
5. Total condemnation: (a) dead, dying and disabled animals; (b) pigs with temperatures of 41°C and higher (other species > 40.6°C); (c) conditions justifying total condemnation on PM examination; (d) animals showing symptoms of toxic, metabolic, nervous, or circulatory disturbance; (e) nutritional imbalances and parasitic diseases – listeriosis, leptospirosis, Aujeszky's disease, tetanus, rabies, anaplasmosis, ketosis, parturient paresis, scrapie, BSE, grass tetany, transport tetany, strangles, acute inflammatory lameness, extensive fistula,

glanders, farcy, swine fever, anthrax, and animals which have been vaccinated with anthrax vaccine within the previous 6 weeks.

Category 5 is considered to be a most important one since these are all casualty animals, many of which have been certified as such by practicing veterinary surgeons under the Slaughterhouses Hygiene Regulations. Although in existence in the USA and other countries, this particular category does not yet apply in the UK. It is, however, a most important sector and one which should be embodied in all meat inspection legislation. The fact that up to 50% of such cases may ultimately be totally condemned is not only a reflection of some standards of veterinary certification but can also be regarded as a waste of the time of meat plant staff, whose health on occasions is also put in jeopardy.

The information gleaned at AM inspection must be recorded and passed to the meat inspectorate. Should a zoonosis, e.g., ringworm or contagious pustular dermatitis (orf), be detected, all staff – especially the lairage personnel – must be alerted. While orf usually occurs as a benign skin lesion on the hands and arms of humans, there is evidence that a serious systemic form occurs and is becoming more prevalent. Extreme vigilance is necessary, therefore, especially with casualty animals. It is not unknown for an anthrax case to be consigned for slaughter!

Antemortem Completum Inspection

It was indicated earlier that a proper examination of the live animal must extend beyond the immediate preslaughter clinical inspection if guarantees of food safety and wholesomeness are to be made.

> The health status of the farm of origin and the husbandry of slaughter animals have a significant effect on the safety and wholesomeness of meat. In this respect, all efforts should be made to collect and evaluate information that might have influence on antemortem and postmortem (Codex Alimentarius October 1991).

The farm is, in fact, the most important hazard analysis and critical control point (HACCP) in all the meat hygiene operations which begin with animal husbandry and end in the consumer's home. (*See* **Hazard Analysis Critical Control Point**.)

Several countries, notably The Netherlands (pigs), New Zealand (sheep), Northern Ireland (cattle), USA, and Canada, which are concerned about current meat inspection systems, are enacting schemes referred to as integrated quality control (IQC) based on abattoir and farm disease data in conjunction with codes of practice for livestock producers (Figure 1). In some cases AM inspection is carried out on the farm, and is repeated at the point of slaughter. Especially for poultry flocks, this would seem to be an ideal which could be easily performed to great advantage.

The on-farm information which is of importance for meat inspection purposes relates to morbidity and mortality rates, animal welfare levels, the use of antibiotics, hormones, and veterinary drugs, results of laboratory tests (microbiological, serological, and chemical for residues), results of tests for tuberculosis and brucellosis and type of feeding. Since one of the main concerns of the meat hygienist is the contamination of carcass meat from filthy hides and fleeces, the standard of farm hygiene, especially of the loose housing of cattle, feeding of sheep on root crops and stock during the winter months, are of vital concern. Commenting on this important issue, which is both a

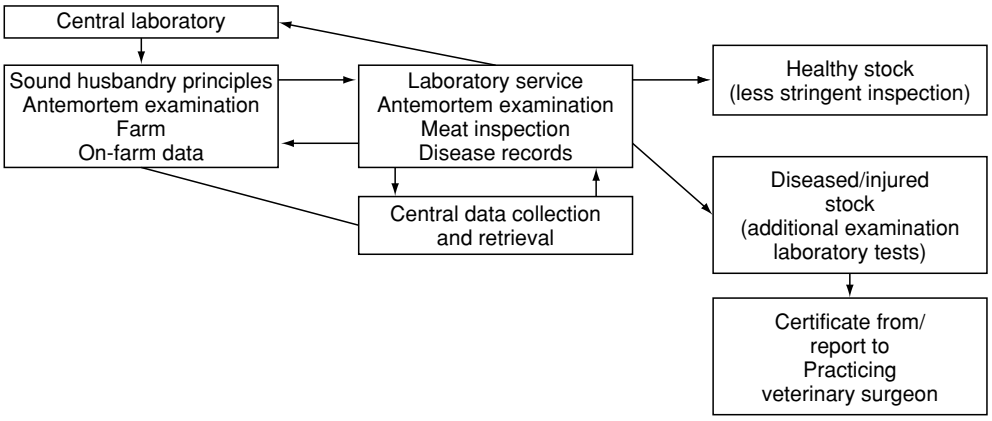

Figure 1 Centralized meat hygiene service. After Skovgaard N (1991) Ante mortem and post mortem meat inspection. Need for improvement. In: Hannan J and Collins JD (eds) *The Scientific Basis for Harmonising Trade in Red Meat*. Dublin: University College, with permission.

hygiene and welfare matter because of the damage to skin, the Richmond Committee on the Microbiological Safety of Food (1991) stated that 'farmers can, therefore, contribute to food safety by producing healthy, clean and unstressed animals for slaughter.' The abattoir data which are transmitted back to the producer for control purposes consist of the disease and injury findings encountered in the stock at slaughter. The practicing veterinary surgeon who supplies certificates for casualty animals should receive a report in respect of such animals.

The first Farm Quality Assurance Scheme for Beef in the UK is already under way in Northern Ireland. At present a voluntary arrangement, it should provide a basis for eventual legislation governing the husbandry of beef cattle. Organized by the Northern Ireland Livestock and Meat Commission (NILMC), it has the following Code of Practice:

> Commitment by farmers to produce a wholesome product with due regard to animal welfare and disease control; 3 months' residence on farm for all accepted stock; feeding to be grass and vegetable protein (root crops, brassicas, molasses, etc., may be approved); no unlicensed growth promoters or feed additives to be used; Department of Agriculture Code of Recommendations for Welfare of Livestock to be adopted; animals to be kept clean and in good condition; dirty animals ineligible for scheme; farm investigators by NILMC may be necessary; only healthy animals, naturally produced, to be eligible; declaration of freedom from BSE necessary; veterinary record and programme of disease control to be kept; strict use of veterinary drugs and observance of withdrawal periods; segregation of sick, injured and fallen animals; stress-free handling and transport; bruised carcasses ineligible for scheme.

Future Developments

AM and PM inspection procedures must always be appropriate to the incidence and type of diseases prevalent in the various species of the food animals. However, a supply of clean, healthy, and residue-free animals for slaughter can only be achieved by careful on-farm and preslaughter inspection, due regard having been paid to proper husbandry methods.

The detection of certain parasitic diseases, e.g., cysticercosis, trichinosis, fascioliasis, hydatidosis, thysanosomiasis, now only possible at PM, may well be carried out at AM by enzyme-linked immunosorbent assay (ELISA) examination of blood at AM, thus obviating the need for the current mutilating and contaminating incisions of meat and offal.

Strict veterinary certification of healthy and casualty stock will also assume a dominant role in the future by providing data for the meat inspectorate to assist in carcass/offal judgments. Animal health will also be promoted through feedback from PM inspection to the farmer and the practicing veterinary surgeon, the latter in relation to casualty and cull animals. Refer to individual meats.

Extracts

A M Pearson, Oregon State University, Corvallis, OR, USA

Introduction

Because of its distinctive and desirable flavor, meat extract has been a highly prized and useful item of commerce since the eighteenth century. As its name suggests, meat extract is obtained upon liquid extraction and concentration of the water-soluble fraction from meat. It is not the same as meat juice (drip) or press fluid since it contains a number of different constituents and others are generally present in higher concentrations. Nevertheless, the term 'meat extract' is not very specific but refers to various extracts made from meat, bones, and liver, which differ in their composition and flavor as a result of differences in

their origin and the components found in various raw materials.

Production of Meat Extract

The famous German chemist Justus von Liebig reported that meat extract could be produced by mixing 10 lb (4.5 kg) of lean meat with 5 lb (2.25 kg) of water and then pressing and collecting the soluble fluid; the process was repeated three times. The combined extracts were filtered, heated, skimmed, reheated, and concentrated under vacuum to give the first commercial product, which was produced and marketed in 1865 by Liebig's Extract of Meat Company Limited. The early procedure included removal of the meat from the bones, trimming off any visible fat, and aerating the remaining tissue for at least 20 h. The aerated lean was then hashed into a series of round-bottom kettles arranged so that the most concentrated meat stock always came in contact with freshly hashed meat and the previously extracted meat was reextracted with clear water. The extraction temperature was maintained at 90 °C or below while concentrating the meat extract. If higher temperatures are used, the alcohol-soluble material decreases and the amount of gelatin extracted increases.

Meat used for making the extract can be pressed or extracted with water or cooked to help remove the constituents responsible for the meaty flavor. The extract is then concentrated by removal of most of the water. Raw bones, preferably without removal of any firmly attached lean meat, and liver can also be the source of raw materials for making two products similar to meat extract, i.e., bone extract and liver extract, respectively.

Argentina is the largest producer of meat extract, which is a byproduct from canning beef and corned beef production. The meat to be canned is given a rapid cook for about 30 min at 95–100 °C. Then the watery stock is filtered to remove the fines and coagulated protein. The excess moisture is initially removed under vacuum and then further concentrated by heating in an open pan. Coarsely ground bones can be used to produce beef stock by adding water, and cooking at 115 °C or above in a pressurized kettle. The fat is allowed to separate and solidified by cooling in order to remove it. The beef stock is then concentrated under vacuum followed by pan evaporation to help develop the flavor.

Meat cooked as described above loses about 40% by weight, with most of the losses being recovered in the cook water. The cooked meat is rinsed with cold water, which is then added to the cook water. This results in about 2.2 l of stock per kilogram of raw meat. Generally, the stock is concentrated by cooking up to six batches of meat in the same stock before it is concentrated further under vacuum. Since the final stock from the combined cook water is more concentrated, there is a saving in the amount of energy needed for production. Figure 1 demonstrates the effect of the number of cooks on the concentration of solids in grams per liter for both the beef extract raw stock and the beef extract heated and filtered stock. The plot demonstrates that each batch increases the amount of solids in a fairly linear manner. It also shows that heated and filtered stock always has less solids than the raw stock due to the removal of the fines and scum or coagulated proteins upon filtering. The duration of boiling also increases the concentration of solids in the extract, although the maximum yield per unit of meat is reached at about 1 h. The increase in yield drops off sharply upon boiling for longer periods.

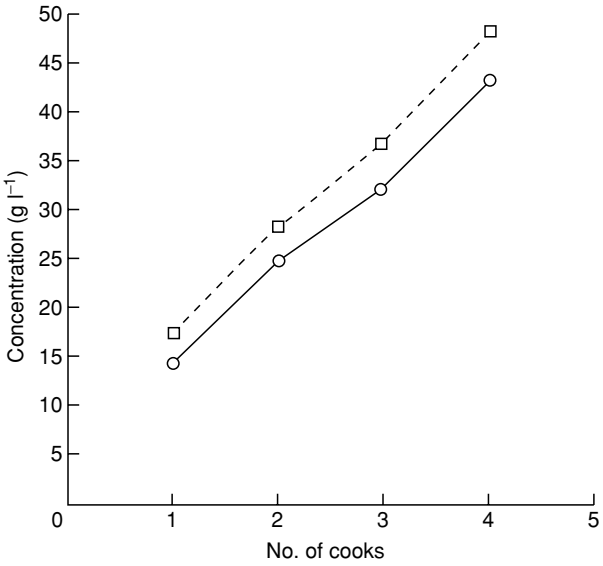

Figure 1 Influence of the number of cooks and filtering on the concentration of beef extract to 16% moisture content. Squares, 16% beef extract raw stock; circles, 16% beef extract heated and filtered stock. Reproduced from Ockerman HW and Pellegrino JM (1988), with permission.

The holding temperature of the stock also has a marked effect upon the concentration, with higher temperatures increasing the solids per unit volume. On the other hand, lower temperatures decrease the rate of concentration.

Types and Grades of Meat Extract

A number of types of meat extract and similar products are available on the market, and include the following: direct extract (essence of meat), no. 1 extract, fluid extract of meat, broth or stock, and liver

extract. However, there are no strict standards of identity, which results in a great diversity and variability between and within products.

Direct extract or essence of meat is manufactured by extracting minced beef muscle with water for a sufficiently long time to produce a gel upon cooling. Gel or jelly formation is due to extraction of collagen by heat so that it solidifies upon cooling. Approximately 13–14 kg of lean meat is required to yield about 1 kg of extract, or essence of meat that contains around 34% moisture.

No. 1 extract, sometimes simply called meat extract, is produced as a byproduct of corned beef. Its production involves immersion of chipped beef into boiling water for a short period of time. Little gelatin is extracted by this procedure. About 50 kg of meat is needed to produce 1 kg of extract containing approximately 17% moisture. The US Department of Agriculture Code of Federal Regulations of 1986 states that meat extract should contain not more than 25% moisture. Thus, it is considered to be a preserved product because it contains only 20% moisture or less and a minimum of 5% sodium chloride and 7% creatinine. The fat content should not exceed 0.6% and the nitrogen content should be at least 8%. The nitrogenous components should consist of at least 40% meat bases and 10% creatine plus creatinine.

Fluid extract of meat is made by cooking fresh meat to produce a stock containing 3–4% of solids. The stock is concentrated and evaporated under vacuum to yield a product with 60% solids. Salt is then added to the water fraction at 25.5% (w/w). This results in an extract containing 9.3% of added salt (10.2 kg of added salt per 100 kg of concentrated extract).

Broth (beef or pork) or stock are terms used interchangeably to describe the product obtained by simmering meat and/or bones (crushed) in water along with seasoning ingredients. The product(s) must have a moisture-to-protein ratio of 135:1. A concentrate of broth or stock can be made by reducing the moisture-to-protein ratio to 67:1.

Liver extract is produced by extracting raw ground livers with slightly acidified hot water at pH 5. The stock is then concentrated to a paste under vacuum at low temperature to a moisture content of 35%. Thus, liver extract contains more moisture than meat extract (35 versus 25%). Its high moisture content makes liver extract highly perishable so more salt needs to be added or it must be refrigerated or heat-sterilized. In contrast to meat extract, which is primarily used as a flavor base for soups, sauces, and other foods, liver extract is used by the pharmaceutical industry as a nutritional supplement.

Although individual companies producing meat extract may have their own grading sytems, there is no standard grading. Some companies divide their products into no. 1 and no. 2 grades on the basis of their creatinine content, with the former containing 7% and over and the latter grade containing less than 7% creatinine. Some other processors produce three grades of meat extract, with International Packers Limited calling their products Supreme, Premium, and Select. Supreme contains 16.75–17.25% moisture, a minimum of 44% soluble organic material and 7% creatinine, and a maximum of 1.5%water-insoluble material, 25% ash, and 4% salt. Premium contains 19–20% moisture, a minimum of 44% soluble organic material and 7% creatinine and a maximum of 1.5% hot-water-insoluble material, 25% ash, and 4% salt. Select contains 23–24% moisture, a minimum of 40.5% soluble organic material and 6.4% creatinine and a maximum of 1.4% hot-water-insoluble material, 23% ash, and 3.75% salt.

Composition of Meat Extract

The chemical compositions of beef extract, mutton extract and liver extract are shown in Table 1. The data provided give the moisture, salt, creatinine, and ash contents as well as the percentages of soluble organic material for beef and mutton extracts. For liver extract, however, the compositional data are presented in terms of moisture content, solids, and ash. Although data are given for a number of B-vitamins for all three extracts, the list of vitamins is more complete for liver extract, reflecting its greater nutritional contribution. Particularly noticeable are the higher values for vitamin B_{12} (15.4 times greater), riboflavin (3.5-fold greater), and pantothenic acid (20-fold higher) in liver extract. (*See* **Beef** and refer to individual nutrients.

Table 2 provides information on the nonvolatile constituents present in meat extract. Particularly note worthy is the presence and relatively large amounts of creatine and creatinine, which are important quality parameters. Although yeast extract is frequently used as a substitute for meat extract, it does not contain either creatine or creatinine. These two guanidine compounds combined should not comprise less than 10% of the total nitrogen on a dry basis in high-quality meat extracts.

Another interesting characteristic of meat extract is the considerable amount of inosine and inosinic acid, which have been shown to be meat flavor enhancers. Thus, inosine and inosinic acid probably make a major contribution to the desirable flavor and/or aroma of meat extract. The relatively high concentration of amino acids may also contribute to the Maillard reaction during heating of the extract

for concentration and play a role in the flavor of meat extracts. (*See* **Browning**: Nonenzymatic; **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Microbiology of Meat Extract

Although commercial meat extract usually contains bacteria and mold spores, pathogenic organisms are seldom present. Boiling of the stock to concentrate it results in a product that is nearly sterile, but subsequent handling and use of contaminated equipment result in recontamination. As meat extract provides an excellent medium for the growth of bacteria and temperatures used during concentration by vacuum are favorable for growth of microorganisms, the finished meat extract contains viable bacteria and molds. The best procedures for controlling the growth of microorganisms are to decrease the moisture content and increase the salt content. Neither procedure, however, can be relied upon to control the growth of microbes alone, although together they provide some degree of safety from spoilage. Combined with a low storage temperature, a low moisture and high salt content are synergistic and help to control microbial growth. (*See* **Spoilage**: Bacterial Spoilage; Molds in Spoilage.)

At a moisture content of 16%, meat extract stored at 20 °C has been shown to be relatively stable during 48 days of storage. At 20% moisture, however, meat extract needs to be protected from microbial spoilage by addition of salt. Since extracts made from liver and bones are hard to dehydrate below 25% moisture, they are more susceptible to bacterial and mold growth so must be either held at low temperatures (> 10 °C) or have a greater amount of added salt or both.

Table 3 presents some average microbial counts for meat extract. The data demonstrate that there is considerable variation in both the kinds and numbers of organisms present. The great amount of variability is no doubt associated with sanitation, processing, and

storage conditions, as well as the final contents of moisture and salt. Although any great increase in the number of thermophilic bacteria would not be expected to occur in a meat extract containing 16% moisture, a potential danger may exist upon adding it to other foods having a higher moisture content. Good sanitation and clean-up and avoiding contaminated tanks, pipes, and evaporators can help to reduce recontamination of meat extracts. Low-temperature storage is also an important step in controlling bacteria and molds.

Uses for Meat Extract

Meat extract is a common flavoring additive for soups, stews, sauces, casseroles, canned meat items, pot pies, bouillon and bouillon cubes, gravies, and other items where meat flavoring improves the products. The flavor of meat extract makes it a desirable additive to a variety of products. The percentage of meat extract needed for flavoring varies widely, depending upon the food to which it is being added, but generally falls in the range 5–25%. Its desirable flavor and aroma may enhance the flavor of some products at even lower concentrations. Although yeast extract is used as a substitute, chefs and food connoisseurs prefer the characteristic flavor and aroma that meat extract imparts to other foods.

MELONS, SQUASHES, AND GOURDS

A A Schaffer, Agricultural Research Organization, Bet Dagan, Israel
H S Paris, Agricultural Research Organization, Ramat Yishay, Israel

Background

The Cucurbitaceae family encompasses over 800 species of plants known collectively as gourds or cucurbits. These include cucumbers, melons, watermelons, pumpkins, squash, and many others. Perhaps more than 20 genera are used for culinary purposes, which usually includes consumption of the mature fruit flesh, whole immature fruits, and/or seeds. Three genera, *Cucumis* (cucumbers, melons), *Cucurbita* (pumpkins, squash), and *Citrullus* (watermelons), rank among the top 10 in economic importance among the vegetable crops of the world, and several others have regional importance. Cucurbits are also grown for use as ornaments and containers, and some are used for medicinal applications and other purposes. Some wild cucurbits have potential economic value. This article reviews the botany, horticulture, and food value of cucurbits, with emphasis on the three leading genera.

Botany

Most cucurbits are herbaceous, tendril-bearing vines that are adapted to warm climates and are sensitive to frost. The natural distribution of most species is in the tropics, but some genera (*Bryonia*, *Cucurbita*, *Ecballium*, *Echinocystis*) contain species that are distributed in temperate regions. In cultivation, cucurbits are distributed in almost all arable regions worldwide. Those cucurbits that are not adapted to cool temperatures and that are grown for their mature fruits and seeds are usually not successful in regions with short, cool summers. Others, most notably cucumber (*Cucumis sativus*) and summer squash (*Cucurbita pepo*), are grown for their immature fruits and are more tolerant of cool temperatures than most cucurbits, and therefore have an especially wide distribution in cultivation.

Most cucurbit species are mesophytes and have large palmate leaves, fibrous roots, and prominent fruits. Under favorable conditions, the plants grow and spread quickly, as stems can elongate 30 cm or more within 24 h. The foliage can be glabrous, softly or stiffly hairy, or spiculate. The plants usually are monoecious, that is, have separate staminate (male) and pistillate (female) flowers on the same plant. Most often, the flowers are nectar-producing and foraged by bees, with green calices consisting of five sepals fused at the base and yellow corollas consisting of five petals fused at the base. Staminate flowers differentiate at lower nodes and are produced in greater numbers than pistillate flowers. However, once differentiated, the pistillate flowers can develop at a faster rate than the staminate flowers. The staminate flowers have thinner, longer pedicels than the

pistillate flowers. The pistillate flowers have inferior ovaries that usually are round or oval in shape. In cross-section, the triloculate ovary can be seen to contain 10 subepidermal main veins, five of which connect the pedicel with the central vein of each sepal and five of which connect the pedicel with the central vein of each petal. In addition to the main vasculature system of the cucurbit ovary, there is also a highly anastomosing vasculature system in the fruit, which contributes to some of the genetic variability of fruit structure in the family. For example, the fibrous flesh of the spaghetti squash (*Cucurbita pepo*) and the fibrous net of the dried sponge gourd (*Luffa cylindrica*) are products of this anastomosing vasculature.

After fertilization, the ovary develops into a fleshy fruit possessing exocarp, mesocarp, and endocarp. Generally, the fruits of wild cucurbits are small, round, and green, and the flesh often extremely bitter due to alkaloid compounds known as cucurbitacins. A fruit can contain as many as several hundred seeds, which, at maturity, contain two cotyledons each but no endosperm. The seeds are not bitter and usually are flat, but there is a greater than 10-fold range in seed length among cucurbit genera, from several millimeters to a few centimeters.

Domestication of some of the Cucurbitaceae is ancient, predating that for some major grain crops. There is evidence that *Cucurbita pepo* (pumpkin, squash) was first domesticated at least 10 000 years ago. Several other cucurbits have also been domesticated for thousands of years. In the Bible (Numbers 11:5), the Israelites longed for the *avattihim* (watermelons) and *qishu'im* (melons, var. *chate*) of Egypt during their wanderings in the Sinai Desert.

Following the thousands of years of domestication by man, the cultivated cucurbits differ from their wild counterparts, most obviously in their larger and fewer vegetative and reproductive parts. Cultivated forms have larger leaves, thicker stems, fewer branches, and larger and fewer fruits and seeds. In some cultivated forms, fruit shape is not round but distinctly elongate. Also, different fruit colors and color patterns occur among cultivated forms. Cultivated forms also differ sharply from their wild cousins by having fruits that are more palatable, being nonbitter and less coarsely fibrous, but higher in starch, sugar, and carotenoid contents. A wealth of variability for fruit size, shape, and color occurs in the Cucurbitaceae family.

Quality traits desired in mature cucurbit fruits in some cases are the same as those desired in immature cucurbit fruits but differ in other cases. Some characteristics, such as sweetness and flesh color, are fully expressed in mature fruits but hardly at all in young fruits. Other characteristics, such as size of the seed cavity, can be important in determining the palatability of immature fruits but are less important in mature fruits. Many of the cultivated cucurbit species have been grown for the culinary use of their immature fruits, and some for their mature fruits. A few, most notably pumpkins and squash (*Cucurbita* spp.) and melons (*Cucumis melo*) have been grown for the dual usage of their immature fruits as well as their mature fruits, or for the use of immature fruits in some regions but for the use of mature fruits in other regions, and as a consequence possess a great deal of intraspecific variation in fruit characteristics.

Among the cucurbits are some of the largest and fastest growing fruits in the plant kingdom. For this reason, some of the larger cucurbits have served as experimental material to study growth rates, carbohydrate import, and translocation physiology in developing fruit. Large pumpkins may show dry weight gains of $1.71\,g\,h^{-1}$, whereas the smaller fruited cucumbers and melons may increase in dry weight by $100–500\,mg\,h^{-1}$. The large differences in fruit size and shape in the cucurbits are already determined at the early stages of ovary development, prior to and immediately after anthesis. These traits are under strict genetic control, although nongenetic factors such as environmental conditions and intraplant competition for photoassimilates play strong roles in determining fruit size. Assimilate supply in the form of photosynthetic products can often be a limiting factor of fruit growth and final fruit size.

Melons

Melons (*Cucumis melo* L.) are prostrate, highly branched, softly hairy vines possessing rounded, heart-shaped leaves and unbranched tendrils. They are most commonly andromonoecious, producing a hermaphroditic flower at the first one or two nodes of the branches and one or more male flowers at all other nodes. Less commonly, they are monoecious, with pistillate flowers being produced instead of hermaphroditic flowers. Rare, recessive mutants produce perfect flowers or pistillate flowers at every node. The flowers are bright yellow but small, approximately 3 cm in diameter. *C. melo* is diploid, with 12 pairs of chromosomes ($2n = 24$), but some members of the genus *Cucumis* are polyploids.

Melons originated from tropical Africa north of the equator, and their cultivation spread northward and eastward thousands of years ago. Much diversity of melons is found in Iran, Turkey, Spain, India, China, and the central Asian republics of the former Soviet Union. Apparently, the first culinary use of melons by man was of the immature fruits, much in the manner

of cucumbers. Immature melons are not sweet but instead bland, similar to cucumbers. Sweet melons are a relatively recent development, perhaps dating back only to the Middle Ages.

Botanically, melons are considered to consist of two subspecies, *C. melo* ssp. *melo* and *C. melo* ssp. *agrestis* Jeffrey. Melons contain a wide diversity of fruit sizes, shapes, and colors (see Figure 1). This diversity has been the subject of many attempts at classification. Probably the most comprehensive and comprehensible classification is that of Pitrat *et al.*, who have recognized 16 cultivar-groups. Their classification is summarized in Table 1. The *inodorus* group includes the winter or casaba melons, as well as the honeydew, Jaune Canary and Piel de Sapo melons. The major netted muskmelons, especially those grown in the USA as 'cantaloupes' are in the *reticulatus* group. These include the heavily netted varieties such as PMR45, Hale's Best Jumbo, Top Mark and also the lightly netted, nonribbed varieties such as the Galia and Persian melons. The French Charentais-type melon, which is ribbed but generally smooth skinned, is classified in the *cantalupensis* group. However, the distinction between groups may become blurred with increasing breeding efforts, since all the groups of *Cucumis melo* are easily hybridized with one another. For example, while, in the past, the smooth cream-skinned honeydew melons were green-fleshed, there are now varieties of honeydew melons with the orange flesh of the *reticulatus* group. In the USA, melons are often classified as either cantaloupes, honeydews or 'specialty melons,' which include all the other types.

Figure 1 (see color plate 104) Melons.

According to FAO statistics, approximately 19 million tonnes of melons were produced in 2000,

Table 1 Classification of melons, *Cucumis melo*, to subspecies and cultivar-groups[a]

Subspecies Group	*Maturity at consumption*	*Description*
agrestis (*ovary with short hairs*)		
conomon	Immature, similar to cucumber, in Eastern Asia	Elongate
makuwa	Mature in Eastern Asia	White flesh, little aroma, flat/round/pyriform
chinensis	Mature in Eastern Asia	Colored flesh, little aroma, pyriform
momordica	Immature in India	Skin bursting when ripe
acidulus		Cooked in India, firm with crisp flesh, no sweetness or aroma
melo (*ovary with long hairs*)		
cantalupensis	Mature in Europe	Sweet flesh, aromatic, smooth or warted, climacteric
reticulatus	Mature in North America, Japan, Western Asia, and Europe	Sweet flesh, aromatic, netted, climacteric
adana	Mature in Turkey	Thin flesh, low in sugar, climacteric
chandalak	Mature in Central Asia	Sweet, climacteric, slightly wrinkled, low aroma
ameri	Mature in Central Asia	Sweet, climacteric, low aroma, netted
inodorous	Mature in Central Asia, Europe, and North America	Sweet, no aroma, usually wrinkled, not climacteric, long-keeping
flexuosus	Immature in North Africa	Very long fruit, climacteric
chate	Immature in North Africa	Elongate
tibish	Immature in Sudan	Small, oval, no sugar, no aroma
dudaim	Mature	Used as an ornamental or aromatic, small, round, no taste, highly aromatic, climacteric
chito		Very small, round, smooth yellow fruits

[a]From Pitrat M, Hanelt P and Hammer K (2000) Some comments on infraspecific classification of cultivars of melon. In: Katzir N and Paris HS (eds) *Proceedings of Cucurbitaceae 2000: the 7th Eucarpia Meeting on Cucurbit Genetics and Breeding*. *Acta Horticulturae* 510: 29–36.

one-third of that in China. Other important producing countries are Turkey, USA, Spain, Romania, Morocco, India, Mexico, and Egypt. The mature fruits of the orange-fleshed melons rank high in ascorbic acid and carotenoid content.

Cucumbers

Cucumbers (*Cucumis sativus* L.) are prostrate, branched, stiffly hairy vines possessing sharply five-cornered leaves and unbranched tendrils. They are placed botanically in the same genus as melons only because the Swedish botanist Linné had done so. They are in fact a distantly related species, with cucumber having a diploid chromosome number of 14 ($2n = 14$). Cucumbers are monoecious, but many newer cultivars are gynoecious and several old cultivars are andromonoecious. The flowers are bright yellow and fairly small, approximately 4 cm in diameter.

Whilst the melons and their relatives are of African origin, the cucumber is native to the foothills of the Himalayas of Nepal, where the wild, bitter-fruited form, *C. sativus* var. *hardwickii* (Royle) Alefeld, can be found. Cucumbers have been in cultivation several thousand years and spread from their native habitat to neighboring eastern and southern Asia, and later to Europe and Africa. Cucumbers are almost invariably used when immature, and eaten raw in salads, but in eastern Asia, they are also cooked. Cucumber contains a large amount of diversity in fruit characteristics when compared with other species, but relatively little when compared with melons, pumpkins, and squash. There is some variation in mature fruit color, immature fruit color, uniformity of color, size, and number of fruit spines, and color of spines. Much variation can be found for the length but not width of mature fruits; thus, fruit size is essentially a function of fruit length. The fruits can range in length from approximately 10 cm in some forms to 60 cm or more in some Chinese cultivars. Mature fruit range in width from 4 to 8 cm.

Cucumbers can be classified into six main groups on the basis of variation in fruit characteristics and geographic origin. The French *cornichons* are short fruits with small, numerous spines and are usually grown for pickling. The European greenhouse cucumbers are long, smooth fruits that are grown for slicing into salads. The American pickling cucumbers are short fruits with protruding warts and large spines. The American slicing cucumbers are medium-long fruits having a thick skin and protruding warts that bear large spines. The Middle Eastern cucumbers are medium-short, spineless, and wartless, and are used for both slicing and pickling. The Far Eastern cucumbers are very long with protruding warts and spines. Interestingly, short-fruited kinds tend to be used for pickling, and long-fruited kinds are used fresh or, in the Orient, for cooking. Two additional groups of cultivars have been reported, one from southwestern China and the other from Nepal and high elevations of India. An interesting novelty is the 'Lemon' cultivar, which bears a striking resemblance to its namesake.

Cucumbers are an important greenhouse crop in Europe, the Middle East, and the Far East. Greenhouse cucumber cultigens differ from those grown in the field by being parthenocarpic, that is, they have the genetic ability to set fruit without pollination, and by being completely gynoecious, that is, they produce female flowers exclusively.

According to FAO statistics, world cucumber production exceeds 29 million tonnes, with China producing over half of that. Other important producing countries are Iran, Turkey, USA, Japan, and Russia. Cucumbers are an important part of the diet in these and other countries, but they are low in nutritional value.

Watermelons

Watermelons (*Citrullus lanatus* (Thunberg) Matsumura & Nakai) are prostrate, basally branched, softly hairy vines possessing deeply and roundly indented, blue–gray–green leaves and branched tendrils. They are monoecious, producing one flower per node. At most nodes, a male flower is produced but a female flower appears at every seventh or eighth node. The flowers are small, approximately 3 cm in diameter, and light yellow. *C. lanatus* is diploid, with 11 pairs of chromosomes ($2n = 22$).

Watermelons originate from tropical Africa south of the equator and are well adapted to warm, seasonally dry habitats. Watermelon culture reached Egypt no later than 3500 years ago. Watermelons require a long, warm growing season and are usually grown for the consumption of their fresh, edible fruit flesh. Unlike melons and pumpkins, the part consumed is the placental region, or endocarp. In some regions, consumption of the seeds is important, too.

There is a great variation in fruit size in watermelons, from approximately 2 kg to over 20 kg. Fruit shape can range from almost spherical to obovate. Fruit color is almost always green, but some rare forms have yellow fruits or bicolor, yellow and green, fruits. The watermelon fruit rind can be of a single green shade, such as black–green, dark green, or light green, or have two green shades as striping. However, the width of the dark and light stripes can vary with respect to one another, that is, the dark stripes can be

much broader, broader, about the same as, narrower, or much narrower than the light stripes. Fruit interior (placental) color can vary from light green to white to light yellow, intense yellow, orange, pink, red, or intense red. Most cultivars have red flesh. 'Crimson Sweet,' a cultivar bred at Kansas State University in the USA that was commercially released in 1966, is a leading cultivar possessing medium-size (8–11 kg), spherical-oval fruits having an attractive rind of broad, dark stripes and high-quality, very sweet, fine-grained red flesh with relatively few small brown seeds. The idea of triploid ($3n = 33$) seedless hybrids was proposed by Japanese and American geneticists in the mid-twentieth century. Seedless cultivars related to 'Crimson Sweet' have been developed, and these are becoming increasingly popular.

In some countries, most notably China, consumption of watermelon seeds is popular. Watermelon seeds can be black, brown, tan, white, red, or green, or a combination or pattern of these. Seed size and number per fruit also vary considerably. Cultivars grown for seed consumption usually have a distinctive seed-coat color (such as red or green) or pattern (such as tan ringed with black) and small fruits that are packed with many medium- to large-size seeds.

Watermelons have the greatest world production of any cucurbit, exceeding 63 million tonnes according to the FAO. Not surprisingly, China is by far the largest producer of watermelons, with over 38 million tonnes. However, this tonnage would not indicate relative economic importance, as other cucurbits, such as melons, summer squash, and cucumbers, have several times the monetary value per unit weight than do watermelons. Most of the other important producers are countries that have regions with hot, dry summers and include Turkey, Iran, USA, Egypt, Mexico, Kazakhstan, Spain, and Saudi Arabia. Watermelons are not high in nutritional content, but their flesh does contain a large amount of carotenoids.

Squash and Pumpkins

Squash and pumpkins belong to the genus *Cucurbita* and encompass four cultivated species. Plants are large, usually viney and branched, with branched tendrils. All are monoecious, bearing showy, large, 10–16-cm-diameter, bright yellow to orange flowers. Usually, one flower is produced per node, with the first nodes producing male flowers exclusively. The species of *Cucurbita* are diploids, all with 20 pairs of chromosomes ($2n = 40$). Fruit size, shape, and color vary greatly among cultigens. The species differ from one another in the aspect of the foliage and shape of the leaves. Edible fruits that are more or less round in shape are usually referred to as pumpkins, and those that are not round in shape are usually referred to as squash. Unpalatable or inedible fruits are referred to as gourds.

The most widely grown species is *Cucurbita pepo* L. This species is native to warm-temperate to temperate regions of North America and was one of the first American plants to have been described and depicted by Europeans. The plants of this species can be viney or bushy, and leaf shape, while generally pentagonal, can vary from not incised to deeply incised. The foliage is spiculate, a characteristic serving to distinguish *C. pepo* from other species of the genus. *C. pepo* is well adapted to all temperate regions and is grown mostly for the use of its immature fruits, also known as summer squash. In cool regions, this species is also grown extensively for the culinary use of the flesh of its mature fruits, for consumption of the seeds or seed oil, and for ornaments. *C. pepo* is perhaps the most diverse species for fruit characteristics in the entire plant kingdom. Fruits range in size from less than 100 g to over 20 kg, ranging in shape from round to extremely long to flat, can be with or without ribs, grooves, furrows, wrinkles or warts, and can be green, yellow, or orange ranging in intensity and shading from almost black to almost white and possess patterns of striping, which is longitudinal, or bicolor, which is latitudinal (see Figure 2). This species is considered to consist of three subspecies and 10 cultivar-groups, as summarized in Table 2. The familiar Halloween and pie pumpkins, the oil-seed pumpkins, the zucchini, cocozelle, vegetable marrow, scallop, crookneck, straightneck, and acorn squash, the unique

Figure 2 (see color plate 105) Squash and pumpkins.

Table 2 Classification of *Cucurbita pepo* (squash, pumpkin, gourd) to subspecies and cultivar-groups[a]

Subspecies Group	*Description*
pepo *(cultivated forms, wild forms unknown)*	
Pumpkin	Spherical, globose, oblate, oval, obovate
Vegetable marrow	Short, tapered cylindrical
Cocozelle	Long, bulbous cylindrical
Zucchini	Uniformly cylindrical
Pepo gourd	Round, smooth or warted
texana *(Scheele) Filov (wild and cultivated forms)*	
Acorn	Top-shaped, furrowed
Scallop	Flat with scalloped edge
Crookneck	Long, narrow neck
Straightneck	Short, thick neck
Ovifera gourd	Oviform or pyriform, smooth
fraterna *(Bailey) Andres (wild forms only)*	

[a]From Paris HS (2000) History of the cultivar-groups of *Cucurbita pepo*. *Horticultural Reviews* 25: 71–170.

'Delicata' and 'Rolet,' as well as the small, fancy ornamental gourds are all members of *C. pepo*.

Another widely grown species is *Cucurbita maxima* Duchesne. Like *C. pepo*, this species is well adapted to warm-temperate and temperate regions. *C. maxima* is native to warm-temperate regions of South America, and the plants are usually viney, infrequently bushy, and with round stems. The leaf blades are more or less pentagonal but are also rounded. The foliage is stiffly hairy. In South America, *C. maxima* is grown for its immature and mature fruits, but elsewhere, it is grown almost exclusively for the consumption of the mature fruit flesh and, in parts of Europe, for consumption of the seeds. There is also a great deal of variation in fruit characteristics. *C. maxima* is well named, as its fruits are the largest of the plant kingdom, and new records for size are established every several years. *C. maxima* pumpkins exceeding 450 kg have been grown. Many of the small-fruited kinds are rated high in quality. Among the familiar named cultigens of *C. maxima* are 'Atlantic Giant,' 'Buttercup,' 'Delica,' 'Delicious,' 'Gold Nugget,' 'Hubbard,' 'King of the Mammoths,' 'Lumina,' 'Queensland Blue,' 'Rouge Vif d'Etampes,' and 'Turk's Turban.'

Yet another widely grown species is *Cucurbita moschata* Duchesne. Unlike *C. pepo* and *C. maxima, C. moschata* is best adapted to tropical climates. The nativity for this species has not yet been confirmed, but apparently, it is in tropical regions of northern South America. The plants of *C. moschata* are large, spreading vines, with angular stems. The leaf blades are pentagonal and cornered, but not incised. The foliage is softly hairy. *C. moschata* is usually grown for consumption of its mature fruits. This species is an important source of nutrition, especially of provitamin A, to peoples of the tropics, particularly in northern South America, Central America, and the Caribbean Islands. A great deal of variation in fruit characteristics can be found in northern South America. Although the fruits of *C. moschata* are generally referred to as tropical pumpkins, this species does include the 'Cheese' pumpkin and 'Butternut' squash, which are grown in temperate climates.

The fourth species of squash and pumpkins is *Cucurbita argyrosperma* Huber, a species that is native to warm lowland regions of Mexico. Closely related to *C. moschata*, this species also has large, spreading vines, angular stems and cornered leaf blades but tends to be less hairy. *C. argyrosperma* is not as widely cultivated as *C. moschata*, but it is important in its native country, more for consumption of its seeds than for its fruit flesh. One cultigen, 'Green Striped Cushaw,' has been grown for centuries in the USA for consumption of its mature fruit flesh.

A fifth cultivated species of the genus is *Cucurbita ficifolia* Bouché. This species is commonly known as the fig-leaf gourd rather than as a squash or pumpkin and has less variation in fruit characteristics than the other cultivated species of the genus. Its fruits usually weigh several kilograms, are round to oval or nearly so, and are mottled green and white. The white, fibrous fruit flesh is most often used for making sweets or preserves. *C. ficifolia* also has large, spreading vines with leaves that usually are similar in shape to those of fig leaves and is grown in the cool, highland regions in low latitudes of the Americas. Although adapted to cooler temperatures, it is day-length-sensitive and does not flower in the long days of summer of the mid-latitude regions.

FAO statistics list pumpkins, squash, and gourds together. As gourds can include members of *Cucurbita* as well as other genera, most notably the bottle gourd (*Lagenaria*), it is difficult to give an accurate estimate of production of *Cucurbita*. The production figures from some large producers of pumpkins and squash, notably the USA, Austria, and Guatemala, are not included in the FAO statistics. According to the FAO, world production of pumpkins, squash, and gourds was over 15 million tonnes in 2000. The leading producers, with approximately one-fifth of the total for each, are China and India, followed by Ukraine, Egypt, Iran, Italy, Mexico, Argentina, Turkey, South Africa, and Spain. Pumpkins and winter squash provide an important source of sustenance in some of the poorer regions of the world. Of the cucurbits, and indeed of vegetable crops generally, pumpkins and squash rank high overall in nutritional value, most familiarly in the carotenoid content of the fruit flesh.

Other Cucurbits

Bottle gourd, *Lagenaria siceraria* (Molina) Standley, has large vines bearing large (approximately 10 cm wide), white flowers that open at night. Their leaves are softly hairy, and large and rounded. This species contains a tremendous variety of fruit shapes and sizes, the result of human selection in different cultures of various regions for a variety of purposes. Young fruits are hairy and usually light green but become glabrous and beige or brown at maturity. The moist, white flesh of the immature fruit dries out as the fruit matures. The young fruits are used for culinary purposes, much like summer squash, in Italy (where they are known as cocuzzi), China, and India. They are also known as calabash gourd. The mature bottle gourds have a variety of other uses, too, first and foremost as containers.

Wax gourd, *Benincasa hispida* (Thunberg) Cogniaux, is important in China and other countries of eastern and southern Asia. It bears some similarities to *Cucurbita* by having long, sturdy vines, large leaves, large yellow flowers, and large fruits. However, the stamens of its flowers are free rather than fused, and the mature fruits are covered with a waxy cuticle. The young fruits are hairy. Fruit color is green, with shapes ranging from round, pumpkin-like to cylindrical, and the flesh is white and crisp. Both the immature and mature fruits are used for culinary purposes. The young fruits are usually cooked or pickled but sometimes eaten raw, and are sometimes referred to as Chinese squash. The mature fruit is sliced or cut into chunks for cooking in soup and is also known as Chinese winter melon.

Sponge gourd, *Luffa cylindrica* (L.) M.J. Roemer is a fairly large vine bearing large, 8–10 cm wide, bright yellow flowers. The cylindrical, green fruits are harvested when young, approximately 10 cm long, and usually boiled, but can achieve a length of 40 cm or so at maturation. They are also called smooth loofah or dishcloth gourd. The endocarp dries out as the fruit matures, forming a sponge that has a wide variety of uses. This fibrous net is the dried remains of the highly anastomosing vasculature of the fruit mesocarp. A related species, the angled loofah (*Luffa acutangula*) is similarly used and referred to as Chinese okra.

Bitter melon, *Momordica charantia* L., also known as Balsam pear and bitter gourd, is a relatively small, glabrous or nearly glabrous vine. The elongate fruits average 15–20 cm in length and several centimeters in diameter and are eaten prior to maturity, as the mature fruits are bitter. The seeds are covered with sweet, red arils, but the seeds themselves are poisonous. This species is grown mostly in southern Asia. It has had considerable medical interest as a treatment for a variety of ailments, including HIV.

Chayote, *Sechium edule* (Jacquin) Swartz, is a perennial vine native to Mexico and Guatemala. Chayote is grown almost entirely in subtropical and tropical areas and does not flower in the long days of summer of the middle latitudes. The green fruits are round to pyriform, averaging 14 cm long, and contain a single seed. The fruits are harvested when immature and cooked.

Snake gourd, *Trichosanthes cucumerina* L., is a hairy vine bearing distinct fringed white flowers that open at night. The mature fruits are up to 150 cm long, very slender, and curved. The immature fruit has distinct broad intense green and narrow pale stripes. As the mature fruit is fibrous and can be bitter, usually only the immature fruits are used for culinary purposes.

Food Value

As described in the previous sections, cucurbit fruits are often consumed when young and immature. Cucumbers, for example, are usually consumed no more than one week after anthesis. Immature cucurbit fruits are generally very high in water content; young cucumbers may contain 96% water and therefore are considered to have little nutritional value on a volume basis (Table 3).

The mature fruits of many cultivated cucurbits are inedible or palatably undesirable for a variety of reasons, including the accumulation of bitter compounds in the mature fruit flesh. However, the mature fruits of some cucurbit species are highly appreciated and have immense worldwide economic value. The cucurbit fruits that are consumed mature can be divided into two categories: those that are enjoyed uncooked for their sweet flesh (melons, watermelons) and those that are enjoyed after being cooked in some manner, such as boiling, stewing, roasting, or baking (pumpkins, winter squash, wax gourd). The water content of the mature fruit is lower than that of the immature fruit, and the different cucurbit fruit are specialized in various types of metabolite accumulation during maturity. For example, melon and watermelon fruit are characterized by soluble sugar accumulation during the final stages of fruit development. In the case of melon, which has been studied most extensively, this sugar accumulation is due almost exclusively to the storage of sucrose, which is practically absent in the immature fruit and can increase dramatically during the final weeks of fruit development to 5% on a fresh weight basis, or 60% on a dry weight basis, of the fruit flesh. This storage of sucrose is determined by developmental changes in

Table 3 Nutrient composition of cucurbits in 100-g edible raw portion

Crop	Water (%)	Calories (kcal)	Protein (g)	Fat (g)	Carbohydrate (g)	Fiber (g)
Melon						
Cantaloupe	90	35	0.9	0.3	8.4	0.8

carbohydrate metabolism in the fruit mesocarp, which is under strict genetic control. There is a large amount of genetic variability among melon cultigens for the trait of sucrose accumulation, and most primitive varieties do not accumulate high levels of sugar. The genetic trait of sweetness in melon is recessive and was selected for during the later domestication of the species.

Mature pumpkins and squash generally store significant amounts of starch, which accumulates during the later stages of fruit development. The starch content is correlated with fruit sensory textural attributes, and the soluble sugar levels in the mature fruit determine the fruit sweetness. Therefore, the balance between starch and soluble sugar plays a major role in determining fruit quality. During storage of the mature fruit, starch is metabolized, and the soluble sugar levels often increase, contributing to the flavor of the cooked fruit.

In addition to the soluble sugar and starch components, the organic acid levels of cucurbit fruit can also contribute to fruit taste, although this subject has not attracted much attention to date. Cucumber fruit accumulate high levels (approximately 1% on a fresh weight basis) of citric acid during the later stages of fruit development, but acid levels are low in immature cucumber fruit. Melon fruit have low acid levels, and their sensory quality is therefore determined largely by their soluble sugar content. However, the fruit of many of the nonsweet melon types accumulate high levels of organic acids during their development, and this genetic trait can be combined with the genetic trait of high sugar content, leading to melon varieties with novel tastes.

With respect to nutritional value, cucurbit fruits are generally not ranked high, as they are fleshy with a high water content. The immature fruits have lower levels of nutritional components than the mature fruits. However, some mature cucurbit fruits contain high levels of vitamins C and A. Of the cucurbit fruit, the melons have the highest vitamin C levels and a 1-cup serving of sweet melon (236 g) can meet the recommended daily requirement for vitamin C. The orange-fleshed melons as well as the orange-fleshed pumpkins and squash have high carotenoid levels and a high vitamin A activity. However, the green-fleshed honeydew melons have low carotenoid levels and, hence, a lower vitamin A activity. The major carotenoids of the orange-flesh fruit are α- and β-carotene and the xanthophyls, lutein and violaxanthin. The red color of the watermelon fruit is due to the carotenoid lycopene, which is also responsible for the characteristic red color of tomato fruit. A daily serving of the orange-fleshed melon meets the recommended daily requirement for provitamin A, making melon the only significantly consumed fruit in the USA that can provide the RDA of both provitamin A and vitamin C. There exists a large amount of genetically determined variation for carotenoid levels in the cucurbit fruit. In the case of *Cucurbita pepo*, which has been studied most extensively, over a dozen genes have been characterized, which affect fruit color ranging from pale cream to intense orange.

Besides provitamin A, vitamin C and carotenoids, cucurbit fruits can contain low levels of additional antioxidants, such as flavonoids, but the total antioxidant activity of the various cucurbit fruit remains to be studied. Cucurbit fruit also contain numerous bioactive compounds, including vitamin E, biotin, and folic acid, and here too, there is no doubt a tremendous amount of genetic variability in the family waiting to be discovered. *Momordica* fruit has high levels of both vitamin C and folic acid.

The cucurbits, especially wild germplasm, frequently contain high levels of the cucurbitacin terpenoids. These are highly bitter compounds, which may also be toxic, and they play roles in herbal and folk medicine. They are found at high concentrations in the colocynth gourd (*Citrullus colocynthis* (L.) Schrader), which is likely the poisonous fruit mentioned in Kings 2:4 of the Bible. Bitterness in the cucurbits is genetically controlled and was selected against early in plant domestication. Nevertheless, the problem of undesirable bitter fruit in melon, squash, and cucumber still occurs.

The fruit of exotic cucurbits may be sources of important pharmacological and bioactive compounds, and these are attracting increasing research attention. For example, the mature fruit of *Siraitia grosvenorii* (Swingle) Lu & Zhang (common name luo-han-guo) contains an unusual terpenoid glycoside, mogroside, which is over 100 times sweeter than sucrose. Bitter gourd (*Momordica charantia*) and snake melon (*Trichosanthes cucumerina*) are just some of the cucurbits that are being tested for potential medical benefits.

Seeds of many cucurbits, such as pumpkin, squash, and watermelon, are consumed largely as snack foods. The seeds generally have high levels of oils and proteins, and may be considered a highly nutritious food. The oils contain mainly unsaturated fatty acids, primarily oleic and linoleic and, here too, there is much genetic variation in fatty acid composition within the family. For example, the seeds of the white-seeded melon have primarily linolenic acid (18:3), and lines of buffalo gourd (*Cucurbita foetidissima* HBK) have been developed, with seeds containing over 80% linoleic acid (18:2). One of the interesting advances in cucurbit seed improvement has been the utilization of the naked seed, or hull-less, mutant in *Cucurbita pepo*. In this mutant, discovered a little over 100 years ago, the seed coat does not develop, thus allowing for the efficient extraction and processing of the oils. Oil extracted from *C. pepo* seeds is highly prized for use on salads and in cooking in much of central and eastern Europe.

Other Uses

In addition to their uses in edible consumption, many cucurbit fruits have also served other utilitarian purposes throughout history. Collectively described as gourds, the dried lignified fruit rinds of numerous cucurbit species have been used primarily as containers of various sizes, and also as fish-net floats, masks, musical instruments, birdhouses and other uses of anthropological interest. Species grown for their dried fruit are primarily from the *Lagenaria* and *Cucurbita* genera. As previously mentioned, *Luffa* gourds are grown for the fibrous interior of the dried fruit, which can serve as a sponge.

Fruit Ripening

Melon cultigens can be divided into two major groups based on their ripening physiology. The *reticulatus* and *cantalupensis* groups are climacteric, meaning that there is a characteristic sharp and rapid peak of respiratory activity during ripening. This is accompanied by the development of an abscission layer between the pedicel and the fruit (termed 'full-slip'). The nonclimacteric melon fruit of the *inodorus* group, such as honeydew and casaba melons, do not show a sharp respiratory peak, and their development generally extends over a longer period of time. They do not develop an abscision layer, and the appropriate stage of ripeness is determined by changes in skin color, from white–green to creamy yellow. In all melons, sugar is accumulated until the fruit naturally abcisses or is removed from the vine, and therefore the tastiest melons are those that are not prematurely harvested. Since no storage starch accumulates in melon fruit, in contrast to the winter squash and pumpkins, there is no postharvest increase in sugar content or sweetness.

The netted climacteric melons have a shorter storage life than the nonclimacteric smooth-skinned melons. However, the traits of rind netting and respiration physiology are unlinked, and recently, new varieties of netted melons with nonclimacteric respiration have been developed, revolutionizing the harvesting and shipping technologies of netted melons due to their long storage life. The climacteric trait in melons is controlled by only two genes, and the breeding of the new types of melon is therefore relatively straightforward.

The cucurbit fruit that are consumed while immature, such as cucumber and summer squash, have very short storage lives due to their undeveloped skin and rind. Ideally, storage of immature fruit should be under a relatively high relative humidity, 85–95%, to reduce fruit water loss. At the other extreme with

respect to storage, pumpkins and winter squash may be stored for a long time, frequently many months, and during this period, the fruit undergoes 'curing,' part of which is the transition of the starch in the stored fruit to sugar. For the long-term storage of winter squash and pumpkins, the optimal relative humidity is generally 70–75%.

Future Research and Development

The tremendous genetic variability for fruit quality components in the cucurbits remains to be characterized and harnessed for the breeding and production of improved melon, squash, cucumber, pumpkin, watermelon, and other cucurbit fruit. Within each species of cucurbit, there exist genotypes, at times primitive landraces, that are extraordinary in their levels of a particular quality component or bioactive compound. This is true for sugar content, acid content, volatile productions, nutritional content, ripening physiology and other metabolically controlled processes in the developing fruit. Future research will survey and uncover these metabolic variations, and their genetic control will be determined, allowing for their efficient utilization. This will set the stage for the production of new and novel varieties with beneficial characterisitics, be it improved taste or nutrition. This effort will be aided by advances in understanding the molecular-genetic control of these metabolic processes. The unfolding of the cucurbit genome, including the cataloging of genes involved in plant metabolism, will help determine the potential for the genetic improvement of each of the cucurbit crops.

Principles of Reverse Osmosis

H N Lazarides and E Katsanidis, Aristotelian University of Thessaloniki, Hellas, Thessaloniki, Greece

Introduction

Vast amounts of liquid food are industrially concentrated for preservation purposes or in order to reduce storage, packaging, handling, and transportation costs. Vacuum evaporation is the predominant method used by the food industry to produce liquid food concentrates, despite serious drawbacks such as poor product quality due to thermal degradation and high energy demand for the evaporation process. Reverse osmosis was first suggested by Sourirajan in 1959 as a method for water desalination. Since then, significant developments in both material science and membrane technology have allowed reverse osmosis to be used in the food industry, mainly for concentrating liquid foods without the disadvantages of vacuum evaporation.

Theory

A membrane is a permeable or semipermeable material (polymer, inorganic, or metal), which restricts the motion of certain species through itself. The membrane, acting as a barrier, controls the relative rates of through transport of various species and thus gives one product depleted in certain components and a second product concentrated in these components.

Membranes are used in many filtration and separation processes. Some representative processes and relative particle sizes are shown in Table 1.

When a membrane separates two solutions of different solute concentrations, water moves through the membrane towards the solution with the high concentration of solutes tending to equalize the solute concentration on the two sides of the membrane. The driving force for the movement of water is the difference in osmotic pressures of the two solutions. This phenomenon is called osmosis.

The osmotic pressure of a dilute solution can be calculated by Van't Hoff's equation:

$$\Pi = cRT/\mathrm{M}$$

where Π is the osmotic pressure (Pa), c is the solute concentration (Kg/m^3), R is the gas constant (J/mol.K), T is the absolute temperature (K), and M is the molecular weight of the solute. For a wider range of concentrations, Gibb's equation has been found to be more suitable for the calculation of the osmotic pressure:

$$\Pi = -(RT \ln x_\alpha)/V_m$$

where x_α is the mole fraction of pure liquid and V_m is the molar volume of pure liquid. When external (hydrostatic) pressure greater than the osmotic pressure is applied, water is expelled from the concentrated solution and we observe a reverse flow, that is a flow against the osmotic pressure gradient. This process is called reverse osmosis. Reverse osmosis involves the

Table 1 Membrane separation processes

Separation process	*Particle size (microns)*	*Applications*
Microfiltration	0.1–10	Clarification, sterile filtration
Ultrafiltration	0.01–0.1	Separation of macromolecular solutions
Nanofiltration	0.001–0.01	Separation of small organic compounds and selected salts from solutions
Reverse osmosis (hyperfiltration)	0.0001–0.001	Separation of microsolutes and salts from solutions
Dialysis	0.0001–0.001	Separation of microsolutes and salts from macromolecular solutions
Electrodialysis	0.0001–0.001	Separation of ions from water and nonionic solutes
Gas permeation	0.00001–0.0001	Separation of gas mixtures

most 'tight' membranes, which are capable of separating the smallest solutes. The pores of the membrane are so small that, in some materials, they can hardly be resolved, even by scanning electron microscopy.

The basis for separation is molecular size, but other factors such as molecular shape and charge can also play an important role.

Membranes currently used in commercial reverse osmosis installations are asymmetric, flat sheet membranes of cellulose acetate (CA) or cellulose triacetate, fine hollow fibers of aromatic polyamides (PA) or cellulose triacetate and thin-film composites (TFC). In TFC membranes an extremely fine layer of highly hydrophilic polymer has been placed on a microporous support usually made from polysulfone. Figure 1 depicts the structure of a typical CA membrane and shows the chemical affinity (selectivity) of the membrane for water molecules. The chemically induced negative sorption (repulsion) of the ions in solution and the preferential sorption of pure water to the membrane result in rejection of ions, thus preventing them from permeating the membrane. It should be noted that very-low-molecular-weight organics and uncharged solutes may pass through the membrane. In general, reverse osmosis membrane efficiency is expressed as a percentage rejection of NaCl, and the typical range for such membranes is 96–99%.

Operational Requirements

In conventional filtration processes, all the material to be filtered flows perpendicularly through the filter where the separation occurs (dead-end flow). Suspended solids captured by the filter tend to build up, slowing down the filtration rate and requiring frequent cleaning.

In reverse osmosis, cross-flow systems are used almost exclusively. In a cross-flow system, the feed

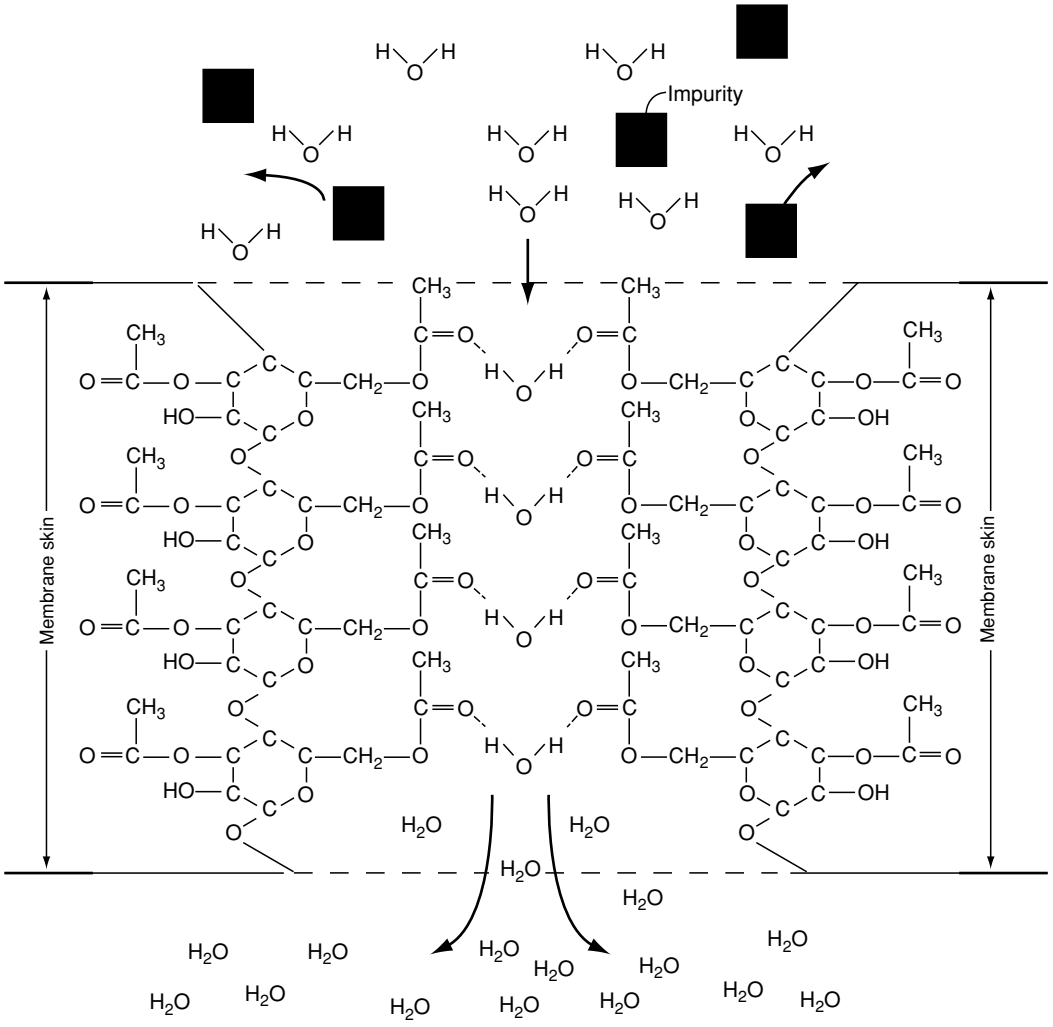

Figure 1 Movement of water through a cellulose acetate membrane. Adapted from Lacey (1972).

stream (influent) flows parallel (tangentially) to the membrane and only a portion of the stream passes through the membrane as permeate or filtrate. The remainder of the stream is called retentate or concentrate. The main advantage of the cross-flow system is that the feed stream constantly removes the accumulated solids (cake) or solutes from the membrane surface, reducing build-up, which allows for less frequent clean-up of the membrane system. The two types of flow and their representative flux and cake build-up are depicted in Figure 2.

In reverse osmosis, the external pressure has to exceed the osmotic pressure of the solution so that solvent (usually water) may be expelled. For example, the osmotic pressure of sea water is approximately 2.3 MPa and a desalination plant utilizing reverse osmosis may operate at pressures of up to 7 MPa. This makes it clear that the reverse osmosis systems must be very robust from a physical standpoint and the membranes must be able to resist mechanical compression (compaction), which can deform their morphology and negatively affect their performance.

Resistance to mechanical pressure is only one of the properties that a good membrane must have. Membranes need to function in a variety of environments, where the operating pressure, temperature, pH, and chemical compatibility need to be taken into account. Cellulose acetate membranes are usually used at temperatures up to 40 °C, but they may be operated at temperatures up to 65 °C.

The typical pH range for CA membranes is 2–8 and for PA 3–11. Membranes may be used outside the above ranges, but their useful life will be shorter.

A good reverse osmosis membrane needs to withstand chemical agents such as chlorine, iodine, other oxidizing agents, oils, and solvents. CA has good chlorine resistance (for sanitation purposes) but TFC PA has poor chlorine resistance.

Several reverse osmosis membranes used in commercial applications and their properties are presented in Table 2.

Membrane Configurations

There are several configurations for the containment and support of the membranes. These configurations need to address all the requirements discussed previously and also need to allow for easy access to the membranes for replacement. There are four major configurations that have been used in the food industry.

Spiral Wound

This module consists of a flat sheet membrane, a support system, and a spacer system, all wrapped around a perforated premeate-collection tube. The feed stream flows across the membrane through the spacer and the permeate is collected in the central permeate-collection tube. Specially designed spacer systems enhance turbulent flow, which helps reduce fouling of the membrane. The main advantages of this

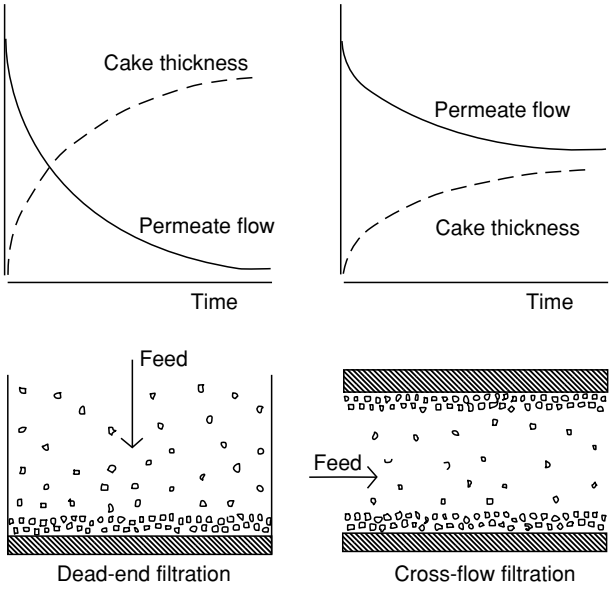

Figure 2 Dead-end vs cross-flow filtration. Adapted from Mannapperuma JD (1997) Design and performance evaluation of membrane systems. In: Rotstein E, Singh RP and Valentas KJ (eds) *Handbook of Food Engineering Practice*, pp. 168–208. Boca Raton, FL: CRC Press LLC.

Table 2 Properties of some commercial reverse osmosis membranes

Membrane type	*Module type*	*pH*	*Chlorine tolerance*	*Oxidation tolerance*
Cellulose acetate blend	Spiral wound	3–8	Fair	Fair
Cellulose triacetate	Capillary fiber	4–9	Fair	Good
Aromatic polyamide	Hollow fiber	4–11	Poor	Fair
Cross-linked polyether TFC	Spiral wound	1–12	Poor	Fair
Aryl-alkyl polyetherurea TFC	Spiral wound	3.5–12	Poor	Fair
Cross-linked fully aromatic polyamide TFC	Spiral wound	1–12	Poor	Fair

TFC, thin-film composites.

module are the high packing density, the high flux, and the fact that the flat sheet membrane can withstand higher pressures than the hollow fiber module.

Capillary (Hollow Fiber)

In this module, the feed stream is pumped into a vessel that contains a bundle of thin hollow fibers (about 40 μm internal diameter). The permeate goes through the thin fibers and is separated from the concentrate. The advantage of this system is that it provides a very large membrane area for the total size of the system (high packing density). The disadvantages are the low flux and the need for pretreatment of the feed solution (i.e., filtration, centrifugation, microfitration, even ultrafiltration).

Plate and Frame (Flat Sheet)

This module consists of flat membrane sheets placed between support frames that create flow channels (about 0.5 mm) for the feed stream, the concentrate, and the permeate. The membrane and its supports are stacked together in large numbers (up to 360 membrane sheets) to create one unit. The main advantages of this module are that it is possible to remove and clean the membrane sheets and that the system is reusable (once the membranes have been cleaned or replaced). The disadvantages are the high labor and time investment required to disassemble and reassemble the module and the low packing density of the unit.

Tubular

This module is relatively uncommon in reverse osmosis. The feed and concentrate streams flow through the inside of the tube (up to 12 mm internal diameter) and the filtrate passes through the membrane and is collected in the housing around the tube. The advantages of this system are the ease of cleaning and the capability to handle high viscosities. The disadvantages are the relatively small membrane area for the size of the system and the high feed rates that are required for the system to operate efficiently (high energy/pumping cost).

The spiral wound and the hollow fiber are the two modules that are mostly used in the food industry. Figure 3 illustrates these module designs. In industrial systems, usually several units are assembled together in series and/or in parallel configuration to achieve the desired results. These systems may be single-pass systems or they may include recirculation loops and pumps so that part of the feed solution passes through the membrane multiple times.

Performance Comparisons

Reverse osmosis is a very efficient process, allowing for the simultaneous concentration, fractionation, and purification of the product and the accomplishment of multiple tasks in a single unit operation. It does not impart pH or chemical changes in the product and, since no significant heating is required, there is no heat degradation of the product. Thus, reverse osmosis has a minimal effect on the quality characteristics and nutritional value of the finished product, especially when compared to evaporative concentration where inevitably there is heat degradation, as well as flavor and nutritional losses.

Since reverse osmosis systems do not require steam, evaporators, and condensers, they require much less floor space and equipment than evaporative systems. Due to their relative simplicity, reverse osmosis systems have shorter come-up and shutdown time. They are also more flexible and easier to modify or upgrade than conventional evaporative systems.

Reverse osmosis is very energy-efficient, because it typically operates at ambient temperature (no heating or cooling required); and, most importantly, there is no phase change requirement for water removal, as in evaporative processes. Overall, reverse osmosis systems require less energy than evaporative systems per unit of water removed from the product. Reverse osmosis systems require almost exclusively electric energy for pumping and recirculating, whereas evaporative systems require steam in addition to electric energy for pumping.

Table 3 Comparison of energy requirements of reverse osmosis and evaporation with either thermal vapor recompression (TVR) or mechanical vapor recompression (MVR)

Type of plant	*Direct energy input*		*Equivalent energy input (kWh kg$^{-1}H_2O$)*
	Steam (kg kg$^{-1}H_2O$)	*Power (kWh kg$^{-1}H_2O$)*	
Evaporation TVR 3 effects	0.20–0.25	0.003	0.17–0.20
Evaporation TVR 5 effects	0.13–0.17	0.003	0.11–0.14
Evaporation TVR 7 effects	0.077–0.13	0.003	0.07–0.10
Evaporation MVR	0.02	0.01–0.03	0.046–0.11
Reverse osmosis		0.005–0.012	0.015–0.048

In this table a heat-to-power ratio of 3 has been used.
Adapted from Hallström B (1988) Preconcentration: new developments. In: Bruin S (ed.) *Preconcentration and Drying of Food Materials*, pp. 46–47. New York, NY: Elsevier.

Thermal energy (steam) can be generated from oil at very high efficiency (80–90%), but electrical/mechanical energy is generated from oil at much lower efficiency (about 30%), yielding a heat-to-power ratio of 3.0. Table 3 compares the energy requirements of reverse osmosis to evaporation with either thermal vapor recompression or mechanical vapor recompression. The relative cost of electric energy to oil or natural gas energy varies a lot in different areas of the world, thus making it hard for generalized comparisons of energy costs of the two processes. However, it seems that in countries such as the USA, France, and Germany, reverse osmosis is much less costly than any multistage evaporative process, with either mechanical or thermal vapor recompression.

In large desalination plants, energy can be recovered from the rejected brine by running it through turbines to generate electricity that can be used in the plant. Such a recovery system can lead to energy savings of up to 30%.

Operational Issues

In membrane systems a reduction of flux over time is often encountered, while all operating parameters remain the same. This is typically due to membrane compaction, concentration polarization, and fouling.

Compaction

As discussed previously, the high operating pressures in reverse osmosis result in increased membrane density, decreased thickness, and deformed (compressed) membrane pores, which reduce the permeate flux through the membrane.

Concentration Polarization

In all cross-flow processes, as soon as the flow begins, a build-up of a polarized layer or a gel-like layer of solutes is observed at the membrane surface. This phenomenon can result in locally increased osmotic pressure in the vicinity of the membrane surface that

will negatively affect the flux through the membrane. Over time, the accumulated solutes can affect the affinity of the membrane for certain solutes or solvents. Concentration polarization is a reversible phenomenon that can be reduced by periodical changes in the velocity of the feed solution (tantalizing), by increasing the velocity, or by decreasing the pressure and concentration of the feed solution.

Fouling

Fouling refers to the irreversible changes that occur on the membrane and result in reduced flux over time. Many factors contribute to membrane fouling. Pore plugging and solute adsorption in the membrane pores can result in a decrease of the pore diameter and reduced flux. Solutes accumulated on the membrane surface due to concentration polarization may undergo irreversible changes over time and form a layer that will cause hydrodynamic resistance to flow. This layer formation depends on the membrane surface chemistry, solute–membrane and solute–solute interactions.

All the above make it clear that pretreatment of the feed stream is crucial in extending the useful membrane life. The objective of the pretreatment process would be to remove as many suspended solids and contaminants as possible before reverse osmosis. The pretreatment process may be a simple filtration or centrifugation step or it may be a much more thorough micro- or even ultrafiltration step. Pretreatment requirements will depend on the type of membrane used, the membrane configuration, and the composition and flow rate of the feed solution.

Cleaning

Mechanical cleaning can be applied in large-diameter tubular modules using oversized sponge balls to clean the tubes.

Hydraulic cleaning can be achieved by back-washing (reversing the flow), by back-shock treatment (back-flushing for very short time), or by the pulsation of flow (increasing and decreasing the pressure of the feed solution). Back-washing and back-shock treatment cannot be applied to TFC membranes because of their tendency to delaminate.

Electric cleaning uses a pulsed electric field resulting in the movement of charged particles away from the membrane. Electric cleaning can be applied without interrupting the process, but requires electricity-conducting membranes and special module design.

Chemical cleaning is the most important method for controlling fouling phenomena. Chemical compatibility between the cleaning agent and the membrane is the most important factor in selecting the proper cleaning agent. Acids (nitric, phosphoric, citric) are usually used for inorganic contaminants and basic (caustic) detergents or chlorine are typically used for organic contaminants (i.e., fat, protein). Other chemicals used may be complexing agents (ethylenediaminetetraacetic acid; (EDTA), enzymes, and disinfectants (H_2O_2, NaOCl).

Applications

Water desalination and/or purification is one of the major applications of reverse osmosis. Brackish water or sea water is treated by reverse osmosis to produce potable water. Also, ultrapure water for medical or industrial applications can be produced.

Reverse osmosis is used in the dairy industry for milk, whey, or lactose concentration. Concentration of whey, produced as a byproduct from the cheese-making process, is the most widely used application in the food industry. Spiral module configurations with CA or TFC membranes are most often used in the dairy industry.

Tubular and spiral module systems equipped with TFC membranes are used for juice concentration. Reverse osmosis is economically efficient for concentrations up to 24% solids, but it could be used to concentrate juices up to 60% solids, if economically feasible. Membranes developed for reverse osmosis have also been used in direct osmosis applications for the preconcentration of liquid foods (i.e., juices) with the use of high osmotic pressure brines on one side of the membrane. In these applications the driving force is not hydrostatic pressure (pressure are rather low; < 500 kPa) but the osmotic pressure difference on the two sides of the membrane.

A thorough discussion of reverse osmosis applications can be found in a following section.

Applications of Reverse Osmosis

M H Abd El-Salam, National Research Centre, Cairo, Egypt

Introduction

Reverse osmosis (RO) is essentially a pressure-driven membrane diffusion process. In practice, RO membranes retain 95–99% of the dissolved solutes (organic and inorganic) from the feed stream into the concentrate, while the permeate can be considered as high-quality water. Therefore, RO is classified as a concentration process. RO has several advantages compared to other concentration technologies. RO is an energy-saving process as removal of the solvent does not require change in phases. Compared to other competing processes, RO is more economic in concentrating diluted solutions and for medium concentrations. Also, RO concentrated fluids are not subjected to any heat damage or losses in aroma compounds, as has occurred in other concentration processes. This is of utmost importance in concentrating liquid foods. Like other membrane processes, RO offers flexibility in different applications and scales, RO concentration is best explained as the mechanism of preferential sorption capillary flow. According to this mechanism, permeation occurs due to the preferential sorption of constituents from fluid mixture and their permeation through the porous membrane. For RO to take place, it is essential that a membrane has the right chemical nature (polar and nonpolar effects) and that its pores are of appropriate size and number (steric effect).

Although RO is mainly applied in the production of potable water from sea and brackish water, the use of RO in food processing is growing steadily. Until recently, the application of RO in the food industry has been based on the use of cellulose acetate membranes. During the 1980s a wide variation of thin-film composite membranes appeared on the market. This new generation of membranes gave food processors the opportunity to apply more rigorous cleaning routines and greater plant sanitation. Also, these membranes exhibit better recovery of valuable compounds in processed liquids, e.g., aroma compounds.

Reverse Osmosis in the Dairy Industry

RO was introduced into the dairy industry in the 1970s and rapidly expanded with time. It is estimated that about 75 000 m^2 surface area of RO membranes has been installed in the dairy industry until 1996 and is still increasing. Most of this area (76%) is used in concentrating whey, followed by permeate (20%) and milk (3%). A smaller surface area of RO membrane has been used to recover milk solids from rinse water in the dairy plant.

As lactose and minerals are almost completely retained by RO membranes, the osmotic pressure of the processed dairy liquid limits both the permeate flux and the maximum concentration achievable. Milk, whey, and permeate have nearly the same osmotic pressure, which is around 7 bar, a pressure that must be exceeded in RO processing of these fluids. On the other hand, milk and whey concentrated by RO to 25–28% total solids (maximum concentration) has an osmotic pressure of 27–35 bar. However, for practical and economic considerations, twofold RO concentration of whey and milk is usually carried out.

Concentration of whey by RO has several advantages:

- decrease in costs for transport and storage of whey
- as a preconcentration step in the manufacture of whey powder, demineralized whey powder, and whey cheeses
- improving the ultrafiltration performance of whey for the preparation of whey protein concentrates.

Figure 1 shows the use of RO in the manufacture of different whey products. One of the major concerns of dairy processors is the microbiological quality of the concentrate obtained when unpasteurized whey is processed. The microbiological quality of RO whey concentrates is controlled by the microbial load of

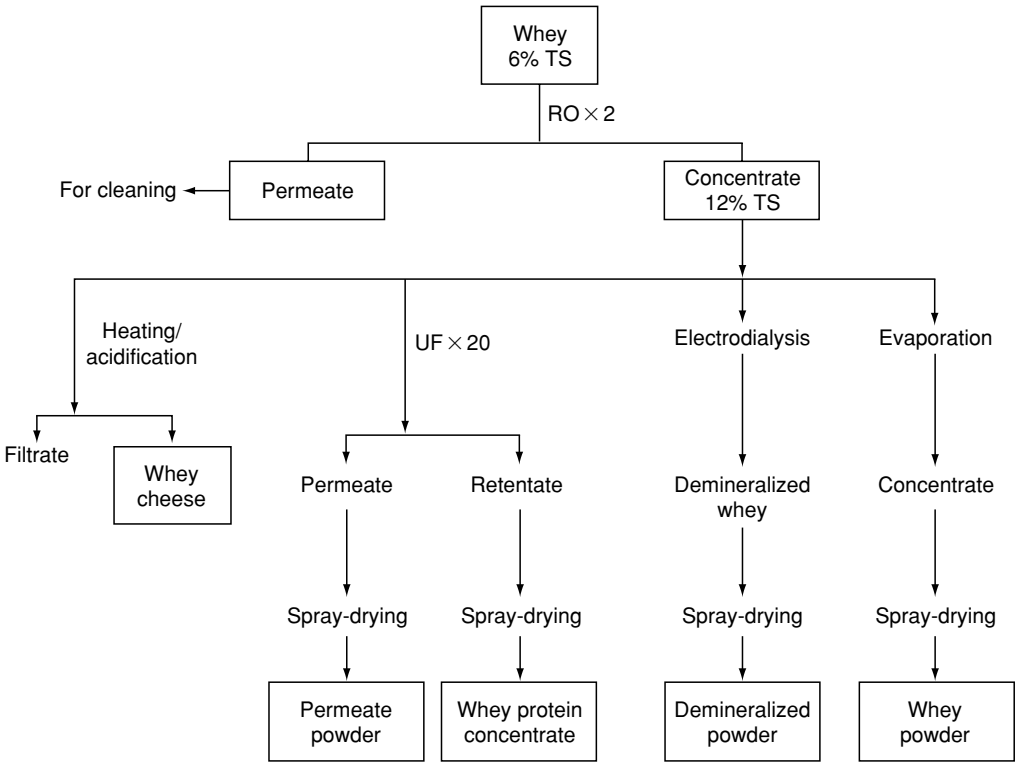

Figure 1 Application of reverse osmosis (RO) in the manufacture of different whey products. TS, total solids; UF, ultrafiltration.

the processed whey, RO operating temperature, and residence time in the RO equipment. However, the number of bacteria during RO of whey seldom multiplies by more than the concentration factor. When RO cellulose acetate membranes are used, an operating temperature of 10 °C has been recommended for control of the microbiological quality of RO whey concentrate, but when concentration is carried out with RO membranes from other synthetic polymers, higher temperatures can be used. However, RO concentration of whey must be carried out at a temperature < 55 °C to avoid precipitation of calcium phosphate and fouling of the membrane. (*See* **Membrane Techniques**: Principles of Reverse Osmosis.)

Concentrating permeate from the ultrafiltration of whey and milk by RO is widely practiced as the first step in the manufacture of lactose. RO cannot completely replace evaporation in lactose manufacture, as the concentrated permeate must contain 60% total solids in order to separate lactose crystals. This concentration cannot be achieved by RO processing alone. However, RO can be used for the preconcentration of permeate as a very economic way of removing the large bulk of the water from permeate. The concentration of ultrafiltration permeate to 15–18% total solids followed by evaporation up to 60% is considered an optimum combination for the manufacture of lactose. Even in already existing lactose manufacturing plants using evaporation only, the inclusion of RO can improve the efficiency of the plant.

The feasibility of concentrating milk by RO has been established in several studies. However, the industrial application of RO in concentrating milk is still limited. Whole milk can easily be concentrated by RO up to twofold. The presence of milk fat has a very limited effect on the permeation rate of whole milk compared to skim milk. The main objective of concentrating milk by RO is to reduce the storage and transport costs, which represent a significant part of the processing costs in some countries, such as Australia. Also, concentrating milk by RO increases the efficiency of processing facilities in the dairy plant and as a preconcentration step in the manufacture of dried milk. Generally all dairy products can be made from milk concentrated by RO with no marked effect on the quality of obtained products.

RO can also be used in the dairy industry for the recovery of waste solids from the dairy rinse water. This process can achieve two purposes: first, a decrease in the biochemical oxygen demand (BOD) of the plant effluent, which reduces the costs of waste water treatment, and second, recovery of valuable solids that can

be dried and used for feeding purposes. Both objectives increase the profitability of the dairy plant.

The RO permeate from the processing of different dairy fluids has a low BOD, in the range of 30–300 mg l^{-1}. Therefore it can be used as a good-quality supply of water for cleaning purposes.

Fruit and Vegetable Juices

Juices of most fruits and vegetables are characterized by their high osmotic pressure. However, they can be concentrated by RO to relatively high solids contents. The resulting concentrates are of premium quality as they are subjected to minimum heat damage during processing. However, early studies on RO concentration of juices were concerned with two factors:

1. The rapid fouling of membranes due to the presence of fibers and pectin in the juices. Therefore, pretreatment may be needed before concentrating juice by RO. The development of optimum RO operational conditions, and the selection of type of membrane and module configuration were established for several juices. In this respect a study showed that hollow fiber modules performed better than spiral-wound modules because of their low concentration polarization effects.
2. The variable retention of the different aroma volatiles during RO concentration. The balance in the concentration of these compounds is critical to obtain a concentrate with similar characteristic flavor of the fresh juice. In this connection, thin-film composite RO membranes show better retention for aroma volatiles than cellulose acetate membranes.

Different studies have shown the technical feasibility of concentrating the juice and purée of different fruits and vegetables, including orange, grapefruit, pineapple, apple, pear, passionfruit, apricot, cherry, strawberry, sugar beet, tomato, roasted coffee beans, and green tea extract. However, industrial processing by RO has been limited to the juices described below.

Tomato Juice

Tomato juice is a very variable material depending on the fruit variety, soil, and climatic conditions and processing conditions. However, the quality of the tomato juice has little effect on its behavior during RO processing. Early attempts at concentrating tomato juice by RO were based on removal of the suspended material (mainly dietary fiber) by centrifugation or ultrafiltration, concentrating the clear serum by RO, followed by mixing the concentrate with the insoluble precipitate or concentrate. However, this method has not been applied commercially.

The advent of the new generation of RO thin-film composite membranes enabled food processors to concentrate tomato juice using RO on a commercial scale. The different parameters for RO of tomato juice have been optimized. It is of interest to note that changing feed velocity has a small affect on flux. This unusual behavior has been attributed to the rheological properties of tomato juice. Several plants are now concentrating tomato juice by RO from 4.5–5.0 to 8 Brix. The different tomato juice concentrates – sauces (8–12 Brix), passata (16 Brix), and pastes (27–28 or 37–38 Brix) – can then be made from RO concentrate by evaporation. The rejection of the tomato juice solids is little affected by the quality of the fruit and the operating conditions. However, a rejection of 99% or more of tomato juice solids has been recorded. The RO tomato juice concentrate is characterized by improved color and flavor.

Citrus Juices

Unlike tomato juice, the retention of aroma and flavor is much more critical for the quality of the concentrate of most fruit juices. It is estimated that the various volatiles which give the characteristic flavor of fresh orange juice are removed with the first 15–20% of water removed by evaporation. These volatiles are partially recovered by appropriate condensation and stripping and added back to the concentrate prepared by evaporation. However, the flavor of the concentrate is different from that of the fresh juice. Orange juice can be directly concentrated by RO up to 30% solids at acceptable flux and with good-tasting product. An ultrafiltration/RO system has been developed for the preparation of orange juice and grapefruit juice concentrate that avoids the limitations of the traditional method for concentrating the juice. In this method, the fresh juice is first fractionated by ultrafiltration into concentrate and ultrafiltration permeate. The ultrafiltration concentrate is concentrated by evaporation and sterilized, while the ultrafiltration permeate is concentrated by RO. The RO concentrate is then mixed with evaporated ultrafiltration concentrate before aseptic packaging. When the prepared concentrate (double strength) is diluted, it is of similar quality to the fresh juice.

When lemon juice was concentrated by RO, 79.9% of volatiles were recovered. Loss of the volatile compounds has been attributed to adsorption in the polymeric matrix of the membrane.

Apple Juice

The presence of pectin in apple juice affects the behavior of the juice during RO concentration and the

quality of the concentrate. Therefore, apple juice is usually depectinized either by enzymatic treatment or by removal of pectin by microfiltration. Depectinized apple can be concentrated by cellulose acetate RO membranes from 10 to 20–25 Brix at 20 °C, with good retention of volatile flavor compounds. Using noncellulosic membranes, depectinized apple juice can be economically concentrated to 20–25 Brix at 30–50 °C, with better retention of soluble solids and flavor compounds. Economic evaluation showed that a RO unit used to concentrate apple juice to reduce shipment costs would pay for itself in 4 months.

The retention of aroma volatiles during RO concentration of apple juice varied between different compounds, with *trans*-2-hexenal showing the highest and hexyl acetate the lowest retention.

Coffee

Roasted coffee extract contains about 13% total solids. This extract can be concentrated by RO up to 36% solids content without appreciable loss of solids or aroma compounds. The RO concentrate of coffee extract can be used as a base for the preparation of instant coffee. (*See* **Coffee**: Roast and Ground.)

Alcoholic Beverages

Wine

Grape must with a low sugar content of < 17% makes table wine of inferior quality and insufficient alcohol content to meet legal requirements. The traditional method of combatting this problem is called chaptelization, in which sucrose or glucose is added to the must before fermentation. This method can be replaced by RO concentration of must. The wine results from RO concentrated must have improved flavor without any adverse effects on general quality.

Removal of bitterness has been reported as another application of RO in the wine industry. Red wine of poor quality can be subjected to RO concentration using cellulose acetate membrane, with an approximate molecular cut-off of 300 Da. The bitterness-causing compounds (probably ketones) pass in the permeate while the concentrated wine has improved quality. This wine concentrate has much shorter cold stabilization time to remove tartrate. (*See* **Wines**: Production of Table Wines.)

Low-Alcohol Beer

The demand for beer with low alcohol content has increased recently. This can be achieved either by controlling the fermentation conditions to develop less alcohol or the partial removal of alcohol from normal beer. The first trend has the disadvantage of impairing the development of flavor compounds in addition to alcohol.

With the use of special RO membranes, it is possible to remove the alcohol partially from beer. This has been applied commercially in many breweries in different parts of the world. A thin composite RO membrane with a molecular cut-off of 100 Da has been used to remove 25–30% of alcohol content in beer. The beer is processed by RO while diluting the retentate with water to a constant volume under carbon dioxide. Therefore, the alcohol content of the beer can be changed to the desired level. The quality of water used for diluting the concentrated beer determines the quality of the final product.

Corn Wet Milling

Corn wet milling is a process that gives starch as the main product output in addition to several other products, namely, oil, protein, and fiber. This process is a water-intensive technology as 1.5 m^3 of fresh water per ton of corn is needed in modern corn wet milling. RO has been used to recover water from the light middlings (the overflow from the hydrocyclone starch system). The recovered water is then used to wash starch. Application of this process in a corn wet milling plant reduced the load of the steep water evaporator to 30% of the original value. The use of RO in corn wet milling had no adverse effect on the quality of the produced starch.

Concentration of Dextrose Syrup and Sweet Water

In the manufacture of dextrose syrup, the syrup is usually concentrated by evaporation from 30–34% to 40–45% total solids before decolorization with carbon. Evaporation can be successfully replaced by RO concentration, with marked savings in energy.

Also, during the manufacture of the high-fructose syrup, an effluent called sweet water results from washing the ion exchange and carbon columns and storage and transportation facilities. The sweet water contain 3–8% sugar content. This effluent can be preconcentrated more economically by RO compared to evaporators.

Removal of Solvent from Micella

The edible oil industry is based on oil extraction from seeds with suitable solvent, degumming and bleaching of the extract, followed by removal of the solvent from the micella by evaporation.

Using special RO membranes, it is possible to remove large amounts of the solvent from the micella, and removal of the residual solvent can be completed by evaporation. However, most of the material used in RO modules does not resist the destructive action of the solvent.

Principles of Ultrafiltration

D Pal, National Dairy Research Institute, Karnal, Haryana, India

Introduction

Though very rapid progress has been made in all the membrane processes during the last two to three decades, ultrafiltration, because of its unique nature and diverse uses, has received more attention worldwide. This article discusses the principle of the ultrafiltration process, the membrane materials, and their configurations. Some major limitations and operating conditions are also included.

What is Ultrafiltration?

A pressure-driven, cross-flow membrane system that can simultaneously purify, concentrate, and fractionate organic molecules of a feed stream is known as ultrafiltration. The process is very simple (**Figure 1**). The pressurized influent stream is passed across a semipermeable membrane which separates it into two effluent streams known as permeate and retentate (concentrate). Permeate is that fraction which has passed through the semipermeable membrane and contains some small dissolved molecules. Retentate is that stream which has been enriched in the solutes or suspended solids not passed through the membrane. The physical and chemical nature of the membrane itself controls which components permeate and which are retained.

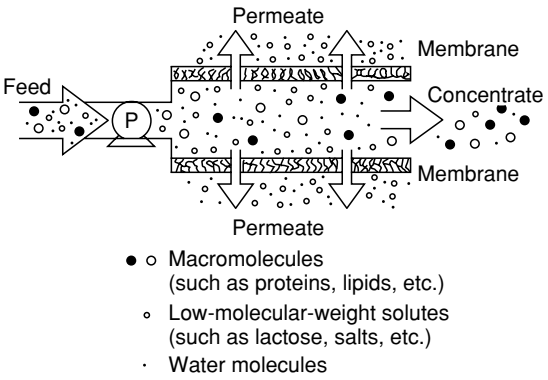

Figure 1 Principle of ultrafiltration process. P, pump. Reproduced from Membrane Techniques, Principles of Ultrafiltration, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Table 1 Molecular weight and relative diameters of some milk constituents

Milk constituent	*Molecular weight (Da)*	*Diameter (nm)*
Water	18	0.3
Chloride ion	35	0.4
Calcium ion	40	0.4
Lactose	342	0.8
α-Lactalbumin	14 500	3.0
β-Lactoglobulin	36 000	4.0
Blood serum albumin	69 000	5.0
Casein micelles	10^7–10^9	10–600
Fat globules	–	200–10 000

Data from Kessler HG (1981) *Food Engineering and Technology*. Freising: A Kessler.

Principle of Ultrafiltration

The mechanism of separation in ultrafiltration is essentially a sieving process in which constituents of a feed stream are separated according to their molecular weight. The ability of the membrane to retain the majority of the defined macromolecules of known molecular weight is generally used to specify the porosity of the membrane. The term used is molecular weight cut-off (MWCO), which should be the molecular weight of the smallest test macromolecule that is largely rejected by the membrane. Most ultrafiltration membranes reject the constituents having a molecular weight in the range 1–1000 kDa. Table 1 shows the molecular weight and relative diameter of major milk constituents. Since the majority of ultrafiltration membranes have pore sizes ranging from 1 to 50 nm, essentially all milk constituents except water, lactose, ions, and some water-soluble vitamins are rejected. Ultrafiltration membranes are completely impermeable to lipids and proteins and substances bound to them.

Ultrafiltration

Nearly all ultrafiltration membranes are asymmetric in morphology. It means they have a thin dense layer or skin (about 0.2 μm) on top of the membrane which defines the degrees of separation affected, and a spongy support layer (about 100 μm thick) underneath. These membranes are usually homogenous in material, in that they consist of the same polymer or copolymer throughout their structure. The following materials have been used successfully in the preparation of ultrafiltration membranes.

Cellulose Acetate (CA)

These were perhaps the first commercially developed ultrafiltration membranes. The CA membranes, however, are not used so widely now in ultrafiltration equipment because of the following limitations:

1. poor thermal (up to 35 °C) and chemical (pH range 3–7) stability;
2. poor tolerance to chlorine;
3. more susceptible to microbial spoilage than other types;
4. undergo creep or compaction to a relatively greater extent.

Polysulfone (PS)

Ultrafiltration membranes made of the tough, relatively inert polysulfone polymer are perhaps the most widely used currently in the food industry. In fact, polysulfone is considered a breakthrough for ultrafiltration principally due to its following advantages:

1. It can be operated at higher temperatures (up to 75 °C), with some manufacturers claiming that their PS membranes can withstand temperatures up to 125 °C.
2. It is compatible with a much wider pH range (0.5–13), and thus their cleaning is easy.
3. It is available in a wide range of pore sizes, ranging from 0.001 to 0.02 μm.
4. It has a better resistance to chlorine.

The only limitation of the PS membranes is that they can only be operated in a very narrow pressure range (170–700 kPa).

Mineral or Ceramic Membranes

The latest membranes on the market for ultrafiltration applications are mineral membranes. These are formed by the deposition of alumina, zirconia, carbon, or silver on to a microporous support of the same material. Since these are made up of inorganic materials, they are free from the disadvantages of polymeric membranes, such as narrow range limitations for temperature, pH, and operating pressure. The manufacturers claim that the ceramic membranes can withstand pressures up to 2.0 MPa without creep or compaction, and tolerate the whole pH range and temperatures up to 400 °C. The cleaning of these membranes is very easy. They can be sterilized by autoclaving. The limitations of ceramic membranes include their availability only in tubular configuration. The large pore sizes restrict their applications. Also, these membranes are very expensive.

Ultrafiltration Membrane Configuration

The commercial ultrafiltration plants are available in four designs, namely tubular, hollow fiber, plate and frame, and spiral wound. The general characteristics of each module are discussed here. Their advantages and drawbacks are listed in Table 2.

Tubular Module

Tubular modules were perhaps the earliest design of industrial-scale ultrafiltration equipment using synthetic membranes. In this module, the membrane itself may be cast directly on to a fiberglass tube, or they may be cast on to a separate paper tube which is then inserted into a perforated stainless-steel tube (Figure 2). Bundles of several individual membrane tubes are housed together in a stainless-steel shell. These modules have relatively large open-feed channels with internal diameters of 12–25 mm and lengths of 0.6–6.4 m. The feed solution, under turbulent conditions, flows inside each tube, whose inner wall contains the membrane. The permeate passes through the membrane and support material and is collected in the housing.

Hollow Fibers

These are in the form of self-supporting tubes with the dense 'skin' layer on the inside of the tube, the diameter of which generally ranges from 0.5 to 1.1 mm (Figure 3). Hundreds of these fibers, depending on fiber diameter and size of the housing, are sealed into a cartridge in a 'shell-and-tube' arrangement and bonded at each end into an epoxy tube sheet. The feedstream flows through the inside of the fibers and the permeate is collected on the outside. Each industrial cartridge may contain from 0.7 to 2.8 m^2 of membrane area. These are operated in laminar flow using high shear to control concentration polarization.

Plate and Frame

In this configuration, flat sheets of the membrane are placed between support plates which form flow channels over the membrane with heights in the range 0.5–2.5 mm. This arrangement is very similar to a conventional plate and frame filter press. The membrane and their supports are sandwiched together in

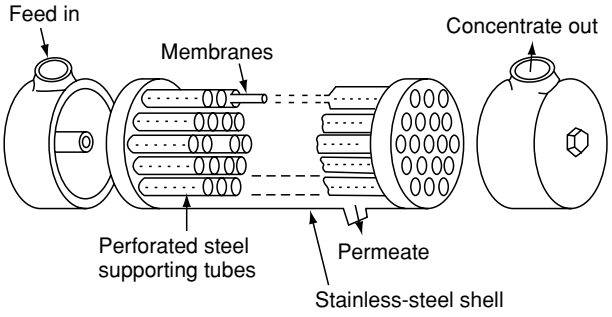

Figure 2 Tubular ultrafiltration module. Reproduced from Membrane Techniques, Principles of Ultrafiltration, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Table 2 Advantages and limitations of different ultrafiltration configurations

Configuration	*Advantages*	*Limitations*
Tubular	Handles suspended solids with larger particles Able to predict membrane performance using simple fluid dynamics Possible to replace individual membrane on site, so replacement cost is less Cleaning easy	Highest energy consumption per unit volume of permeate High pressure drop Lowest surface area-to-volume ratio, so needs maximum floor space Hold-up volume per unit area high
Hollow fiber	Energy consumption lowest among the modules Highest surface area-to-volume ratio, lowest hold-up volume Only module that allows backflushing	Since no support for the hollow fibers, operates in narrow pressure range (170–270 kPa) Fibers are susceptible to plugging Handling of large particles and suspended solids problematic Complete cartridge needs to be replaced in case of leakage, so replacement costs high
Plate and frame	Energy consumption moderate; less than tubular In case of leakage the particular membrane is replaced; so replacement cost is lowest Surface area-to-volume ratio and hold-up volume intermediate between tubular and spiral wound	Cleaning of membrane more difficult Initial capital costs relatively high
Spiral wound	Allows very high applied pressure without damage to the membrane Very economical in terms of energy consumption and membrane replacement Capital costs very low Surface area-to-volume ratio very high Low hold-up volume	Relatively difficult to process fluids having high suspended solids or fibrous matter Large particles may hang up in the mesh spacer, so causing cleaning problems High pressure drop

larger numbers (e.g., 180 spacer plates and 360 membrane sheets totalling 27 m^2 of active membrane area) to form one module. The plates containing membrane sandwiches on either side are generally horizontally stacked together in ultrafiltration plants, and the feed is pumped between the plates (Figure 4). The permeate may be collected either from each sandwich or together from the whole stack. Most plate units tend to be operated in laminar flow, although some wide-channel configurations could be under turbulent flow.

Spiral Wound

Like plate and frame, the spiral wound module also makes use of economical, flat sheet membranes. Two membrane sheets with a mesh-type spacer in between, to form the permeate channel, are pasted along three sides (appearing like an envelope). The fourth side is pasted to a perforated tube through which the permeate passes. Another mesh-type spacer is placed on top of the envelope and the whole arrangement is rolled around the perforated central permeate tube (Figure 5). The feed channel height is controlled by the thickness of the mesh-type spacer placed between two envelopes; spacers of 0.75–1.55 mm are common. The feed, under laminar flow, is pumped lengthwise along the unit, while the permeate is forced through the membrane sheets into the permeate channel and spirals its way towards the perforated central tube.

Operating Conditions

The processing parameters during membrane processes are optimized with a view to attaining maximum possible flux, which is the volumetric rate of flow of the permeate through the membrane. Four vital parameters that affect the flux during ultrafiltration processing are discussed here.

Pressure

For a particular membrane, the flux is directly proportional to pressure of the feed and inversely proportional to viscosity (the Hagen–Poiseuille's pore theory) and can be expressed as

$$J = A(\Delta P_t - \Delta\pi) \qquad (1)$$

where J is the flux ($l\,m^{-2}\,h^{-1}$), A is the diffusivity constant, ΔP_t is $P_f - P_p$ (P is the hydraulic pressure) and $\Delta\pi$ is the osmotic pressure. The subscript f refers to feed and p to the permeate. Since the osmotic pressure of the retained macromolecules in ultrafiltration is negligible, the flux is directly proportional to applied transmembrane pressure, i.e., $J = A\,\Delta P_t$. This relationship, however, holds true under ideal conditions only. When concentration polarization, associated boundary layer, and/or fouling takes place the flux becomes pressure-independent. The membrane itself also provides some resistance to the flux.

Feed Concentration

In the mass transfer-controlled region, the flux can be expressed employing the film theory as:

$$J = k\,\log_e(c_g/c_b) \qquad (2)$$

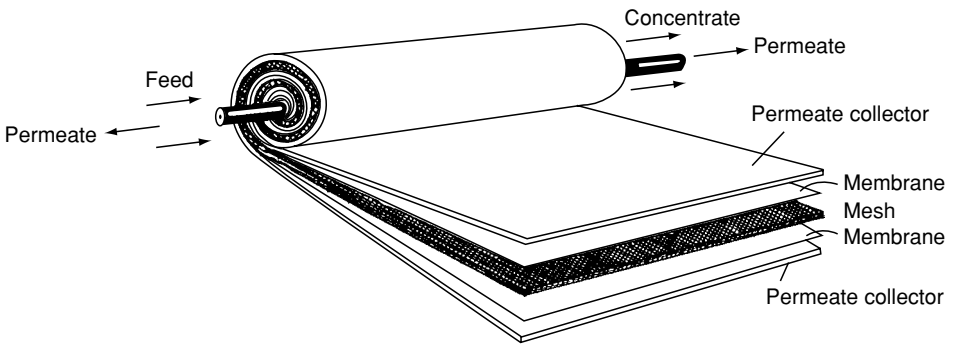

Figure 5 Spiral wound UF module. Reproduced from Membrane Techniques, Principles of Ultrafiltration, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

where k is the mass transfer coefficient, c_g is the concentration of gel at the membrane surface, and c_b is the concentration of solutes in the bulk. According to this theory, the flux should decrease with increasing feed concentration, and $J = 0$ when the concentration of solutes at the membrane and in the bulk are the same.

Temperature

A higher operating temperature reduces the viscosities of the feed and permeate and so increases the diffusivity. Thus it helps increasing the flux in both pressure-controlled and mass transfer-controlled regions. In general, it is best to operate at the highest possible temperature compatible with the feed and the membrane.

Feed Velocity

Higher turbulence has a major beneficial effect on flux in the mass transfer region. The higher the feed velocity (flow rate) across the membrane, the faster is the 'sweeping' of the built-up solutes away from the membrane surface, thereby reducing the thickness of the concentration boundary layer. Turbulence during the operation of ultrafiltration can be generated by stirring or by pumping of the feedstream.

Flux-Limiting Factors

The performance of membrane systems is generally gauged by the flux behavior. During ultrafiltration processing, the flux is lower than that of pure water. Concentration polarization and fouling are perhaps the main factors for this decline.

Concentration Polarization

During ultrafiltration, the solution is brought to the membrane surface by hydraulic transport. Because of the semipermeable nature of membrane, a portion of solvent, with or without some solutes, permeates through the membrane. This leads to a higher concentration of solutes at the membrane surface compared to the bulk. The building-up of the solutes on the membrane surface, known as concentration polarization, causes a steep concentration gradient within the boundary layer and results in a backdiffusion of solutes into the bulk. Eventually, a steady state is reached when the movement of the solutes towards the membrane by convective transport and their return to the bulk by diffusive transport balance each other. An increase in applied pressure will not help in this situation.

The solutes rejected by the membrane are usually deposited on the membrane surface in the form of a fairly viscous and gelatinous layer. This gel layer is considered to be mainly responsible for the lower flux, due to hydrodynamic resistance. When the concentration of solutes in the gel layer reaches the supersaturation point, fouling of the membrane begins.

Formation of the gel layer can be minimized by proper fluid management, such as (1) lowering the pressure, (2) lowering the feed concentration, and/or (3) increasing the feed velocity.

Membrane Fouling

The fouling of membranes is another major limiting factor in ultrafiltration processing. In contrast to concentration polarization, which is considered a time-independent, reversible process, fouling is an irreversible phenomenon. During fouling, flux drops with operating time, usually rapidly in the initial stages and slowly in later stages. Fouling is generally attributed to:

1. the accumulation or absorption of macromolecules or colloidal particles, such as proteins, lipids, microorganisms and/or inorganic salts, on the membrane surface;
2. the precipitation of permeable solutes, such as sugars and salts, due to overcrowding within the membrane pores.

The fouling of membranes not only reduces the flux but also makes the cleaning operation more difficult and expensive. The rejection properties of the membrane are also altered due to the formation of this secondary layer.

The fouling problem can be alleviated by proper: (1) selection of the membrane and plant design; (2) pretreatment of the feed; and (3) cleaning of the membrane. In fact, the pretreatment of the feed plays a most important role in reducing fouling problems, and differs from feed to feed.

In addition to concentration polarization and fouling, changes in membrane properties, either due to compaction or chemical deterioration, are also responsible for a decline of flux. The compaction of membranes generally takes place due to faulty operating conditions (high pressure and temperature), and the use of strong cleaning solutions is responsible for chemical deterioration.

Cleaning and Maintenance of Ultrafiltration Membranes

The most important consideration in cleaning and maintenance is never to allow the feed constituents to dry out on the membrane surface. While deciding on the cleaning schedule for an ultrafiltration membrane, the nature of the feed constituents that foul the membrane, and the recommendations of the membrane and detergent manufactures should be kept in mind. The following procedure can be adopted for routine cleaning of a membrane:

1. After the processing is complete, the feed stream is flushed out from the whole plant with water. The highest temperature of wash water compatible with the membrane should be used. Flushing is stopped when clear water starts coming out of the system.
2. Then a commercial detergent solution is circulated through the plant. For PS membranes, alkali (1%) and acid (0.5%) detergents are circulated one after the other. The addition of a sequestering agent, e.g., hexametaphosphate, to cleaning detergents is very beneficial. In the case of CA membranes and excessive fouling of PS membranes, the use of a proteolytic enzyme is essential.
3. After each circulation of detergent, the whole system is thoroughly rinsed with hot water.
4. To insure proper cleaning, the flux rate with water under standard conditions is tested. If the water flux is lower than the initial flux, step (2) is repeated.
5. The membrane is sanitized and stored in 0.5% formaldehyde solution. It is never allowed to remain dry. (*See* **Cleaning Procedures in the Factory**: Types of Detergent; Types of Disinfectant.)

Applications of Ultrafiltration

D Pal, National Dairy Research Institute, Karnal, Haryana, India

Introduction

The applicability of ultrafiltration has widened considerably because of substantial decrease in cost of membranes, availability of better designed units and decrease in fouling problem of membrane. It is now being used in diverse fields such as water treatment, chemical processing, food processing, and biotechnology. Dairy applications probably account for the largest share of installed membrane capacity. Current estimates suggest that over 300 000 m^2 of membranes are installed in the dairy industry worldwide. This article focuses on the use of ultrafiltration in the processing of milk and whey, clarification of fruit

juices and beverages, and some biotechnological applications.

Processing of Milk

The ultrafiltration process alters the chemical composition and physicochemical properties of milk. These changes are discussed here, with particular reference to cheesemaking.

Effect of Ultrafiltration on Chemical Composition

Ultrafiltration membranes are completely impermeable (about 100% rejection) to lipids and proteins and to all those substances associated with them. Hence their concentration in the retentate increases in proportion to the concentration factor. Since the rejection of lactose by ultrafiltration membrane is virtually zero, almost all of it passes into the permeate. This results in either the same or a lower concentration of lactose in the retenate than in the milk.

Most of the water-soluble vitamins pass through the membrane and their concentrations do not increase in the retentate. Vitamin B_{12} and folic acid bound with proteins and vitamins A, D, E, and K bound with fat become increasingly concentrated.

The rejection of minerals by ultrafiltration membranes depends on their nature and state in milk. Typical rejections can range from about 25% to over 90%. Calcium, magnesium, zinc, iron, copper, and phosphate are partly associated with the casein micelles and partly present in solution. Only the bound form of these minerals is concentrated in the retentate, while those in solution pass through the membrane. The net result is that the concentration of minerals in the ultrafiltration retentate increases, but not in proportion to the concentration factor. The nonprotein nitrogen (NPN) fraction, which consists of urea, amino acids, and ammonia, is not concentrated in ultrafiltration retentate. Table 1 shows the distribution of the major milk constituents in an ultrafiltration permeate and retentate. (*See* **Milk**: Dietary Importance.)

Factors like membrane composition, pasteurization, and/or homogenization of milk do not affect the rejection of components. However, treatments like acidification or changes in pH may alter the distribution of minerals, particularly calcium phosphate, between retentate and permeate. Diafiltration (that is, adding water to the retentate and its reultrafiltration) can reduce the concentration of both lactose and minerals in the retentate.

Change in Viscosity

The viscosity of the retentate increases during ultrafiltration in proportion to the increase in protein concentration, and a significant non-Newtonian behavior can be observed. Viscosity may increase up to 10 times by increasing the protein from 3 to 18% at 50 °C, and as high as 100 times at 15 °C. Hence higher operating temperatures are preferred during ultrafiltration. The increase in viscosity is higher for whole-milk retentate than for the skim-milk equivalent. As a consequence of high viscosity, the ultrafiltration retentate cannot be cooled quickly, and this may cause rapid growth of microbial contaminants. Another problem associated with high viscosity is that the entrapped air bubbles in the retentate are not released quickly, resulting in a spongy texture in cheese produced subsequently.

Influence on Fat Globules

Recirculation of pressurized whole milk during ultrafiltration processing damages the fat globule membrane; this leads to fat separation in the retentate during storage. The extent of fat separation depends on the quality of the raw milk and the characteristics of the plant. Such destabilization of fat globule membrane affects the textural properties of certain cheese varieties and other dairy products. Use of skim milk

Table 1 Distribution of major milk constituents between retentate and permeate during ultrafiltration

Constituents	*Retentate*			*Permeate*		
(%)	*1 ×*	*3 ×*	*5 ×*	*1 ×*	*3 ×*	*5 ×*
Total solids	12.9	28.6	43.3	5.7	6.1	6.7
Fat	3.9	12.6	21.8	0	0	0
Protein	3.1	9.8	16.1	0	0.06	0.49
Nonprotein nitrogen	0.18	0.18	0.18	0.18	0.19	0.19
Lactose	4.7	4.1	3.2	4.8	5.1	5.2
Ash	0.77	1.3	1.9	0.53	0.53	0.54

Data from Glover FA (1985) *Ultrafiltration and Reverse Osmosis for the Dairy Industry*, Technical Bulletin no. 5. Reading: NIRD.

for ultrafiltration and subsequently adding cream to the retentate may overcome this problem.

Effect on Proteins

Under normal operating conditions, casein and whey proteins are not normally affected by ultrafiltration process. Air incorporation into the retentate may however lead to denaturation of whey proteins at the air–water interface. Though low-temperature processing does not affect the whey proteins, ultrafiltration processing at high temperature (> 55 °C) even for a short period like 2 h may cause complexing of β-lactoglobulin with casein. Such complexing increases with residence time, concentration level, temperature, and amount of air entrapped. Diafiltration of retentate may also contribute to whey protein denaturation.

Effect on Starter Activity

Milk proteins and insoluble salts of calcium and phosphate, responsible for buffering action, are concentrated by the ultrafiltration process. Increased buffering capacity causes technological problems in the manufacture of cheese from highly concentrated retentate because a relatively large amount of lactic acid must be produced to obtain the desired pH. Consequently, the use of very active starter culture is necessary to produce the desired level of lactic acid; failure to reduce the pH would enhance the risk of growth of undesirable microorganisms in the cheese. (*See* **Starter Cultures**.)

Effect on Rennet Coagulability

The renneting time, in general, decreases as the concentration of ultrafiltration increases. The faster and more effective collision of micelles, due to the increase in protein content or increased calcium concentration, may result in more secondary-phase interactions and a decrease in clotting time.

Protein Standardization by the Ultrafiltration Technique

Protein standardization has now become an important international issue mainly because of the following reasons:

1. Seasonal and regional differences in protein contents of milk are inherent features which affect the quality and composition of products made therefrom, hence the need for equalizing protein.
2. Fortification of milk with total protein to increase the nutritional value.
3. Manufacture of total milk protein concentrates for use in special and dietetic foods.

Ultrafiltration can be used with great success for upward standardization of milk proteins in all the above-mentioned situations.

Cheesemaking with the Ultrafiltration Process

Several varieties of cheese are commercially produced employing the ultrafiltration process. Ultrafiltration helps to obtain a retentate with a composition identical to that of the desired cheese. Ultrafiltration technology offers the following advantages:

1. The increase in cheese yield is the most attractive benefit. In the traditional cheesemaking process, all the whey proteins and some casein fines, which account for nearly 20% of total milk proteins and some fat particles, are lost into whey. Ultrafiltration processing helps to retain all these constituents in the cheese. Though the actual increase in the yield depends on the level of concentration achieved during ultrafiltration and the type of cheese made, about 8% higher yield for hard cheese (e.g., Cheddar cheese) and up to 30% for semihard and soft varieties of cheeses is commercially obtainable.
2. Mechanization and automation of cheesemaking are possible.
3. The requirements for starter culture and rennet are reduced.
4. The amount of whey to be disposed of is either substantially reduced or completely eliminated, and the byproduct of the ultrafiltration process, the permeate, has many useful applications. Thus the biochemical oxygen demand (BOD) of the cheese waste steam is considerably reduced. (*See* **Effluents from Food Processing**: Composition and Analysis.)
5. The milk-handling capacity of existing cheesemaking equipment can be increased without increasing the vat size or floor area.
6. The overall energy requirements are low for the concentration of milk, as well as for heating and cooling the retentate.

Classification of Ultrafiltration Methods for Cheesemaking

Based on the levels of concentration achieved, the manufacture of cheese by the ultrafiltration process can be broadly divided into three categories.

Low-concentration factor (LCF) method Milk is usually concentrated up to twofold by ultrafiltration followed by cheesemaking employing traditional processes and equipment. Alternatively, milk is concentrated up to fivefold, and then used to supplement

whole/skim milk intended for cheesemaking to the extent that the concentration of solids in the supplemented milk does not exceed twofold the original level. The method can be used for most varieties of cheese without difficulty. The quality of cheeses produced from LCF retentate is generally identical to the traditional cheese. Better utilization of existing cheese vats and production of cheese of identical protein content throughout the year are two of the advantages of the LCF process. Since the drainage of whey occurs just as in the traditional cheesemaking process, the benefit of higher yield is not achieved. (*See* **Cheeses**: Chemistry of Gel Formation.)

High-concentration factor (HCF) method In the HCF process, milk is concentrated between three- and sixfold. Beyond sixfold it is not possible to concentrate milk with the present generation of membranes. Since many changes in composition and other properties of the retentate take place during high concentration, modified process and equipment are required for cheesemaking. This method is used for the manufacture of some hard and semihard varieties where partial drainage of whey is essential to achieve the desired total solids and/or for texturizing the product. The most successful commercial application of this process is in the manufacture of Cheddar cheese. Based on the fivefold concentration of milk, the CSIRO Dairy Research Laboratory, Australia and APV Ltd have jointly invented a commercial process for making Cheddar cheese (known as APV Siro curd process). Cheddar cheese made by this method is identical to traditional cheese.

Precheese method Skim milk or whole milk is concentrated up to the solids equivalent desired in the final cheese. There is usually no production of whey, which enables 100% utilization of whey proteins and casein in the final product. This process is based on completely new cheese technology and new equipment. A true precheese ultrafiltration process is most successful for the preparation of soft and semihard varieties, i.e., those cheeses containing more than 45% moisture, e.g., cream cheese, quarg, ricotta, feta, mozzarella, and camembert. (*See* **Cheeses**: Types of Cheese.)

Other Uses of Ultrafiltration Retentate

The ultrafiltration retentate can also be used in the manufacture of some other fermented dairy products like yogurt, shrikhand, and ymer. The ultrafiltration retentate can be spray-dried in the flush reason and utilized in the lean season for manufacturing cheese. Ultrafiltration in combination with diafiltration helps to produce highly purified food-grade proteins with low lactose content, and having highly improved functional properties such as emulsion capacity and foaming stability (Table 2). Such functional proteins are finding increasing applications in the food industry. (*See* **Drying**: Spray Drying.)

Table 2 Composition and functional properties of skim milk, ultrafiltered (UF) retentate (5 ×) and whole-milk protein isolates (WMPI) of cow and buffalo milk

Components	*Skim milk*		*UF retentate*		*WMPI*

Treatment of Whey

Whey is a byproduct of cheese and casein manufacture, and of the 6.5% solids present in whey, the proportions of protein, lactose, and minerals are 12, 75, and 9%, respectively. Small amounts of fat and some organic acids are also present. Whey is a heavy pollutant with a BOD as high as 50 000 p.p.m. Until the advent of membrane technology, whey had to be either drained into the sewers or given to livestock growers. Because of its very high water content, the processing of whey employing conventional evaporators and driers is highly uneconomical. The high lactose-to-protein ratio is another factor limiting the proper utilization of concentrated and dried whey. (*See* **Whey and Whey Powders**: Production and Uses.)

The development of the ultrafiltration process has undoubtedly proved a boon for the cheesemakers in the treatment of whey. The use of ultrafiltration to fractionate and concentrate whey proteins, followed by evaporation and spray drying, is now a well-established commercial process for the manufacture of whey protein concentrate (WPCs). WPCs prepared by ultrafiltration technology, having 35–80% protein, are now available commercially. WPC can be further separated into β-lactoglobulin and α-lactalbumin fractions, or used for the manufacture of casein macropeptide, a compound that may have pharmatherapeutic value. The main attraction of ultrafiltration for processing whey includes an almost 100% recovery of whey proteins for edible and other useful applications, with a simultaneous reduction in lactose content. It is possible to concentrate protein up to 20 times with a 95% reduction in volume; further increases in protein and reductions in lactose content are possible employing the diafiltration technique. The energy requirements for removing water from whey using the ultrafiltration process are minimal compared with any other dewatering techniques. Since ultrafiltration is carried out at low temperatures (about 50 °C), the native and functional properties of whey proteins are kept intact. The pollution load of whey is remarkably reduced and, in combination with reverse osmosis, the BOD value of whey can be reduced by about 98%.

Decline in the flux rate due to fouling of the membranes is the main limitation in processing of whey by ultrafiltration. In fact, whey is one of the most notorious foulants of all the fluid milk products. Some remedial steps to alleviate fouling problem are given below:

1. Whey should be separated and clarified before processing in order to remove suspended casein fines and lipid constituents.
2. In general, the flux is lowest at the isoelectric point of protein and becomes higher as the pH deviates from this point. A combined treatment of heating to 80–85 °C for 15 s followed by pH adjustment to about 3 or 7 is very useful for acid whey (casein whey); pH adjustment is not necessary for sweet whey (e.g., Cheddar cheese whey).
3. Complexing of proteins (e.g., casein micelles with β-lactoglobulin) by heat treatment or solubilization of proteins by either enzymatic treatment or the use of carboxymethyl cellulose is reported to increase the flux.
4. Salts, particularly calcium phosphate, exaggerate the fouling problem. Addition of sequestering agent, e.g., ethylenediaminetetraacetic acid (EDTA) or sodium hexamataphosphate, to an acid whey has a very beneficial effect on the flux. Partial replacement of calcium with sodium or its removal by a demineralization process may also be adopted.

Clarification of Fruit Juices and Beverages

Many juices and beverages contain colloidal and suspended solids which need to be removed before the product is marketed. It is economically feasible to use an ultrafiltration process for the commercial production of many 'single-strength' beverages. The principle behind the ultrafiltration clarification process is that the beverage flows over the membranes, and while the clarified beverage passes through the membrane in the form of permeate, the colloidal and suspended solids are rejected into the retentate stream. Hence, the permeate is the desired stream and the retentate is discarded.

Fruit Juices

Traditionally, press juice is subjected to pasteurization followed by enzymatic hydrolysis of pectin. Then a fining agent (gelatin) is added to the juice, and the suspension is held for about 20–30 h. After decanting, the juice is passed through a filter aid. The application of ultrafiltration to fruit juice clarification helps replace the holding, decantation, and filtration steps. All the undesirable components, such as pectin, large carbohydrates, and tannin protein complexes, which are responsible for cloudiness and sedimentation, are retained by the ultrafiltration membrane. Polyphenol oxidase, which causes browning of fruit juices, is also not allowed to permeate along with the clarified juice.

So far, the largest application of ultrafiltration in the juice industry has been in the production of apple juice; a flow diagram of the process in given in

Figure 1. Since microorganisms are larger than the pore size of the membranes, these are retained in the residue and the clarified juice is essentially sterile. The aseptic handling of this juice can either completely eliminate or substantially reduce the subsequent heat treatment prior to storage and bottling. It is also possible to minimize the losses of sugar and low-molecular-weight solutes by diafiltration of the retentate and blending of the permeate, after concentration, into the clarified juice. Other fruit juices that can be clarified by ultrafiltration include citrus, grape, cranberry, and pear.

Some of the potential benefits of ultrafiltration over the traditional processing of fruit juices are:

1. a superior-quality juice in terms of organoleptic properties and clarity can be produced;
2. it is possible to develop a continuous and automated process, thereby lowering production cost;
3. a marginally higher recovery of juice in the ultrafiltration process (95–98%) is possible in comparison with traditional processing (90–93%);
4. enzyme requirements can be reduced by more than half (as compared with the traditional process) because of partial depectinization;
5. waste disposal can also be minimized.

A major drawback of the ultrafiltration system is that it can only handle clear juices. Other problems such as reduction in flux, primarily due to fouling, is less in ultrafiltration than in microfiltration, which can be rectified by selecting the correct membrane material and configuration, and pretreating the feed.

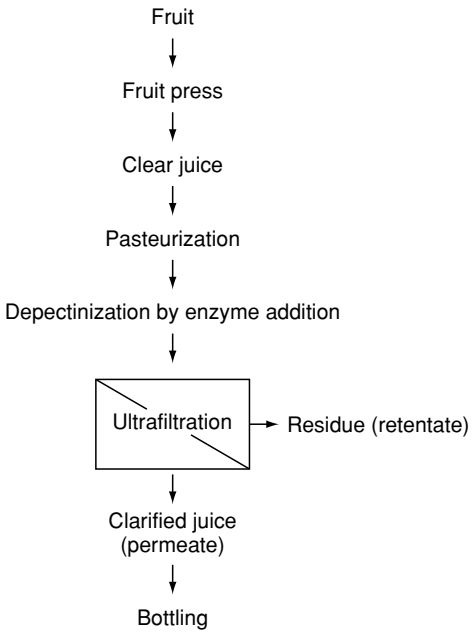

Figure 1 Flow diagram for clarification of apple juice.

Some vegetable juices, such as tomato, carrot, celery, and cucumber, can also be clarified by the ultrafiltration process with most of the advantages discussed above for fruit juices.

Wine and Beer

The application of ultrafiltration improves the organoleptic properties and stability of wine and beer. In wine production, a clear quality product is insured by treating either the must or the finished wine with ultrafiltration so as to remove undesirable microorganisms, stabilize proteins, and reduce the decolorizing and astringent-tasting polyphenol compounds, such as tannins. Other undesirable components, which otherwise require more expensive and time-consuming steps in conventional methods, are also removed by ultrafiltration membranes. (*See* **Beers**: Chemistry of Brewing; **Wines**: Production of Table Wines; Production of Sparkling Wines.)

Vinegar is produced by fermenting wine into acetic acid. After fermentation vinegar shows a slight turbidity due to low levels of polysaccharide and protein. Ultrafiltration is an ideal process for producing clarified vinegar with yield more than 97%. (*See* **Vinegar**.)

Biotechnology-Oriented Applications

Lately, membrane technology has been applied to the biotechnological processes. Ultrafiltration can be used to harvest microorganisms from fermentation broths with much higher recoveries than traditional filtration and centrifugation processes. For example, hollow-fiber ultrafilters can give 100% rejection of *Lactobacillus bulgaricus* cells in whey permeate fermentation broth. The fouling problem with ultrafiltration membranes during cell harvesting is less than with the microfiltration process. Ultrafiltration can be used for numerous applications related to the preparation of enzymatic hydrolysates from milk proteins, including:

1. the removal of enzyme and unhydrolyzed proteins from a reaction mixture;
2. the adjustment of the molecular-weight distribution profile of peptide mixture;
3. other compositional adjustments related to salts or free amino acids;
4. the removal of bitterness and antigenic molecules from casein and whey protein hydrolysate; and
5. the selective concentration of highly functional peptides.

Enzyme extracted from plant and animal tissues can also be purified by the ultrafiltration process. Ultrafiltration membranes containing immobilized enzymes or whole microbial cells function as continuous bioreactors. These bioreactors have been

reported to provide an opportunity for greatly improving the performance and productivity of fermentation. Ultrafiltration is also used for the production of high-quality water suitable for pharmaceutical and biotechnology purposes. The most efficient removal of pyrogens, bacteria, and particulates at low energy are the main advantages of ultrafiltration over other water treatment techniques. (*See* **Water Supplies**: Water Treatment.)

Other Applications

Other useful applications of ultrafiltration in the food industry include production of concentrates and isolates from soya, sunflower, and cotton seeds; removal of glucose from egg white and its partial concentration prior to drying; refining of sugar solutions; fractionation and concentration of gelatin, and many more.

MENSTRUAL CYCLE: NUTRITIONAL ASPECTS

F Ford, University of Sheffield, Sheffield, UK

Background

The effects of dietary intake on the menstrual cycle have been the subjects of a great deal of research, but many aspects are still poorly understood. The relationship between nutritional status and menarche will be reviewed, together with the influences of: body weight, body fat, dietary restraint, dietary fat and energy intake, lignans, isoflavones, vegetarianism, and PCB residues on the menstrual cycle.

Nutritional Status and Menarche

Some research shows that girls who experience early menstruation reach their mature height sooner than girls who experience late menarche (the onset of

menstrual periods). In one study, girls who ate primarily protein foods were shown to reach menarche sooner, and girls who eat primarily carbohydrates reached menarche later. However, in other studies of all the dietary variables analyzed, only energy intake was related to age at menarche. In a longitudinal study, girls who consumed more (energy-adjusted) animal protein and less vegetable protein at ages 3–5 years had an earlier menarche, and girls aged 1–2 years with higher dietary fat intakes and girls aged 6–8 years with higher animal protein intakes became adolescents with earlier peak growth. Controlling for body size, girls who consumed more calories and animal protein 2 years before peak growth had a higher peak growth velocity. These findings may have implications regarding adult diseases whose risks are associated with adolescent growth and development factors.

Body Weight and the Menstrual Cycle

It is well established that starvation and emaciation are almost invariably associated with amenorrhea (lack of menstrual periods), the most profound disturbance of the menstrual cycle. The work of Frisch in the USA identified the link between body composition and ovulation in the human female. She suggested that fat must comprise at least 22% of body weight for the maintenance of ovulatory cycles and also observed that in normal postpubertal women, fat is about 28% of body weight. It is well recognized that the relationship is to the fat content of the body rather than absolute body weight. Trained athletes of average or above average body weight may have a very low body fat content and may be oligo- or amenorrheic. Frisch observed that amongst trained athletes who became fit after a normal menarche, 60% continued regular cycles, but 40% had irregular cycles and presumably associated subfertility.

Eating disorders such as anorexia nervosa and bulimia nervosa are also causes of oligo- or amenorrhea. In anorexia nervosa, amenorrhea and failure to maintain a body weight within 15% of that expected are both diagnostic criteria. However, many women engage in pathologic dieting behaviors without meeting the current diagnostic criteria for anorexia or bulimia nervosa. Clinical eating disorders are only the most extreme form of pathologic eating attitudes and behaviors that are present in many young women. Specific food choices and nutrient intakes may be associated with altered gonadal hormone status of these dieters.

Extreme weight loss is not a prerequisite for menstrual cycle disturbances because dieting can induce missed cycles before substantial weight loss occurs. Even a very short-term (i.e., 4-day) acute energy shortage can interfere with luteinizing hormone pulsatility and thereby affect cycle function. In humans, dieting with minor or moderate weight loss has been shown to cause menstrual cycle disturbances or may be a risk factor for the development of reproductive dysfunction in normal weight healthy women. Cognitive factors may also be associated with the stability of the menstrual cycle. One such factor is cognitive dietary restraint, the perception that food intake is constantly being limited in an effort to control body weight. Menstrual differences between women with high and low restraint scores were detected in a number of studies. One study found that women with high restraint scores had significantly shorter cycle lengths, shorter luteal-phase lengths, and lower mean luteal-phase progesterone concentrations. In a group of women with a wide range of physical activity levels who were initially confirmed to ovulate normally, it was found that the luteal-phase length was shorter, without alteration of cycle length, in women with high restraint scores.

Cycle disturbances are associated with obesity as well as with energy shortages. A high prevalence of obesity among amenorrheic women was reported many years ago, and anovulatory cycles appear to be more common in obese women. Weight loss in obese women results in improved ovulation and pregnancy rates. It has been suggested that high androstenedione concentrations observed in obese women may activate the conversion of estradiol to estrone in adipose tissue. Estrone in turn may trigger higher luteinizing hormone concentrations, leading to ovarian hyperstimulation, thus increasing testosterone concentrations, resulting in anovulatory cycles.

The Nurses Health Study in the USA has also produced some interesting information about the relative risk of menstrual cycle irregularity not only in the underweight but also in the overweight woman. For women with a body mass index (BMI) below 20, at the age of 18 years, ovulatory infertility was found with a relative risk of about 1.2 compared to women with a BMI of 20–25. Interestingly, however, the relative risk of ovulatory infertility was 1.5 in those with a BMI of 28 and more than 2 in the obese group with a BMI above 30. About half of the risk is associated with polycystic ovarian syndrome, in which ovulatory infertility and obesity coexist, but there is still a doubling in relative risk of ovulatory infertility in women with a BMI above 30 who do not have ultrasonically detectable polycystic ovaries.

Energy Intake and the Menstrual Cycle

The biological regulation of appetite is currently an important topic in nutrition, because of its relationship with the increasing burden of obesity. Cyclical fluctuations in food intake occur in women across the menstrual cycle, with a periovulatory nadir and a peak in the luteal phase. These alterations in food intake, in response to ovarian steroid hormone changes, may be more than 2.5 MJ per day, with the mean reported changes shown in 19 separate studies of 1.0 MJ per day. Hormonally induced fluctuations in food intake could, therefore, contribute to energy imbalance and consequent weight gain. The regulation of food intake by menstrual cycle hormones suggests that it is essential to consider the phase of the menstrual cycle in studies of nutrient intake performed in women.

Vegetarian Women and the Menstrual Cycle

The question of whether menstrual disturbances are more common in vegetarian than in nonvegetarian women in complex. Three general mechanisms that could contribute to menstrual disturbances that may differ between vegetarians and nonvegetarians include energy imbalances associated with body-weight disturbances or exercise, psychosocial and cognitive factors, and dietary components. Although results from several cross-sectional studies suggest that clinical menstrual disturbances may be more common in vegetarians, a prospective study that controlled for many potential confounders found that subclinical disturbances were less common in weight-stable, healthy vegetarian women. Because the sample studied may not be representative of all vegetarian women, however, these results cannot be generalized. Population studies are needed to draw definitive conclusions.

Effects of Exercise on the Menstrual Cycle

Several prospective studies have shown that menstrual function does not change with exercise, provided that increases in activity are gradual, and body weight is maintained. This suggests that adequate energy availability may be a key factor in maintaining normal hormonal function with exercise.

A study was conducted to determine whether rigorous exercise training adversely affects ovarian hormone levels and bone health in cyclically menstruating trained runners. Results indicated that lower estrogen production, especially during the early follicular phase, but not progesterone, was associated with a lower whole body calcium per kilogram of soft lean tissue and probably bone mineral density.

Dietary Components and the Menstrual Cycle

Research suggests that concentrations of ovarian hormones or their metabolites may be lower at various points in the menstrual cycle in women consuming diets high in fiber, low in fat, or both. This is consistent with cross-sectional studies reporting inverse associations between hormone concentrations and fiber intake, direct associations between hormone concentrations and fat intake, and lower serum estrogen concentrations with a faster intestinal transit. It also corroborates the lower estradiol and progesterone concentrations observed in women 2 years after being randomly assigned to a low-fat, high-carbohydrate diet for a study in breast cancer risk reduction. However, the data must be interpreted cautiously because many experimental studies were conducted over only one or two menstrual cycles, and other data suggest that changes observed acutely may not persist over time. In addition, some subjects were free-living and others were housed in metabolic wards, which could affect the menstrual cycle differently.

Studies have been conducted to explore the effects of two classes of phytoestrogens, lignans and isoflavones. One study examined the effects of flaxseed powder, which is high in lignan precursors, in 18 women with normal ovulatory cycles using a randomized, crossover design. Each women followed her usual omnivorous, low-fiber diet for three cycles and then followed her usual diet supplemented with flaxseed powder for another three cycles. The last two cycles of each dietary period were compared. During flaxseed supplementation, luteal-phase lengths were significantly longer, and the ratio of progesterone to estradiol during the luteal phase was higher. Moreover, no anovulatory cycles occurred during flaxseed supplementation, but three anovulatory cycles occurred during the control diet period.

In another study, the effects of isoflavones were examined in six women with regular ovulatory cycles. It was found that diets containing 60 g of soy protein per day (with 45 mg of isoflavones) significantly increased follicular-phase length compared with control diets. Subsequently, they showed that a soybean product from which the isoflavones had been extracted had no effect on the cycle. Thus, lignans and isoflavones, two different classes of phytochemicals, appeared to have different effects: flaxseed lignans increased luteal-phase length and did not affect follicular-phase length, whereas soybean isoflavones

increased follicular-phase length but did not influence luteal-phase length.

Previous studies have suggested that high soybean intakes are associated with lower concentrations of serum cholesterol and may be related to decreased rates of coronary artery disease, cancer, and osteoporosis. One of the postulated mechanisms of these effects is that soy products, particularly the isoflavones in soy, act through changes in endogenous hormonal balance. Isoflavones significantly improved the lipid profile across the menstrual cycle in normocholesterolemic, premenopausal women. Although of small magnitude, these effects could contribute to a lower risk of developing coronary heart disease in healthy women who consume soy over many years.

Relationship Between Diet, Menstrual Hormones, and Breast Cancer

There is compelling evidence linking ovarian hormonal activity to breast cancer risk. Since the mid-1980s, dietary fat intervention studies have been conducted to investigate the effect of fat intake on endogenous estrogen levels. A meta-analysis of dietary fat intervention studies that investigated serum estradiol levels reviewed the nature of the evidence provided by prospective analytic studies of fat consumption and breast cancer risk. Results indicated that dietary fat reduction can result in a lowering of serum estradiol levels and suggest that a low-fat high-carbohydrate diet may reduce the risk of breast cancer by reducing exposure to ovarian hormones that are a stimulus to cell division in the breast.

Intake of soybean protein is associated with a reduced risk of breast cancer in a case-control study. It has also been demonstrated to increase menstrual cycle length in an experimental setting.

Most epidemiological studies of the relationship between alcohol consumption and breast cancer risk over the past decade have shown that persons who consume a moderate amount of alcohol are at 40–100% greater risk of breast cancer than those who do not consume alcohol. Dose–response effects have been observed, but no causal relationship has been established. However, it has also been shown that alcohol consumption in premenopausal women is associated with increases in total estrogen levels and amount of bioavailable estrogens. This may help to explain the relationship between the risk of breast cancer and alcohol intake.

Dietary Contaminants and the Menstrual Cycle

Highly contaminated Lake Ontario sport fish represent an important human dietary exposure to polychlorinated biphenyls (PCBs) and other toxic contaminants that may disrupt endocrine pathways. In one study, women anglers were interviewed by telephone to determine menstrual cycle length and fish consumption in order to calculate a PCB exposure index. Multiple regression analyses identified significant cycle-length reductions with consumption of more than one fish meal per month and a moderate/high estimated PCB index. Women who consumed contaminated fish for 7 years or more also had shorter cycles.

Menstrual Cycle and Iron-deficiency Anemia

Menorrhagia (heavy menstrual bleeding) is a benign yet debilitating social and health condition. The widely accepted clinical definition of menorrhagia is blood loss of 80 ml or more per period. This figure is derived from population studies that have shown that the average blood loss is between 30 and 40 ml, and 90% of women have blood losses of less than 80 ml. Excessive menstrual bleeding is the commonest cause of iron deficiency in the UK, affecting 20–25% of the fertile female population. Menorrhagia is a common problem accounting for 12% of all gynecological referral in the UK.

Conclusion

The evidence presented above appears primarily to show associations between dietary factors and the menstrual cycle rather than causation. What does, however, seem clear is that the relationship between normal ovarian hormone function and diet is complex and needs further evaluation from prospective rather than epidemiological research studies.

MERCURY

Contents

Properties and Determination

C J Cappon, Cappon Associates, Henrietta, NY, USA

Introduction

Mercury is probably the most ubiquitous heavy metal in the environment, resulting from natural geological activity and industrial pollution. Although it is extremely useful, it is also highly toxic, depending on its specific chemical form. The hazards of mercury and its compounds have been long known and of much concern. Its history as an occupational hazard has been linked to its elemental and divalent ionic – inorganic – forms, mostly due to volatility and skin contact. However, there has been much recent concern for widespread environmental contamination from organic mercury species, namely the alkylmercuries – methyl, ethyl-, and phenylmercury. Alkylmercury poisoning has been almost exclusively linked to methylmercury pollution of waterways and aquatic food sources, specifically in Japan, Sweden, and Canada. This has initiated several comprehensive worldwide analytical surveys of foods to assess human mercury intake levels and potential adverse health effects. It has also highlighted the critical need for more accurate and reliable mercury analytical methods for a variety of materials. Most modern methods involve mercury speciation separation schemes. This article discusses the environmental sources and toxicological impact of mercury in food, with special emphasis on analytical speciation

methodology – sample preparation procedures and instrumental techniques.

Uses of Mercury

Mercury has been utilized since antiquity. Although a comparatively rare element – ranking 16th from the bottom of natural element abundance – almost 3500 applications for mercury compounds are currently recognized. The major uses of mercury are summarized in Table 1.

Environmental Input and Speciation

Mercury in food can come from natural or human activities. Mercury from natural activities can enter air, soil, and water via weathering, dissolution, vaporization, and biological processes. Three oxidation states are possible in nature: metallic (Hg^0), mercurous (Hg_2^{2+}), and mercuric (Hg^{2+}). The two main categories of human mercury release are: (1) agriculture – run-off of excess pesticide application and absorption by vegetation roots and foliage; and (2) industry – waste-water discharge, disposal of solid waste containing mercury residues (thermometers, fluorescent lamps, labware, paints), burning of coal and petroleum-based materials.

Table 2 lists the specific mercury species that have been identified in air, soil, and water. Water is the most significant and direct source of food mercury contamination. Of special importance are the factors which favor highly toxic methylmercury formation in soil and water (including sediment), resulting in subsequent uptake by edible vegetation and animal food sources. In addition, biotransformation of methylmercury from inorganic mercury (and vice versa) can occur in specific marine and terrestrial food animal species.

Table 1 Uses of mercury

Dissipative	Paints, agriculture, dental, catalyst, pharmaceuticals, pulp and paper, metallurgy and mining
Recyclable	Chlorine and caustic soda production, electrical, measurement, laboratory

Table 2 Environmental mercury contamination: input sources

Agriculture	Fungicides and seed preservatives
Industrial	Chlorine and caustic soda production; amalgamation, pulp and paper preservative; catalyst for plastic production, pharmaceuticals (drugs, antiseptics); prints (fungicide), electrical and measurement instruments (thermometers, switches, neon lamps); power production (coal burning)
Geological	Weathering of rocks, volcanic activity

Occurrence and Speciation in Food

Mercury occurs in a wide variety of foods, most commonly fish and seafood, where the typical total mercury concentration range is 0.05–3.0 p.p.m. (fresh weight). Grain and dairy products, animal meats, and certain vegetable crops usually have a lower and narrower range (0.01–0.05 p.p.m.). There is no reported evidence of external mercury contamination of food during processing, packaging, or storage, so that food mercury content results solely from the natural and human sources previously identified.

In the mid-1960s, methylmercury was identified as the major mercury species in fresh-water and marine fish. Since the early 1970s, several comprehensive analytical surveys of total, inorganic, and methylmercury content of fish and other types of seafood have been undertaken. Methylmercury levels in the edible fillet of most fish species is typically 70–95% of the total mercury content. Methylmercury contents below 50% have been reported for a limited number of fish samples. A notable example is Pacific blue marlin, the only pelagic species having a large amount (> 80%) of total muscle mercury present as inorganic compounds. Inorganic mercury also predominates in shellfish (molluscs, crustaceans) and other nonfish species (e.g., octopus, squid). Other common organomercurials – ethylmercury and phenylmercury – are generally not found in seafood. (*See* **Fish**: Spoilage of Seafood; **Shellfish**: Contamination and Spoilage of Molluscs and Crustaceans.)

Mercury content and speciation have also been reported for other food sources. Some examples include marine mammals (seal, whale), terrestrial wild and domestic animals (chicken, otter, beaver, deer), and vegetable crops. Regarding edible vegetation, mercury uptake and methylmercury percentage are enhanced in the tuberous and leafy regions of crops grown on sludge- and compost-treated soil. Compared to the relatively low mercury concentrations in edible vegetation, mushrooms and related fungi accumulate higher amounts of total mercury and methylmercury.

Table 3 summarizes mercury levels and speciation in a variety of foods.

Impact of Mercury in the Environment

Knowledge of mercury speciation is very critical when evaluating the impact of environmental mercury pollution and consumption of mercury-contaminated food, since different chemical forms of

mercury have different metabolic and biotransformation properties which influence their overall toxicity.

Historically, mercury poisoning has been a well-documented occupational hazard. However, it was only well into the twentieth century that specific outbreaks of environmental mercury poisoning demonstrated that specific mercury species could exert serious health effects on exposed human populations. Examples of major outbreaks are: (1) Japan (Minamata, Niigata), from the mid-1950s to the early 1960s from ingestion of contaminated fish and shellfish from waters polluted by industrial discharges; (2) Sweden and Canada, in the mid- to late 1960s, from similar but milder cases of industrial pollution; and (3) Iraq in the early 1970s, from ingestion of grain and grain products originating from seed treated with a mercury fungicide. In each case, methylmercury was the causative agent.

Environmental mercury – whether from natural or human activities – will continue to enter the human food chain. Presently, the aquatic food chain is more susceptible than the terrestrial food chain. However, the ability of mercury to undergo biotransformation to more toxic organic species in various environmental compartments (air, soil, aquatic sediment, water, animal tissue) justifies the essential need to evaluate mercury speciation when assessing mercury contamination of foodstuffs. Therefore, any analytical methodology for mercury must be capable of qualitative and quantitative determination of specific mercury species found in food.

Properties and Effects of Food Preparation

Introduction

Environmental mercury species that eventually become incorporated in food may be classified as inorganic or organic. This section considers the specific physical and chemical properties of the various forms that would also allow the element to enter the food chain. The effect of food-processing methods on mercury content and speciation will also be discussed.

Properties of Mercury Species

Inorganic The two inorganic forms are elemental and ionic, the latter commonly occurring as the divalent species Hg^{2+}. The high vapor pressure of elemental mercury renders it quite volatile from water and soil surfaces. However, it is readily soluble in these media in the whole range. It is readily oxidized to Hg^{2+} by bacterial action or chemical oxidizing agents. Divalent inorganic mercury can form insoluble salts with the ions O^{2-}, Cl^{-}, I^{-}, and S^{2-}, rendering it less mobile and bioavailable to food-chain organisms. However, its solubility and bioavailability can be enhanced through complex formation with Cl^{-}, CO_3^{2-}, and OH^{-} ions, with ammonia and chelation with humic substances. An acidic pH environment will also enhance its solubility. Divalent mercury can be reduced to elemental mercury by interaction with bacteria, specific inorganic reducing agents, and sunlight. It also binds strongly to sulfhydryl (– SH) ligands on plant and animal tissue proteins. Monovalent mercury (Hg_2^{2+}) can originate in the environment from Hg^{2+} disproportionation, but the predominance of oxidizing conditions in water and soil insures its transformation to Hg^{2+} species.

Organic Of all the possible organomercurials, the monomethylmercury ion (CH_3Hg^{+}) is the most common environmental species. It originates from Hg^{2+} through bacterial synthesis, organic oxidants, and chelation. Its formation from Hg^{2+} in natural waters is optimized at low salinity. It also has a high affinity for sulfhydryl ligands on tissue proteins, but these protein complexes rapidly break down at very low pH. Its solubility – and bioavailability – in soil and water is enhanced by its ability to

complex with anions (mostly OH^-, Cl^-) and humic materials. Under conditions of very low (< 2.0) or very high (> 11.0) pH, the methylmercury ion is converted to inorganic mercury via bacteria or by sunlight. Dimethylmercury is the only divalent organic form commonly reported. Its higher volatility allows it to exist mostly in air. However, acidic conditions cause it to convert readily to monomethylmercury.

Impact of Food Preparation

Little is known about the influence of food processing (dehydration, steaming, preservation, and other additives), storage (packing medium and container material, temperature, time period), and cooking (backing, freezing, smoking) techniques on mercury content and speciation in food. Infact, little is known about the exact chemical nature of inorganic mercury and methylmercury in food that may influence their relative bioavailability.

Processing Research from the author's laboratory concerning the distribution of inorganic mercury and methylmercury in processed and nonprocessed fish and seafood revealed different mercury distribution patterns. Freshwater and older processed (canned, > 5 years' storage) marine fish had the majority (55–90%) of total mercury tissue content in a water-extractable form. Only 22–47% was extractable for nonprocessed and newly processed (< 2 years' storage) samples. Water-extractable mercury is of interest because it represents mercury bound to lower-molecular-weight tissue proteins or unbound (neutral, ionic) species. Such species may be more readily absorbed from the intestine into the blood stream, thus having higher bioavailability. These specific mercury distribution patterns possibly result from differences in the mercury source and form in marine and fresh-water food chains.

Storage The above marine fish mercury distribution pattern suggests that food storage time may have a greater impact on tissue mercury form and distribution than food processing. Although processing may initiate a change in mercury distribution, further changes can occur over an extended storage period. Samples of canned tuna and seafood showed no apparent effect of packing medium (water, oil) on the percentage of water-extractable mercury. Both types of packing media contained mostly inorganic mercury, but this represented a very small fraction (generally < 2%) of the corresponding total mercury sample content.

Cooking Broiling, baking, or smoking fish meat does not alter the total and methylmercury content. However, smoking increased the methylmercury percentage in brown trout fillets. (*See* **Smoked Foods: Principles.**)

Analysis: Sample Preparation

Introduction

Sample preparation is a key component in any analytical procedure, yet it is often the most time-consuming to conduct and optimize. Ideally, it should be simple, rapid, reproducible, provide quantitative analyte recovery, and effectively remove all interfering substances prior to instrumental assay. The specific sample preparation procedure used depends on: (1) complexity of the sample matrix; (2) physical and chemical properties of the desired mercury species; and (3) the instrumental technique. For food analysis, the sample matrix may be relatively simple (water, beverage) or quite complex (vegetation, soft tissue). For total mercury analysis of food, sample preparation is greatly simplified by the use of mineral acid (nitric, perchloric, sulfuric). However, mercury speciation usually necessitates more elaborate solvent extraction, clean-up, and analyte isolation steps.

Sample Preservation and Storage

Preservation of total mercury concentration in aqueous samples is critical, especially at microgram per kilogram levels. The major mercury loss occurs by conversion of Hg^{2+} (and Hg_2^{2+}) to elemental vapor and subsequent loss to air. Another source of loss is from adsorption of mercury on the container walls. Several factors affect mercury preservation, and include mercury concentration, container type, method of container cleaning, and types of oxidizing/complexing agents used as preservatives. Generally, low pH, high ionic strength, acidic (nitric or sulfuric acid) dichromate as an oxidizer/preservative insures optimum mercury preservation. Acid-washed containers of Teflon, polypropylene, polyethylene, Pyrex, and soft glass are satisfactory for mercury storage and preservation. Methylmercury preservation in aqueous solutions requires storage in acid-washed polytetrafluoroethylene (PTFE) containers under slightly acidic pH as optimum conditions for long-term preservation.

The need for mercury preservation in solid food samples is less demanding since nearly all of the mercury – organic and inorganic – is tightly bound to tissue proteins, which minimizes absorption and

volatilization losses. However, to minimize mercury biotransformation – especially organomercury breakdown – by bacterial activity, all food and beverage samples should be kept frozen (−20 °C) until analysis preparation.

Sampling

Sample homogenization is a convenient way to insure that a more representative subsample will be obtained for analysis. This is commonly achieved using a blender and/or homogenizer, after which the sample is sieved using 30–40 mesh. Deionized, organic-free water is then added and the homogenate is further mixed to a more uniform texture. However, care must be taken not to contaminate the food sample through contact with the container walls. A more recent sampling procedure which further enhances sample homogeneity is digestion with a mixture of 40–45% sodium hydroxide (50%), 1% cysteine, and 1% sodium chloride. This is the basis for preliminary sample preparation in several (vapor atomic absorption spectroscopy (VAAS) and gas–liquid chromatography (GLC)) extraction procedures. Alternatively, for samples having mercury levels approaching the lower detection limit of a given method, lyophilization provides a dry powder more concentrated in mercury.

Sample Extraction

Total mercury Most food sample preparation procedures for total mercury involve various degrees of chemically treating the sample (i.e., wet ashing). This is mandatory since inorganic and organic mercury are essentially volatilized by dry ashing. Wet ashing with mineral acids usually destroys organic matter, which can sometimes produce interferences, depending on the instrumental technique being used. Acids and acid mixtures that have been used successfully and produce negligible mercury loss are: perchloric, nitric, sulfuric; nitric/sulfuric/perchloric, nitric/perchloric, sulfuric/nitric. With the acid mixtures oxidants such as hydrogen peroxide, permanganate, and vanadium oxide have also been used. Loss of mercury can be minimized by refluxing/condensing the acidic digest vapors.

Mercury speciation Since organomercury species are readily degraded to inorganic mercury under the drastic acidic and oxidizing conditions for total mercury, much milder digestion conditions are required. In food samples, any protein-bound inorganic mercury and organomercury requires an acidic medium (usually hydrochloric, hydrobromic, and sulfuric acids are employed) for liberation prior to solvent extraction. Depending on the complexity of the original sample, one or more organic solvent cleaning steps are usually required. Aqueous or ethanolic thiosulfate is the most widely used cleanup reagent because of its rapid quantitative extraction of organomercurials. The organic mercury species are usually isolated either as a volatile halide derivative (chloride, bromide, iodide for GLC assay) or as a water-soluble thiol complex (for high-performance liquid chromatography (HPLC) assay). Typical overall organic mercury recoveries are 70–100%.

Inorganic mercury assay by GLC requires prior derivatization of the nonvolatile inorganic species into a volatile organic form. Reagents that have been used for this purpose are listed in Table 4. Cold VAAS (CVAAS) employs specific reagents – tin chloride and cadmium chloride – to convert separately inorganic mercury and both inorganic and organic mercury, respectively, to elemental mercury.

All of the above wet-ashing procedures can be partially or fully automated. This has been successfully implemented for CVAAS. Semiautomated headspace analysis has been used for GLC analysis of methylmercury in biological samples.

Table 4 Modern mercury speciation techniques

Technique	*MDL*
Gas-liquid chromatography (GLC)	
Detector	
Electron capture (ECD)	5–200 pg
Atomic absorption (AA)	0.1 ng
Microwave-induced plasma (MIP)	0.2–0.6 pg
Direct-current plasma (DCP)	0.5 ng
High-performance liquid chromatography (HPLC)	
Detector	
Electrochemical (EC)	40 pg
Atomic absorption (AA)	0.1 ng
Inductively coupled plasma (ICP)	0.3–0.7 ng
Ultraviolet (UV)	0.5 ng
Atomic absorption spectroscopy (AAS)	
Mode	
Cold vapor	0.02 ng
Graphite furnace	0.05 ng

MDL, minimum detection limit.

Analysis: Instrumental Techniques

Because of environmental and toxicological considerations, most modern mercury analysis methods for food emphasize speciation instead of total element assay. Therefore, this review will highlight modern mercury speciation techniques and summarize classical – total mercury – techniques.

Total Mercury Techniques

Numerous analytical methods for total mercury in biological media are summarized in Table 5.

Table 5 Early mercury analytical techniques

Total mercury	*Chromatographic speciation*
Titrimetric (indicator, thermometric, amperometric, potentiometric)	Ion exchange
Neutron activation analysis	Thin-layer
Spectrophotometry	Paper
Catalysis	Column
X-ray fluorescence	Radiochemical
Polarography (alternate current, anodic stripping voltametry)	
Atomic spectroscopy	
Absorption (flame, furnace, cold vapor)	
Emission (inductively coupled plasma, fluorescence)	

While many of these methods are still reliable, they suffer from major limitations which render them unsuitable for routine analysis of food samples: (1) they cannot accurately detect or measure mercury at low levels (micrograms per kilogram), which are normally background levels in foods; (2) they cannot be adopted for speciation; and (3) most are time-consuming and are subject to numerous inorganic and organic interferences from the sample matrix. In addition, some techniques – X-ray fluorescence (XRF), neutron activation – require the use of expensive specialized equipment and skilled operators.

Mercury Speciation Techniques

Chromatography Chromatographic methods provide specific identification of the form in which mercury is present. Early methodology in this area was primarily intended for sample purification prior to mercury determination by other methods. These early techniques are listed in Table 5. The microgram detection limits and time requirements have greatly restricted their routine application. Modern chromatographic mercury speciation techniques for food analysis are GLC and HPLC. Both are highly powerful and sophisticated techniques which demand more technical attention and skill for optimization and routine operation. However, they can be highly automated in terms of sample preparation and introduction, operation, and data processing. Each technique is summarized in Table 4.

GLC has been the most widely used chromatographic method for routine mercury speciation. It was initially used for this purpose in the mid-1960s, being applied to water, fish, and related seafood samples. The major focus was on methylmercury, the most toxic chemical form. Eventually, ethyl-, phenyl-, and inorganic mercury were also included. Currently, conventional (i.e., packed) column chromatography coupled with electron capture detection (ECD) is still the most commonly used GLC system. However, recent significant improvements in GLC mercury speciation involve the use of capillary columns and element-specific detectors. Capillary columns exhibit enhanced performance over packed columns – greater separation efficiency and shorter analysis times. Wide-bore (0.53 mm internal diameter) based silica capillary columns are the most popular compared to narrower-bore and borosilicate glass columns. During the 1980s atomic emission and absorption spectroscopic detectors began to be used more for GLC mercury speciation. These detectors provide better elemental selectivity and sensitivity compared to ECD, along with freedom from contaminant interferences. (*See* **Chromatography**: Gas Chromatography.)

HPLC mercury speciation application to food analysis has been more recent. However, its use has increased significantly since the late 1970s. Key reasons for this are due to the advantages of HPLC over GLC: (1) no analytical restrictions on sample volatility and thermal stability; (2) more versatility in optimizing instrument operation parameters because of specific separation modes (normal-phase, reversed-phase, ion exchange), wide selection of mobile phases, and use of solvent and flow gradient programming; (3) sample derivatization can be performed using precolumn, on-column (*in situ*) or post-column techniques. This greatly simplifies sample preparation; and (4) larger sample extract volumes can be injected, typically, up to 250 μl against 10 μl and 1 μl, respectively, for packed and capillary column GLC. Recently, the availability and application of more sensitive and element-specific detectors have allowed HPLC to be a more viable mercury speciation alternative to GLC. These include electrochemical (EC) and atomic spectroscopic (AAS, inductively coupled plasma (ICP), and microwave-induced plasma (MIP)) detection. Because of cost, simplicity, and commercial availability, the EC detector is the most widely used. Currently, reversed-phase chromatography (RPC) using conventional analytical columns with 5 or 10 μm C_{18} packings is the most commonly used HPLC separation mode for mercury speciation. The polar aqueous-based mobile phase is compatible with the newer selective detectors and offers greater flexibility in optimizing analyte resolution. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Atomic Spectroscopy

Two modes of this technique – CVAAS and graphite furnace (GFAAS) – have been successfully applied to

routine assay of biological materials containing low levels (microgram per kilogram) of organic and inorganic mercury. While neither mode can identify the exact form of organic mercury, they are still useful if one considers that methylmercury is by far the predominant organomercury species in foods and most other biological materials. CVAAS is the more commonly used technique. It selectively reduces inorganic mercury to mercury vapor via tin chloride, while both inorganic and organic mercury (i.e., total mercury) are reduced via cadmium chloride with tin chloride. Organic mercury is calculated by difference. The total sample aliquot as its acid or alkaline digest is normally used. In GFAAS, mercury (organic/inorganic) is released as mercury vapor during absorption or thermal decomposition of the total sample aliquot. However, it requires prior separation of both mercury forms using extraction procedures similar to those of GLC, and the use of special matrix modifiers to facilitate volatilization removal of chemical interferences.

Both techniques have distinct advantages over GLC and HPLC in the area of mercury speciation: (1) the entire sample/aliquot can generally be used; (2) they are less subject to matrix interferences, thus simplifying sample handling and eliminating the need for solvent clean-up. They can also be more extensively automated regarding sample handling, mixing, and injection. Increased sample throughput is also a major advantage.

Recently, isotope dilution inductively coupled plasma–mass spectroscopy (ICPMS) using flow injection analysis has been successfully applied to determining organic mercury in seafood. This technique offers lower detection limits, freedom from spectral interferences, and rapid sample throughput. As with GFAAS, it does require prior isolation of RHgCl from the sample. (*See* **Mass Spectrometry**: Principles and Instrumentation.)

Mercury's environmental ubiquity and specific chemical properties allow the element ease of entry to the human food chain in several chemical forms. The resulting long-term health and economic impact man-dates the use for mercury analysis of modern instrumental analysis techniques which are capable of qualitative and quantitative mercury speciation at submicrogram per kilogram levels. Currently, such methods include GLC, HPLC, and flameless AAS (CVAAS, GFAAS).

Toxicology

G L Klein and W R Snodgrass, The University of Texas Medical Branch, Galveston, TX, USA

Introduction

This section will cover the absorption and bioavailability of mercury, its distribution within and excretion from the body, the mechanisms involved in its harmful effects, toxic levels in humans, and accepted treatment.

Absorption and Bioavailability

Since mercury is a toxic heavy metal with no known role in normal metabolism, absorption must be interpreted in the broadest possible terms. Vapor inhalation, enteric ingestion, and skin contact are the chief routes by which mercury enters the body. A more recent concern has been mercury contamination of hepatitis B immune globulin as well as the adjuvant for the hepatitis B vaccine. Inhalation of mercury

vapor may come from its release from 'silver' dental amalgams, which are approximately 50% mercury, and from which vapors are released into the mouth by chewing or brushing the teeth. Humans have been documented to absorb a mean of 10 μg day^{-1} from this source, with a range of 1.2–27 μg day^{-1}. Metallic mercury, as a contaminant of latex paints, batteries, or electrical industrial equipment, vaporizes and, either in its metallic or inorganic form, is almost totally absorbed across the pulmonary alveolar membrane, perhaps owing to its high lipid solubility. (*See* **Heavy Metal Toxicology.**)

Toxicology

The mechanism of mercury absorption across the skin from topical application of various fungicidal preparations is uncertain. Absolute absorption rate increases directly with increasing topical mercury concentration, until a plateau is reached. (*See* **Fungicides.**)

A major organic salt of mercury, methylmercury, is approximately 100% absorbed in the intestines of humans and mice, while inorganic mercury salts (mercurous and/or mercuric) are only about 15% absorbed in human volunteers. Mercury is primarily concentrated in the aquatic food chain as a result of release of inorganic mercurials as industrial contaminants into either salt or fresh water. The inorganic mercury compounds are acted upon by methanogenic bacteria, producing methyl mercury. As such, it is taken up by various forms of sea life and enters the human food chain by direct consumption of fish and other seafood. It has been suggested that high selenium concentrations in fish can be protective against methyl mercury toxicity. There is intracellular colocalization of mercury and selenium and both have been reported to be bound in a complex with a plasma protein. Methylmercury can also enter the human food chain indirectly by means of human consumption of poultry and hens' eggs when the poultry have been raised on mercury-contaminated fish meal. (*See* **Fish Meal.**)

Distribution and Excretion

It is thought that the broadest exposure to mercury now comes from mercury vapors from dental amalgams. Studies in sheep and cynomolgus monkeys have demonstrated large concentrations of mercury in the mandible, kidneys, and liver. Significant concentrations have also been found in brain tissue. In pregnant sheep, fetal tissues begin to accumulate mercury within days of amalgam placement in the mothers and fetal tissue accumulation increased progressively during gestation. In monkeys a significant quantity of mercury has also been found in bile and in the colon. With methylmercury the distribution is similar but more uniform. There is a significant difference between methylmercury and inorganic mercury with regard to the red cell-to-plasma ratio (i.e., the distribution between red blood cells and plasma), with methylmercury in erythrocytes approximately 10-fold higher than inorganic mercury. This difference in concentration may affect the interpretation of urinary mercury excretion since it may affect the amount of mercury available for filtering through the kidneys. Furthermore, there is a great deal of interspecies variability in the red cell-to-plasma concentration of methylmercury, with the rat having the greatest and humans the least. Interestingly, the rat has the highest blood–brain mercury ratio, while humans have the lowest.

While mercury is excreted primarily by the urine, its appearance in the bile and colon after ingestion of dental amalgam vapor by monkeys suggests that the intestine is another source of mercury elimination. The mercury body burden varies directly with the excretory half-time. Thus, humans, with an excretory half-time of 70 days, develop steady-state tissue levels of mercury 10 times that of the mouse, which has an excretory half-life of only 7 days. However, this is merely an illustrative point because, based on autopsy data of brain mercury concentrations in two human beings after 15–25 years of Minamata disease, the true mercury excretory half-life in humans may be much longer than 70 days.

The excretion of mercury has been studied in rats, and three steps have been identified. The initial rapid phase involves approximately one-third of the total dose, lasts a few days, and is associated with high concentrations of mercury in liver and feces. The two slower phases involve the remaining two-thirds of the mercury intake and have a combined excretory half-life of approximately 130 days. These slower excretory phases are primarily associated with urinary excretion of mercury. Mercury is probably also excreted by the renal tubules and not the glomeruli. Mercury may bind to sulfhydryl groups within the tubular cells and, during excretion, damage to the tubular cells could trigger the exfoliation of mercury-containing tubular cells with a resultant increase in urinary mercury excretion.

Binding to metallothionein may play a protective role in both liver and kidney. In liver, biliary mercury excretion is reduced with a high-zinc diet, suggesting that zinc induces metallothionein to bind mercury and the biliary excretion of mercury is primarily related to nonmetallothionein-bound mercury. In kidney, administration of mercury to rats is

associated with an increase in urinary metallothionein. (*See* **Zinc**: Physiology.)

Mechanisms of Toxic Effects

Once absorbed from the digestive and respiratory tracts, or absorbed transcutaneously, mercury produces a variety of symptoms affecting the marrow, kidneys, skin, and blood cells. In children it produces a syndrome complex called acrodynia, or 'pink' disease. Acrodynia is characterized by redness of the lips and pharynx, loss of teeth, a strawberry tongue, swelling, redness, and desquamation of the skin, with pink or red fingertips, palms, and soles. Redness of the conjunctival membranes, photophobia, cervical lymph node enlargement, joint pain, loss of appetite, and vascular thromboses are also observed. Neurological manifestations include irritability, apathy, withdrawn behavior, proximal muscle weakness and hypotonia, and diminished reflexes.

Methylmercury ingestion, which has occurred twice in Japan and in Iraq on epidemic scales, produces acute and sustained neurotoxicity. In exposed infants, cerebral palsy-like symptoms developed, including psychomotor retardation, microcephaly, spastic or flaccid paralysis, ataxia, athetotic movements of the hands, constriction of the visual fields, and generalized tonic convulsions. *In utero* exposure can result in distinct toxicity to the embryo, including low birth weight, dysplasias of the cerebral and cerebellar cortices, and an abnormal migratory pattern of neurons. Gross findings, such as severe mental retardation, have been reported in these epidemics, as have more subtle findings, such as failure to achieve developmental milestones, observed on follow-up studies.

Occupational exposure to mercury vapour has led to acute cases of respiratory distress, renal failure requiring dialysis, and severe oropharyngeal inflammation and a 'flu-like' syndrome. With more prolonged exposure, proteinuria develops. The hypothesized mechanism for proteinuria is stimulation by mercury of T lymphocytes to produce an antibody to the glomerular basement membrane. This may be mediated in part by mercury binding to nucleoprotein of T lymphocytes. However, it has recently been shown that methylmercury induces T-cell apoptosis (programmed cell death), possibly by damaging mitochondria and inducing oxidative stress that activates pathways for apoptosis.

Neurological symptoms in workers exposed to mercury 20–35 years previously have included reduced muscle strength and coordination, increased tremor, decreased sensation, and increased prevalence of abnormal reflexes. It is hypothesized that progressive neuron loss with aging may unmask previous exposure to mercury. Furthermore, mercury has been demonstrated to persist in neurons for many years after exposure has ceased. A survey of workers previously exposed to mercury failed to reveal any impairment of reproductive function.

Also of interest, although not directly observed in humans, *in vitro* experiments with human platelets have shown that mercury can produce platelet aggregation and increase production of eicosanoids by platelets. Increased platelet aggregation may contribute to the thrombus formation seen in acrodynia as well as some of the neurological structural abnormalities produced by hemorrhages in the brain secondary to mercury exposure of animals. Despite the considerable exposure to mercury from dental amalgams, no toxicity has yet been reported in humans resulting from this exposure.

In animals, toxicity is of a similar nature to that observed in humans. Rats given mercuric chloride intravenously develop complete proximal tubular necrosis. If given a high-protein diet 48 h prior to mercury ingestion, they develop only partial proximal tubular necrosis, and blood urea nitrogen and creatinine concentration are normal. Mechanisms for renal injury are, at least in part, felt to be autoimmune. Mercuric chloride administration to the brown Norway rat not only resulted in production of antiglomerular basement membrane antibodies but also induced a rise in CD4+ splenocytes, CD4+ and CD8+ (helper and suppressor) T cells, and B lymphocytes in peripheral lymphoid organs. In glomeruli there was an increase in CD8+ (suppressor) T lymphocytes. These findings suggested that the mechanism for autoimmunity is T lymphocyte-dependent. Glomerular basement membrane autoantibodies are both immunoglobulin G (IgG) and IgM, detectable 7 days after mercury injection. The degree of proteinuria seen in this group of rats did not correlate with autoantibody levels. Although glomerular histology was unremarkable in these rats, by day 18 after injection there were vascular changes, including endothelial cell swelling in arteries and arterioles. Antiglomerular basement membrane IgG appeared by day 9 after injection, peaked by day 15, and then declined. Proximal tubular basement membrane IgG appeared on day 9 and peritubular capillary basement membrane IgG appeared on day 15. These antibodies persisted for at least 30 days. Urinary metallothionein increased after mercury administration, probably reflecting mercury induction of tissue metallothionein as a means of self-protection.

Significant neuropathology has also been produced by mercury *in vivo*, both in the fetus and in more mature animals. In pregnant rats given an intraperitoneal

injection of methylmercuric chloride effects were seen in the fetal nervous system within 2 h. These early changes included mitochondrial degeneration of the endothelium of cerebral capillaries leading to subsequent hemorrhage, which interferes with normal neuronal migration and normal development of cortical cytoarchitecture. It is of interest that alterations in vascularity leading to thrombus formation are seen in the kidney, as mentioned above. Methylmercury also disrupts neuronal microtubular assembly. Mercury is thought to reduce glutathione peroxidase activity in cells, to interact with the sulfhydryl groups of natural tubular and membrane proteins, and to cause peroxidative injury. Mercury has been found in organelles, primarily in lysosomes, bound to selenium. When injected intraperitoneally into the rat, methylmercuric chloride distribution was uniform in cerebellar Purkinje cells and Golgi cells, as well as in cerebral cortical layers III, IV, and VI. In rats exposed to inorganic mercury, only scattered mercury was isolated in level VI. Once in the brain, methylmercury is slowly converted into inorganic mercury. Both methylmercury and inorganic mercury accumulated in the anterior horn motor neurons of the spinal cord.

Functionally, subcutaneous administration of methyl mercuric chloride to neonatal rats resulted in movement and postural disorders developing during the fourth week of life. These occurred in association with a selective degeneration of cortical interneurons, which use γ-aminobutyric acid (GABA) as a neurotransmitter. In the putamen and caudate nucleus, GABAergic and somatostatin immunoreactive interneurons showed degenerative changes. Sodium-dependent high-affinity uptake of tritiated choline in cerebral cortex was also reduced, suggesting that both cholinergic and GABAergic neuronal function may be disturbed. Finally, *in vitro* incubation of rat cerebellar granular cells with methylmercury caused a delayed but increased phosphorylation of selected cellular proteins. The time course from exposure to phosphorylation was 12–24 h, a time period consistent with mercury alteration of gene expression.

Long-term neurotoxic effects from methylmercury exposure have also been demonstrated in cynomolgus monkeys. In one group of monkeys given methylmercury orally from birth to 7 years of age, whole blood concentrations of mercury fell almost immediately after the cessation of oral administration. However, monkeys assessed neurologically 6 years later exhibited insensitivity to touch and pinprick, clumsiness, and slowness. Other monkeys were exposed to methylmercury *in utero* by administration of methylmercury to their pregnant mothers and continuing postpartum administration to the infants for 4–5 years. There were more profound visual defects in the monkeys with prenatal and postnatal exposure compared to those exposed after birth only.

Toxic Levels in Humans

The most accessible sampling sites in humans are urine, hair, and whole blood. Urinary concentration of mercury is the monitoring test which is most often reported and is considered to be the analysis of choice for chronic mercury exposure. Normal values for urinary mercury concentration are less than $100\,\text{nmol}\,\text{l}^{-1}$ ($20\,\mu\text{g}\,\text{l}^{-1}$). These reference values were obtained as a result of a World Health Organization (WHO) study in 1961. Urinary mercury concentration was determined in urine samples from 1107 adults in 15 countries, and 85% of the subjects had urine mercury concentrations within the abovementioned range. No reference values exist for children, although acrodynia has been reported in children with urinary mercury concentrations as low as $249\,\text{nmol}\,\text{l}^{-1}$ ($50\,\mu\text{g}\,\text{l}^{-1}$). Urinary mercury concentrations do not correlate with ambient mercury levels due to the long half-life of mercury in the body (approximately 40–70 days). In addition, mercury is eliminated by other routes, such as sweat and bile. Young children generally have higher urinary mercury concentrations than adults because they crawl on floors, where the highest concentrations of mercury vapor tend to accumulate; toddlers also tend to become dirty and may mouth objects that have been lying in mercury-contaminated soil.

Workers occupationally exposed to mercury 20–35 years prior to being tested had neurological symptoms, including weakness, tremors, decreased sensation, and abnormal Babinski reflex (upgoing toes), with peak urinary mercury levels of $0.6\,\text{mg}\,\text{l}^{-1}$ ($3.0\,\mu\text{mol}\,\text{l}^{-1}$). Initial serum mercury concentration in two patients with acute intoxication from occupational mercury exposure were 550 and $490\,\mu\text{g}\,\text{dl}^{-1}$ (27 and $24\,\mu\text{mol}\,\text{l}^{-1}$). Serum or whole blood mercury concentration is a sensitive indicator of acute mercury loading, especially with inorganic mercury, owing to the near-equal distribution between red blood cells and plasma, with normal serum mercury concentration being $< 50\,\text{nmol}\,\text{l}^{-1}$ ($1\,\mu\text{g}\,\text{dl}^{-1}$). Hair mercury content is reported to be a reliable indicator of methylmercury load. When methylmercury has undergone distribution to various body parts, the blood and hair are in equilibrium, with hair concentration being approximately 250 times that of whole blood. Normal hair content of mercury is less than $7.5\,\mu\text{g}\,\text{g}^{-1}$ hair.

Ranges of Dietary Intakes

Mercury levels in the diet, especially of methylmercury, are of great importance, but are often poorly documented. Recently, data have been reported on the mercury content of poultry and dairy products from hens and broilers raised on fish meal from a number of countries in Europe and North America. Table 1 lists these values and, notably, most products fall within the acceptable tolerance limits of 50 p.p.b. wet weight set by the Food and Agriculture Organization (FAO) and the WHO of the United Nations. However, these FAO/WHO limits were established for foods other than fish and other seafood. Acidification of lakes by acid rain has increased the levels of mercury in the edible tissues of fish and has resulted in the prohibition of sport fishing in many American and Canadian lakes and rivers. In addition, the sale of shark and swordfish has been restricted, owing to their high mercury content.

Inhalation of mercury vapor is also a significant source of mercury intake as inorganic mercury is volatile at room temperature, and absorption through the respiratory tract occurs readily. Mercury can be detected in human volunteers within 30 min following exposure. Current recommendations by the American Conference of Governmental Industrial Hygienists are for a threshold limit value of mercury of 25 $\mu g\ m^{-3}$ (125 $nmol\ m^{-3}$) for a 40-h work week, while the US National Institute of Occupational Safety and Health (NIOSH) for workplace mercury vapor exposure for 10 $h\ day^{-1}$ is 250 $nmol\ m^{-3}$ (50 $\mu g\ m^{-3}$). For mercury concentration in household air, the US Agency for Toxic Substances and Disease Registry mandates an acceptable level of only 2.5 $nmol\ m^{-3}$ (0.5 $\mu g\ m^{-3}$). In the ambient outdoor air in a major US city such as Detroit, mercury concentration is reported to be as low as 0.015 $nmol\ m^{-3}$ (0.003 $\mu g\ m^{-3}$). In contrast, indoor mercury concentrations in a house just painted with mercury-containing latex paint can be as high as 847 $nmol\ m^{-3}$ (170 $\mu g\ m^{-3}$), falling to 8 $nmol\ m^{-3}$ by 7 days after the painting is completed. However, this latter amount is still three times greater than the recommended indoor ambient concentration.

Mercury tends to accumulate near the floor. Thus, in the room of a child in the UK who developed acrodynia from mercury accumulation in a vacuum cleaner, ambient mercury concentration was 1.0–1.2 $\mu g\ m^{-3}$ (5–6 $nmol\ m^{-3}$), while at the floor level it was 30.0 $\mu g\ m^{-3}$ (150 $nmol\ m^{-3}$). Similar findings have been reported in the USA, with a range of ambient mercury reported from 0.5 to 50.0 $nmol\ m^{-3}$ (0.1–10 $\mu g\ m^{-3}$).

Table 1 Mercury content (methylmercury and total mercury) of poultry products and eggs reported from Europe and North America

Incidences of Mercury Toxicity and Scares

The most notable occurrences of epidemic mercury exposure were described in a group of cities bordering Minamata Bay in Japan in 1956 and 1965, and in Iraq in 1971–72. In the Japanese epidemics, an acetaldehyde plant utilizing mercury released the mercury in its industrial waste into Minamata Bay, thus entering the aquatic food chain. In the case of Iraq, wheat contaminated with a mercury-containing fungicide was used to make bread. Follow-up studies in 1986–87 of 35 victims of Minamata disease, diagnosed between 1968 and 1978, revealed not only persistent and progressive neurological dysfunction but newly appeared lesions of spontaneous nystagmus in nine cases (25%). Fourteen affected Japanese patients from the Niigata area demonstrated temporal lobe gyrus degeneration, loss of small myelinated fibers, and a reduction in large neurons in the cochlear nerve. These findings suggested that hearing impairment in these victims may have been caused by progressive or irreversible degeneration of neurons or nerve fibers. It is from these epidemics that we have learned most about methylmercury poisoning.

Treatment

Both dimercaprol (BAL) and D-penicillamine have been used to treat victims of mercury poisoning. Use of BAL has been complicated by an increase in brain concentration of mercury. Dimercaptosuccinic acid (DMSA or succimer – Chemet®), is currently considered to be the chelator of choice to reduce the body burden of mercury.

METABOLIC RATE

W P T James, IASO/IOTF Offices, London, UK
A Ferro-Luzzi, Istituto Nazionale della Nutrizione, Rome, Italy

Introduction

The metabolic rate of the body is the overall rate of tissue oxidation of fuels by all the body's organs. The dietary fuels are the carbohydrate, fat, protein, alcohol, and minor dietary components that are oxidized in the tissues, oxygen being taken up by the lungs and the combusted end products (carbon dioxide, water, and urea) being excreted by the lungs, urine, and skin. The total rate of body metabolism is assessed by monitoring the rate of oxygen uptake by the lungs. The sources of fuel can then be estimated from the proportion of carbon dioxide produced and the rate of urea production. The equations for calculating these are set out below. The rates of utilization of body stores of carbohydrate (c, expressed in terms of monosaccharide units) and fat (f), in g h^{-1}, were calculated from the VO_2 and VCO_2 (1 h^{-1}) and the rate of leucine oxidation (L, mmol h^{-1}) using formulae derived by Garlick (1987). C and F are the rates of dietary intake of carbohydrate and fat. In the fasted state, the rates were as follows:

$$c = (4.574 \times V_{CO_2}) - (3.260 \times V_{O_2}) - 0.864L$$

$$f = (1.673 \times V_{O_2}) - (1.682 \times V_{CO_2}) - 0.434L.$$

In the fed state, the rates were as follows:

$$c = (4.574 \times V_{CO_2}) - (3.260 \times V_{O_2}) - 0.850L - 0.077F - C$$

$$f = (1.673 \times V_{O_2}) - (1.682 \times V_{CO_2}) - 0.383L - 0.947F.$$

The energy equivalence of oxygen varies, depending on the precise nature of the fuels being oxidized, but a value of 20 kJ per liter of oxygen is taken as an appropriate average. (*See* **Energy**: Measurement of Food Energy.)

Factors Affecting Metabolic Rate

The process of oxidation involves a series of enzymatically controlled biochemical reactions leading

eventually to the combination of oxygen with the carbon and hydrogen components of the body's fuels to yield the carbon dioxide and metabolically derived water. The incompletely oxidized nitrogen is excreted as urea, which is synthesized by the liver and excreted by the kidneys. The intermediate steps in the metabolism of the body's fuels are linked biochemically to drive the generation of phosphate-containing organic molecules, such as adenosine triphosphate (ATP), which in turn serve as the direct energy sources for all the body's cell activities, including the synthesis of complex molecules, the maintenance of tightly controlled ionic gradients in the cell, and the excretion of ions and molecules outside the cell. Thus, the oxygen being taken up by the lungs reflects the tissue metabolism of the fuels needed to regenerate the ATP used up in either biochemical 'internal' work or mechanical external work undertaken by the body's muscles. The rate at which the body burns its own stored fuels in the fasted, resting and relaxed state, i.e., in the basal state in a warm room, is called the basal metabolic rate (BMR). This varies with the age of the individual, mainly because of the varying sizes of metabolically very different organs at different ages. Thus, a child has a relatively large brain, liver, and intestine with a higher metabolic rate per kilogram of body weight than a more muscular adult. Body fat cells are metabolically active but contain a substantial amount of inert fat, so that the larger fat mass of a woman has a lower BMR per unit weight than a man, but if the oxygen uptake is calculated in terms of the metabolically active fat-free mass, then her metabolic rate is the same. As men and women age, they tend to lose lean tissue and store extra fat, so that the BMR on a weight basis falls with age. Again, the BMR remains the same when expressed in terms of the fat-free mass of the body.

Figure 1 depicts the changes in BMR of girls and women as they grow and age. Equations can now be used to estimate a group's BMR from their sex, age and bodyweight (see Table 1), but there is a range of BMR amounting to $\pm$ 20% of the mean value at each weight. Thus, in a young 25-year-old woman of 55 kg, the anticipated mean BMR is 1305 kJ per day but could vary under normal conditions from 1063 to 1547 kJ per day. The kilojoule is the standard measure, and 4.184 kJ corresponds to 1 kcal, which was originally defined in energy terms as that required to increase the temperature of 1 g of pure water by 1 °C from 14.5 to 15.5 °C. The variation in BMR at a constant weight in part reflects differences in the fat content of individuals of the same weight. Thus, the BMR per unit fat-free mass varies by 12–15% rather than by $\pm$ 20% as for weight. About 40% of the BMR may be explained by differences in the size of the body's organs, e.g., liver, intestine and muscle, but there is a residual difference between individuals, which seems to be explicable only in terms of differences in the rate at which every organ of the body metabolizes its fuel. This in turn is controlled principally by the circulating concentration of thyroid hormones. Adults with a normal but above-average level of thyroid hormones in their blood tend to have a BMR in the upper part of the normal range. Smokers also have a BMR that is about 5% above the normal, but whether or not this relates to changes in thyroid hormones is unknown. Young women who have normal menstrual cycles show a swing in BMR that is at its lowest in the late follicular phase, just before ovulation. On ovulation, the basal body temperature rises rapidly by about 0.5 °C. The BMR is also increased but rises further to a peak in the later luteal phase, immediately before menstruation. This metabolic cycle with swings of $\pm$5% of the mean is independent of changes in food intake, but the recognized

Table 1 Equations for prediction of basal metabolic rate (used in Figure 1)

Age range (years)	*Males*	*Females*
0–3	0.255W − 0.226	0.225W − 0.214
3–10	0.0949W + 2.07	0.0941W + 2.09
10–17	0.074W + 2.754	0.056W + 2.898
18–29	0.063W + 2.896	0.062W + 2.036
30–59	0.048W + 3.653	0.034W + 3.538
60–74	0.0499W + 2.930	0.0386W + 2.875
75+	0.0350W + 3.434	0.0410W + 2.610

5–10% fall in intake during the follicular phase with a similar rise in the luteal phase may accentuate the hormonally dependent swing. The effects of contraceptives that inhibit ovulation and the subsequent rise in basal temperature are unknown. The previous day's food intake does not affect the BMR unless there has been substantial overeating. However, the mixture of fuels combusted during fasting is influenced by the proportion of the previous 3–4 days' intakes, which is derived from carbohydrate, much of the glucose from glycogen being metabolized in the fasting state if carbohydrate intake was previously high. When the carbohydrate store of glycogen in the liver is nearing exhaustion, the body's output of carbon dioxide falls as the body switches to using body stores of fat. The oxygen uptake for combusting the fatty acids continues since the demand for regenerating ATP is unaffected by the change in fuel supply, but a carbohydrate-rich diet tends to induce a slightly higher fasting metabolic rate than an energy-equivalent, fat-enriched diet, probably because of a slight induction of thyroid metabolism by dietary carbohydrates. (*See* **Hormones**: Thyroid Hormones.)

The BMR falls by between 2 and 5% when individuals transfer to live in a tropical warm environment, and in uninsulated houses, seasonal changes in the BMR were readily seen with a 5–10% rise from summer to winter being observed in the Japanese before World War II. The BMR formulae shown in Table 1 ignore any temperature effects. The BMR of some people living in the tropics may be as much as 10% below the values shown, but these studies have been conducted on children and adults who are, or were, undernourished. Poor nutrition may have both an immediate and a long-term effect in lowering the basal metabolic rate. Semistarvation leads to a fall in BMR from about day 4, and within 2 weeks, the BMR can fall by 15% as thyroid metabolism changes and the body's organs become more efficient. More prolonged or severe semistarvation leads to a progressive loss of the body lean tissues as well as fat, and the BMR therefore continues to decline in proportion to the loss of lean tissues. Body weight can eventually stabilize at a new low level and, if physical activity is also reduced, semistarved volunteers can come back into energy balance on 50% of their initial intake. However, this requires a 40% loss of weight and marked lethargy if energy balance is to be preserved on such a low intake.

The Components of Metabolic Rate

Traditionally, the metabolic rate is divided into three components: BMR, postprandial thermogenesis, and physical activity. The BMR usually amounts to 50–60% of an individual's total energy expenditure, and postprandial thermogenesis to 10% used for the metabolic cost of processing, i.e., eating, absorbing, transporting, and storing food. The remaining energy is used for physical activity.

Postprandial Thermogenesis

The surge in oxygen uptake after a meal, known as postprandial thermogenesis, has been variously described as the specific dynamic action of food, dietary-induced thermogenesis or the thermic effect of feeding. The last term is particularly favored by animal nutritionists. It is difficult to measure it accurately because after ingesting the food with minimum physical effort, an individual has to lie at complete rest while the oxygen uptake and carbon dioxide production are monitored for many hours until the metabolic rate has returned to the basal rate. This may take more than 10 h, which explains why BMR is measured after a 14-h fast. Separate feeding of different fuels shows that the maximum effect on oxygen uptake occurs after protein. This response is equivalent to about 30% of the protein's energy; glucose induces a 5–10% effect, fat only a 2–5% effect, consistent with its slow absorption by the lymphatic tissue, and alcohol a 0–8% effect. Certain dietary components also increase metabolic rate, e.g., a caffeine equivalent to two cups of tea increases metabolic rate by 1–3%, and spices, such as those found in an Indian curry, increase it by 25% compared with a nonspiced meal. Moderate exercise amplifies the metabolic response to a standard meal, so that the combined effect of exercise and food is greater than the sum of the response to each stimulus given separately. The effect, however, is small and amounts to 2% of the total energy expenditure. (*See* **Thermogenesis**.)

Differences in postprandial energy expenditure have been sought as an explanation for the propensity of some individuals and animals to obesity. Results are often conflicting because in any person, the response tends to vary from day to day and is readily influenced by changes in gastric emptying. A proportion of obese subjects have a reduced metabolic response to a meal; this effect may prove to depend on the degree of abdominal insulation since the response is reduced if volunteers are swathed in insulation to reduce the abdominal heat loss, thereby increasing the temperature of the blood entering and leaving the liver. This seems to reduce the stimulus to body metabolism. Lactating mothers (and pregnant women) have a lower postprandial thermogenesis that returns to normal after they have stopped breast-feeding. Smoking and postprandial thermogenesis interact synergistically so the thermic output

after a meal is enhanced. The small response during lactation is consistent with that observed in many species of animal in which brown adipose tissue is used as the organ for modulating heat production as a mechanism to maintain body temperature. However, this organ is not very active in humans.

Prolonged underfeeding and overfeeding lead to changes not only in postprandial thermogenesis but also in BMR. The effects of semistarvation (see above) are modest, but overfeeding can produce a much greater response, provided that the intensity of overfeeding (especially with carbohydrate) is high. Thus, progressive overconsumption of 6.3 MJ (1500 cal) per day leads to a 33% increase in daily energy expenditure. This composite response to more prolonged overfeeding is usually classified as dietary-induced thermogenesis. Nevertheless, this apparent mechanism for dissipating excess energy is limited because, at most, 27% of the excess intake is metabolized, the remaining 73% being stored, two-thirds of it as fat and about a third as lean tissue. The majority of the excess response in metabolism is accounted for by the theoretical cost of fat synthesis from carbohydrate, although the human capacity to transform carbohydrate into fat is limited, preference being given to the selective storage of the fat component of the ingested energy.

Physical Activity

The energy cost of physical activity is predictable, but in order to obtain a reasonable estimate of energy expenditure on a daily basis, an analysis of activity patterns on a minute-by-minute basis is required. Children can be very active, making a detailed analysis difficult because the type of activity needs to be specified if an energy cost is to be assigned to each type of activity. Weight-bearing movement and anti-gravitational moves, e.g., walking up a hill with a load, are particularly expensive. The simplest way of estimating individual costs is to use the extensive tables now collected on the energy cost of different movements in children and adults. For simplicity, these can be expressed as a ratio of the BMR, since, in this way, differences between the sexes and individuals of varying size are removed. Table 2 illustrates how this is achieved for a female domestic worker. The physical activity ratios (PARs), i.e., energy costs in relation to BMR, can be assigned on the basis of extensive measures of similar activities. If the average energy requirement of the individual is to be estimated, account must be taken of the different types of work involved throughout the year. Thus, the individual shown, working in a Mediterranean environment, worked both as a domestic help and as an agricultural seasonal laborer. Each type of day is compartmentalized on a minute-by-minute basis, a division being made for convenience between occupational and other work. Maintenance of the individual's household varies depending on the day of the week and the season. Socially desirable activities encompass a variety of activities, including, for example, visiting friends, walking, churchgoing or dancing. The assumption is also made that some intensive exercise, amounting, on average, to 15 min daily, is undertaken; this is desirable if muscle tone and physical fitness are to be preserved. After integrating all

Daily total PAL[c] *(MJ)*							
Integrated PAL (MJ) is 1.69 (9.78)		1.53	(8.86)	1.81	(10.50)	1.88	(10.89)

[a]Day type 1, 4 out of 7 days for 10 months (48% of the year); day type 2, 3 out of 7 days for 10 months plus 1 out of 7 days for 2 months (38% of the year); day type 3, 6 out of 7 days for 2 months (14% of the year).
[b]Integrated Energy Index (IEI) is the energy cost of the activity including pauses for rest, expressed on a minute or hourly basis and calculated as a ratio of BMR.
[c]PAL, physical activity level.

these activities, the ratio of the total energy expenditure to the BMR is found to average 1.69; the ratio is designated the physical activity level (PAL). Table 3 provides a listing of PAL values for adults of all ages according to their activity patterns. Thus, by knowing the sex, age, and bodyweight of individuals, it is possible to estimate their BMR (see Table 1). Given this BMR figure in MJ per day, multiply by the PAL value shown in Table 3, and the energy needs can be estimated. Note that individuals vary in their energy needs by $\pm 15\%$, so that an individual's needs cannot be predicted very accurately unless his or her BMR is measured. Nevertheless, the total energy expenditure of an individual child or adult is remarkably consistent from day to day, varying by only 1–2% provided that food intake and physical activity are meticulously standardized, and account is taken in women of the stage of the menstrual cycle. Thus, the energy needs of individuals are surprisingly stable, and once this BMR is measured, the total energy needs of the child or adult can be readily estimated from a knowledge of their activity patterns. The factors modulating BMR or the metabolic response to food are many, but their effect is small, so that it is not surprising that energy expenditure is very predictable; the human body is therefore a finely tuned and well-regulated machine. Abnormalities of regulation, e.g., in obesity, only arise because of a consistent discrepancy between the physiological controlled intake and expenditure, which, if discrepant by 1–2%, produces a 2–5 kg weight change in a year. (*See* **Exercise**: Muscle; Metabolic Requirements.)

New measures of total energy expenditure estimated over 2–3 weeks can be obtained by the use of the double-labelled water technique, which relies on the difference in labelling of urine or saliva with the two heavy isotopes of water, deuterium and ^{18}O. The differential dilution of deuterium and ^{18}O in urinary water is monitored over a 2–3-week period following a single oral dose of $D_2{}^{18}O$. The ^{18}O content is diluted more rapidly than the deuterium because the oxygen in water exchanges rapidly with the body's bicarbonate pool, which is turning over rapidly as carbon dioxide is produced by tissue metabolism. Thus, the difference in dilution rates of ^{18}O and deuterium provides a measure of the rate of carbon dioxide production. The technique is expensive and difficult to perform analytically but very convenient for the subject being studied, since only single daily or occasional urine or saliva specimens are needed over the period of observation. This method is likely to be increasingly used, but classical methods have allowed current estimates of energy needs to be calculated. These are accurate for groups of people but not for individuals who vary not only in their physical activity patterns but also in their metabolic rate at rest. Figure 2 gives an indication of the decline in energy needs during adult life. This results from the atrophy of the lean tissues, which may be related to the fall in physical activity. Lack of exercise is therefore a handicap because it directly reduces energy expenditure, and it may also lead to a slow shrinkage of tissues, such as muscle, thereby producing a long-term fall in

Table 3 Development of the International Labour Organization's classification to derive simple estimates of PAL values[a] for each occupational group separated into averages for developed countries (DC) and less developed countries (LDC)

	Occupational PAL values			
	Males		*Females*

[a]PAL, physical activity level. These values are based on different proportions of the population being assumed to be engaged in light, medium, and heavy activities. The assumption is made that in less developed countries, there will be a greater demand for physical activity because the mechanization of transport, work, home, and leisure time activities will be appreciably less than in developed countries.
[b]Excludes female laborers.

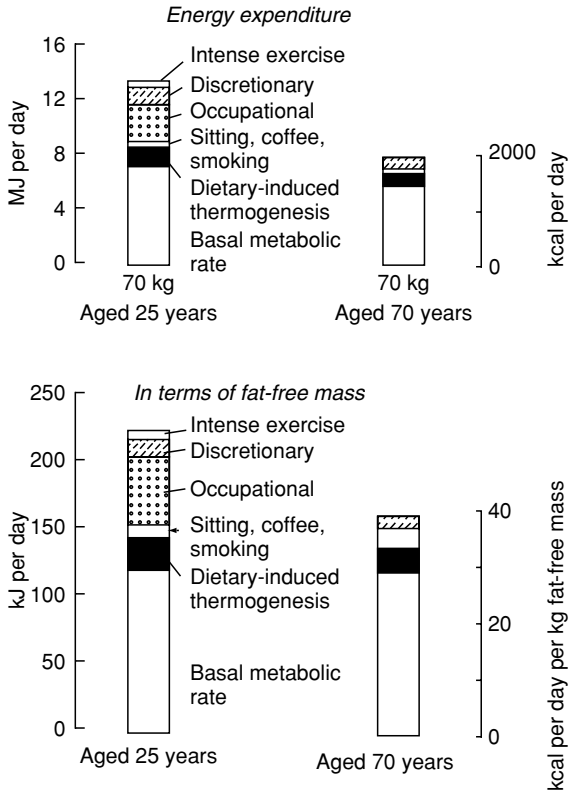

Figure 2 Different components of energy expenditure in a young man and the impact of aging. The energy expenditure falls mainly because of a decline in physical activity. There is also a fall in the basal metabolic rate, but this is in line with the reduction in the lean tissues, i.e., fat-free mass, in the elderly. Reproduced from Metabolic Rate, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

metabolism at rest. Unless people adapt their intake extraordinarily well to this progressive decline in energy output, energy storage, weight gain, and obesity are inevitable.

Extra Energy Costs

The cost of growth amounts to 20 kJ per gram of new tissue deposited; the value can be higher if fat with little lean tissue is laid down. A newborn has a high energy requirement of about $480\,kJ\,kg^{-1}$, but by 1 year of age, this has fallen to about $400\,kJ\,day^{-1}$ as growth slows. Without sufficient energy, a child will fail to grow, but the causes of growth failure usually relate to a deficiency of other nutrients or to infection, rather than to a lack of dietary energy. Adolescents, particularly boys, who are physically very active, may have a high demand for energy. However, the actual cost of even rapid growth rates at this age is modest. (*See* **Adolescents; Children:** Nutritional Requirements.)

Traditionally, pregnancy is considered a time of great demand for food. Good nutrition is extremely important, but the need for additional energy as such is small. The total cost of the 9 months of pregnancy has been estimated as 293 MJ (70 000 kcal) once the cost of tissue deposition (167 MJ) and increase in BMR (126 MJ) have been allowed for. In practice, however, physical activity declines, particularly in late pregnancy, and some enhanced metabolic efficiency, with an early fall in BMR in early pregnancy, seems to occur. The overall extra demand is very small, amounting to $420\,kJ\,day^{-1}$ in the last third of pregnancy only. (*See* **Pregnancy:** Safe Diet.)

Lactation imposes a greater demand on mothers, since their milk contains $1.9\,MJ\,day^{-1}$ after birth, rising to about $2.3\,MJ\,day^{-1}$ on exclusive breast-feeding at 3 months. Extra energy is involved in making this milk, and the total extra energy demand is 2.4–$2.9\,MJ\,day^{-1}$. Part of the energy for this comes from the extra fat stored by the mother during pregnancy, so that the effective extra need amounts to 1.9 MJ at birth and 2.4 MJ in the third to sixth month of exclusive breast-feeding. This explains why mothers are more hungry when nursing their child than when pregnant. (*See* **Lactation:** Physiology.)

Convalescent patients who need to put on weight need extra food, but the cost of this weight gain amounts to between 20 and 40 MJ per kilogram weight gain. If 1 kg is gained per month, the extra food needed therefore amounts to about $1\,MJ\,day^{-1}$.

METALS USED IN THE FOOD INDUSTRY

Ph Decléty, Chemin de la Treille, Vernouillet, France

Background

When talking about materials in the food industry, it is practically impossible to avoid use of the term 'stainless steel,' as so much of this material is used in the fabrication of storage, processing, handling, and other plant and equipment essential to the industry. After a brief recall of the definition and characteristics of the stainless steels, reference will be made to their properties relevant to food industry engineering, and the main applications where these properties are utilized will then be surveyed.

Definition and Classification of Stainless Steel

Stainless steels make up a family of corrosion- and heat-resistant iron-based alloys containing a minimum of about 12% chromium. The corrosion resistance is improved by increasing the chromium content. Both corrosion resistance and fabricating characteristics are further improved by addition of nickel. Other important alloy additions include molybdenum, titanium, and nitrogen.

Stainless steels may be divided into three groups according to composition and metallurgical characteristics:

1. *Austenitic stainless steels* contain chromium and nickel, frequently with additions of other elements. These steels are normally nonmagnetic and can be hardened only by cold working. The commonly used grades containing 18% chromium and 8–10% nickel account for about two-thirds of stainless steel produced. They are in general use in food industry engineering. Steels containing up to about 2.5% molybdenum are used when the corrosive environment is particularly severe. For specialized applications involving the most corrosive environments, higher-alloy grades containing up to 20% chromium, 25% nickel, and 6% molybdenum are available.
2. *Ferritic stainless steels* contain chromium as the principal alloying element. They are magnetic and can be hardened only by cold working. The most commonly used ferritic grade contains 17% chromium with a carbon content of about 0.05%. The ferritic steels are for general use where the corrosive environment is not too severe.
3. *Martensitic stainless steels* are iron–chromium alloys containing a significant level of carbon, which allows the steel to be hardened by heat treatment. Other alloying elements are sometimes added. The most commonly used steels of this family contain 12–13% chromium. Mechanical parts subject to heavy wear and knife blades are their principal applications. The martensitic steels are magnetic. They are not so resistant to corrosion as the ferritic and austenitic grades.

To these three main groups must be added a fourth class, the duplex stainless steels, which have a mixed austenitic/ferritic structure. These steels have a higher chromium content and a lower nickel content than the austenitic stainless steels and may have additions of molybdenum, nitrogen, and copper. They are characterized by good corrosion resistance and high strength. Use of these relatively new materials may be expected to increase.

Table 1 gives the compositions of the main stainless steels available for food industry applications.

Stainless Steel Properties

Physical and Mechanical Properties

Tables 2 and 3 list the physical and mechanical properties of the stainless steels most commonly used in the food industry. The following points should be noted:

1. the relatively low thermal conductivity and high coefficient of thermal expansion of austenitic steels;
2. the high strength of the stainless steels relative to carbon steel;
3. the high tensile ductility of the austenitic steels, which, coupled with good weldability, contributes to the excellent fabricability of these steels.

It should be noted that the austenitic stainless steels offer mechanical strength and ductility also at high temperatures.

Corrosion Resistance

The corrosion resistance of the stainless steels results from the formation of an invisible protective surface oxide film, which is able to repair itself by contact with an oxygen-containing environment if accidentally destroyed. A minimum of 12% chromium is

Martensitic steels	7.7	10	26

necessary to form this 'passive film,' and, as indicated earlier, its protective properties are improved by an increase in the chromium content and by addition of other alloying elements such as nickel and molybdenum. (*See* **Corrosion Chemistry**.)

Ferritic stainless steels are used for food industry equipment where service is not particularly onerous, but, in general, nickel-containing austenitic stainless steels must be selected. In the presence of most foodstuffs, AISI type 304 grade offers a good resistance to general corrosion and pitting corrosion, and it is only for some particularly aggressive products or processes that recourse to more resistant materials containing molybdenum, notably AISI type 316, is necessary.

In welded constructions, a particular type of corrosion can occur in the zone affected by heat during welding. This type of corrosion, termed 'intergranular corrosion,' is due to precipitation of chromium carbide at the grain boundaries, which results in chromium depletion of the adjacent material. This chromium-depleted zone is subject to corrosive attack if exposed to some aggresive media. To avoid the risk of this form of corrosion, it is necessary to prevent the carbide precipitation, and this is achieved by lowering the carbon content or by adding a stabilizing element (titanium or niobium). In practice, extra low-carbon grades (types 304L and 316L) or stabilized grades (types 321 and 316Ti) should be used for welded structures that are to be exposed to aggressive media.

Stress corrosion cracking can occur if a structure has residual surface tensile stresses (resulting from welding or a deep-drawing operation or, in service, from differential expansion effects or vibration) and is exposed to particular chloride corrosive environments at temperatures above about 60 °C. In particular, care is needed to remove any traces of chlorine-containing cleaning agents (which can result readily in chloride contamination) after a cleaning operation. Enhanced resistance to chloride stress

corrosion cracking is shown by the relatively new high-strength duplex stainless steels (e.g., 22% chromium, 5.5% nickel, 3% molybdenum, nitrogen), and this grade has been used for, *inter alia*, sugar industry applications in which stress cracking had been a problem. The higher alloy austenitic grades (e.g., 20% chromium, 25% nickel, 4% molybdenum, copper, and 20% chromium, 18% nickel, 6% molybdenum, copper, nitrogen) also offer enhanced resistance to chloride cracking, and their use for critical applications is expected to develop.

Crevice corrosion can occur in stainless steels when a chlorine-containing solution is trapped under stagnant conditions within a confined crevice, as may be formed under a bolt head or under deposits on a stainless steel surface. Laps and cold shuts in poor-quality welds, inadequately dressed, can form typical sites for crevice corrosion. Design and manufacture of plant and equipment intended to work with chlorine-containing solutions must avoid such crevices, and if deposits are likely to occur during operation of the plant, arrangements should be made to remove these on a regular basis. To avoid risk of crevice corrosion, particular care should be taken to eliminate chlorine-containing solutions after a cleaning operation. In general, it is good practice to avoid prolonged contact with stagnant chlorine-containing solutions.

Stainless Steel Products

Stainless steel is available in all forms known for carbon steel: hot-rolled and cold-rolled flat products; seamless and welded round tubes; square and rectangular welded tubes; flat, round, square, and hexagonal bars; wires; forgings; castings; hot-rolled or extruded sections.

As far as flat products are concerned, cold-rolled sheets and strip thicknesses range usually from 0.25 to 6 mm. For thicknesses over 6 mm, sheets are delivered in the hot-rolled condition.

Thin wall sections can be obtained from sheets and strips by brake or roll forming.

Plates, Sheets, and Strip Surface Finish

The standard mill finishes available are described in Table 4.

Special finishes are available from mills, steel service centers, or independent finishing specialists. Such finishes range from highly reflective electropolished and mirror-polished surfaces to textured and colored surfaces, and epoxy and tern-coated surfaces.

In selecting a surface finish, it is important to recognize that a bright finish offers, generally, superior corrosion resistance and superior cleanability. It is also important when using oriented polished finishes

Table 4 Standard mill finishes of stainless steel flat products

Finish designation		*Description*
AISI	*BS*	
1	1	A rough dull surface produced by hot rolling, followed by annealing and descaling
2D	2D	A dull finish produced by cold rolling, followed by annealing and descaling
2B	2B	A bright finish produced by cold rolling, followed by annealing, descaling and final light cold rolling on polished rolls
BA (bright annealed)	2A	A bright, cold-rolled, highly reflective finish obtained by annealing under a controlled atmosphere
3	3A	A cold-rolled polished surface obtained by finishing with an approximately 100 grit abrasive
4	4A	A cold-rolled polished surface obtained by finishing with an approximately 150 grit abrasive or finer

to arrange for the direction of polishing to be vertical if this is possible. It is also important to be aware that polishing is a costly operation and that, from an economic point of view, it is preferable to select a bright, cold-rolled mill finish whenever possible.

Finish 1 (Table 4) is a rough finish, specific to hot-rolled plates of thicknesses over 6 mm. It is not the best finish from the cleanability point of view and would require extensive grinding and polishing to achieve a satisfactory finish. Where a heavy plate (over 6 mm thick) is necessary, the most economic solution is often to use carbon steel plate clad with thin-gauge stainless steel rather than a solid stainless steel plate.

Properties Particularly Relevant to the Food Industry

Chemical Neutrality Towards Foodstuffs

Stainless steels of the appropriate grade are resistant to attack by a very wide range of foodstuffs and can be regarded as chemically neutral. Specifically, provided the correct grade is selected, there is no significant transfer of metallic elements, and the taste and color of the product are not affected.

Cleanability and Retention of Bacteria

Soil contamination on a surface can harbor bacteria and also hinder removal of bacteria that may be attached directly to the surface. A surface with desirable hygiene characteristics must, therefore, readily release soil contamination on cleaning and also readily release bacteria attached to the surface. Furthermore, the surface must be resistant to any disinfectants used to kill residual bacteria.

The stainless steels meet these requirements to a high degree. Specifically, the smooth surface of the steels facilitates removal of contamination, and, with the hardness and impact resistance of stainless steels, this surface characteristic is little affected during service. The high resistance to corrosion of the stainless steels allows more aggressive cleaning and disinfectant solutions to be used to ensure effective disinfection.

The cleanability of stainless steel as a food contact surface has been studied by several authors. One study concluded that stainless steel was not as cleanable as glass or china, but was more cleanable than aluminum and four other plastics tested. More recently, it has been shown that stainless steel domestic sinks retain 10 times fewer bacteria than other sinks (in enameled steel, polycarbonate plastic and mineral–resin composite) after standardized simulated wear, contamination, and spray wash treatments,

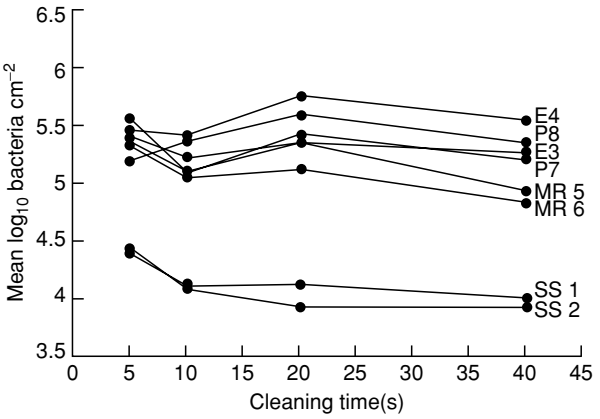

Figure 1 Comparative cleanability of abraded sink material after spray treatment. Mean logarithmic bacteria retained per square centimeter (15 trials) versus cleaning time for a range of abraded sink materials. SS, stainless steel; E, enamelled steel; P, polycarbonate; MR, mineral resin. The numbers refer to the sink number. Holah JT and Thorpe RH (1990) Cleanability in relation to bacterial retention on unused and abroaded domestic sink materials. *Journal of Applied Bacteriology* 69: 599–608 with permission.

and that stainless steel with its high resistance to abrasion and impact damage is more likely to retain its hygienic characteristics throughout a working life (see Figure 1).

The choice of cleaning and disinfectant products for use with stainless steels depends on the nature of the contamination. Some products containing chloride, iodine, or peracetic acid require care in their use. They may cause crevice corrosion if allowed to remain in contact with surfaces under stagnant conditions, for example at seals. Chlorine-containing solutions can lead to stress corrosion cracking if allowed to remain in contact with stressed surfaces at elevated temperatures. There are three precautions to be observed when using such products: the temperature should be kept low and not higher than 40 °C, exposure time should not exceed 30 min, and the plant or equipment should be thoroughly rinsed with clean potable water after the cleaning operation. (*See* **Cleaning Procedures in the Factory**: Types of Detergent; Types of Disinfectant.)

Mechanical Properties

The high strength, toughness, and wear resistance, particularly of the austenitic stainless steels, offer important advantages for applications in the food industry.

The high strength coupled with the absence of need for corrosion allowances permits the use of thinner gauges and sections when compared with carbon steel, for example. This brings about savings in weight and costs. The good impact and wear resistance

coupled with the high resistance to corrosion and ease of cleaning results in low maintenance costs and long life. Overall, stainless steel will often prove to be the best material choice on a lifecycle cost basis.

Main Stainless Steel Applications

Dairy Industry

Stainless steel is used for almost all equipment along the chain of milk production, milk processing and milk distribution. (*See* **Milk**: Processing of Liquid Milk.)

At the farm, milking machines as well as piping for transporting the milk up to the refrigerated storage tank are in type 304 stainless steel. The inside of the storage tank is always made from type 304 stainless steel, but type 430 ferritic grades can be used for the outside cladding.

For collecting milk at the farm, stainless steel tankers of suitable size are used. They are fitted with stainless steel accessories: piping and refrigerating circuits, pumps, automatic cleaning equipment, etc.

At the dairy processing plant, all equipment is in stainless steel: storage tanks, pasteurizing plate heat exchangers, piping, pumps, cleaning circuits, etc. Type 304 stainless steel is of general use, but type 316 molybdenum-containing stainless steel is sometimes used for heat exchanger plates to prevent any risk of stress corrosion cracking when aggressive solutions are employed for disinfection.

Equipment for butter processing is also made from type 304 stainless steel, but type 316 molybdenum-containing grades must be selected for equipment used for processing salted cheese because of the better resistance to chloride corrosion. It is also worth noting the use of stainless steel wire for cheese trays.

Generally speaking, surface finish in the dairy industry must be of a high quality in order to facilitate the rigorous cleaning and disinfection required.

Wine Industry

In the wine industry, it is of prime importance to prevent the deterioration of taste and color of products, which can occur through loss of flavoring esters, and through contamination, notably by iron and copper. (*See* **Contamination of Food**.)

Stainless steels meet these requirements with their chemical neutrality when in contact with a wine: they do not modify the pH of the wine, they do not transfer any metallic taste or induce 'ferric breaking' to white wines, and they do not interfere with the biochemical fermentation process.

Many tests have been conducted on stainless steel behavior in wines of various qualities. Their results, confirmed by a long experience, can be summarized as follows:

1. For the storage of red wines in full tanks, for the wine-processing tanks and for wine tankers, austenitic chromium nickel type 304 stainless steel without molybdenum can be used.
2. For the storage of sulfited white wines, when the tanks are not completely full, molybdenum-containing stainless steel type 316 must be used because of the risk of corrosion by sulfur dioxide condensates above the wine surface. In order to reduce cost, it is current practice to limit the use of type 316 to the upper parts which may be exposed above the wine surface; the lower submerged parts are made with type 304 stainless steel. (*See* **Wines**: Production of Table Wines; Production of Sparkling Wines.)

The surface finishes currently used on cold-rolled sheets in the wine industry are 2B finish and bright annealed finish. Weld beads must be ground and polished in order to eliminate oxides, laps, and similar defects.

It should be noted that stainless steel offers the possibility of setting up storage tanks outside protective buildings. The atmospheric corrosion resistance of type 304 stainless steel is generally quite satisfactory, but the molybdenum-containing type 316 steel would be necessary if the tanks are to be exposed to marine environments.

An important advantage of stainless steel over nonmetallic wine tanks is the ease of fitting an external double wall where a refrigerating fluid is circulated for the control of the fermentation temperature. Such control is increasingly used for the production of quality wines.

Vinegar obtained from wine is more aggressive than vinegar obtained from alcohol. It contains elements originating from the wine, such as iron, copper and manganese salts, and, sometimes, chlorides and fluorides, which activate the corrosive action of acetic acid. Type 316 molybdenum-containing stainless steel must be used for the processing and storage equipments of wine vinegar. (*See* **Vinegar.**)

Brandy and cognac are particularly sensitive to contamination from the organoleptic point of view and may be spoiled by a very small quantity of iron. For this reason, the use of type 316 stainless steel is advisable for production and storage equipment (Figure 2). (*See* **Brandy and Cognac**: Armagnac, Brandy, and Cognac and their Manufacture.)

Beer-making Industry

Today, stainless steel has replaced copper, which was the traditional material used for beer-making plant

Figure 2 A battery of wine storage tanks made from chromium nickel molybdenum stainless steel. Addition of molybdenum allows the tanks to be used for white as well as red wine. (Courtesy of UGINE S.A., France.)

and equipment. (*See* **Beers**: Biochemistry of Fermentation; Chemistry of Brewing.)

All equipment is usually in type 304 stainless steel, the corrosion resistance of which is well suited to the product and to the solutions used as cleaning agents. As mentioned previously, some precautions must nevertheless be taken when using chlorine-containing cleaning solutions, and the cleaning instructions given by equipment fabricators must be strictly observed. Type 316 stainless steel is used for brewing equipment when the chloride content of available water is particularly high (Figure 3).

Practically all new beer barrels are now fabricated in stainless steel in substitution of aluminum barrels which, as a consequence, play a declining part in beer storage and transportation. Stainless steel barrels, fabricated from two deep-drawn half-shells of type 304 stainless steel welded together, are price-competitive and bring decisive advantages: high strength, easy cleaning and disinfection and limited maintenance while maintaining a similar weight (Figure 4). (*See* **Barrels**: Wines, Spirits, and Other Beverages; Beer Making.)

Mineral Water, Soft Drinks, and Fruit Juice

Stainless steel is now in general use for equipment used in the collection and treatment of mineral waters as well as for the processing of soft drinks. According to the type of water and its temperature and, for soft drinks, the nature of additions, type 304 or type 316 stainless steel is used.

For fruit juices and fruit juice-based drinks, use of type 316 molybdenum-containing stainless steel is recommended to avoid any risk of contamination by iron or copper, which could spoil the taste or destroy vitamins.

Fruits and Vegetables

There is a great diversity of processes for the preparation and treatment of fruit and vegetables and, as a consequence, a great diversity of processing equipment. Generally speaking, stainless steel type 304 is used for all surfaces in contact with the product at any stage of its preparation. Nevertheless, for some products and, in particular, for treatments at elevated temperature, it is necessary to call for molybdenum-containing stainless steel type 316. In the processing cycle of tomato concentrate, for instance, evaporators are made from type 316 stainless steel.

For the storage of virgin olive oil, EC regulations now specify the use exclusively of type 304 stainless steel for the fabrication of storage tanks. This is to avoid any risk of quality alteration during storage. Owing to the aggressiveness of hot fatty acids, edible oil refining equipment, operated at elevated temperature, needs the use of type 316 stainless steel. (*See* **Vegetable Oils**: Oil Production and Processing.)

In the beet sugar industry, the use of thin-wall welded tubes of ferritic or austenitic stainless steel for the fabrication of evaporators is expanding, in substitution for carbon steel. It appears the most economic solution on a lifecycle cost basis. (*See* **Sugar**: Refining of Sugarbeet and Sugarcane.)

Meat Industry

Stainless steels are used for the fabrication of virtually all equipment for slaughtering, preparation, and

Figure 3 (see color plate 106) Stainless steel fermentation vessels and associated pipework in a modern brewery. (Courtesy of Courage Ltd and British Steel plc.)

handling of meat. They provide a guarantee of cleanability and hygiene. (*See* **Meat**: Slaughter.)

Type 304 stainless steel is generally satisfactory, and its applications range from conveyors, cutting machines, and work surfaces to easy-clean wall covering. For the collection and treatment of blood, however, type 316 molybdenum-containing stainless steel must be selected for this more aggressive use. The same grade must also be used for meat salting plants.

Miscellaneous Food Industry Equipments

Stainless steel is used in many food-processing industries other than those reviewed above. These include confectionery, chocolate and biscuit manufacture, industrial bakery, food deep freezing, fish preparation, and canning. As a general rule, stainless steel is used at least for parts in contact with foodstuffs but increasingly for the whole equipment of the plant. A recent tendency is to move to stainless steel for the

Figure 4 (see color plate 107) Stainless steel's hygienic and corrosion resistance properties are vital in the brewing industry. Today, all new beer barrels are made with type 304 stainless steel. (Courtesy of British Steel plc.)

framework of equipment traditionally made from painted carbon steel; the advantages of this substitution are a better cleanability and a lessening of maintenance works, which compensate quickly for the higher initial cost. Refer to individual processes.

Some equipment is used by several food industries, for example bottling and packing machinery; stainless steels are used for parts in direct contact with the beverages and foodstuffs handled. These include band or chain conveyors, tanks of filling machines, cladding of machinery framework and, sometimes, as mentioned above, also for the supporting framework itself.

At the end of the food-preparation chain, the preparation of ready cooked dishes and their preservation by chilling, deep freezing, vacuum packing or canning, and the catering industry with its kitchen and serving facilities must be mentioned. Stainless steel is extensively used in equipment for these industries where cleanability and hygiene are a prime necessity.

MICROBIOLOGY

Contents

Classification of Microorganisms

A A A Kwaasi, King Faisal Specialist Hospital & Research Centre, Riyadh, Saudi Arabia

Background

Microorganisms comprise prokaryotes as well as some eukaryotic organisms, and these include bacteria, fungi, viruses, protozoa, and algae. Food can be defined as anything that, when taken into the body, serves to nourish or build up the tissues, or to supply body heat: essentially, an aliment or nutrient. This definition of food encompasses all items that are consumed by man and other animals. Water, beverages, and all edible solid material are food. Food sources are plankton, seaweed, fish, crustacea, mushrooms, molluscs, meat, poultry, fruits, vegetables, edible algae and fungi, as well as grains.

Microbes are in contact with food whether it is on the farm or in the forest, garden, lake, pond, river, or sea. Food in storage, industrial processing machines, supermarkets, warehouses, brewery holdings, restaurants, hotels and public dining places all have, at one stage or another, harbored or been in contact with microorganisms.

A number of microorganisms are in themselves food or can be exploited and used as food. Some are contaminants on food and food products, and a number can also cause food spoilage or produce toxins in foods leading to foodborne illnesses in man and animals. Some microorganisms are also capable of transforming a food's properties in a beneficial way such as the various food fermentation processes. Since there are a large number of different microorganisms with diverse habitats and different attributes, food microorganisms will be classified here in terms of the way in which they are associated with foods in different habitats, cause food spoilage, contaminate food, or harm the consumer by the production of noxious metabolites. Microorganisms are ubiquitous and can survive and grow at different temperatures at which food is either kept or processed. They exist from the coldest of salty ponds in the frozen wasters of the polar regions to the boiling water of hot springs. Actively growing bacteria may occur at temperatures in excess of 100 °C in thermal volcanic vents at the bottom of the deeper parts of the oceans, in acid wastes from mines, or in alkaline waters of soda lakes. Microbes have been isolated from black anaerobic silts of estuarine mud and also have been found in the purest waters of the biologically unproductive or oligotrophic lakes. This means that, irrespective of the environment, microorganisms can find a way of adapting, surviving, and multiplying at different temperatures, and they exist in a similar manner on food.

Microorganisms on Food Crops in the Farm or Garden

Crops are established by sowing seed or planting vegetatively propagated materials such as tubers, corms, stem cuttings, or suckers. These vegetative materials are rich in food reserves and, given suitable conditions of temperature, moisture, and light, they are hydrolyzed into simple sugars, which are then utilized in the early growth of the rudimentary young plant or seedling. Under certain conditions, however, these sugars are utilized by soil-inhabiting fungi with the result that the seed or propagative material rots before it can germinate to produce a seedling, or else causes the rotting of the young seedling at soil level. An example of such a microorganism is the saprophytic fungus *Pythium ultimum*, which causes the diseases, referred to as pre- and post-emergence damping-off. *Rhizoctonia solani* causes damping-off on a wide range of cultivated plants – cereals, potato, root and fodder crops, legumes, and vegetables. On lettuce, this fungus is often associated with some *Pythium* spp. and pathotypes of *Botrytis cinerea*. In most cases, the fungus remains quiescent on the consumable material and only grows actively when conditions are favorable. Onions are commonly attacked by *Botrytis alli*, and beet is often colonized by *Pleospora bjoelingii* (*Phoma betae* in pycnidial stage).

Viruses are no exception in their association with foods, for several viral 'mosaics,' 'crinkles,' and

'yellows' are caused by the virus called arabis mosaic virus, which mostly affects strawberries, raspberries, and grapes.

Plant pathologists and agriculturists often refer to microorganisms as being field or storage microorganisms. Microbial flora of cereals undergo pronounced and significant changes in the field. Grains may become colonized by field fungi, and these include species of *Cladosporium, Alternaria, Helminthosporium*, and *Chaetomium*. After harvest, however, the numbers of these field flora decrease, giving room to storage fungi, the commonest of which are *Penicillium, Aspergillus*, and some nonpathogenic species of *Fusarium*. When leaves unfold, they act as spore traps for airborne microbial propagules, some of which grow and form the phylloplane, or leaf surface flora. Close observation has revealed that these propagules can be found on leaves that animals graze and man uses in cooking or as raw components of salads. The majority of these are fungi of the *Ascomycotina* and the commonest recorded are *Cladosporium* spp., *Epicoccum nigrum, Aureobasidium pullulans*, and *Alternata tenuis*. There are frequently true yeasts of the genera *Sporobolomyces* and Bullera, the so-called mirror yeasts on plant leaf surfaces.

An interesting and richer association of yeast in the wild is to be found with nectaries of flowers and the surfaces of fruits. The presence of some of these fungi is a prerequisite in the spontaneous fermentation of fruit juices, such as grape in the production of wine. Palm wine obtained from the oil palm (*Elaeis guineensis*), date palm (*Phoenix dactylifera*), and the raffia palm (*Raphia vinifera*) in parts of the world are also fermented in a similar manner by wild epiphytic and airborne yeasts.

Food crops are commonly colonized by Gram-negative rods such as *Erwinia, Pseudomonas*, and *Xanthomonas*, but several Gram-positive bacteria such as *Lactobacillus* and *Leuconostoc* are present, which are important in the production of fermented vegetable products such as sauerkraut (fermented pickled cabbage) (Table 1). When leafy vegetables that are consumed fresh are colonized, it is almost impossible to eliminate these microflora completely by ordinary washing, but in most cases they are harmless to the consumer.

A rather unusual association of some microorganisms and food plants can be found in the rhizoplane. Root nodules of the Leguminosae are formed as a result of a symbiotic association of a bacterium *Rhizobium melioloti* with root nodules of alfalfa (*Medicago sativa*). This symbiotic relationship greatly increases the nitrogen content not only of the soil but also of the plant crop at maturity. Some mycorrhizal associations between fungi and roots of some food plants not only offer protection to the roots but also contribute indirectly to their overall crop yield. Similarly, some microorganisms can establish associations with members of the botanical family Fabaceae (Papilionaceae and Leguminosae), which provide man and other animals with the most important plant proteins, the pulses. In spite of their low water content after drying, they are usually attacked by lipolytic molds of the genera *Aspergillus* (such as *A. niger, A. tamarii), Penicillium* and *Paecilomyces*.

The ability of some soil microorganisms to degrade complex organic materials makes these microbes potent spoilage agents, if they are present on foods. At times, the soil can be a harsh and competitive environment, and many soil microorganisms adapt to these sudden changes by producing resistant structures such as endospores (by the bacterial genera *Bacillus* and *Clostridium*), chlamydospores, and sclerotia of many fungi (such as *Claviceps purpurea* or ergot). The subsequent germination of these structures is responsible for the occurrence of food spoilage and food poisoning caused by the clostridia and bacilli. The spore-forming anaerobe *Clostridium* can be predominantly proteolytic or saccharolytic. Both of these activities are accompanied by gas production and cause some infected cans on supermarket shelves to swell, resulting in the 'blown can' effect.

Microorganisms on Food in Transit or in Storage

Food in transit is often damaged by a number of microorganisms if conditions are ideal for their growth. Considerable losses of vegetables such as carrots, potatoes, onions, and celery are caused by bacteria causing soft rot and the species belonging to the Genus *Erwinia*, such as *E. carotovora, E. atroseptica* (black leg), *E. aroideae*, and *E. chrysnthemi*. This situation is usually worsened when there are bruises and lesions, but at high temperatures and high humidity, *Bacillus polymxya* is capable of reducing potato in storage to a yellow sticky mass with a distinct fruity odor. *Pseudomonas phaseolicola* perennates on dwarf bean (*Phaseolus vulgaris*), and this same fungus causes the diseases leaf spot and halo blight.

Fungal survival, or their contamination of foods, in transit is a common phenomenon, and several genera are involved. Species of the fungus *Rhizopus* are capable of causing considerable damage to peaches, grapes, sweet potato, crucifers, cucurbits, tomatoes and eggplant (*Solanum melongena*) and produce soft rot very rapidly at temperatures above 10 °C. Potatoes are commonly attacked by *Fusarium caeruleum*, causing dry rot of the tuber. Ergot of cereals is a disease caused by members of the genus *Claviceps*.

Table 1 Foodborne pathogenic bacteria

Organism	*Food source*	*Illness*
Salmonella spp.	Poultry, eggs, milk, swine, water, shrimps, raw meats	Typhoid and typhoid-like fever
Clostridium botulinum	Any food with pH above 4.6; all canned meats, honey, vegetables	Foodborne botulism (intoxication)
Staphylococcus aureus	Most foods not kept hot or cold enough	Staphylococcus food poisoning (staphyloenterotoxicosis)
Yersinia enterolitica	Meats, icecreams, milk	Yersiniosis, bacteremia, arthritis
Campylobacter jejuni	Water, unpasteurized milk, meat, poultry	Enteritis, gastroenteritis, campylobacteriosis
Listeria monocytogenes	Milk, cheese, icecream, vegetables, fermented raw meats, all meats raw or smoked	Listeria meningitis
Vibrio cholerae	Contaminated water (poor sanitation)	Cholera
Vibrio parahaemolyticus	Raw improperly cooked or contaminated fish and shellfish	Gastroenteritis, diarrhea, cramps, nausea
Vibrio vulnificus	Oysters, clams, crabs (raw or contaminated)	Gastroenteritis, wound infection, septicemia
Clostridium perfringens	Improperly prepared food: meats, meat products, gravy	Food poisoning, pig belly disease
Bacillus cereus	Meats, milk, vegetables, fish (vomiting is associated with rice, potato, pasta, cheese, and food mixtures)	Diarrhea-type, food poisoning, vomiting
Aeromonas hydrophilia	Beef, pork, lamb, poultry, shellfish, fish	Gastroenteritis to septicemia
Plesiomonas shigelloides	Contaminated water or raw shellfish	Gastroenteritis (self-limiting), fever, chills
Shigella spp, *S. sonnei*, *S. boydii*, *S. flexneri*, *S. dysenteriae*	Salads, raw vegetables, milky dairy products, poultry	Bacillary dysentery
Miscellaneous Gram-negatives: *Klebsiella*, *Enterobacter*, *Proteus*, *Citrobacter*, *Aerobacter*, *Providencia*, and *Serratia*	Dairy products, raw shellfish, fresh vegetables, water	Gastroenteritis
Group A *Streptococcus* spp: *S. pyogenes*	Group A: milk, icecream, eggs, steamed lobster, ground ham, potato salad, egg salad, custard, rice pudding, shrimp salad	Tonsillitis, high fever, septic sore throat
Group D *Streptococcus* spp. *S. faecalis*, *S. faecium*, *S. durans*, *S. avium*, *S. bovis*	Dairy products, raw shellfish, fresh raw vegetables	Scarlet fever, diarrhea, abdominal cramps, vomiting, septicemia
Enterotoxigenic, *Escherichia coli*	Contaminated water, dairy products, e.g., semisoft cheeses	Gastroenteritis, travellers' diarrhea
Enteropathogenic *E. coli*	Raw beef, chicken, and any food exposed to fecal contamination	Infantile diarrhea
Enteroinvasive *E. coli*	Hamburger, meat, unpasteurized milk	Mild dysentery

It is widely distributed throughout the world, and the most economically important is ergot of rye caused by *Claviceps pupurea*. This fungus is important not so much for the effect it has on the growth of crop but for the characteristic fungal fruiting structures called ergot (sclerotia), which can contaminate cereals during harvest and cause poisoning in man and animals. Feeding livestock with cleanings from contaminated grain or grazing pastures with infected grass heads can lead to abortions and peripheral gangrene.

Bread can be infected with the bread mold at several locations, even in the fridge, and it has been known to cause infections due to colonization by *B. cereus*. There have been a number of instances where survival of pathogens or their toxins have caused problems in products such as dried herbs, rice, dried milk, chocolate, pasta, and eggs, and generally, *Salmonella* and *Staphylococcus aureus* have been associated with these outbreaks. Xerosporic (nonwater wettable) microorganisms can survive almost indefinitely on dried products.

Bananas in transit are subject to several fungal rots, and the most troublesome and commonest of these, which is considered largely responsible for the decline in the quality of Jamaican bananas imported into England, is attributed to rotting by *Gleosporium musarum*. Stone and pome fruits are particularly prone to brown rot, and the three main fungi involved belong to the genus *Sclerotinia*. *Sclerotinia fructigena* and *Sclerotinia laxa* occur in Europe, and *Sclerotinia fructicola* occurs in the USA. Apples infected by *Sclerotinia fructigena* are initially covered with conidial cushions, and the infected fruits gradually shrivel and become mummified. A species of this fungus *Sclerotinia sclerotiorum* is particularly dangerous, because it can continue to cause rotting of vegetables at temperatures near freezing point. Fungi also cause considerable damage to citrus fruits in transit: *Penicillium italicum* and *Penicillium digitatum* cause the diseases called blue and green mold, respectively, and *Penicillium expansum* causes a soft rot in apples. Other common diseases of apples and pears include the black spot or scab caused by the Ascomycotina fungus called *Venturia inaequalis* (anamorph *Spilocaea pomi* = *Fusicladium dendriticum*). Lemons are transported under relatively high temperatures, and this condition permits the development of *Phytophthora* brown rot.

An especially widespread mold on fruit and vegetables is the gray mold *Botrytis cinerea*, which is an imperfect stage of the Ascomycete, *Botryotinia fuckeliana* (= *Sclerotinia fuckeliana*). In canned fruits, the low pH and heat treatment means that most molds are killed, but some members of the Eurotiales are sufficiently heat-resistant and survive. The best known are species of *Byssochlamys*, but recent spoilage of some exotic fruits in canneries has been due to *Neosartorya fischeri* (anamorph *Aspergillus fischerianus*) and *Talaromyces flavus* var. *macrosporus* (anamorph *Penicillium* sp.).

Survival of remnants of fungal pathogens on seeds is very common: it is usual to find a reservoir of the loose smut disease agent of wheat and barley *Ustilago nuda* in the scutellum. Similarly, the hyphae of the fungus that causes loose smut of oats, *Ustilago avenae*, are common on the embryo, seed, or fruit coat of oats, and *Tilletia caries* and *Septoria apiicola* can be commonly detected on the seeds of wheat and celery, respectively. Species of the fungus *Aspergillus* can cause considerable deterioration of stored grain. The best studied is *A. flavus*, which is also capable of producing several toxic materials, collectively known as aflatoxin. This toxin, which is carcinogenic, has been found in most stored products such as peanuts, dates, and an array of foods.

Relatively few viruses survive on, and are transmitted by, seeds, and lettuce mosaic virus is a common example. When crops are harvested, they may harbor several microbes. As a rule, field microbes give way to the colonization of storage microorganisms, often resulting in fruit and fleshy storage organs rotting, and dry cereal grains becoming moldy. The pathogens responsible for this type of spoilage are frequently those that do not develop at all, or develop only to a limited extent on the host in the field. An example of such an organism is *Fusarium solani* var. *coeruleum*, which causes dry rot of potato tubers. Similarly, potato blight (*Phytophthora infestans*) can be initiated from tubers. The air of farmyard barns may contain many millions of spores of Actinomycetes per cubic meter. Spores of some species such as *Thermoactinomyces vulgaris* and *Micropolyspora faeni* cause lung allergy in farmers, and some geosmin-producing strains of *Streptomyces* may be responsible for earthy odors and off-flavors in potable water; also, geosmin can impart earthy taints to food such as shellfish.

Microorganisms in Water

Aquatic environments represent the largest part of the biosphere, and many species of microorganisms are found in both marine and freshwater environments. Open oceans contain salt and many marine bacteria, referred to as oligotrophic psychrophiles, which have a requirement for salt and can grow at relatively low temperatures. The surfaces of fish caught from cold water in the open sea contain psychrophilic and psychrotrophic bacterial flora that are capable of breaking down proteins, polysaccharides, and lipids, and can double in numbers at refrigeration temperatures of 0–7 °C in as short a time as 10 h. The implication of this is that a single bacterium on freshly caught fish can multiply to 2^{22} or between 10^7 and 10^8 in just 9 days, and in this situation, cold-stored fresh fish starts giving off off-odors.

The sea has been used by man as a dumping ground for sewage and other waste products. Unfortunately, many shellfish used for food grow in these polluted coastal waters and actually feed by filtering out particles from large volumes of seawater. Therefore, there is always a high risk of contamination by enteric organisms from infected individuals, and the microbes concentrate in numbers within the organism as a result of the filter-feeding habits of shellfish. Severe diseases such as hepatitis and typhoid fever, and milder illnesses such as gastroenteritis, have been caused by eating contaminated oysters and mussels that look sound in appearance and taste normal. In warmer seas with unpolluted water, high numbers of the bacterium *Vibrio parahaemolyticus* may also be concentrated through the filter feeding of shellfish.

This bacterium then becomes part of the stable commensal enteric flora and has been responsible for episodes of food poisoning associated with seafood.

Fresh water from lakes and rivers has a complex flora, which includes genuinely aquatic microbial species as well as those introduced from terrestrial, animal, and plant sources. Like other water sources, fresh water may act as a repository and vehicle for bacteria, protozoa, and viruses of fecal origin, which can also cause diseases.

Fungi are also found in marine and fresh waters, but they are not as important in their association with food as the groups of microorganisms described above. There are true aquatic fungi, and these include some that are pathogens of molluscs and fish. The most well-adapted aquatic fungi belong to all the major groups of terrestrial fungi, namely: *Ascomycotina, Basidiomycotina, Deuteromycotina*, and *Zygomycotina*. There is the possibility that some of these could be responsible for spoilage of some food commodities, including salad crops cultivated with overhead irrigation from rivers or lakes. The aquatic photosynthetic microorganisms, the cyanobacteria (or blue–green algae), and the eukaryotic dinoflagellates are groups of microorganisms that may also become concentrated in shellfish and can cause severe illness such as paralytic shellfish poisoning.

A significant global problem is the viral contamination of water. In the past, about half of the foodborne disease outbreaks through water were unrecognized, primarily as a result of inadequate diagnostic methods and sampling. Recently, with improved diagnostic methods, it has been established that most of these food and waterborne outbreaks are caused by caliciviruses and are a major cause of seafood associated gastroenteritis.

Bacterial strains of the genus *Aeromonas* are well-recognized enteropathogens of man. The main source of infection by this organism seems to be untreated water, because these microorganisms can be found in virtually all aquatic environments. Furthermore, some enterotoxigenic pathotypes of *Aeromonas* are capable of rapid growth and toxin production at temperatures as low as 5 °C. This means that vegetable products irrigated with contaminated water may reach critical *Aeromonas* levels during refrigeration and could represent a serious public health hazard when these vegetables are consumed as uncooked salads.

Microorganisms in Milk

Raw milk becomes laden with microorganisms from three sources: udder interior, teat exterior and its surrounding, and the milking and milk handling equipment. Milk expressed aseptically from a healthy cow may be sterile or contain low numbers of microorganisms, usually about 10^2–10^3 cfu ml^{-1}. The most frequently isolated organisms are micrococci, streptococci, and *Corynebacterium bovis*. Higher microbial counts are often seen if the animals suffer from mastitis, and under these circumstances, many types of bacteria are seen. The most important of these are the potential human pathogens *Staphylococcus aureus*, *Escherichia coli*, *Streptococcus agalactiae*, *Streptococcus uberis*, *Pseudomonas aeruginosa*, and *Corynebacterium pyogenes*. Occasionally other human pathogens, such as *Salmonella*, *Listeria monocytogenes*, *Mycobacterium bovis*, and *Mycobacterium tuberculosis*, are isolated.

The udder exterior, the teats, and the cow's immediate environment such as bedding and manure can also be a source of heavy contamination (10^5 cfu ml^{-1}) of the milk. In these situations, the microorganisms involved are mostly human pathogens such as *E. coli*, *Helicobacter* (*Campylobacter*) from bedding and manure, *Salmonella* and *Bacillus* spp. from soil, and *Clostridium butyricum* and *Clostridium tyrobutyricum* from silage. These *Clostridium* spp. are the cause of a form of spoilage called 'late blowing cheese.' In some parts of the world, a potent contaminant of milk and meats is caused by *Brucella* spp.

In most developed countries, milk is chilled soon after it is issued from the cow, and under these circumstances, only psychrotrophic organisms are found in raw milk. The most common are Gram-negative rods of the genera *Pseudomonas*, *Acinetobacter*, *Alcaligenes*, and *Flavobacterium*, the psychrotrophic coliform *Aerobacter*, and Gram-positive *Bacillus* spp. In order to reduce the numbers of harmful organisms, milk is either pasteurized or ultraheat-treated. Raw milk after pasteurization may contain organisms, referred to as thermodurics, that can survive this process. These organisms are generally Gram-positive, such as the spore-forming bacteria and members of the genera *Microbacterium*, *Micrococcus*, *Enterococcus*, and *Lactobacillus*, but it is usual to find some strains of the Gram-negative bacterium *Alcaligenes tolerans*. Spoilage of pasteurized milk is due to the growth in milk of the Gram-negative rods *Pseudomonas*, *Alcaligenes*, *Acinetobacter* and *Psychrobacter*, which may be inadvertently introduced after pasteurization. *Salmonella* has been isolated from icecream that has been stored at −23 °C for 7 years.

Microorganisms on Meat

In theory, freshly harvested meat should be relatively free from microorganisms, but microbial numbers

detected in aseptically sampled tissues contain some microbes, usually less than 10 cfu kg^{-1}. There is evidence, however, that these numbers can increase under conditions of stress and if the animal is suffering from an infection, as in the case in *Brucella*-infected animals. Most meat contamination is from the heavily colonized areas of the animal, such as the skin (fleece) and the gastrointestinal tract, and the type and numbers found will reflect both the animal's indigenous microflora and its environment. The animal hide carries mixed microbial population of micrococci, staphylococci, pseudomonads, yeasts, and molds as well as organisms derived from soil and feces. After dressing and chilling, the surface microbial numbers are typically of the order of 10^2–10^4 cfu cm^{-2} and are usually higher in sheep carcasses than in beef, and even higher still in pigs. In some parts of the world, the fur on sheep, cattle and pigs is thoroughly burned soon after slaughtering the animal. Traditionally, the method is used as a way of imparting flavor to the meat, but it should also be lauded and seen as a first step in reducing the microbial numbers on the skin that could otherwise contaminate the flesh. Likewise, after defeathering, in some traditions, birds are flamed before the flesh is cut, and this treatment also greatly reduces the potential contamination of the poultry meat by microbes on the skin.

Species of the genus *Brucella* are known human pathogens that can cause undulant fever, and are associated with a particular animal host: *B. abortus* in cattle, *B. melitensis* in sheep and goats, *B. suis* in pigs, and *B. canis* in dogs. Even though the diseases are contracted from close contact with infected animals, they can also be contracted by the consumption of milk, milk products, and meat from these animals.

The processing of poultry is different from red meat, and this has microbiological implications: an active processing plant that can handle 12 000 birds per hour leaves little chance for effective sanitation and favors the spread of microbes between carcasses. After scalding, birds are mechanically defeathered, and a number of studies have suggested that this method actively passes organisms like *Salmonella* from one carcass to the other. The intestinal tract of poultry also contains high numbers of the human pathogens *Salmonella* and *Helicobacter* (*Campylobacter*); these are easily passed on and are the two major causes of foodborne illness in the UK. Interestingly, *Campylobacter coli* and *C. jejuni* do not grow at temperatures below 30 °C and only become pathogenic when food contaminated by these bacteria is consumed and the microbes start thriving under the higher human body temperature. Being microaerophillic, they are also able to survive the low-oxygen conditions of modern storage processes.

The first indication of spoilage of meat is the production of off-odors, which become apparent when the microbial numbers in meat reach 10^7 cfu cm^{-2}. Aerobic storage of chilled red meats, whether covered or uncovered, produces a high redox potential at the meat surface that favors the growth of psychrotrophic aerobes. Nonfermentative Gram-negative rods grow most rapidly, causing spoilage, and the principal genera are *Pseudomonas*, *Acinetobacter*, *Psychrobacter*, *Pseudomonas fragi*, and *Pseudomonas lundensis*. Other microbes that form a minor component of the spoilage microflora are members of the Enterobacteriaceae, such as *Serratia liquefasciens* and *Enterobacter agglomerans*, lactic acid bacteria and the Gram-positive bacterium *Brochothrix thermosphacta*.

In vacuum-packed meat, the microflora of the meat changes as a result of the accumulation of CO_2 and lack of oxygen. This restricts the growth of *Pseudomonas*, and colonization is dominated by Gram-positives, lactic acid bacteria of the genera *Lactobacillus*, *Carnobacterium*, and *Leuconostoc*.

The perception of spoilage is subject to a number of influences, particularly social: foods acceptable in some cultures are unacceptable in others. Matured cheeses and game birds (e.g., pheasants) that have been hung for several weeks are seen in some cultures as objectionable, but these same products are treasured and sold for large amounts of money to the affluent in other societies.

Microorganisms on Fish (Teleosts and Elasmobranchs), Crustaceans, and Molluscs

Like meat, the muscle and internal organs of freshly caught healthy fish are usually sterile, but the skin, gills, and alimentary track carry large numbers of bacteria. These can be as high as 10^7 on the skin and up to 10^9 in the gills and the gut, and these are mainly Gram-negatives of the genera *Pseudomonas*, *Shewanella*, *Psychrobacter*, *Vibrio*, *Flavobacterium*, and *Cytophaga*, as well as a few Gram-positive micrococci and coryneforms.

Fish can be easily contaminated by human pathogens during handling on board, at the dock, and at markets when they are being offered for sale. The common foodborne illness pathogens associated with fish are *Vibrio cholerae*, *Vibrio parahaemolyticus*, *Vibrio vulnificus*, *Clostridium botulinum* Type E, enteric viruses, and those that cause Scombroid fish poisoning and paralytic shellfish poisoning.

Spoilage of chilled fish is mainly due to the activity of the psychrotrophic Gram-negative rods *Shewanella putrefaciens* and some *Pseudomonas* species.

Shewanella putrefaciens can grow under a variety of conditions, producing trimethylamine and hydrogen sulfide to spoil even vacuum-packed fish. Work in Denmark has demonstrated that marine Vibrios like *Photobacterium phosphorous* cause nonsulfurous spoilage of fish produce.

Foodborne Viruses

Viruses are obligate intracellular parasites and can only multiply in a susceptible host cell. Recently, viruses have been recognized as an important source of foodborne diseases (Table 2), and over one hundred human enteric viruses have been implicated. These viruses are spread mainly by the fecal–oral route, making foods for human consumption a potential route for transmission. However, the genus enterovirus includes the polio and the hepatitis A and E viruses, all of which are known to be foodborne. Hepatitis A is transmitted by the fecal–oral route, primarily spreads by person-to-person contact, but food- and waterborne outbreaks do occur. Foods such as milk, strawberries, raspberries, lettuce, and shellfish are common food vehicles.

The causative agent of enterically transmitted nonA nonB virus, which is now designated as hepatitis E virus, is also transmitted fecal–orally. Other viruses have been implicated in gastroenteritis by their sheer large numbers (10^8–10^{10}) and are also known to cause diarrhea and other foodborne gastroenteritis. Most of these enteric viruses may be introduced into foods either as primary contamination at source of food production (harvest) or as secondary contamination during handling, preparation, or serving. Fruits and vegetables that are fertilized with human excrement are thought to be the sole source of contamination. Shellfish are grown commonly in shallow, inshore, coastal waters and are often contaminated with viruses. The problem is compounded by the fact that some shellfish such as oysters are consumed with little or no cooking (as in most Mediterranean countries). In the UK, strict guidelines aimed at inactivating the hepatitis A virus exist for the cooking of cockles.

Spongiform encephalopathies (SEs), Creutzfeldt–Jakob disease, and other scrapies are degenerative disorders of the brain caused by the so-called 'slow viruses,' which are contracted by consumption of meat from infected animals. Lassa fever, which occurs in Nigeria, Guinea, Liberia, and Sierra Leone, is caused by an arenavirus in infected rats, the main reservoir of infection.

Foodborne Protozoa

Only a few protozoa are associated with food or are foodborne (Table 3); the flagellate *Giardia*, the amoeboid *Entamoeba* and three sporozoids of the phylum *Apicomplexa*, which include the genera *Toxoplasma*, *Sarcocystis*, and *Cryptosporidium*, are some of the commonly encountered protozoa.

Giardia lamblia (also called *G. intestinalis* or *Lamblia intestinalis*) survives on food and water as cysts. The cysts, which are aided by gastric juices to release the infective flagellate protozoa, have been found on salad vegetables such as lettuce, fruits such as strawberries, and any food that is washed with contaminated water or handled by infected persons. The cysts are resistant to chlorination but can be disabled if the food is well cooked. *Entamoeba histolytica*, which causes amoeboid dysentery, is widespread and almost endemic in many poor communities. It is estimated that an actively infected person can shed up to 50 million cysts per day, and the potential of these to cause fecal–oral infections cannot be overemphasized. It has been suggested from epidemiological studies that foods such as raw sausage are a risk factor in the sporozoid infection cryptosporidiosis. The organism *Cryptosporidium parvum* can go through its entire life cycle in a single host, and the host could be human, cattle, or sheep. Two species of *Sarcocystis*, however, are obligate parasites: *S. hominis*, which

Table 2 Foodborne pathogenic viruses

Organism	*Food source*	*Illness*
Hepatitis A	Contaminated water and food, sandwiches, fruit and fruit juices, milk and milk products, vegetables, salads, shellfish and iced drinks	Mild fever, malaise, nausea, anorexia, abdominal discomfort and jaundice
Hepatitis E	Water	Malaise, anorexia, abdominal pain, arthralgia, fever
Rotavirus	Salads, fruits, hors d'ouvres	Viral gastroenteritis, infantile diarrhea, winter diarrhea
Norwalk viruses	Water and foods	Nausea, vomiting, diarrhea, abdominal pain
Other gastroenteritis viruses	Food and water	Nonbacterial viral gastroenteritis
Parvo-like virus	Shellfish	Viral gastroenteritis

Table 3 Foodborne pathogenic protozoa

Organism	*Food source*	*Illness*
Giardia lamblia	Contaminated water, food contaminated by food-handlers, contaminated vegetables	Giardiasis, nonbacterial diarrhea
Entamoeba histolytica	Drinking water and foods	Amebiasis
Cryptosporidium parvum	Raw milk and sausage, and any food touched by infected food-handlers	Intestinal, tracheal and pulmonary cryptosporidiosis
Cyclospora cayetanensis, *Acanthamoeba* spp. and *Naegleria fowleri*	Food, water, fresh fruits and vegetables (basil, berries, mesclun lettuce)	Cyclosporiasis infection of small intestines, diarrhea, weight loss, nausea, stomach cramps, muscle ache, vomiting, fatigue

infects cattle, and *S. suihominis* from pigs cause human infections if beef and pork have been undercooked. Even though domesticated or wild cats are hosts to *Toxoplasma gondii* this organism can cause foodborne infections in humans through consumption of undercooked pork or mutton.

Prokaryotic cyanobacteria and blue–green algae are microorganisms, as are the benthic and the planktonic algae. These are used as food and are very expensive in restaurants in different parts of the world. However, some of these can produce very toxic compounds that may be transported to mussels, clams, and small herbivorous fish. Shellfish are not harmed or affected by these high levels of toxins, but a number of distinct illnesses from these sources are now recognized as a result. The illnesses they cause include paralytic shellfish poisoning, neurotoxic shellfish poisoning, diarrheal shellfish poisoning, amnestic shellfish poisoning, and ciguatera fish poisoning. The dinoflagellates *Gonyaulax catenella* and *G. tamarensis* (now *Alexandrium*) cause paralytic shellfish poisoning. Some cyanobacteria, including *Microcystis*, *Anabaena*, and *Aphanizomenon*, are main constituents of algal blooms in lakes, ponds, and reservoirs, and can easily contaminate water drunk by animals and man. It is worth noting here that protozoa are important in assisting in the breakdown of organic matter in ruminant nutrition.

Microorganisms Exploited by Man for Food

The fact that microorganisms can transform organic matter was not known until the middle of the nineteenth century. However, man had used certain microbial metabolic processes, since prehistoric times, for the preparation of food and drink, e.g., in the production of beers and wine, the leavening of bread, and the manufacture of vinegar, cheese, butter, and, more recently, yogurt. The advent of microbiology has led to the development of entirely new industries based on the use of microorganisms not previously exploited by man. In wine production, the grapes are pressed, and the mulch yeast, molds, and bacteria derived from the surface of the ripe grapes, including the so-called true wine yeast, *Saccharomyces cerevisiae* var. *ellipsoids*, start the fermentation process.

The soil has a rich reservoir of microorganisms, and many of these microbial strains have been exploited for use in industrial production of enzymes, amino acids, antibiotics, enzymes, and vitamins that are used in the food industry.

Modern yogurt processing involves inoculating milk with *Streptococcus thermophilus* and *Lactobacillus bulgaricus*. For the production of Russian kefir, milk is inoculated with kefir grain, which is essentially symbiotically growing *Lactobacillus* and yeasts. Indian Idhi (Dosai) used in south India is essentially fermented by *Leuconostoc mesenteroides*, but *Streptococcus faecalis* is also present and contributes to its acidic content.

In West Africa, the use of naturally fermented acidic porridges and dough forms the basis of their staple 'ethnic foods'. Gari (a fermented and fried cassava grit) is prepared from an acid-fermented ground cassava. The principal fermenter is *Corynebacterium manihot*, which hydrolyzes the starch, producing lactic acid and formic acid (evolving heat). At the optimum fermentation temperature of 35 °C, any cyanide-containing sugars present in the cassava (*Manihot utilissima*) are hydrolyzed, removing the cyanide. As the product becomes more acidic (around pH 4.25), a yeast-like fungus *Geotrichum candidum* (also found in Camembert cheese) develops. Other acid porridges are made from millet and maize (ogi and koko), maize and wheat (mahewu), and sorghum. Production of ogi and mahewu proceeds better at temperatures of about 50 °C, which also favors the rapid development of *Lactobacillus delbrueckii*.

Edible mushrooms and some types of seaweed can be considered as foods that are themselves microorganisms. Mushrooms are the fruiting bodies of the fungi and are mainly the stalk surmounted by the cap, which in reality is a mass of closely packed hyphae.

Many lactic acid bacteria occur normally in milk and are responsible for souring. They produce large amounts of acid, which inhibits the subsequent development of other microorganisms. The manufacture of cheese involves two main steps: curding and ripening, and this ripening step is carried out by the action of various bacteria and fungi. Ripening of the curd is a complex process: Cheddar and ordinary American cheese is ripened by lactic acid bacteria in the curd. As these organisms die, proteolytic and fat-splitting enzymes are released from the cells, slowly breaking down the milk fat and proteins with the formation of materials that impart the characteristic cheese flavor. The so-called mold-ripened cheeses such as blue cheese and Camembert are produced by inoculating the curd with special kinds of fungi, which develop either throughout the curd, as in blue cheese, or over its surface, as in Camembert. Swiss cheese is ripened by propionic acid bacteria, which ferment the lactic acid present in the curd to propionic acid, acetic acid, and carbon dioxide. The 'holes' in Swiss cheese are produced by carbon dioxide and the characteristic flavor by propionic acid.

Butter manufacture is also in part a microbiological process, since the microbial souring of the cream is desirable for a good subsequent separation of the butterfat during the churning process. Certain lactic acid bacteria found on plant materials are responsible for souring processes that occur in the preparation of pickles. Some lactic acid bacteria belonging to the genus *Leuconostoc* produce large amounts of the extracellular polysaccharide dextran from sucrose.

In the Far East and Pacific, seaweed has been used as a source of food for millennia. Seaweed's diversified composition makes it far superior to higher plants nutritionally being rich in polysaccharides, minerals (especially iodine), and vitamins, and containing 33–35% total fiber. The green alga *Ulva lactuca* (sea lettuce) is occasionally used fresh in salads, and members of the family Fucaceae like *Fucus* spp. (also called rockweed or bladderwrack) and *Ascophyllum* spp. are used in animal feeds. Rockweeds have been used in recipes like clambakes, as flavorings, and as teas. *Laminaria longicruris* (oarweed or kelp) is a useful source of algin in oriental markets, sold as 'kombu' in health food stores, or may be cooked as vegetables or added to soup. *Laminaria digitata* is used as a vegetable and as flavoring in baked beans. Red algae of the *Porphyra* spp. have seen various uses as a seasoning, in soups, and as a constituent of leven bread.

Microorganisms have been used to produce certain foods, beverages, condiments, and animal feeds, and recently, several new commercial microbial processes have been developed. These include the production of single-cell proteins from microbes to supplement animal feeds, mushrooms (*Agaricus campestris*) for human foods from agricultural wastes (from beet and cane sugar molasses), microbial rennet for cheese making, meat-like flavorings using Chinese soy sauce and Japanese miso processes (employing *Aspergillus soyae* and *Aspergillus oryzae*) xantha, and some vitamins. Algae have also been used as a source of single-cell protein, and the genera *Chlorella* and *Scenedesmus* have been grown for food in Japan. *Spirulina* species have been eaten for many years by the inhabitants of the northern shores of Lake Chad in Africa and by the Aztec Indians in Mexico.

Detection of Foodborne Pathogens and their Toxins

J W Austin and F J Pagotto, Bureau of Microbial Hazards, Ottawa, Canada

Background

Microbiologists often need to enumerate bacteria in food samples or determine the presence or absence of low numbers of specific foodborne pathogens or their toxins. Detection and quantification of foodborne pathogens and their toxins are necessary for several reasons. The most obvious application is for inspection of consumer foods to determine their quality and/or safety. Pathogen detection and enumeration are also necessary for determination of possible sources of contamination during development of a Hazard Analysis and Critical Control Point plan. Enumeration of bacteria, or detection of specific toxins, is necessary for assessing the growth potential of pathogens in foods.

Traditional techniques have relied upon either direct detection using microscopy or, more commonly, cultural methods that involve growth of microorganisms in selective and/or differential culture media. Traditional techniques are still used but are gradually being replaced by more rapid methods employing detection of specific antigens (i.e., immunoassays) or DNA sequences (i.e., nucleic acid hybridization or polymerase chain reaction (PCR)). These latter methods are very specific and allow detection of specific pathogens within minutes or hours, compared with days using traditional cultural techniques. While these newer methods do not require microbial growth and allow for more rapid detection, they typically detect both viable and nonviable microorganisms. When it is desirable to know if viable microorganisms are present, a culture method is preferred.

Direct Detection Using Light Microscopy

Light microscopy allows useful magnifications up to 1000 times and allows examination of food samples for the presence of bacteria and the morphology of the contaminants. Direct microscopic counts involve smearing a known volume of specimen over a defined area of a microscope slide or counting chamber, fixing and staining the specimen, and counting bacterial cells. This method is useful only for samples with at least 10^6 bacteria per milliliter. The best-known example of direct microscopic counts is the Breed smear, which is used to enumerate bacteria in milk. The numbers of bacterial cells in several fields are counted and averaged to obtain the count of bacteria in the original sample.

The direct epifluorescent filter technique involves concentration of microorganisms on membrane filters to increase the limit of detection, followed by detection of specific microorganisms using a fluorescent label. Depending upon the fluorochrome used, the technique can be used for several applications. When stained with acridine orange, for example, viable cells generally fluoresce orange–red, whereas nonviable cells fluoresce green. Fluorescently tagged antibodies specific for bacterial surface antigens can be used to identify specific bacteria.

Cultural Techniques

Cultural techniques usually involve several steps, including enrichment for the target organism, isolation using selective and differential media, and finally identification of the isolate using phenotypic or genotypic analysis. Cultural methods such as the most probable number (MPN) technique and plate counts are used to isolate and enumerate microorganisms in foods.

Enrichment

Preenrichment media are designed to increase the numbers of the target organism, without suppressing the growth of other organisms. Preenrichment may allow repair of damaged organisms and encourage multiplication of the target organism from a few cells to 10^5 or more per milliliter over a specified period of time. Selective enrichment media are then employed to increase the numbers of the target organism, relative to the other bacteria in the specimen, by using chemical, physical, or biological methods that favor the growth or survival, or effect the physical separation of the target organism. Physical enrichment methods may make use of conditions such as growth temperature, heat treatment, or size characteristics of specific organisms. Chemical enrichment methods may employ antibiotics or specific toxic agents to suppress the growth of unwanted bacteria, while allowing the growth of the target organism. Selective agents include antibiotics, dyes, detergents, and various organic and inorganic chemicals.

Differential Media

Once the numbers of the target organism are increased during various enrichment steps, isolation is attempted using differential plating media, often incorporating selective agents. Differential media allow

the target microorganism to be distinguished from other microorganisms based on a recognizable reaction produced by the growth of the target microorganism. There are many media that include pH indicators to allow for a visual detection of changes in pH as a result of the metabolic reactions that take place as the bacteria grow on the media. Commonly used indicators include bromophenol blue (red in acid; blue in alkaline), methyl red (red in acid; yellow in alkaline), bromocresol green (yellow in acid; blue in alkaline), and phenolphthalein (colorless in acid; red in alkaline). Bacterial colonies that exhibit the expected reaction are streaked on nonselective media to ascertain purity. Pure cultures are then characterized by genotypic or phenotypic methods to obtain a positive identification.

MPN

The MPN technique involves making replicate dilutions of a sample in an appropriate liquid growth medium and incubating for growth. The sample is diluted until aliquots are estimated to contain one viable cell each. Some aliquots will contain a single viable cell, whereas others will not contain a viable cell. Theoretically, a single cell will grow and cause turbidity or will be recorded via a biochemical reaction giving recognizable changes in the medium. The tubes showing no growth have presumably not received a single cell capable of growth. By counting the number of positive and negative tubes at each dilution, and referring to statistical tables, the MPN can be determined. The MPN technique is useful when the organism cannot be grown on solid medium, if it is easily overgrown by other bacteria, or if it produces a unique substance that can be assayed in broth. An example is determination of numbers of *Clostridium botulinum* in a sample by dilution, followed by detection of botulinum neurotoxin in the cultures using the mouse bioassay.

Direct Plate Counts

Direct plating on solid agar media allows isolation of single clones of bacterial cells, in addition to determination of numbers of bacteria in a sample. Dilutions of food samples are evenly spread on to solid growth media and incubated to allow formation of discrete colonies. Alternatively, dilutions of samples can be mixed with melted agar and poured into Petri plates. Such 'pour plates' give rise to colonies within the agar that can be counted to enumerate the bacterial cells in the original sample. As a rule, to obtain accurate results, the lower number of colonies per plate is often specified as 20 (lower numbers give less statistically significant results), whereas the upper limit is usually 200 colonies per plate (higher numbers are difficult to count, and colonies may coalesce).

Physiological Tests

The presence of a particular microorganism may be indicated by detection of a metabolic product or toxin unique to that organism. Proteolytic strains of *Clostridium botulinum* are phenotypically identical to *C. sporogenes*, with the exception that the former produced botulinum neurotoxin. Detection of botulinum neurotoxin with the mouse bioassay is an example of a physiological test to indicate the presence of a specific microorganism.

Dye Reduction

Dye-reduction assays use dyes to estimate the number of viable cells that are present in certain food products. The most commonly used dyes are methylene blue and resazurin. Supernatants of food products are prepared and are added to predetermined solutions of methylene blue or resazurin. Dye reduction time, inversely proportional to the number of cells in the sample, causes a color change from blue to white (methylene blue) or slate blue/pink to white (resazurin). In foods that do not contain many inherent reductive compounds, the dye reduction assay is comparable with the standard plate count method. The most common food analyzed is milk.

Bioluminescence

Bioluminescence-based methods for the detection of bacteria can be divided into two: adenosine triphosphate (ATP) measurement, and *lux* gene technology. Extraction and measurement of bacterial ATP can be indicative of the number of organisms present in a sample. The firefly luciferin–luciferase system is the most commonly used method. In the presence of ATP, the enzyme luciferase causes light emission, which can be readily measured using a luminometer. The amount of light emitted is directly proportional to the amount of ATP in the sample. Specific inhibitors are often used to destroy nonbacterial sources of ATP in food samples. The assay is attractive in determination of microbial load owing to its rapidity in obtaining results (usually within 10 min).

Some marine bacteria, such as *Vibrio fischeri* and *V. harveyi*, are able to luminesce, and the genes encoding this capacity have been characterized. Coding for the bacterial luciferase, the *luxA* and *luxB* genes have been inserted in species-specific bacteriophages. The bacteriophages are not metabolically active and do not emit light. However, when the bacteriophages attach themselves to their target (for example, a *Salmonella typhimurium*-specific bacteriophage would only attach itself to *S. typhymurium* if it were present

in the sample), the phage genetic material becomes inserted into the bacterial cell, where it can replicate and cause the host cell to luminesce. The reaction between luciferase and a long-chain aliphatic aldehyde substrate (such as dodecanal) provided exogenously in the sample results in the production of light.

Immunoassays

Agglutination

Agglutination reactions involve particulate antigens capable of binding antibody molecules. Since antibody molecules are multivalent, suspended particulate antigens form large clumps or aggregates, easily visible without magnification, when exposed to specific antibodies. Antibodies that cause this reaction are referred to as agglutinins. Agglutination assays can be used to determine concentrations of specific antibodies in a patient's immune sera. A constant amount of a suspended particulate antigen is added to a series of tubes containing a twofold dilution of patient's immune serum, and the titer of antibody in the serum is the reciprocal of the highest serum dilution showing agglutination of the particulate antigen. Agglutination reactions are routinely used for identification and serotyping of a wide range of bacterial foodborne pathogens.

Passive Agglutination

Whereas agglutination allows the use of particulate antigens to determine concentrations of antibodies in sera, passive Agglutination allows the determination of the presence and concentration of soluble antigens. In passive particle (indirect) agglutination, soluble antigens are coupled to large particles such as erythrocytes or latex spheres. When specific antibodies are added to coated erythrocytes or latex spheres, antibody bridges are formed between the particles, and agglutination occurs. By addition of a constant amount of coated particles to various dilutions of antisera, the titer of antibodies to the antigen used to coat the particles can be determined.

Alternatively, to determine the concentration of a soluble antigen, particles can be coated with antibody specific to the soluble antigen and added to dilutions of sample containing the soluble antigen. Agglutination of the antibody-coated particles indicates the presence of the soluble antigen.

Enzyme-linked immunosorbent assay (ELISA)

ELISA uses antibodies linked to enzymes to detect nanogram to picogram amounts of antigen. ELISAs rely on the fact that antigens or antibodies can be bound to a solid support, and antibodies can be coupled to enzymes without the enzyme losing activity or the antibody losing binding activity. Enzymes coupled to antibodies include alkaline phosphatase, horse-radish peroxidase, and β-galactosidase. Bound antibody–enzyme conjugates are detected by the formation of a colored reaction product produced by the enzyme. Two basic ELISA methods are used: the double antibody sandwich ELISA (or direct ELISA, Figure 1), for detection of soluble antigen, and the indirect immunosorbent ELISA, used for measuring presence and concentration of antibody in sera.

The double antibody sandwich, or direct ELISA, employs a capture antibody immobilized to a microtiter plate. The capture antibody 'captures' specific soluble antigens and immobilizes them on to the microtiter plate. A reporter antibody binds to the captured antigen to complete the 'sandwich.' This reporter antibody is conjugated to an enzyme (e.g., alkaline phosphatase or peroxidase), allowing detection of the reporter antibody. If the specific soluble antigen is not present, the sandwich of the capture antibody–antigen–reporter antibody does not form, and the reporter antibody is not available to produce a colored reaction product.

Immunofluorescence

Antibodies can also be coupled to fluorescent dyes, allowing detection of bound antibodies by fluorescence. Immunofluorescence can be used as a rapid procedure to detect a specific agent in a specimen containing a mixture of microorganisms. In the

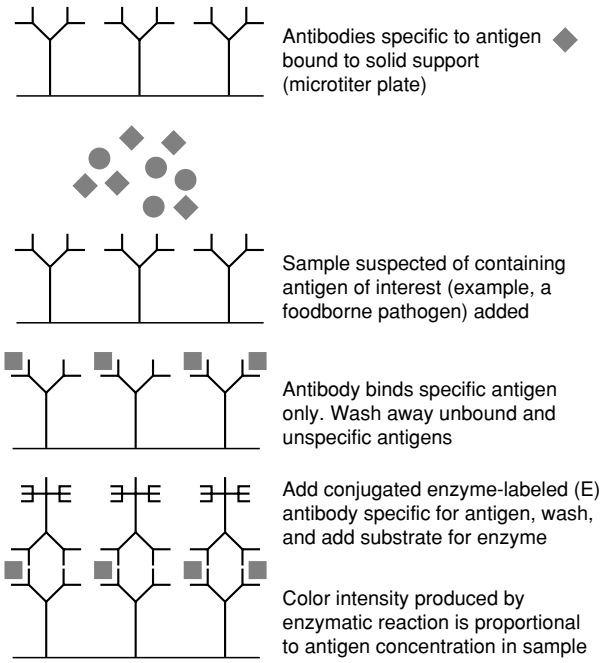

Figure 1 Direct ELISA assay.

direct fluorescent antibody technique, a smear of the sample is incubated with a solution containing specific antibody that is directly labeled with a fluorescent dye. After allowing the fluorescent antibodies to bind to the microorganisms, unbound fluorescent antibodies are removed by washing, and fluorescent bacteria are observed by epifluorescence light microscopy. The indirect fluorescent antibody technique is similar, but the smear is first incubated with unlabeled antibody. Bound antibody is then detected by incubation with a second fluorescent-labeled antibody against the immunoglobulin of the animal species used for the preparation of the initial antibody.

Immunomagnetic Separation

Immunomagnetic separation involves coupling of biological macromolecules, such as specific antibodies, to superparamagnetic iron oxide (Fe_3O_4) particles. Superparamagnetic particles exhibit magnetic properties when placed within a magnetic field but have no residual magnetism when removed from the magnetic field. This technology has been incorporated to make uniform porous polystyrene spheres, approximately 2–5 μm in diameter, with an even dispersion of magnetic Fe_3O_4 throughout the bead. These magnetic beads are coated with a thin polystyrene shell that encases the magnetic material and provides a defined chemical surface area for the adsorption of coupling of molecules such as antibodies and streptavidin.

The magnetic particles are added to a heterogeneous suspension to bind to the desired target (bacterial cells, viruses, proteins, nucleic acids, etc.) and form a complex composed of the magnetic particle and target. A magnet is used to immobilize the magnetic particles complexed with the target against the vessel wall, and the remainder of the material is removed. Washing steps to remove food material and other microorganisms are easily performed while the particle–target complex is retained. The target then can be detected using conventional immunoassays, pipetting or streaking on to agar culture media, or by using nucleic acid-based methodologies, as the magnetic particles do not interfere with other methods of detection.

Nucleic Acid-based Detection and Typing

DNA Probes

Under the proper conditions, a single-stranded DNA molecule will hybridize selectively with a complementary sequence of DNA, forming double-stranded DNA. If the reformed double helix is composed of DNA strands from different sources it is referred to as a 'hybrid.' The use of a labeled single-stranded DNA molecule (i.e., a DNA probe) allows detection of specific, complementary, nucleic acid sequences. DNA probes can be designed at varying levels of specificity to detect to species level, or beyond species level to particular pathogenic strains. Hybridization is a very specific method and has been used to detect several specific foodborne pathogens.

For hybridization to occur between a DNA probe and the target sequence, the double-stranded target DNA must be denatured into two separate strands by an increase in temperature. When the temperature is lowered, the strands will reform a double helix if strands contain similar sequences. The temperature and salt concentration used for hybridization are critical. If the temperature is too low, hybrids can be formed by strands that are not exactly complementary (low stringency). If the temperature is too high, strands that are exactly complementary may not hybridize, resulting in a negative reaction. The salt concentration is also adjusted to increase or decrease the stringency of the hybridization. Together, temperature and salt concentrations are used to optimize the hybridization conditions so that only the probe and a filter-bound nucleic acid that is highly homologous to that probe will bind to each other.

PCR and Other Amplification-based Methods

PCR (Figure 2a) is used for *in vitro* amplification of specific sequences of DNA. Specific sequences can be detected by amplification up to several million times. The amplified DNA can be visualized by electrophoresis on an agarose gel, followed by staining with ethidium bromide. The PCR reaction requires two oligonucleotide primers, complementary to sequences on opposite DNA strands. The two strands of the target DNA are separated by an increase in temperature (94 °C), and the primers are allowed to anneal to the complementary sequences in the denatured target DNA at a reduced temperature (50–70 °C). A thermally stable DNA polymerase from the thermophilic bacterium *Thermus aquaticus* (*Taq* polymerase, although other polymerases may be used) is used to synthesize the second strands. Two double-stranded DNA molecules have now been created from a single double-stranded molecule. The process is repeated, with each amplification step doubling the number of strands of target DNA.

Immuno-PCR combines the powerful amplification of PCR with antibodies to detect specifically low levels of antigens. This method is similar to an ELISA, but the reporter antibody is linked to a DNA fragment that can be amplified by PCR. Immuno-PCR has been shown to be 10^2–10^5-fold

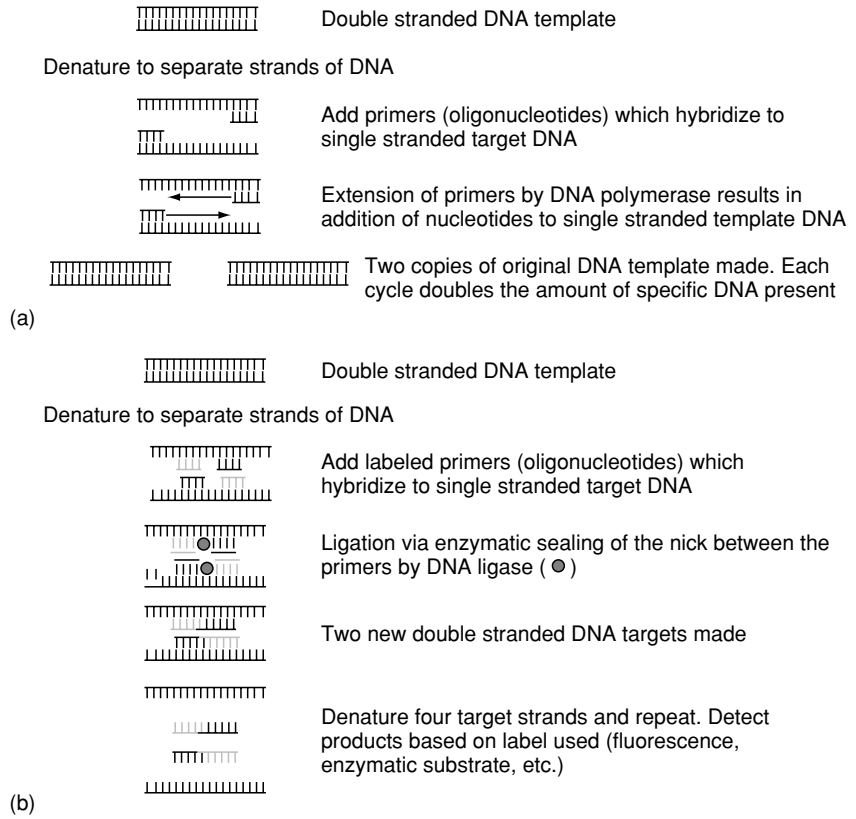

Figure 2 Diagrammatic differences between (a) PCR and (b) LCR. PCR generates a new target via synthesis of new DNA, whereas LCR joins primers that become the new target DNA molecules.

more sensitive than standard ELISA methods and has been used to detect antigens such as hormones, tumor markers, botulinum neurotoxin, and viral antigens.

Several techniques that employ PCR-based DNA fingerprinting of microorganisms have been developed in the last decade. PCR-based DNA fingerprinting is based on binding of primers to regions of DNA followed by the generation of species or strain-specific PCR amplification products. Randomly amplified polymorphic DNA assay (RAPD), also referred to as arbitrarily primed PCR, employs a single short (typically 10 base pairs) primer that is not targeted to any specific bacterial DNA sequence. At low annealing temperatures, the primer hybridizes at multiple random chromosomal locations and initiates DNA synthesis. Owing to its arbitrary nature, RAPD-PCR is susceptible to technical variation which may cause problems in reproducibility.

The ligase chain reaction (LCR, Figure 2b) uses two contiguous oligonucleotides that are joined by DNA ligase upon perfect hybridization to their target. The ligated probes are then amplified via thermal cycling with complementary oligonucleotides. LCR is better suited than PCR for diagnostic purposes, although there still remain few data comparing the two techniques in clinical settings. LCR makes use of known sequences for the sole purpose of detection, and this aspect makes it attractive for detection of foodborne pathogens. PCR, however, generates new DNA or RNA molecules that may require further verification or characterization (such as RFLP or direct sequencing). Although no report exists describing LCR as a detection system for foodborne pathogens, a major advantage would be the high specificity of the assay. Automation of any amplification-based method makes such technologies attractive for diagnostic laboratories.

Nucleic acid sequence-based amplification, or NASBA, is a technique that amplifies RNA and DNA targets as antisense, single-stranded RNA by the concurrent activity of reverse transcriptase, RNase H, T7 RNA polymerase, and two primers. NASBA is commonly used to determine HIV load in clinical samples. However, the technology should be applicable to food microbiology. Recently, a method for detection of viable oocysts of *Cryptosporidium parvum* in environmental samples using the NASBA technique was described. Another report described the use of NASBA to detect *Escherichia coli* isolates, which included enterohemorrhagic serotype

0157:H7. A 140-fg amount of total RNA could be amplified reproducibly to give a clear, detectable signal. In addition, a single *E. coli* cell in a sample could be detected in less than 14 h.

Pulsed-field Gel Electrophoresis (PFGE)

When bacterial DNA is digested with restriction enzymes that cut at a small number of sites within the genome (usually five to 20), high-molecular-weight fragments of DNA are obtained. These large fragments of DNA can be separated in a pulsed electric field, where the direction of the electric field is alternated between forward and reverse directions, with the forward pulse being longer in duration than the reverse pulse. Alternatively, contour-clamped homogeneous electric field gel electrophoresis, where a hexagonal arrangement of six electrodes are used to generate uniform electric fields at 120° to each other, can be used to separate DNA molecules as large as 3 million bases. When the agarose gel is stained with ethidium bromide, a restriction map is obtained with the pattern specific to individual bacterial isolates.

PFGE is highly discriminatory, capable of distinguishing between isolates within the same species or serotype. The major limitations of PFGE include the requirements for technical skill, sophisticated equipment, and the long duration until completion of the analysis. Not all strains of bacteria can be typed using PFGE because of degradation of DNA as a result of extracellular DNase production or the resistance of cell walls of some bacteria to lysis. Equally, some organisms may not yield sufficient discriminatory information using PFGE.

Ribotyping

Ribotyping makes use of ribosomal RNA gene restriction pattern analysis to discriminate between bacterial isolates. Ribosomal RNA (rRNA) is present in ribosomes of all bacterial cells and is composed of molecules of three different sizes: 23S, 16S, and 5S. The DNA encoding for rRNA is highly conserved among closely related bacteria, making ribotying less discriminatory than other DNA-typing procedures. Ribotyping involves isolation of total bacterial DNA followed by digestion of the DNA with specific restriction enzymes. The digested DNA is separated by electrophoresis on an agarose gel and transferred on to a nylon or nitrocellulose membrane. The DNA fragments on the membrane are then probed with labeled DNA fragments complementary to the rRNA gene sequences. After probing, each fragment of bacterial DNA containing a ribosomal RNA gene will be highlighted, creating a fingerprint pattern. An automated ribotyping system is available from DuPont Qualicon that allows identification of bacterial isolates, beyond the species level, in approximately 8 h.

DNA Sequencing

Automated DNA sequencing procedures now allow rapid sequencing of extended DNA sequences. This has facilitated sequencing of entire genomes, including the human genome. Perhaps the ultimate bacterial identification procedure of the future will be genome sequencing. Certainly, current technologies allow for rapid amplification and sequencing of the genes, such as the 16S rRNA of bacterial isolates. Because 16S rRNA genes are conserved among isolates of the same species, yet vary between species, phylogenetic trees describing their evolutionary relationships have been described. Indeed, the universal phylogenetic tree describing the phylogeny of the living world has been based on 16S or 18S rRNA comparative sequence analysis.

MICROCAPSULES

C Thies, Washington University, St. Louis, MO, USA

Background

Microencapsulation is the coating of small solid particles, liquid droplets, or gas bubbles with a thin film of coating or shell material. Although no officially approved definition of a microcapsule exists, most workers use the term microcapsule to describe particles with diameters between 1 and 1000 μm that contain a desired ingredient of some sort. Particles smaller than 1 μm are called nanoparticles; particles greater than 1000 μm can be called microgranules or macrocapsules.

Many terms have been used to describe the contents of a microcapsule: active agent, actives, core material, fill, internal phase, nucleus, and payload. Many terms have also been used to describe the material from which capsules are formed: carrier, coating, membrane, shell, or wall. For the sake of consistency, in this article, the material being encapsulated is called the core material, and the material from which the capsule is formed is called the shell material.

Several reviews discuss the general features of microencapsulation technology, including encapsulation techniques and applications not discussed here. A number of authors have reviewed the preparation of microcapsules that contain food components and the application of microcapsules to food products.

An understanding of microencapsulation technology and the potential contribution that microcapsules can make to food products rests on a knowledge of mass transport phenomena, properties of coating materials, and an understanding of processes by which small particles are produced. Since the primary purpose of microencapsulation is to control in some manner mass transport behavior, the shell of a microcapsule must control diffusion of material either from a microcapsule or into a microcapsule (**Figure 1**). The shell can provide protection of sensitive food components such as flavors, vitamins, or salts from oxygen, water, light and heat, convert difficult-to-handle liquids into free-flowing powders readily incorporated into various foods or isolate specific food components during storage.

In most cases, food components concentrated inside microcapsules are released as the food is consumed or during a food preparation step. Release is achieved by destroying the integrity of the microcapsule shell. This is done by dissolving it in water, melting it, or mechanically rupturing it. There are cases where no release of core material is desired until after the food has been ingested and is present in the digestive system. Perhaps, the intent is for the core material carried by a microcapsule never to be released. In these latter situations, the capsule shell must remain intact throughout the food preparation and ingestion steps.

In order to develop microcapsules with shells that function as intended, it is essential to understand the fundamentals of mass transport through shell materials from which microcapsules are formed, especially under use conditions. In many cases, the shell is thin, perhaps having a thickness of a few micrometers or less. Thus, the morphology or structure of a capsule shell has a significant impact on microcapsule performance. Overall, capsule morphology also affects capsule performance. The geometry of a microcapsule sample can vary significantly and often is a function of the process by which the microcapsule was formed. **Figure 2** illustrates two typical capsule structures, with **Figure 2a** representing a continuous core/shell capsule in which a single continuous shell of uniform thickness surrounds a continuous spherical region of core material, and **Figure 2b** representing a multinuclear capsule in which a number of small domains of core material are distributed uniformly throughout a matrix of shell material.

During the development of microcapsules for a specific food application, it is tacitly assumed that a food-grade microcapsule shell material with suitable

barrier and fabrication properties is available at an economically viable price. Proper selection of such materials requires an appreciation of the properties of candidate coating materials and requires an understanding of materials science. Significantly, few, if any, candidate capsule shell materials are able to provide all desired functions economically, so compromises must consistently be made when selecting specific shell materials for a given application.

Table 1 lists representative examples of capsule shell materials currently used to produce microcapsules for commerical food products, and the chemical class to which the shell material belongs, the encapsulation process typically used to produce microcapsules with each shell material and frequent food applications. Although gelatin–gum arabic complex coacervate capsules treated with glutaraldehyde are approved for limited consumption of selected food flavors, they are not approved for general food use (see Figure 3). Shell material costs vary greatly. As expected, the food industry favors the cheapest acceptable shell materials that are capable of providing desired performance, are available in commercial quantities, and are approved by the FDA.

Microencapsulation Processes

General Comments

Many microencapsulation processes exist. Some are based exclusively on physical phenomena. Some utilize polymerization reactions to produce a capsule shell. Others combine physical and chemical phenomena. Because there are so many encapsulation techniques, it is logical to make an effort to attempt to categorize or classify them in some manner, thereby providing a means of identifying the concepts on which various encapsulation technologies are based. Many authors do this by identifying encapsulation processes as either chemical or mechanical processes. This author prefers to classify them as Type A or Type B processes, since so-called mechanical or physical processes actually may involve a chemical reaction, and so-called chemical processes may rely exclusively on physical phenomena. Table 2 lists representative examples of Type A and B processes. Type A processes are processes in which microcapsules are immersed in a liquid-filled stirred tank or tubular reactor throughout the encapsulation procedure. In a Type B process, a gas phase is involved at some stage of the encapsulation process. Microcapsules are formed by spraying droplets of coating material on a core material being encapsulated, solidifying liquid droplets sprayed or ejected into a gas phase, gelling droplets sprayed or ejected into a liquid bath, or

Table 1 Shell materials used to produce commercially significant microcapsules

Shell material	*Chemical class*	*Encapsulation process*	*Applications*
Gum arabic	Polysaccharide	Spray drying	Food flavors

by carrying out a polymerization reaction at solid/gas or liquid/gas interfaces.

No encapsulation process developed to date is able to produce the full range of capsules desired by potential capsule users. Some processes readily produce small, liquid-filled capsules, whereas others produce relatively large capsules with a solid core material, capsules with water-soluble shells, or capsules with water-insoluble shells. In order to provide insight into which process is most appropriate for a specific food application, features of Type A and B encapsulation processes used by the food industry are summarized in the following sections. Processes that produce capsules not approved for food applications are discussed elsewhere.

Type A Encapsulation Processes

Complex coacervation Complex coacervation is a phenomenon in which cationic and anionic water-soluble polymers interact in water to form a liquid, polymer-rich phase called a complex coacervate. This coacervate is used to form a microcapsule shell (see Figure 3). Gelatin is normally the cationic polymer used. A variety of natural and synthetic anionic water-soluble polymers interact with gelatin to form a complex coacervate, but the food industry appears to use gum arabic exclusively. When the complex coacervate forms, it is in equilibrium with a dilute solution called the supernatant. The supernatant acts as the continuous phase in which the complex coacervate is dispersed. If a water-insoluble core material such as a flavor or fat is dispersed in the system, each droplet or particle of dispersed core material is spontaneously coated with a thin film of coacervate provided that the coacervate adsorbs on the surface of the dispersed oil droplets. When this liquid film is gelled, capsules are formed. The 'wet' complex coacervate gel is a very rubbery shell that deforms extensively without rupturing. In order to increase the strength of the water-swollen shell and create a gel structure that is not thermally reversible, complex coacervate capsules shells are typically cross-linked with glutaraldehyde.

Complex coacervation encapsulation processes can encapsulate many water-immiscible oils such as vitamins, plant oils and flavors as well as water-insoluble solids. Such processes routinely produce single capsules 20–800 μm in diameter that contain 80–90 wt.% core material. Capsules outside these size and core

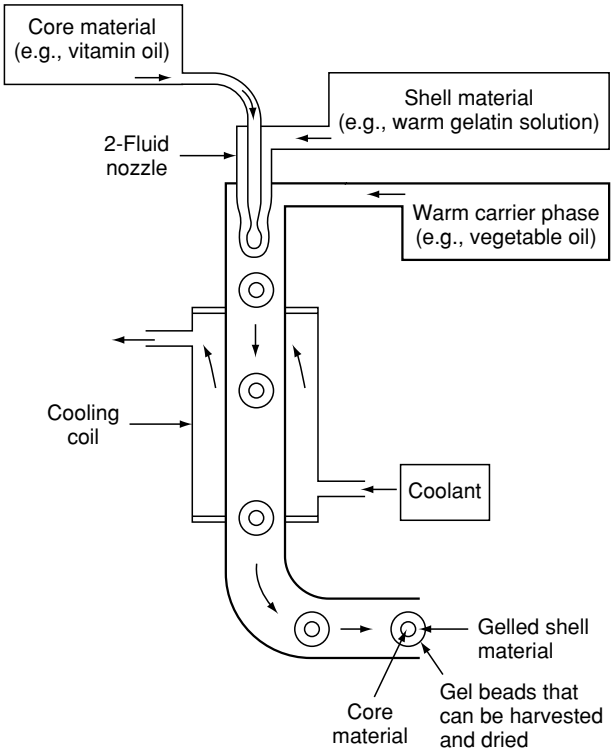

Figure 4 Stationary two-fluid nozzle used to produce capsules.

content ranges can be produced, although considerable experience may be required. Most coacervate capsules approach the continuous core/shell structure shown in Figure 2a, but the shell may not have a uniform thickness. Complex coacervation processes are adversely affected by active agents that have a finite water solubility, are surface active, or are detrimentally affected by pH conditions used to produce the microcapsules. The shell of dry complex coacervate capsules is sensitive to variations in atmospheric moisture content and becomes plasticized at a relative humidity of 70% or higher. Thus, the release properties of a complex coacervate capsule can be affected significantly by environmental conditions to which the capsules are exposed during storage.

Submerged centrifugal force and nozzle processes
Several Type A processes use submerged centrifugal force or nozzles to form microcapsules (see Figure 4). The nozzles can be rotating, stationary, or vibrating. They may be single or multifluid nozzles. An example of the former is the spinning cup encapsulation apparatus developed by the Atlantic Coast Fisheries Company. This consists of a spinning cup that contains a row of small holes. When the cup is immersed in a container filled with mineral oil or vegetable oil, an oil-in-water (o/w) emulsion fed into the interior of this spinning cup is extruded dropwise by centrifugal force through the openings into the oil phase that surrounds it. This creates a suspension of o/w emulsion droplets suspended in an oil phase. The continuous phase of these droplets is an aqueous solution of a polymer that gels on cooling (e.g., gelatin), whereas the dispersed phase is a water-immiscible liquid like a vitamin or fish oil. As the extruded droplets sink in the oil phase, the aqueous phase of the emulsion gels thereby creating gel beads throughout which an oil such as a vitamin or fish oil is dispersed. The beads are harvested from the oil phase by a solvent wash and dried. The dried beads have the structure shown in Figure 2b (see Figure 5).

Various submerged stationary and vibrating nozzles are used to produce microcapsules. A number of different nozzle configurations exist, and these produce capsules with a variety of structures. Sophisticated multifluid vibrating nozzles have been incorporated into capsule production units. Such units typically produce microcapsules by coextruding an aqueous polymer solution that gels on cooling and an oil to be encapsulated into a third or suspending fluid. The suspending fluid is a cooled oil phase in which the aqueous polymer solution gels, thereby forming gel beads with a continuous core/shell structure, as shown in Figure 2a. Such beads are isolated from the suspending fluid, washed in order to remove residual oil from the suspending medium, and subsequently dried.

To date, submerged Type A centrifugal force and various nozzle encapsulation processes are used primarily for the encapsulation of a variety of water-immiscible oils. The capsules tend to be larger than 250–500 μm but are typically formed from food-grade shell materials that can be gelled thermally.

Type B Encapsulation Processes

General comments Type B encapsulation processes utilize centrifugal force, extrusion, coextrusion, and spray technology in order to produce microcapsules. They predate Type A encapsulation processes, since spray drying encapsulation was developed in the 1930s. This class of encapsulation processes generally utilizes self-contained encapsulation units marketed by equipment manufacturers. In contrast, equipment for Type A encapsulation processes is typically custom-designed and manufactured for a specific capsule producer. It is the author's opinion that Type B processes often cannot produce microcapsules < 100 μm economically, whereas many Type A processes can. A notable exception is spray drying. Other exceptions undoubtedly exist, but there is clearly a question of how well many current Type B processes function when an effort is made to use them to produce economically viable amounts of small (e.g., < 100 μm) microcapsules.

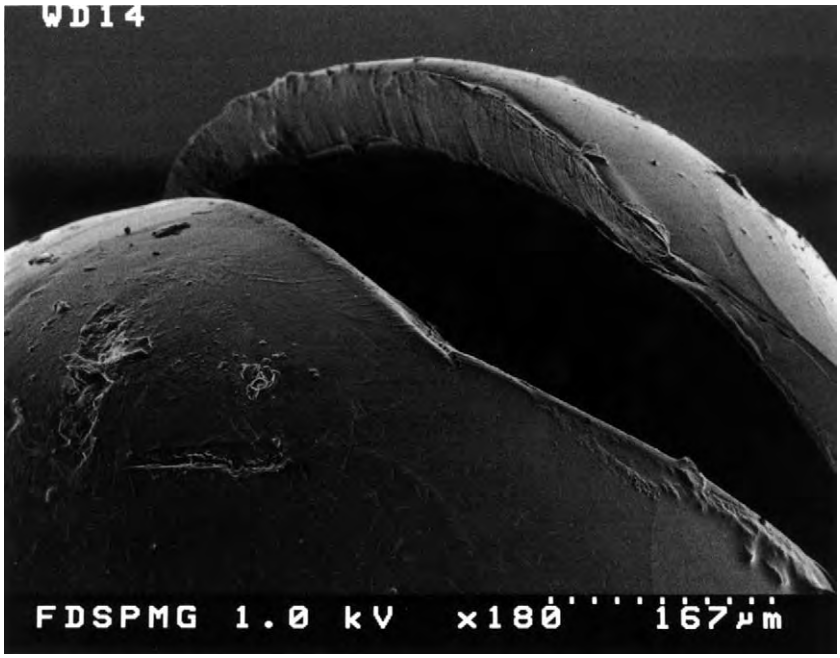

Figure 5 Scanning electron photomicrograph of a cut flavor capsule produced by a submerged nozzle encapsulation apparatus. Magnification: 180 ×. Courtesy Thies Technology.

Spray drying Spray drying is used to produce a variety of encapsulated food components. The first step is to emulsify the core material, typically a water-immiscible flavor, vitamin, fish or plant oil, in a concentrated (35–60 wt.%) aqueous solution of shell material until 1–3 µm oil droplets are obtained. The shell material normally is a water-soluble material like gum arabic, maltodextrin (hydrolyzed starch), modified starch, hydrolyzed gelatin, sugars, or various mixtures of these materials. All are approved for food use. They are water-soluble and not chemically cross-linked. Capsules prepared from them dissolve in water and release core material without leaving any residual capsule shell debris. Figure 6 illustrates the steps involved in the process. (*See* **Drying**: Spray Drying.)

Once a suitable core material/shell material dispersion has been prepared, the resulting emulsion is fed as droplets into the heated chamber of a spray drier. The droplets are rapidly dehydrated, thereby producing dry capsules that fall to the bottom of the drying chamber where they are harvested. Capsules produced in this manner are typically 10–300 µm in diameter. They may have an irregular geometry and be aggregates of a number of small particles. Spray-dried capsules contain a number of small droplets of core material dispersed throughout it, as illustrated in Figure 2b.

Spray-dry encapsulation has a number of advantages:

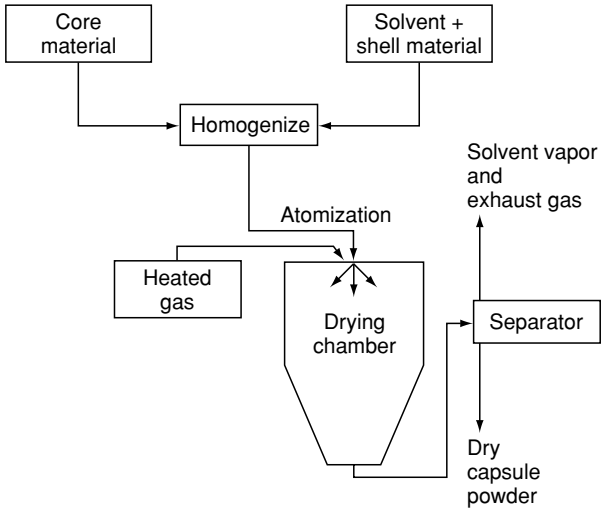

Figure 6 Steps involved in a spray-drying encapsulation process.

1. It is a well-established technology.
2. It utilizes readily available equipment.
3. It can produce large amounts of capsules economically.

It also has several limitations. For example, the list of candidate water-soluble shell materials is limited to candidate materials that form concentrated (30–60 wt.% solids) aqueous solutions of sufficient low viscosity that they can be pumped. Another limitation

is the 20–30% core loading carried by most spray-dried capsules. Spray-drying protocols that allow core loading up to 50–60% have been reported, but current spray-dried capsules carry a lower loading. A persistent problem with spray-dried capsules is free or surface core material. Because water evaporation from a capsule in the chamber of a spray drier occurs rapidly, it is not uncommon to harvest spray-dried capsules that have a significant amount of free or unencapsulated oil. This free oil exists because of discontinuities in the capsule shell, some of which form as a result rapid evaporation of water from the droplets being dried, thereby forming microcapsules. The higher the core loading, the more pronounced this problem can become. Free or surface oil is undesirable, since it is susceptible to oxidation and development of an off-odor or off-taste when the encapsulated core material is a fragrance or a flavor, respectively. It has been found that maximizing core loading and minimizing free core content involve a judicious choice of coating material, emulsifying agent, and spray-dryer operating conditions. Finally, it is important to stress that low-boiling-point compounds with a finite degree of water solubility have posed a persistent problem to spray-drying encapsulation. Such compounds volatilize from the capsules in the spray-drying chamber.

In summary, spray drying is a viable commercial method of forming microcapsules for the food industry. It is an established, comparatively low-cost encapsulation technology that continues to develop. To date, spray drying for food products has primarily been used to encapsulate flavors, various fish and plant oils as well as liquid vitamins.

Spray chilling Spray chilling, cooling, or congealing are variations of conventional spray-drying. In these cases, chilled air is used to solidify molten capsule shell material formulations rather than volatilize a solvent. Various fats, waxes, fatty alcohols, fatty acids, or combinations of these materials are the shell materials used. In such encapsulation procedures, the active agent is dispersed in a molten shell material with the aid of an emulsifier, if necessary. The resulting dispersion is atomized through heated nozzles into a cooling chamber analogous to that used in a spray drier. The shell material is solidified by cooling, thereby producing solid particles.

Particles produced by this method have water-insoluble shells. The processing temperature has an influence on shell material polymorphism, a phenomenon that is characteristic of many fats. If polymorphic changes in a fat coating occur on storage, such changes can have a significant negative effect on capsule storage and release properties.

Fluidized-bed coaters Fluidized-bed coaters function by suspending a bed or column of solid particles in a moving gas stream, usually air. Three types of fluidized beds are available: top-spray, tangential-spray, and bottom-spray (see Figure 7). These units differ in location of the nozzle or nozzles used to apply the coating formulation. Nevertheless, in each case, a liquid coating formulation is sprayed on to the individual suspended particles, and the freshly coated particles are cycled into a zone where the coating formulation is solidified either by solvent evaporation or by cooling. This coating and drying sequence may be repeated until a desired coating thickness has been applied. (*See* **Drying:** Fluidized-bed Drying.)

In a bottom- or tangential-spray unit, droplets of liquid coating material leaving a spray nozzle move

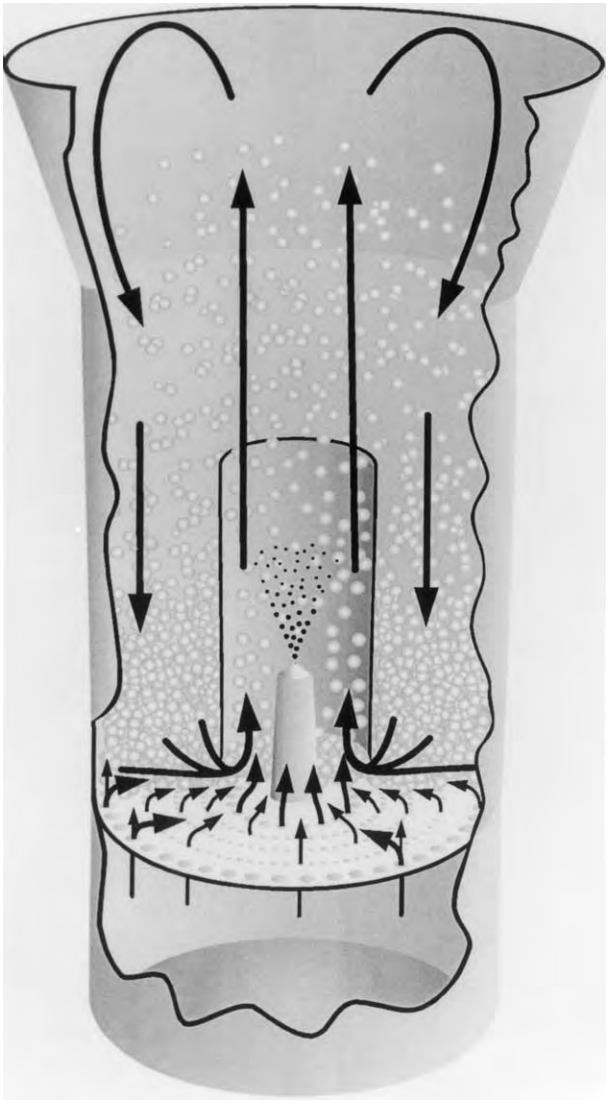

Figure 7 Bottom spray or Wurster fluidized-bed coating apparatus. Courtesy Coating Place, Verona, WI.

concurrent with the gas stream used to suspend the bed of solid particles being coated. In a top-spray unit, the coating formulation is sprayed down on and into the top of the fluidized bed. The droplets of spray leaving the nozzle move countercurrent to the gas stream until they impact the particles being coated. In the former case, a uniform film of coating material can be deposited when the coating formulation contains a volatile solvent. In the latter case, volatile solvent(s) in the coating formulation can evaporate from the spray droplets, thereby increasing the solids content, perhaps to such a degree that they cannot spread on to the particles being coated. This spray-drying effect has been used to explain why solvent-based coating formulations applied in top-spray fluidized bed coaters often yield coated particles with a degree of internal void volume and porous coatings. Enteric coatings applied as aqueous latex dispersions are an exception. Such coatings applied in a top-spray fluidized-bed coater form a continuous coating analogous to that obtained with tangential- and bottom-spray units. Molten fats also can be applied by top-spray units, since, in such cases, there is no solvent evaporation. Although top-spray units have limitations, they are claimed to be simpler to operate and have a higher production capacity than the other types of units.

Application of the capsule shell material in a series of steps, as is typically done in a fluidized-bed coating process, is both an advantage and a disadvantage. The advantage is that sequential deposition of the shell formulation in a number of different cycles covers up or heals defects found in any single application, thereby yielding relatively defect-free coatings. It is also possible to coat layers of different shell materials on a particle surface. The disadvantage is that it takes time to apply the capsule shell in a series of cyclical steps, and this increases the operating costs.

Fluidized-bed coaters can encapsulate only solid particles or perhaps porous particles into which a liquid has been absorbed. However, no other encapsulation technology can apply as broad a range of shell materials: hot melts, aqueous latex dispersions, organic solvent solutions, or aqueous solutions. Several commercial organizations use fluidized-bed coaters to coat various solid food ingredients with fats (see Figure 8). This appears to be the primary use of fluidized-bed coaters by the food industry.

Desolvation or liquid extraction encapsulation technology Desolvation encapsulation processes consist of dissolving a shell formulation in a finite amount of water, thereby forming a concentrated solution (e.g., 40 wt.%) of shell material. Core material is dispersed in this solution with the aid of a surfactant. The dispersion produced can be extruded or atomized directly into a desolvation bath (Figure 9) that solidifies the shell formulation by extracting the solvent used to dissolve the shell material from the spray droplets. Alternately, the core material/shell dispersion can be extruded or atomized into a vessel that contains excess spinning solvent. The spinning bath produces droplets of core/shell formulation that are subsequently solidified in a desolvation bath. Capsules with a relatively low core loading (e.g., 15–20%) are produced, although more recent patents indicate that a core loading up to 40% is feasible.

The core material is generally a water-immiscible liquid such as a flavor. The shell material can be various combinations of carbohydrate(s) or protein(s). Spinning solvents (e.g., mineral or vegetable oil) are immiscible with the shell material solvent (water).

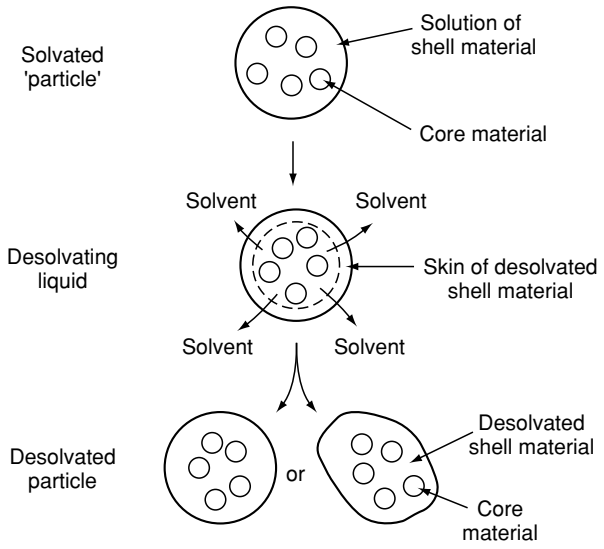

Figure 9 Sequence of steps that occur in a desolvation bath.

Water-miscible desolvation solvents (e.g., isopropanol, ethanol) are nonsolvents for the shell material (s). The desolvation solvent, often cooled, extracts water from the shell formulation, thereby producing solid particles or rods. Residual desolvation solvent is removed from solidified particles by drying. Rods or strands of solidified extrudate can be broken up into small particles by agitation in the extraction vessel or after isolation.

For this encapsulation technology to be successful, the desolvation solvent must be able to extract solvent (e.g., water) from the dispersed core/shell formulation with minimal simultaneous leaching of core material from the formulation. This occurs if the desolvation solvent rapidly solidifies the outer surface region of core/shell formulation droplets or rods to form an outer barrier that prevents diffusion of core material into the extraction solvent, but allows diffusion of water from the interior of the droplets to the extraction medium.

Desolvation encapsulation technology can produce water-soluble food-grade capsules loaded with a range of flavors. Typical shell materials include edible water-soluble materials like gum arabic, maltodextrins, or modified starches (i.e., the same materials used in spray drying). This technology can be carried out in an inert atmosphere and at reduced temperatures, thereby minimizing loss or degradation of sensitive components. It can incorporate water soluble materials in water-soluble shells and produce stable capsules free of unencapsulated core material, since the desolvating liquid extracts actives from defective capsules.

Problems with this technology include the use of solvents other than water that are more costly than heated air, are flammable, must be recycled, and must be essentially eliminated from the final product. Desolvating liquids also can break core/shell material emulsions, thereby preventing suitable particle formation. The formation of stable emulsions in concentrated aqueous shell solutions can pose serious problems, especially if they are heated.

Melt extrusion A melt extrusion encapsulation process (Figure 10) involves dispersing a core material in a molten shell formulation at 85–125 °C with or without the aid of a surfactant. Once formed, the dispersion is extruded as filaments into a relatively cool environment that solidifies the extruded mass. The receiving environment can be a gas phase or a tank that contains a suitable solvent. If extruded into a gas phase, the cooled mass is simply broken up into particles and used. If extruded into a solvent (e.g., −20 °C isopropanol), the solvent simultaneously cools and removes unencapsulated or free core material from the filaments. The solidified product is subsequently dried and broken up to yield particles with the multinuclear structure shown in Figure 11. The particles are glass matrices loaded with dispersed core material. Flavor-loaded particles produced in this manner have an excellent resistance to oxidation during storage. An anticaking agent like pyrogenic silica can be added to enhance particle flow properties. (*See* **Extrusion Cooking**: Principles and Practice.)

The patent literature discloses a number of melt extrusion methods and combinations of shell materials used to produce particles loaded with a core material. Claimed core loading in the final product ranges from 5 to 40% of final particle weight, although a loading of 5–30% is most common. Preferred core materials are flavoring oils. Both oil- and water-miscible flavors have been entrapped. The core/shell formulation typically has a temperature of $\leq 125\,^{\circ}C$ at the time of extrusion. An antioxidant

can be added to heat-sensitive oils. Preferred shell materials are various combinations of sugars, corn-syrup solids, maltodextrins, modified starches, and gum arabic, although other shell materials such as proteins like gluten have been used. In all cases, the water present in the system at the time of extrusion is limited to that required to reduce melt viscosity of the core/shell formulation to a point where extrusion occurs freely. This is usually no more than 10% of the mass of material extruded. Extrusion is carried out under pressure through spinnerets or screw extruders (single and double) with zoned heating. That is, different parts of the extruder screw and die-head are at different temperatures.

The shell formulation in the original extrusion process was corn-syrup solids containing 3–8.5% water. Improved properties were obtained by using a corn-syrup solids shell formulation plasticized with glycerol, and a further improvement in the process was achieved by using a mixture of sucrose and maltodextrins with a dextrose equivalent of less than 20 (preferably 10–15). This mixture produced particles with an improved stability towards oxygen and humidity variations.

Since the processing temperatures involved in melt extrusion are relatively high, loss of volatile components and oxidative degradation of heat-sensitive materials are problems that must be addressed. Accordingly, particle formation and solidification can be carried out in an extrusion system pressurized with an inert gas like nitrogen or carbon dioxide. The final particles are isolated under pressure in order to avoid loss of volatiles resulting from venting or the formation of so-called puffed particles with flaws that cause loss of volatile core material.

Suspended nozzles A number of workers have produced microcapsules by ejecting droplets that contain a core and shell material from suspended nozzles into a gas phase, usually air. The droplets pass through a gas phase until the capsule shell is solidified by cooling, or they fall into a curing bath where they are gelled and subsequently harvested. The particles produced can have a structure like that shown in Figure 2a or b. In all cases, the rate of droplet production and, hence, rate of capsule production is increased by increasing the number of nozzles, using centrifugal force, or a combination of these approaches.

Many types of nozzles have been described: single-fluid, two-fluid, or even three-fluid nozzles. Some are stationary, whereas others are vibrating or spinning. They can be single-fluid tubes through which an emulsion of core material in an aqueous shell solution flows by gravity extrusion or under an applied external pressure. Improved control of droplet, and ultimately capsule, size distribution is accomplished by vibrating the extrusion tubes or orifices. Single-fluid tubes usually produce capsules with a structure like that shown in Figure 2b, since the extruded droplets are dispersions of core material in a solution of shell material.

When droplets are formed by using multifluid nozzles, each droplet formed contains a continuous core region surrounded by a liquid shell or by placing the nozzles in a spinning head through which the droplets are ejected with the aid of centrifugal force. The nature of the shell material determines how ejected droplets are converted into capsules (See Figure 2b). If the shell material is a relatively low-viscosity hot melt that crystallizes rapidly on cooling (e.g., a wax or wax toughened with a polymer), the droplets are converted into solid particles as they fall

away from the nozzle and are cooled. Suitable core materials are typically polar liquids like water or aqueous solutions, since they are immiscible with a range of hot-melt shell materials like waxes.

Alternatively, droplets emerging from the spinning nozzle may have a shell that is an aqueous solution of a gelable polymer. In this case, the compound droplets fall into a gelling bath where they are converted into gel beads. A specific example is the gelation of an aqueous sodium alginate shell by an aqueous $CaCl_2$ gelling bath. The calcium alginate gel beads produced can be dried to give free-flow capsules. In one previously documented encapsulation apparatus, compound droplets produced by a vibrating two-fluid nozzle pass through an aqueous $CaCl_2$ (20%) mist, thereby causing a degree of prehardening before the droplets fall into the actual $CaCl_2$ hardening bath. Prehardening minimizes droplet breakage on impact with the surface of the curing bath.

An understanding of the physical phenomena involved in the formation of microcapsules by nozzle devices requires an understanding of the principles of fluid mechanics. Capsules prepared by centrifugal extrusion tend to be large, with diameters typically ranging from over 250 μm up to several millimeters. Capsules produced by stationary vibrating nozzles can be smaller (e.g., 100 μm in diameter) and very uniform in size. Atomization can produce much smaller capsules, although the particle size distribution can be large, and the capsules may not have a perfectly spherical geometry.

Spinning or rotating disc In spinning disc encapsulation processes, core material dispersed or emulsified in a liquid shell formulation is fed onto the center of a rotating disc. Centrifugal force generated by the rotating disc forces the dispersed core material and liquid coating formulation across the surface of the disc to the outer edge. There, the dispersion is thrown off the disc into a gas phase (usually air) as discrete droplets. If the core material is in particle form, the droplets are discrete particles covered with a thin film of liquid shell formulation. If the core material is an emulsion or a dispersion of particles in a shell formulation, droplets filled with dispersed core material are produced. If the shell is a hot-melt formulation, it cools and solidifies as the particles fall through the gas phase, thereby producing capsules that can be harvested and used. If the shell formulation is an aqueous polymer solution that can be gelled by ions or a combination of ions and cooling, the coated particles fall into a liquid-filled curing bath that gels the shell formulation. The particles with a gelled coating can be used as gel particles or, in principle, can be dried to a free-flowing powder.

Disc geometry, diameter, and speed of rotation, as well as volume flow rate of liquid across the disc are parameters that affect the size of the capsules produced. In the case of gel beads, surface tension of the aqueous phase being dispersed in droplet form affects gel bead geometry. In addition to capsules, one patented spinning disc process produces particles of shell material free of core material. In this process, the disc is operated in such a manner that the particles of shell material collect in a zone or region distinctly separated from the capsules and can be recycled. A variety of hot-melt shell materials can be applied to dispersed solid particles, but a melt viscosity below 5000 centipoises is favored. Capsule shell formulations that do not solidify rapidly pose problems.

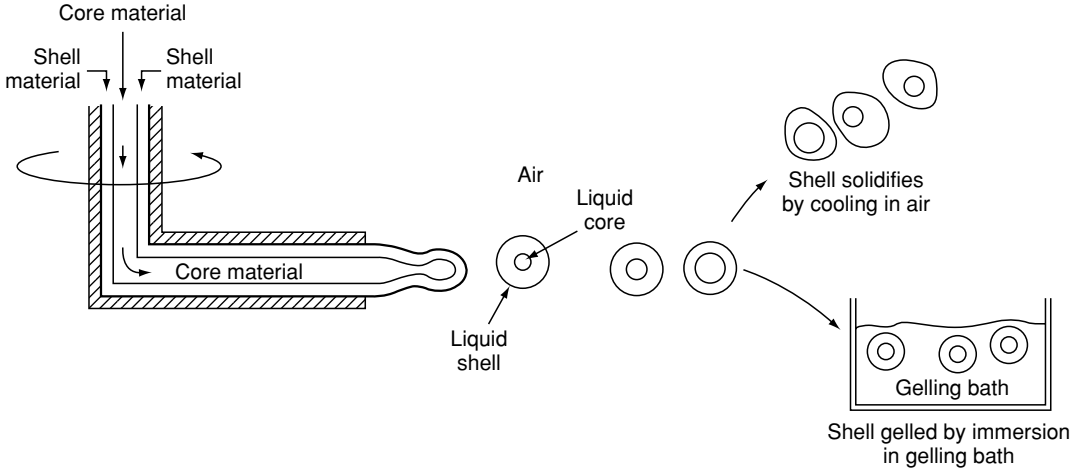

Figure 12 Spinning two-fluid drop-forming device used to produce microcapsules.

Spinning disc processes are claimed to be a fast and efficient way of producing large amounts of capsules economically. Claimed sizes of capsules produced in this manner range from below 100 μm to over 2 mm. Both solid and liquid core formulations have been encapsulated. In the case of solid core formulations, the core material must approach spherical geometry.

Microencapsulated Food Ingredients

A number of food ingredients and additives have been encapsulated and are available commercially. Microencapsulation holds much hidden potential and promise for the food industry in the future.

Solid ingredients encapsulated are typically water-soluble compounds. They are encapsulated with a hydrophobic or hydrophilic coating material usually applied by the Wurster process. Preferred hydrophobic coating materials are partially hydrogenated vegetable oils of varying melting points, monoglycerides, and diglycerides. Hydrogenated vegetable oils used include cottonseed, soybean, and palm. Hydrophilic coating materials tend to be maltodextrins and occasionally gum arabic. Both types of coating materials are well-accepted food-grade products.

Acidulants like citric and lactic acid encapsulated in partially hydrogenated vegetable oil are used in meat processing, where they provide direct acidification and shortened processing times. Sodium acid pyrophosphate encapsulated in hydrogenated vegetable oil is used in frozen cake batters in order to aid mixing and reduce gas release during batter make-up. In both types of applications, release of core material occurs during a heating cycle that melts the shell formulation and releases the core material.

Acidulants like citric, lactic, and fumaric acids encapsulated in a water-soluble maltodextrin shell formulation are used in dry-mix beverages and desserts as well as prepared premixes for the baking and dairy industries. The maltodextrin coating is designed to minimize hygroscopicity, reduce dusting, and minimize reactions with incompatible ingredients. It dissolves in the presence of liquid water to rapidly release the contents of the capsules during a mixing cycle.

Ferrous sulfate, and vitamin C (ascorbic acid) encapsulated in hydrogenated vegetable oil or maltodextrin are used to fortify a nutritional product of some sort. The capsules provide taste-masking, possibly a degree of prolonged release, stabilization of the core material against oxidation, and minimization of reaction with other ingredients in the final product.

Calcium proprionate, and sodium bicarbonate encapsulated in hydrogenated vegetable oil are used in chemically leavened products. Release typically occurs during the baking cycle as a result of melting of the hydrogenated shell material. Sodium bicarbonate encapsulated with maltodextrin is used in dry mix baking and other chemically leavened products. In this case, release occurs during the mixing step. Sodium chloride encapsulated in a hydrogenated vegetable shell is used in various meat products, yeast-containing mixes, and assorted types of dough. The capsules are designed to minimize inhibition of yeast activity, rancidity, and excessive salt binding during product storage.

Liquid food ingredients encapsulated are typically oil-soluble flavors, spices, vitamins, food oils, and fats. These core materials are often encapsulated with a water-soluble shell material applied by spray drying from water, but fat shell formulations are used occasionally. Preferred water-soluble shell materials are gum arabic, modified starch, or blends of these polymers with maltodextrins and sugars. Vitamins are encapsulated with zero bloom strength gelatin by spray drying.

A range of spray-dried flavor-filled capsules primarily with water-soluble shell formulations are used in various dry beverage mixes and other dry food products. Flavors containing ethyl acetate and other low boiling point components have been found to pose problems for successful spray-dry encapsulation. Such components are lost either during the initial emulsification process or during the actual dewatering step as a result of azeotrope formation. Another problem with spray-dry encapsulation is the formation of free surface oil. The rapid desolvation that occurs in the drying chamber can produce blow holes in the capsules, thereby essentially leaving a small amount of flavor oil of free or surface oil that oxidizes on storage and reduces product quality.

Melt extrusion under pressure is an alternate approach to food flavor encapsulation. Rod-like particles loaded with a flavor are often produced in this manner. An advantage of this technology is that it yields essentially defect-free particles with superb shelf-life storage stability. A commercial product (FlavorCell™) has been produced in this manner. Release data have revealed that the FlavorCell™ particles, when placed in ambient-temperature water, release their flavor contents as rapidly as spray-dried capsules that had the same shell formulation. Other approaches to the encapsulation of food flavors include complex coacervation and spray chilling.

Summary

The food industry is currently incorporating a number of different microcapsules into a range of food products. Nevertheless, the volume of capsules

being sold remains small relative to the huge potential that exists. Many groups continue to develop encapsulation technology and microcapsule-based products for the food industry. For this reason, it is anticipated that the volume of microcapsules sold for food use will experience a steady growth for the foreseeable future.

B R Goldin, Tufts University School of Medicine, Boston, USA

Description of the Microflora of the Normal Adult Gastrointestinal Tract

The gastrointestinal microflora of humans is a complex ecosystem. More than 400 bacterial species have been identified in feces from a single person. Ninety per cent of the total microflora is represented by 30–40 different species. Anaerobic bacteria are the predominant microorganisms in the gastrointestinal tract, outnumbering aerobes by a factor of 10^3. The distribution and composition by genera of the most prevalent microflora in the gastrointestinal tract are outlined in Table 1.

The saliva washes the bacteria in the oral cavity deposited on teeth, soft tissue surfaces, and food into the stomach where most of the bacteria are killed by the low pH of the gastric juice. Consequently, only 10–100 organisms are isolated per milliliter of gastric juice. The most commonly isolated bacteria in the stomach are Gram-positive facultative forms such as *Streptococcus* and *Lactobacillus*.

The bacterial population in the small intestine increases from the duodenum to the distal ileum. The bacterial composition of the proximal small bowel is similar to the stomach and the number of organisms per milliliter of contents increases from 10^2 to 10^4 in the distal jejunum. The bacterial counts and complexity of the microflora increase dramatically in the distal ileum. The total concentration of bacteria is between 10^6 and 10^8 per milliliter of contents, and anaerobic bacteria such as *Bacteroides*, *Bifidobacterium*, and *Clostridium* are found in substantial numbers. Distal to the ileocecal sphincter, the number of bacterias increase dramatically. In the colon, the total bacterial count approaches 10^{12} per milliliter of fecal material, and one-third of the fecal dry weight consists of viable bacteria. The complexity of the microflora also increases in the colon, and a number of different strict anaerobes (see Table 1) become predominant components of the flora.

Table 1 Distribution of the bacterial flora in human gastrointestinal tract

Region of the GI tract	*Bacteria*	*Number per milliliter of contents*
Stomach	*Streptococcus*	$10^1 - 10^2$
	Lactobacillus	$10^1 - 10^2$
Small intestine		
Duodenum and jejunum	*Streptococcus*	$10^2 - 10^4$
	Lactobacillus	$10^2 - 10^4$
	Veillonella	$10^2 - 10^4$
Ileum–cecum	*Bacteroides*	$10^4 - 10^8$
	Clostridium	
	Streptococcus	
	Lactobacillus	
	Enterobacteria	
	Bifidobacterium	
Colon and feces	*Bacteroides*	10^{11}
	Bifidobacterium	$10^{10} - 10^{11}$
	Enterobacter	10^{10}
	Peptococcus	10^{10}
	Clostridium	10^{10}
	Streptococcus	$10^9 - 10^{10}$
	Fusobacterium	$10^9 - 10^{10}$
	Lactobacillus	$10^6 - 10^8$
	Veillonella	$10^6 - 10^8$

Development of the Human Intestinal Microflora

The human fetus exists in a sterile environment until birth. Upon passage through the vaginal canal and exposure to the outside environment, the newborn gastrointestinal tract is rapidly colonized. In breastfed and bottlefed infants, by the third day after birth, *Bacteroides, Bifidobacterium, Clostridium*, and *Enterobacter* are isolated from the feces. For breastfed infants, by day 7, Bifidobacterium is the predominant organism accounting for more than 90% of the bacterial population. For bottlefed infants, by day 7, *Enterobacterium* accounts for the majority of the fecal population. At 1 month of age, *Bifidobacterium* is predominant in both breast and bottlefed infants, but breastfed infants have approximately 10-fold higher *Bifidobacterium* counts. With the introduction of a varied diet for bottlefed infants and weaning for breastfed infants, the microflora

becomes more complex, and the numbers of *Bacteroides* and anaerobic Gram-positive cocci increase over a period of a few months until their numbers equal those of *Bifidobacterium*. By the second year of life, the child's intestinal microflora come to resemble those of an adult.

Intestinal Microflora of the Elderly

Studies in the elderly have indicated that there are some changes that occur in the flora of humans in the seventh through the ninth decade of life. Some of the more significant changes are shown in Table 2. The numbers of *Lactobacillus, Streptococcus, Enterobacter*, and *Clostridium perfringes* increase, and *Bifidobacterium* decreases.

Interaction of the Microflora with the Intestinal Mucosa

Owing to the difficulty of sampling human colonic mucosa, there is limited information on the type (and number) of bacteria that are firmly attached to the colonic epithelial mucosa. The current information available indicates that Gram-positive rods and cocci and spirochetes are located on the mucosal layer. There is a maximum of 10^8 bacteria adhering per gram of colonic mucosal epithelial tissue, and *Bacteroides* is the most common isolated organism. Antibiotics can reduce by 5 logs the number of bacteria on the colonic surface.

Alteration of Normal Gastrointestinal Microflora

The composition of the gastrointestinal microflora is relatively stable. New bacteria introduced into the gastrointestinal tract have difficulty permanently implanting into an established flora. Diet can affect alterations in the microflora, but comparative studies on human populations eating radically different diets have revealed only selective changes (see below) and not a general shift in the flora. In animals, it has been demonstrated that limiting nutrient intake can cause major changes in the composition of the microflora. In humans, it is not known if self-imposed severe dieting or anorexia will result in substantial changes in the composition or distribution of the microflora.

Two known perturbants of human gastrointestinal ecosystem: antibiotics and chemotherapeutic agents can drastically alter the microflora, and this is often reflected in diarrhea and, in some cases, an enteritis. A specific example is the development of *Clostridium difficile*-induced pseudomembraneous colitis after antibiotic treatment. The antibiotic alteration of the intestinal flora interferes with the normal suppression of sporulation of *Clostridium difficile* with subsequent pathogenic toxin production.

Table 2 Comparison of counts per gram of feces for selected bacteria of the fecal flora

Bacterial genera	*Log of counts*	
	Adults	*Elderly*
Lactobacillus	5.8	7.5
Enterobacter	7.8	8.2
Streptococcus	7.9	7.4
Clostridium perfringens	4.4	6.6
Bifidobacterium	10.0	9.4

Diet and the Gastrointestinal Microflora

There have been a number of studies in humans investigating the ability of diet to alter specific components of the adult flora. One study reported no change in the predominant organisms in the fecal flora of individuals changing from an omnivorous to a vegetarian diet. The most detailed study involved a comparison of subjects eating a Western diet with Japanese eating a traditional diet and vegetarian and nonvegetarian Seventh-Day Adventists. The subjects eating a Japanese diet had higher fecal counts of *Streptococcus faecalis, Eubacterium lentum*, and *Eubacterium contortium*, and lower counts of *Bacteroides*.

In summation, dietary studies indicate that different eating patterns influence specific bacteria in the intestine, but overall, changes in the composition of the flora are hardly dramatic.

Effect and Role of the Gastrointestinal Microflora

Metabolic Activities of Microflora

In order to discuss the effects and role the microflora has on the host, a discussion of the metabolic activity of the flora should be considered. The more than 10^{14} organisms that occupy the intestinal tract at any given time can perform a large number of different reactions, which can impact on the host. Any compound taken orally or any substance entering the intestine through the biliary tract or the blood or by secretion directly into the lumen can potentially be a substrate for bacterial conversion. Table 3 lists some of the major reactions performed by the intestinal bacteria. Most bacterial reactions can be classified as reductive, hydrolytic, or removal of various functional groups. A brief description of these reactions is presented below. The potential impact on the health and physiology of the host is discussed later in this article.

Table 3 Reactions performed by the gastrointestinal microflora

Reaction	*Example of substrate or products*
Hydrolysis	Estrogen glucuronide
Glycosides	Lactose
Sulfamates	Cyclamate
Amides	Methotrexate
Esters	Acetyldtigoxin
Nitrates	Pentaerythritol trinitrate
Dehydroxylation	Bile acids
C-hydroxy groups	*N*-hydroxyfluorenyl-acetamide
N-hydroxy groups	
Decarboxylation	Amino acids
Demethylation	Biochanin A
Deamination	Amino acids
Dehydrogenation	Cholesterol, bile acids
Dehalogenation	DDT
Reductive	*p*-nitrobenzoic acid
Nitro groups	Polysaturated unsaturated
Double bonds	Fatty acids
Azo bonds	Azo dyes
Aldehyeles	Benzaldehdes
Alcohols	Benzyl alcohols
N-Oxides	4-Nitroquinoline-1-oxide
Nitrosamines	Dimethylnitrosamine
Gas production	Products CO_2, H_2
Fermentation of sugars	Products lactate, butyrate, propionate, acetate, formate
Fiber, inulin, oligosacchrides, starch	Disaccharides, monosacchides, short-chain fatty acids
Fermentation of amino acids	Products H_2, CO_2, CH_4, amines, phenols, indoles, NH_3, organic acids
Aromatization	Quinic acid
Aceylation	Histamine
Esterification	Galic acid

Role and Effect of the Intestinal Flora

Metabolic Role

The hydrolysis of the glycoside linkage is one of the most important reactions performed by the intestinal microflora. Among the reactions performed by the bacteria are α- and β-glucosidase and galactosidase, β-glucuronidase, xylosidase, and cellobiase, and α-mannosidase and fucosidase. These reactions are responsible for the hydrolysis of oligo- and polysaccharides, as well as a wide range of exogenous and endogenous compounds conjugated by a glyosidic bond with glucuronic acid or other sugar moities. The bacterial glycosidases can remove terminal sugars as well as hydrolyzed bonds in the middle of a polysaccharide. The hydrolysis of amides, glucuronides, esters, and nitrites, and a number of other reactions listed in Table 3 relate to conversion of drugs, pesticides, and various endogenous compounds, such as cholesterol, estrogens, bile acids, and their conjugates produced in the liver. Decarboxylation and deamination are reactions related to the bacterial fermentation of amino acid, and the bacterial reactions of the Embden–Meyerhof–Parnas glycolytic pathway result in fermentation of hexoses to short-chain fatty acids.

Glycosides

Glycosides enter the intestine from two major sources: from the diet or via the biliary tract. The diet contains fiber, resistant starch, and phytochemicals, such as the glycosides of flavonoids and isoflavonoids. These compounds are not normally absorbed in the upper gastrointestinal tract and, therefore, serve as substrates for the vast majority of microflora that reside in the distal ileum, colon, and rectum. Glycosides coming from the liver include endogenous compounds, an example being estrogens and other biological molecules, and drugs or environmental agents that are conjugated by the liver via glycoside formation primarily with glucuronic acid subsequently secreted into the bile, which is deposited in the duodenum. The intestinal flora then hydrolyze the glycoside bond, leading to the release of potentially biologically active agycones (nonsugar moiety).

There are a number of proven examples of the importance of the action of bacterial glycosidases on the host. Cycasin is a compound that is found in the cycad plant, also referred to as tropical fern. The compound is a glycoside of methylazoxymethanol, which can cause intestinal tumors in conventional and germ-free mice and rats. Germ-free animals lack an intestinal microflora and do not develop tumors when given cycasin; in contrast, conventional animals when fed cycasin develop intestinal tumors. These data suggest that the bacterial glycosidase in the intestine is necessary for the carcinogenic activity of cycasin. This has been confirmed when germ-free animals are monocontaminated with bacteria having different levels of glycosidase. The carcinogenicity after feeding cycasin has been found to be positively correlated with the specific implanted bacterial strain.

The action of the intestinal microflora on the plant glycoside rutin is another example of the potential for generating carcinogens. Rutin is not mutagenic prior to the hydrolysis of the glycoside linkage, but the hydrolysate is mutagenic.

There are a number of drugs whose action and/or pharmacokinetics are influenced by bacterial glycosidases. The metabolism of the cardiac glycoside digoxin is an example of the effect of bacterial action. To produce the drug's pharmacological action, the

bacterial flora must remove a trisaccharide from the parent compound, releasing diagoxigenin. The fecal flora of 36% of the residents of New York given digoxin has been found to reduce the double bond in the lactone ring, resulting in the formation of dihydrodigoxigenin. This metabolite is not pharmacologically active. The extent of this bacterial modification is reflected in the observation that 14% of New Yorkers had high levels of digoxin metabolites in their feces. This would result in lower-than-predicted serum levels in these individuals. In this example, the intestinal microflora inhibit the action of an orally administered drug. The opposite is true for the cathartic agent, Cascara Sagrada. This agent is a mixture of glycosides that are not pharmacologically active until bacterial glycosidases in the intestine release the active aglylone.

An important physiological implication of the bacterial hydrolytic glycosidic reaction is the cleavage of disaccharides. Lactose, sucrose, and maltose are disacchrides that are normally absorbed in the upper small intestine after hydrolysis by tissue enzymes located in the intestinal mucosal brush border. Therefore, contact with the majority of intestinal microflora does not occur. However, because of either a genetic defect or an acquired disorder, individuals who have few or no disaccharidases do not absorb the disaccharides in their small intestine. The sugars are transported to the ileum and large bowel, where bacterial sucrase, lactase, and maltase hydrolyze the disaccharidases. The final bacterial end products are short-chain fatty acids. An osmotic imbalance results from the increased concentration of short-chain fatty acids, and water flows into the lumen of the bowel, resulting in diarrhea.

The most common disorder is lactose intolerance, which is common in adults residing in temperate and warm climates. Less frequently encountered is intolerance towards sucrose or maltose.

Amino Acids and Other Amines

To some extent, food-derived proteins can remain intact until they reach the large bowel. In addition, proteins from the epithelial cells, and digestive secretions and mucins all contain protein. Bacteria deaminate amino acids by five different mechanisms. Amino acids also undergo bacterially derived decarboxylation. These reactions result in the formation of a wide range of different amines and short-chain organic acids that can be absorbed from the colon. This process helps the host reclaim energy. The overproduction of, or lack of, absorption of hydroxy short-chain fatty acids derived from amino acid fermentation can cause diarrhea.

Fermentation of Carbohydrates

In this section, a more general description will be given of the fermentation of carbohydrates by the intestinal microflora. The major source of fermentable carbohydrates in the human colon is plant cell-wall polysaccharides, such as pectins, cellulose, and hemicellulose. Other sources of carbohydrate in the colon are resistant starch and intestinal mucus. It is estimated that between 20 and 70% of carbohydrates are fermented per day. The end products of carbohydrate fermentation in the feces are acetate, propionate, and butrarate. This fermentation also leads to the production of hydrogen, carbon dioxide, methane, and water.

Bacterial Lipid Metabolism

In humans, most of the fatty acids derived from dietary lipids are absorbed in the small intestine. The human colonic anaerobic microflora can hydrogenate and hydrate unsaturated fatty acids. Evidence for these reactions comes from the isolation of 10-hydroxystearic acid in the feces. The metabolism of lipids by the intestinal flora has only a minor role in humans.

Bacterial Conversion of Cholesterol, Bile Acids, and Bile Pigments

Cholesterol is a precursor of bile acids, and both classes of compounds are structurally similar. These compounds are endogeously synthesized in the liver initially from two carbon units.

Cholesterol is also a component of the diet. Between 75 and 200 mg of cholesterol and its metabolites are excreted in the feces daily. There are two principal fecal metabolites of cholesterol, coprostanone and coprostanol, and one minor product, cholestenone. The formation of coprostanol requires a steroid nuclear hydrogenation of the 5,6 double bond. The conversion of cholesterol to coprostanone results from the reduction of the 4,5 bond and a C3 oxido-reductase converting the hydroxyl to a keto group. Coprostanol accounts for approximately 50% of the total fecal neutral sterols, coprostanone 10–15%, and unmetabolized cholesterol the remainder. In germ-free animals, only cholesterol is recovered in the feces, providing evidence that the intestinal microflora is solely responsible for the metabolism of cholesterol in the intestine. The precentage of intestinal cholesterol conversion varies from 70 to 85% in Americans and Western Europeans to 55 to 65% in Africans and Asians.

Bile acids synthesized in the liver are conjugated via an amide bond to glycine or taurine. The conjugated

bile acids are secreted in bile and are deposited in the upper small intestine. The principal intestinal bacterial reactions involve bile acids, primarily occuring in the distal ileum and colon. The bacterial conversion of bile acids includes: the hydrolysis of the amide bond to release free bile acid from the glycine and taurine conjugates; an oxidoreduction of the hydroxyl groups at C3, C7, and C12 to form either oxo bile acids (hydroxyl to keto groups) or α-hydroxyl groups after the reduction of the keto groups (inversion products); and dehydroxylation at C7, and to smaller extent at the C3 and C12 positions. The result of these reactions is the conversion of primary bile acids to secondary bile acids and the reabsorption of free bile acids from the terminal ileum and, to a lesser extent, from the large bowel.

Bile pigments derive from the breakdown of hemoglobin. Between 200 and 300 mg of bilirubin, the product derived from heme, are excreted daily in the bile. Approximately 90% of bilirubin is conjugated to glucuronic acid. The bilirubin conjugate is hydrolyzed by the intestinal microflora releasing the free compound, which can be reabsorbed in the intestine. Alternatively, bilirubin can be reduced by the microflora to urobilonogen. Approximately 20% of urobilinogen is reabsorbed from the intestine of humans. The major components of bile, namely, cholesterol, bile acids, and bile pigments, are subject to bacterial action in the intestine. Additional compounds secreted in the bile such as, androgens and estrogens (discussed below), are also subject to the action of the intestinal microflora.

Additional Intestinal Bacterial Reactions

Vitamins

The bacteria residing in the human intestinal tract can synthesize homologs of vitamin K_2 (menoquinone 7). The bacterial conversion, in part, occurs in the ileum where menoquinone can be absorbed. Human adults given low vitamin K diets for several weeks did not exhibit a deficiency. Treatment of subjects with antibiotics at the same time as they were fed a low vitamin K diet had a significant decrease in plasma prothrombin levels. The synthesis of the peptides in the prothrombin blood-clotting complex requires menoquinone. These human studies demonstrate the importance of intestinal bacterial metabolism with respect to vitamin K synthesis.

Humans depend solely on this action of intestinal microflora for their vitamin B_{12} (cyanocobalamin) requirement indirectly via the consumption of meat from ruminants that derive B_{12} from synthesis by their microflora. In addition, the human intestinal microflora contributes significant amounts of vitamin B_{12}, and approximately 5 μg is excreted in feces daily. At least two organisms, *Pseudomonas* and *Klebsiella*, have been shown to synthesize vitamin B_{12} in the small intestine.

Biotin is synthesized to a major extent by the intestinal flora. The administration of high doses of antibiotics can cause biotin deficiency in laboratory animals. The administration of antibiotics can lower biotin urinary levels.

Several other B complex vitamins, namely folic acid and thiamin, are synthesized by the human intestinal microflora. The amount synthesized by bacteria is not sufficient to eliminate the requirement for dietary sources of folate and thiamin.

Estrogens and Androgens

Estrogens and androgens are modified by the intestinal microflora. Estrone, estradiol, and estriol are three major circulating estrogens excreted in the bile, conjugated to glucuronic acid and/or sulfate. Bacteria found in the feces can hydrolyze these conjugates, releasing the free estrogens. The nonconjugated estrogens are then subject to further bacterial action. A major reaction involves oxidoreduction of the C17 position. Bacteria can convert estrone to estradiol, and the fecal flora can also convert 16 α-hydroxyestrone to estriol.

Several intestinal bacterial conversions of androgens are also catalyzed by the human fecal flora. The intestinal microflora can reversibly oxidize and reduce the 3-hydroxy group, reducing steroid nuclear double bonds at the 1- and 4-positions and resulting in a complex interconversion of androgens. Evidence for an introduction of a double bond into the androgen nucleus has also been described. However, this reaction only occurs under aerobic conditions and therefore would be unlikely to occur in the highly anaerobic environment of the colon.

Role of the Intestinal Flora in Health

Colon Cancer

Colon cancer is a common disease in Western Societies. Epidemiological studies have shown that the incidence of colon cancer is higher in North America and Western Europe than in Africa, Asia, and South America. A number of studies have shown a positive correlation between consumption of beef, fat, and protein, and a negative correlation with fiber, and the incidence of colon cancer. It has been proposed that the dietary influence on the etiology of colon cancer results, in part, from alteration of the metabolic activity of the

intestinal microflora, more specifically, the ability of intestinal bacteria to convert procarcinogens to proximate carcinogens. This conversion would be greatest in the large bowel where the bacterial population is highest, and the transit time for the fecal stream is the slowest. Several bacterial enzymes have been implicated in the formation of mutagens, carcinogens, and tumor promoters. Among the enzymes that have the potential to increase the incidence of colon cancer are: β-glucosidase, β-glucuronidase, β-galactosidase, azoreductase, nitroreductase, 7-α-steroid dehydrogenase, and 7-α-hydroxy-steroid dehydroxylase.

There have been at least five different classes of mutagens isolated in the feces that have the potential to cause colorectal cancer. The final step in the synthesis of fecapentenes (dodecapentaenyloxy-1,2 propanediol), one class of mutagen, involves the action of the intestinal flora.

Bile acids, particularly the secondary bile acids, can act as colon tumor promoters, and, as discussed previously, the fecal microflora are responsible for the generation of secondary bile acids in the colon.

Heterocyclic aromatic amines are also procarcinogens, which can be acted on by bacterial and intestinal tissue enzymes to generate proximal carcinogens. Nitrosamines, which are also present in the colon, are often direct-acting and spontaneously breakdown to electrophiles, which react with DNA and do not require activation by bacteria or tissue enzymes. The final broad class of known potential colon carcinogens are polycyclic aromatic hydrocarbons, which are generally activated by tissue microsomal enzymes. From this brief discussion, it is apparent that the intestinal flora can be an important factor in the etiology of colon cancer.

Bacterial Overgrowth

Bacterial overgrowth occurs when there is a significant increase in the bacterial population in the small intestine and stomach. The proliferation of bacteria in the upper gastrointestinal tract can be caused by anatomic or physiologic derangements. One common cause of bacterial overgrowth is the underproduction of gastric acid. Gastric acid limits bacterial growth in the stomach and upper small intestine. There are a number of different causes for decreased gastric acid production, such as atrophic gastritis, pernicious anemia, surgical resections, and drug therapy. The consequences of bacterial overgrowth are numerous, including steatorrhea, vitamin deficiencies, and carbohydrate malabsorption.

More than 20 different species of bacteria have been identified in the upper small intestine of patients with bacterial overgrowth. The most common clinical manifestation of bacterial overgrowth is malabsorption of fat and fat-soluble vitamins. Small bowel bacterial overgrowth can also cause megaloblastic anemia, which results from vitamin B_{12} deficiency. Binding of vitamin B_{12} to bacteria in the upper small intestine can prevent absorption of the vitamin in the distal ileum. *In-vitro* studies have demonstrated that *Bacteroides*, among the most common of intestinal bacteria, bind the intrinsic factor–cobalamin complex. Patients with bacterial overgrowth can have high levels of B_{12} in the lumen of the small intestine, from nonabsorbed dietary sources and from local bacterial synthesis. Despite this, patients can still suffer from vitamin B_{12} deficiency because of the lack of absorption from the intestine.

Other consequences of bacterial overgrowth include impaired amino acid and carbohydrate absorption. Fecal nitrogen content is increased, serum proteins are low, and this could result in a clinical protein-calorie malnutrition.

Diarrheal Diseases

Disruption of the intestinal flora by antibiotics or other drugs can lead to diarrhea. A disruption in the balance of the intestinal microflora can lead to the overgrowth of pathogens in the large bowel. An example is antibiotic-induced *Clostridium difficile* colitis. This pathogen resides as a spore in the colon of a significant number of healthy individuals. Patients receiving antibiotics for various infections have, as a result of their treatment, a decrease and shift in the population of the normal flora. In some instances, this leads to situations in which sporulation of *Clostridium difficile* takes places with a concomitant production of toxin, resulting in severe diarrhea and, in some cases, a pseudomembraneous colitis. The use of antibiotics in general, in a hospital setting, results in diarrheal disease in 30–50% of the antibiotic-treated patients.

The etiological agents in most of the cases are unknown. Another common cause of diarrhea is the introduction of pathogens from food, water, or other orally ingested material. The enterobacteriaceae groups of Gram-negative rods include a number of diarrheal pathogens, including specific strains of *Escherichia, Shigella, Salmonella*, and *Yersinia*. Other pathogens are *Vibrio cholerae* and *Mycobacterium*. Most of these pathogens are not normal residents of the intestinal tract; however, these agents can disrupt the normal intestinal flora.

Health Implications of Probiotics

Just as bacterial pathogens introduced into the lumen of the intestine can cause disease, the feeding of

Salmonella *and* Shigella *infections*	Cancer	
Flatulence	Hypercholesterolemia	
Crohn's disease	Food allergies	
Diarrhea		
Antibiotic-induced		
Infantile		
Travelers		

specific types of bacteria can be beneficial to the host. The term probiotic has been given to bacteria that, when fed, confer health benefits to the host.

Table 4 lists some of the microorganisms currently being fed to humans and animals. A large number of health benefits have been attributed to probiotics. A partial list of these therapeutic claims for probiotics is given in Table 5. A brief discussion of some of these claims is included below.

Diarrheal Diseases

An initial report with five patients treated with *Lactobacillus rhamnosum* strain GG (LGG) for relapsing diarrhea caused by *Clostridium difficile* toxin showed that this probiotic could stop the diarrheal symptoms. An additional 32 subjects were subsequently studied. Of these 32 patients, 84% were cured by initial treatment with LGG daily for 2 weeks. Three additional patients were cured upon retreatment with LGG, resulting in an overall cure rate of 94%.

LGG was also shown to lower the rate of diarrhea in Finnish travelers to Turkey. A study has also been performed with American travelers to developing countries fed either LGG or a placebo in a double-blind study design. The subjects taking the placebo had a 7.4% per day risk of developing diarrhea, and travelers who ingested LGG had a 3.9% per day risk. These data indicate that LGG provides a 47% protection rate against traveler's diarrhea.

LGG has also been shown to be effective for treating children hospitalized for severe diarrhea. Children given LGG had a decrease in the duration of their diarrhea from 2.5 to 1.1 days.

These studies indicate that a probiotic can be helpful in preventing antibiotic-induced, travelers', and young childhood diarrhea.

Lactose Intolerance

Ingestion of yogurt when compared with feeding milk containing equal amounts of lactose resulted in one-third the amount of hydrogen in the breath. Breath hydrogen is an indicator of the passage of intact lactose to the lower intestine. The reason for this observation rests on the fact that the *Lactobacillus* and *Streptococcus* in yogurt hydrolyze the lactose in the yogurt, as well as in the upper small intestine.

Food Allergy

Casein in milk can cause the first allergic reaction in infants. *Lactobacillus* can degrade milk proteins to smaller peptides and amino acids. One of the symptoms of milk allergy is atopic eczema. Several studies have been performed showing that the feeding of LGG to infants significantly decreased clinical allergic symptoms when compared with a placebo group. These results suggest that probiotics down-regulate intestinal inflammation and hypersensitivity

reactions in infants with food allergies and resulting atopic eczema.

Liver Disease

Studies in rats chronically fed alcohol have shown that feeding LGG reduced liver pathology and plasma endotoxin levels. These findings suggest that probiotics may be useful in preventing alcohol-induced liver damage, a common human medical problem.

Colon Cancer

There have been a number of studies showing that feeding *Lactobacillus acidophilus* or LGG lowers colon tumor incidence in rats administered the carcinogen dimethylhydrazine. There are no human clinical intervention trials that have been performed to determine if probiotics can prevent colon cancer.

Probiotics

J L Rašić, Jasenova 11/II (Lerak), Belgrade, Yugoslavia

Introduction

The word 'probiotic' derives from the Greek words meaning 'for life.' It refers to live microbial dietary supplements which contribute to the intestinal microbial balance, thus benefiting host health; they can also beneficially affect the properties of the indigenous flora. The use of probiotics in the diet stems from Metchnikoff's theory (1907) that the consumption of large amounts of yogurt containing lactobacilli prolongs life. Many reports since then have shown that gut organisms, such as bifidobacteria, and other lactobacilli also beneficially affect the host, including human hosts.

The indigenous gut microorganisms have their own protective function against invading pathogens. Various factors, including diet, can affect the protective gut flora. Special ingredients selectively stimulate the growth and/or activity of a small number of beneficial organisms in the colon. The potential benefits of ingested bifidobacteria and lactobacilli include various healthful aspects. Selection of microbial strains is important in the development of improved probiotics. There is evidence that probiotics ingested can influence the gut flora.

Overall Concept of the Importance of the Gut Flora

The gut microorganisms colonize available habitats in the gastrointestinal tract and, although not essential for life, they live in a stable relationship with their host. Their presence is manifested by their effects on the development of resistance factors, including defense systems of the host, the protective effect of the flora, and the production of microbial products.

Defense Systems and the Protective Flora

Experiments with gnotobiotes (animals which are either germfree or have been inoculated with one or more known species of microorganisms) have shown that the lymph nodes are larger and more numerous, and the number of lymphocytes within the nodes is greater in conventional animals (those which retain their normal gut flora) than in germfree animals. Lymphocytes are the major constituents of the lymphatic tissues, and are associated with immunity. Specific lymphocytes participate, via plasma cells, in the production of immunoglobulins.

The levels of plasma cells and immunoglobulins are much lower in germfree than in conventional animals, but when germfree animals are exposed to microorganisms, the lymphatic tissues rapidly enlarge and there is a gradual increase of plasma cells and immunoglobulins. Consequently, microorganisms are the major source of antigens in normal animals, including humans, with dietary constituents making a secondary contribution. The macrophages from germfree animals digest bacteria, but more slowly than those from conventional animals.

The gut microorganisms have their own protective function. They prevent colonization of an area in the gut by invading pathogens by competition for essential nutrients and for attachment sites on the epithelium. They inhibit the growth of invading pathogens by the production of organic acids, particularly volatile fatty acids, by the deconjugation of bile salts, and by the production of antibacterial substances other than acids. The protective effect of the indigenous gut flora against pathogens has been proved experimentally. For example, *Shigella* spp. are lethal to germfree guinea-pigs, whereas they are unable to establish in conventional guinea-pigs. Similarly, mice treated with streptomycin show increased sensitivity to *Salmonella*. The indigenous gut flora normally acts synergistically with its host's immunological system in protecting against infections by intestinal pathogens.

Microbial Metabolic Products

The gut microorganisms break down undigested or unabsorbed dietary constituents, body secretions, and ingested foreign compounds; they also produce certain vitamins. Consequently, numerous metabolic products occur in the gut. These include a variety of organic acids, protein degradation products, dehydroxylated bile acids, cholesterol metabolites, and others. Many such products are potentially harmful to humans, but most of them are detoxified in the liver before excretion. High levels of some products (e.g., dehydroxylated bile acids, cholesterol metabolites) found in the gut, due to the effect of long-term changes in diet on the metabolic activities of the indigenous flora, may be implicated in the etiology of some degenerative diseases and cancerous conditions. The type of diet influences the levels of harmful microbial products. (*See* **Bile**; **Protein**: Synthesis and Turnover.)

Influence of Diet on the Gut Flora

Effects of Composition of the Flora

It is difficult to induce major changes in the indigenous gut flora by alterations in the diet of healthy adults. Dietary effects on the composition of the fecal flora are demonstrably slow and their long-term effects may be variable. Subsequent studies suggest that the type of diet may be the major factor causing the variation in fecal flora and enzyme activity among various populations.

One study examined the fecal flora of nine rural healthy Japanese people and eight urban healthy Canadians, who were consuming typical Japanese and western diets, respectively. The number of eubacteria, bifidobacteria, lactobacilli, and veillonelae, and the frequency of occurrence of bifidobacteria were higher in the Japanese than in the Canadians, but larger numbers of *Bacteroides* and lecithinase-negative *Clostridium* were found in the Canadians. In another study, the fecal flora of 15 healthy elderly persons in a rural area in Japan were compared with the flora of persons living in urban areas. The diet of elderly persons was characterized by a high intake of dietary fiber. Significantly larger numbers of bifidobacteria, but not of clostridia, were found in the group of elderly persons. Dietary fiber composed of cellulose, noncellulosic polysaccharides (hemicellulose, pectin, inulin, guar, and plant gums) and lignin is resistant to digestion by the human intestinal tract. Some of the fiber is degraded in the colon by the flora, and the main products of digestion are volatile fatty acids, gases, and energy. (*See* **Dietary Fiber**: Properties and Sources.)

Effects on Microbial Metabolism

The metabolic activities of the gut flora may be affected by alterations in the diet, and extreme diets may induce great changes in the bacterial activities. For example:

1. Bacteria isolated from persons living on a high-fat diet were more active in the dehydroxylation of bile acids than were similar bacteria isolated from persons living on a low-fat diet.
2. Bacteria isolated from persons living on a diet rich in dietary fiber may be more active in digesting cellulose and noncellulosic polysaccharides than are similar bacteria isolated from persons living on a low-fiber diet, because the enzymes catalyzing polysaccharide degradation are inducible.
3. A diet rich in meat products but low in fiber indirectly provides the flora with urea, amino acids, bile acids, and neutral steroids. As a result, increasing concentrations of ammonia, amines, indole, dehydroxylated bile acids, and cholesterol metabolites occur in the gut, along with increasing activities of beta-glucoronidase, azoreductase, and nitroreductase enzymes. (*See* **Dietary Fiber**: Physiological Effects.)

Influence of Special Ingredients (Prebiotics)

Special ingredients refer mainly to nondigestible oligosaccharides, that benefit the host by selectively stimulating the growth and/or activity of one or a limited number of beneficial bacteria (e.g., bifidobacteria and lactobacilli) in the colon. These ingredients, called prebiotics, are not hydrolyzed in the small intestine; they are not absorbed and reach the colon where they are selectively utilized by the bacterial flora.

The best-known prebiotics are: fructooligosaccharides such as oligofructose and inulin, lactulose, maltooligosaccharides, galacto-, xylo-, gentio-, palatinose-oligosaccharides, etc. Among many nondigestible ingredients, lactulose has been most extensively studied for its growth-promoting effect *in vivo* for bifidobacteria and lactobacilli. It is not present in a free state in milk but, upon heating milk, a part of the lactose is converted to lactulose, and in sterilized liquid formula feeds it amounts to 2–8% of the total carbohydrate content. High levels of lactulose have laxative effects, leading to diarrhea. (*See* **Carbohydrates**: Metabolism of Sugars.)

Lactulose is used for babies in some formula feeds, and for adults to promote the growth of bifidobacteria and lactobacilli. It is also used in the management of liver disease, and in the treatment of chronic constipation.

Other nondigestible ingredients occur naturally in many foods (e.g., Jerusalem artichoke, onion, wheat), and some are isolated or synthesized. They are commercially available under various trade names.

Potential of Ingested Bifidobacteria and Lactobacilli

Selected strains of bifidobacteria and lactobacilli are commonly used in probiotics to suppress harmful microbial populations in the gut and encourage beneficial organisms.

The major potential benefits of ingested bifidobacteria and lactobacilli are claimed to be:

1. modification of the gut flora in infants (bifidobacteria)
2. prophylactic and therapeutic functions
3. improved lactose utilization (lactobacilli)
4. possible anticarcinogenic activity
5. control of serum cholesterol

Modification of the Gut Flora in Infants

It may be possible to modify the gut flora of formula-fed infants if large numbers of *Bifidobacterium bifidum* (10^8–10^9 cells day^{-1}) are fed, if they survive gastric transit, and if a fermentable carbohydrate is available to the cells in the large intestine. Since lactose of formula feeds does not reach the large intestine in sufficient amounts to promote the growth of bifidobacteria, the addition of bifidogenic substances could provide a fermentable carbohydrate. The improved formulation of milk is also an important factor. (*See* **Infants**: Breast- and Bottle-feeding.)

Prophylactic and Therapeutic Functions

There is a clear evidence that bifidobacteria and lactobacilli are antagonistic to various harmful bacteria in the gut. Bifidobacteria (*B. bifidum, B. longum, B. infantis*, etc.) produce acetic and lactic acids, with small amounts of formic acid; and some strains produce antimicrobial substances other than organic acids. The antagonistic effect of acetic acid against Gram-negative bacteria is stronger than that of lactic acid, and the former is produced in greater amounts by bifidobacteria. Lactobacilli, such as *Lactobacillus acidophilus* and *L. casei*, create lactic acid and small amounts of hydrogen peroxide to suppress harmful bacteria; some strains of *L. acidophilus* produce antibiotic-like substances, including acidophilin, lactocidin, acidolin, and possibly others. Deconjugation of bile salts to free bile acids by both bifidobacteria and lactobacilli may also function in the control of the bacterial flora. Large numbers of bifidobacteria and lactobacilli in the gut may involve competitive antagonism against invading pathogens.

The protective effect of bifidobacteria and lactobacilli against enteric infections and the side-effects of oral antibiotic therapy was shown in human studies. Comparative feeding studies of two groups of infants, one receiving formula feeds containing viable *B. bifidum* and lactulose, and the other receiving a buttermilk preparation, showed that enteric infections were eight times more frequent in the buttermilk-fed group than in the formula-fed group. The beneficial effect of *L. acidophilus* or *L. casei* in the prevention of side-effects of oral antibiotic therapy (e.g., moniliasis, staphylococcal enteritis) in children was also shown. It has been suggested that daily ingestion of large numbers of the lactobacilli (e.g., *L. acidophilus*) may protect consumers from diarrhea caused by intestinal pathogens (e.g., traveler's diarrhea). Dietary supplements of bifidobacteria and lactobacilli have beneficial effects in children with enteric infections. For example, the ingestion of a freeze-dried culture of *B. bifidum* in conjunction with lactulose was shown to eradicate enteropathogenic *Escherichia coli* strains in more than 80% of cases. Many reports indicated the beneficial roles of bifidobacteria in the management of chronic liver

disease. The ingestion of *B. bifidum* together with lactulose was shown to assist in reestablishing the balance of the gut flora, which is usually disturbed in liver cirrhosis, and this was accompanied by a decrease in fecal pH and by a reduction of ammonia and free phenols in the blood. (*See* **Liver**: Nutritional Management of Liver and Biliary Disorders.)

The beneficial effects of ingested bifidobacteria and/or lactobacilli may be obtained if: (1) large numbers of viable cells (10^8–10^9 cells day^{-1}) are introduced; (2) they survive gastric transit and, preferably, can adhere to epithelial surfaces and grow; (3) a fermentable carbohydrate is available in the gut; and (4) they have a strong antagonistic effect against harmful microorganisms.

Improved Lactose Utilization

It was shown that lactase-deficient persons can digest lactose in yogurt better than the same amount of lactose in unfermented milk. Yogurt bacteria, *Streptococcus salivarius* subsp. *thermophilus* and *L. delbrueckii* sp. *bulgaricus*, produce the enzyme, lactose (beta-galactosidase), which hydrolyzes lactose to glucose and galactose. It is possible that they supply preformed lactase to the gut, thus allowing digestion of lactose. *L. acidophilus* and *L. casei* also allow digestion of lactose by producing lactase. These organisms survive in the gut better than yogurt bacteria, thus suggesting that lactase from the bacterial cells remains in the small intestine for a longer time.

Possible Anticarcinogenic Activity

The potential anticarcinogenic activity of some lactobacilli and bifidobacteria has been shown in many studies. The effect of *L. acidophilus* on Ehrlich ascites tumor was studied using mice as an animal model. Feeding acidophilus milk resulted in a smaller number of tumor cells in mice than in those not receiving *L. acidophilus*. Similar results were obtained with mice, transplanted with Meth-A ascites tumor cells, that received a suspension of *B. infantis*, repeated four to six times. (*See* **Cancer**: Diet in Cancer Prevention.)

Other studies with mice indicated a possible role of macrophages in suppressing the growth of tumor cells. Intraperitoneal injection of *L. casei* in mice was shown to increase the phagocytic activity of peritoneal macrophages and their acid phosphatase activity. In addition, the consumption by mice of milk containing *L. casei* resulted in activation of the macrophages, measured by increased levels of lactic dehydrogenase activity.

Some of these effects may be due to substances produced by the organism during growth, and/or to the stimulation of the host immune response. It is also possible that some lactobacilli and bifidobacteria inhibit the growth of organisms which may convert procarcinogens into carcinogens in the gut. The oral administration of *L. acidophilus* (10^{10} cells day^{-1}) to meat-fed rats was shown to reduce the activity of azoreductase, beta-glucuronidase, and nitroreductase. These fecal enzymes can catalyze procarcinogen conversion to a proximal carcinogen. In a study with human subjects it was found that feeding 500 ml of milk containing 2×10^6 cells of *L. acidophilus* ml^{-1} day^{-1} for 4 weeks significantly reduced beta-glucuronidase, azoreductase, and nitroreductase activities. When feeding with lactobacilli had ceased, fecal enzyme levels returned to normal after 4 weeks.

Another mechanism for the anticarcinogenic effect refers to nitrosamines (potent carcinogens) which are synthesized *in vivo* from amines and nitrite. The synthesis of nitrosamines may be reduced by enzymatic degradation carried out by some strains of lactobacilli and bifidobacteria. (*See* **Nitrosamines**.)

Apparently, various mechanisms may be involved in the potentially anticarcinogenic effects of lactobacilli and bifidobacteria.

Control of Serum Cholesterol

The influence of gut bacteria on sterol metabolism may be of significance in human nutrition in preventing the accumulation of cholesterol. The feeding of a milk formula supplemented with *L. acidophilus* to infants was shown to result in lower levels of blood cholesterol than those recorded in infants receiving the milk without *L. acidophilus*. Similar results were reported on rats supplementary-fed skim milk fermented with *L. acidophilus*, compared to those fed unfermented skim milk.

Laboratory studies have shown that strains of *L. acidophilus* originating from humans actively assimilate cholesterol, but there are considerable differences in the activity of strains. These results are supported by experiments with pigs using pig isolates of *L. acidophilus*. It was shown that supplementary-feeding *L. acidophilus* to pigs resulted in lower blood cholesterol than in those not receiving *L. acidophilus*.

Strains of *L. casei* and *B. bifidum* were also shown in laboratory studies to assimilate cholesterol to varying degrees. In a study with human subjects it was found that the ingestion of large numbers of *B. bifidum* daily during 6 weeks, significantly reduced the levels of serum cholesterol and serum triglycerides in subjects suffering from elevated serum lipids. This treatment was without effect in subjects with normal values of serum lipids. (*See* **Bile**.)

Stimulation of the Immune System

There are indications that the ingestion of lactic acid bacteria and/or bifidobacteria stimulates the immune response of the host. A significant increase in the number of B lymphocytes and T lymphocytes, was observed, as well as an augmentation of some immunoglobulins in mice given yogurt or other lactic acid bacteria. Also, phagocytic activity of macrophages was shown to be enhanced in mice supplementary-fed with lactic acid-producing bacteria (e.g., *L. acidophilus, L. casei, B. longum*).

Studies with human subjects also showed the immunogenical effects of lactic acid bacteria. For example, (1) a significant increase of phagocytic activity of leukocytes in peripheral blood, and an increase of immunoglobulin A (IgA) were found in subjects given fermented milk containing *L. acidophilus* strain Lal for 3 weeks. This effect was observed at least 6 weeks after termination of the consumption fermented milk; (2) a significant increase in numbers of B lymphocytes and natural killer cells, the augmentation of IgG, and an increase of the serum levels of gamma-interferon were observed in subjects given large numbers of yogurt bacteria for 28 days.

The immunogenic effects of lactic acid bacteria and/or bifidobacteria may be influenced by: (1) the bacterial strain characteristics; (2) the numbers of culture bacteria ingested; and (3) a duration of ingesting culture bacteria. Further research is needed.

Selection of Microbial Strains

Development of improved microbial supplements involves selection of proper strains of the organism. If the ingested bacteria are to survive, they must be resistant to all antimicrobial factors which exist in the gut. Gastric acidity is an important barrier to gut colonization, but some protection is afforded by the buffering effect of the food and food boli will tend to raise the pH of the stomach. Various strains of lactobacilli and bifidobacteria were shown to differ significantly in acid tolerance. Other factors affecting bacterial survival in the gut include bile acids, lysozyme, and organic acids. The ability of bacteria to adhere to the gut epithelium is also an important factor. Adhesion is host-specific, e.g., only lactobacilli and bifidobacteria originating from the human gut have the potential to attach to human epithelial cells. The adhesion ability varies between bacterial species, and even different strains of the same species show variations. It was also shown that growth in milk enhances the ability of lactobacilli to adhere to epithelial cells.

Various strains of lactobacilli and bifidobacteria were shown to differ significantly in the antagonistic effect against harmful bacteria. Other desirable properties include immunogenic effects, assimilation of cholesterol, and hydrolysis of lactose.

The selection of probiotic strains may include the following criteria: (1) not pathogenic; (2) of human intestinal origin; (3) survival of intestinal passage; (4) adhesion to epithelial cells; (5) clinically tested for the specific therapeutic effect; and (6) applicable for manufacturing food products.

Evidence of Influence of Ingested Bacteria

The maximum effect of ingested probiotic bacteria is obtained when the protective indigenous flora have been changed by diet, antibiotic therapy, disease, or some other factors, as the following examples illustrate.

1. A disturbed balance of the gut flora in 28 patients with leukemia was shown to be improved by ingesting 2×10^9 bifidobacteria and 2×10^9 *L. acidophilus* in 200 ml of milk daily for 3 months. The counts of *Klebsiella* spp., *Proteus* spp., *Candida* spp., and *Pseudomonas* spp. in the feces decreased, and the levels of urine indican and blood endotoxin reduced, compared to patients not receiving supplements.
2. Fifteen patients (mean 2.5 years) received antibiotics, such as cephema, penicillins, and aminoglycosides, for curing septicemia and respiratory tract infections. During treatment, diarrhea occurred and lasted for 1–10 weeks. The counts of bifidobacteria decreased in the feces, and those of *Candida* and *Enterococcus* increased. The ingestion of bifidobacteria and *L. acidophilus* improved the stool frequency within 3–7 days, along with the restoration of the gut flora.

The beneficial effects of probiotics may be enhanced by including special ingredients (prebiotics), and thus improving host health.

Probiotic bacteria can affect the composition of the gut flora and/or its metabolic activity during the period of ingestion and for some time after. For example:

1. Milk fermented with *L. acidophilus* fed to human volunteers reduced the *E. coli* count and increased the lactobacillus count, but when the supplement ceased, the bacterial counts returned to normal after 9 days.
2. Five healthy volunteers ingested 3×10^9 *B. longum* daily for 5 weeks; during feeding, counts of bifidobacteria increased and those of clostridia decreased; in addition, ammonia levels and beta-glucuronidase activity decreased in the feces and serum.

3. As already mentioned, feeding *L. acidophilus* to humans reduced beta-glucoronidase, azoreductase, and nitroreductase activities, but when the supplement ceased, enzyme levels returned to normal after 4 weeks.

It is difficult to achieve a permanent colonization of ingested probiotic bacteria. However, their ingestion continuously or at regular intervals may insure the desired benefits.

Light Microscopy and Histochemical Methods

J H Holgate and J Webb, Reading Scientific Services Ltd, Whiteknights, Reading, UK

Background

Light microscopy has been in use in the food industry since the first instruments were introduced. In the early years, its primary application was for detecting adulteration of foodstuffs. Identification was dependent primarily upon the recognition of structural features combined with the reaction to selected microchemical tests. (*See* **Adulteration of Foods**: Detection.) Today, a wide range of routine and research microscopes and microscopy techniques are available, providing the food scientist with microstructural information on the nature and form of individual food components and on their distribution within a product. This allows the role and interactions of food ingredients to be examined and provides information valuable to the understanding of the properties of finished products, cooking and manufacturing processes, and the influence of both the type and form of ingredients. Electron microscopy techniques complement this approach, allowing the microstructure of the same types of food materials to be examined at greater magnifications and with different types of preparation procedures. (*See* **Analysis of Food**.) The light microscope is probably one of the most versatile laboratory instruments available to the food scientist. A basic instrument, available today for the same price as a good-quality balance, provides a wide range of magnifications and other facilities to provide structural information on almost any form of food sample.

Principles

The light microscope is an instrument for visualizing fine detail of an object. It does this by creating a magnified image through the use of a series of glass lenses, which first focus a beam of light onto or through an object, and convex objective lenses to enlarge the image formed. In the majority of light microscopes, the image is viewed directly through binocular eyepieces that act as a secondary lens in the form of a magnifying glass to observe the projected image. Such instruments are termed 'compound microscopes,' and the total magnification is the sum of the objective magnification and the eyepiece magnification. The magnification range extends from $\times 10$ to $\times 1000$, with a resolving power of the order of $0.2\,\mu m$, depending on the type and numerical aperture (area available for passage of light) of the objective lenses. A number of books are available, providing comprehensive details on the theory of the light microscope and guidance to the practical use of the instrument, including methods of image enhancement and instrument care. The reader is referred to these, in particular an extensive series of handbooks published by the Royal Microscopical Society, for further information.

Microscopy Techniques

Microscopy techniques for use in the food industry are frequently a combination of those used in biological and materials sciences. Samples are viewed using either transmitted or incident (reflected) illumination. Most frequently, transmitted light is used where a beam of light is allowed to pass through a relatively thin object. The microstructural detail becomes visible due to the absorption of a portion of the light. Incident light is used mainly for the examination of solid, opaque objects, although it now forms the basis for all modern fluorescent microscopes, referred to as 'epifluorescence.' (*See* **Spectroscopy**: Fluorescence.)

The light source is often a single or multicoil tungsten lamp or quartz halogen lamp. However, xenon arc or mercury vapor lamps provide more intense beams, as required for fluorescence microscopy.

Contrasting Techniques

Though many structures are visible by standard (bright field) transmitted light, there are components

that are nonabsorbent and appear transparent or lack any contrast. This can be overcome, or additional information may be gained by using one of several contrasting techniques available that will introduce or enhance image contrast, frequently with minimal disruption of the specimen. The most frequently used are phase contrast, differential interference contrast, and polarized light.

When using phase contrast or differential interference contrast (Nomarski) optics, for example, the phase of part of the light is altered, and this is then recombined with light that has passed through the specimen and thus yields improved differentiation within a specimen. Phase contrast images are characterized by enhanced contrast and visibility of unstained materials and are used routinely for examination of microorganisms isolated from food. Interference contrast provides a distinct relief appearance, with a shallow depth of focus often giving the appearance of a three-dimensional image. It has proved particularly valuable for examining small particles and emulsion droplets (Figure 1).

A different type of contrast is generated in certain samples when they are viewed under crossed polars. Plane polarized light (light vibrating in only a single plane) is generated using a polarized filter and allowed to impinge upon the specimen. The light then travels through a second polarization filter (the analyzer), which is orientated at 90° to the first, effectively blocking the uninterrupted plane polarized light. Any material that is anisotropic or birefringent, e.g., crystals, is capable of rotating the light plane so that the polarization of emerging light will be altered and partially extinguished and will have an orientation that will pass through the analyzer filter. The resultant image is of bright features against a black background.

The use of polarized light has many applications in the study of food. Food starches and many crystalline food ingredients, e.g., sugar, have characteristic sizes, shapes, etc., that can be observed using polarized light. Intact starch granules are strongly birefringent but lose this property during gelatinization (e.g., cooking), and polarized light microscopy is frequently used to follow this process during, for example, the baking of bread doughs. (*See* **Starch**: Structure, Properties, and Determination.)

Fluorescence

Irradiation of samples with light of specific short wavelengths can result in reemission of this energy as light of longer wavelengths. This is referred to as 'fluorescence.' The emitted light, different in color from the excitation light, may be separated by the use of specific filters. Some components of food, for example collagen and lignin, fluoresce naturally after excitation with light (autofluorescence). However, such fluorescence is often very weak, and it is more common for selective, strongly fluorescent dyes (fluorochromes) to be used to produce a high contrast within a sample (Figure 2). (*See* **Lignin**.)

Almost all modern fluorescence microscopes use epifluorescence, in which the specimen is illuminated by a high-density mercury vapor source (via a beam splitter through the objective) to excite only the surface layers of the sample.

The technique has particular value in food microscopy as it can be used to detect substances at low concentrations and for rapid sample screening at low magnification where the particles of interest are in localized regions within the sample. Dyes in common use in food microscopy are Acridine orange for staining bacteria and milk proteins and Nile blue for fats. However, the availability of fluorescent dyes

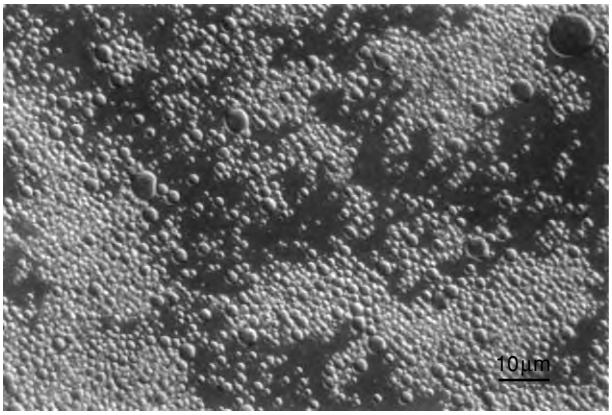

Figure 1 Emulsified droplets of fat in a salad cream. Preparation viewed using Nomarski interference contrast.

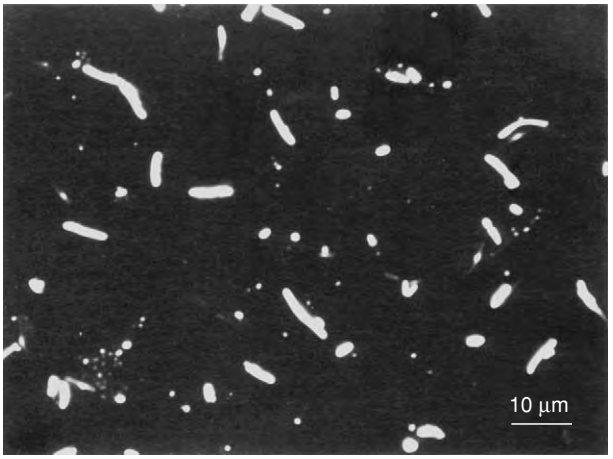

Figure 2 Bacteria isolated from milk. Preparation is stained with Acridine orange and viewed using epifluorescence.

is steadily increasing, especially in combination with highly specific labeling agents such as antibodies (immunolabeling) and lectins, and is likely to be one of the main growth areas within food light microscopy over the coming years.

Sample Preparation

The majority of food materials and their ingredients require some kind of preparation before the microstructure can be examined by light microscopy. The choice of sample preparation will depend on the material being examined and the kind of information required. It may range from simple whole mounts and smears, to more complex, sectioned preparations.

Often, food samples or their ingredients, e.g., milk powders, can be examined simply by direct viewing on a glass microscope slide; alternatively, further valuable information can be gained after supporting the sample in a transparent mounting medium. Such media are frequently inert as well as transparent and include water, liquid paraffin, glycerol, chloral hydrate (used to 'clear' plant cells), and many commercial mountants. The choice will depend on the nature of the material to ensure that little or no change, for example dissolution or swelling, occurs prior to examination.

Liquid or semisolid foods, for example viscous pastes, fats and emulsions, are often viewed as 'smears' across a slide. However, it is important to be aware of the potential disruption of the microstructure during this type of preparation and the differences in detail provided by samples of different thickness. Contrast is often enhanced by phase or interference contrast. The more traditional preparation for light microscopy, and one frequently used for food samples, is the preparation of thin slices or sections through the material. Such sections are mounted on to slides, their contrast often enhanced by multiple staining before examination by bright-field illumination.

Sectioning

Sectioning techniques for light microscopy range from the relatively simple freehand sectioning with a knife or razor blade to the precision cutting of embedded material using sophisticated bench microtomes or ultramicrotomes. A few foods can be sectioned with little or no prepreparation, and it is still commonplace in a food laboratory to see initial freehand sectioning. A bench microtome, however, enables ribbons of sections of more uniform size and thickness (5–50 μm) to be cut. Stainless-steel knives are used most frequently, although more resilient materials, such as tungsten carbide, are often used to cut hard materials and provide longer-lasting blades. Alternatively, freshly cleaved glass knives, used routinely for ultrathin sectioning for transmission electron microscopy, are used to cut thinner sections (< 5 μm) for light microscopy. Food plant material, particularly dried tissue and some solid composite foods, can be sectioned successfully with no prior preparation or treatment. However, the majority of foods and their ingredients require some preparation prior to sectioning to ensure that they are rigid enough to enable sections to be cut with minimum distortion. Wax or resin embedding and low-temperature 'cryofixation' are the most frequently used preparative techniques and have been used in food microscopy for many years.

Fixation/embedding

Whatever the embedding media used, the food material needs to be chemically preserved or 'fixed' prior to infiltration and embedding with the wax or polymer. Successful fixation depends on the type of food material being prepared, in particular the ease of penetration of the fixative into the material. The use of traditional aldehyde fixatives (e.g., formaldehyde or glutaraldehyde) is common, as is the use of osmium tetroxide, in liquid or vapor form, particularly with fats present. However, many different fixation procedures have now been adapted and developed for specific foods in order to achieve optimum preservation of individual components. These include a number developed more specifically for electron microscopy. After fixation, the specimen is usually dehydrated with solvent prior to being infiltrated and then embedded in a wax or polymer. Solidification or polymerization of the embedding media produces a hard, rigid preparation from which sections can be cut. Wax embedding remains one of the cheapest preparation procedures for light microscopy; the procedure can be readily automated for routine use, and considerable improvements have been made to the waxes available. However, it is considered an awkward, somewhat time-consuming and messy procedure and is increasingly being replaced with resins and other polymeric materials for preparing food samples. A wide range of different types of resins and polymers are now available, providing high flexibility in viscosity and conditions for polymerization, e.g., temperature and time and including some acrylic polymers that provide low-temperature hardening (often using ultraviolet light polymerization). The use of the newer resins for embedding samples generally offers a significantly

improved safety in the form of the reduced hazards of the solvents used compared with wax embedding and in the handling of the resins compared with the previously used epoxy resins, etc.

Cryostat Sectioning

Cryofixation of samples, followed by 'cryostat' low-temperature sectioning, has the significant advantage of speed. Samples are supported (using a gel or commercial preparation such as Tissue-Tek) on metal blocks (often after an initial chemical fixation), and then fast-frozen, generally in liquid nitrogen (−196 °C) to preserve or 'cryofix' their structure. The frozen block is sectioned at approximately −20 to −30 °C using a conventional bench microtome housed in a refrigerated unit (cryostat). The technique obviously has particular application for frozen foods such as icecream, but is also used frequently for foods that have high water contents or that are difficult to handle in any other way. However, some food products are unsuitable for sectioning when frozen, for example, if they remain soft or become brittle. Also, the initial capital expenditure can be high and, although the sections can be preserved and permanently mounted, the frozen block can only be kept if stored under liquid nitrogen. Sections are collected on to glass slides, sometimes aided by a thin coating/layer of adhesive such as egg albumen, and allowed to warm to room temperature. They are often further chemically fixed at this stage prior to staining.

Staining Methods

Other than using the optical contrasting techniques described above, the use of dyes to stain components specifically is the most common way of increasing contrast for light microscopy. Staining techniques rely on the interaction or absorption of the dyes with the sample components. Many different stains are now available, and procedures have been developed for food and food ingredients in order to color specific individual components and thus produce enhanced contrast and enable identification of protein, fat, starch, and sugar, for example, (*See* **Protein**:, Determination and Characterization; **Starch**: Structure, Properties, and Determination.)

Frequently, two or more stains can be used in a single preparation. Within food microscopy, many different stains are now readily available for the differentiation of different types of protein, carbohydrate, and fats. Some of these are available in vapor form, e.g., iodine for starch and osmium tetroxide for fats, which has a particular advantage in causing little disruption to the specimen. The selection of stains and the procedures used will vary, depending not only on the type of food material under examination but also on the sample preparation technique employed and the exact information required. However, stains are still often classed according to the nature of their binding to the specimen. Acidic or basic dyes are used for attaching to positively or negatively charged sites, respectively, and thus can be used, for example, to distinguish between different types of proteins. Solubility dyes rely on the dye being more soluble in one component than another. The Sudan family of stains use this property to stain fats in food.

Stains are described as 'histochemical' when a specific chemical reaction is used to attach the chromophore to a particular chemical grouping in the specimen. The most frequently used is the periodic acid Schiff (PAS) reaction used to demonstrate the presence of different polysaccharides by the formation of aldehyde groups following oxidation.

Applications of Light Microscopy

The versatility of the preparation procedures and techniques for light microscopy makes them applicable to a wide variety of different foods and ingredients. Selected samples are presented below, although many more are presented in other parts of the Encyclopedia as well as numerous food microscopy publications.

Powders

A wide range of food materials, in particular raw ingredients, exist in powdered form. Common examples include ground spices, spray-dried flavors and milk powders, and freeze-dried beverages and proteins. Light microscopy provides a way of examining the size, shape, and often the internal structure of individual powder particles. Liquid paraffin is frequently used as a simple mountant, although glycerol is more successful when fat is present. Examination under polarized light shows the presence of crystalline or other birefringent structures, enabling their size and location to be determined. The presence of lactose crystals, for example, is often demonstrated by their characteristic tomahawk shape when viewed under polarized light (Figure 3). In more complex powder mixtures, individual components can also be discriminated by selective staining. The use of an iodine/potassium iodide solution or simply iodine vapor will stain starch a distinctive blue/black color, whereas fat appears pale brown, and proteins appear yellow.

Animal-based Products

Many meat and comminuted meat products are readily prepared using cryostat sectioning. A variety of staining procedures are available for identifying

individual components including fats, muscle, connective tissue, and bone. These range from single-step stain mountants, for example, Toluidine blue, to more complex sequential staining with three or four different solutions (e.g., the Picro–Mallory technique). Polarized light can further complement the use of stains in order to locate crystalline fatty regions and connective tissues and to differentiate fresh and processed muscle tissue.

Fruit and Vegetables

Many cellular structures are visible using phase contrast, but more detailed information on changes to cell wall and cell contents can be obtained following staining for cellulose, pectins, etc. The understanding of the effects of processing of fruit and vegetables by brining, freezing, cooking, etc. has been greatly facilitated by microscopical studies on samples taken at different stages of such processes (Figure 4).

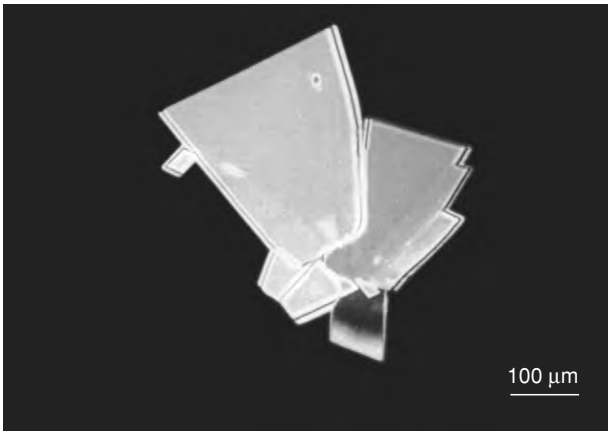

Figure 3 Characteristic tomahawk crystals of lactose viewed under crossed polars.

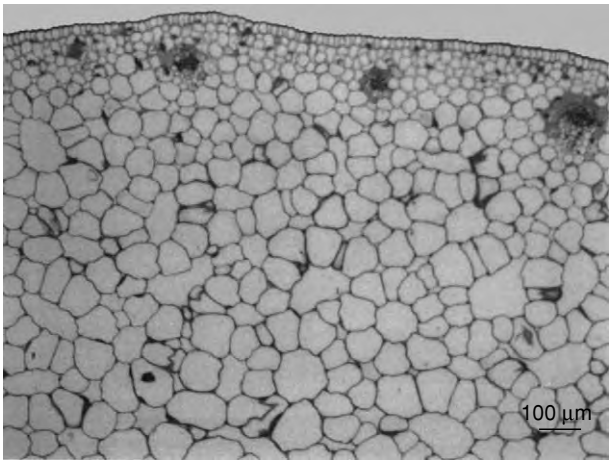

Figure 4 Section through a fresh onion shoot; Toluidine blue staining.

Bakery Products

A combination of preparation and observation techniques has been important in examining the complex microstructure of many bakery products, e.g., bread, cakes, and biscuits. Such techniques have enabled the changes in ingredients, especially starch and protein, to be followed and correlations to be made between the microstructure and the physical and sensory (e.g., texture) properties of the finished products. One of the key changes in baking is the gelatinization of starch, which can be followed successfully through examination of preparations using polarized light.

Photomicrography

The recording of images obtained by light microscopy is an important area in its own right and thus, unfortunately, beyond the scope of this article. The advent of high-resolution digital cameras has facilitated image acquisition, enabling rapid recording of images, and, where the investment has been made, even short 'videos' can be made, e.g., for studying the dissolution of particles. As always, the food microscopist still needs to experiment to ensure that high-quality images observed through binocular eyepieces are permanently recorded for future reference.

Developing Areas within Light Microscopy

The two areas of most recent development in the field of light microscopy have been the use of specific labeling techniques, in particular immunolabeling, and the availability of confocal instruments. In the former, labeled antibodies are used as specific reagents for the detection/staining of specific specimen components. Labeling is most frequently achieved by fluorescent dyes. Although antibodies have been raised for many biological and biomedical applications, they are currently limited for foods mainly because the antigenic sites are modified as a result of food processing and manufacture.

In a confocal microscope, a confocal image is built up point by point by scanning a sample with a focused beam of laser light. It is a noninvasive technique enabling optical sectioning of a sample and producing images with well-defined focal planes but without the problems of out-of-focus blur. Combined with current developments in image-processing techniques, confocal microscopy is being applied widely in non-food areas and is beginning to be applied to food, and has considerable potential for the future.

Light microscopy offers versatility in the number of optical techniques available for examining food materials, combined with ease of preparation and

operation at a relatively low cost. Although a decline in its routine use was evident after the introduction of electron microscopes, it has reemerged as an invaluable instrument for investigations into the science of food and food processing.

Scanning Electron Microscopy

J Webb and J H Holgate, Reading Scientific Services Ltd, Whiteknights, Reading, UK

Introduction

A scanning electron microscope uses a finely focused beam of electrons to reveal the detailed surface characteristics of a specimen and provide information relating to its three-dimensional structure. It also has a particular advantage of providing great depth of field. With the introduction of the first commercial instruments in the mid-1960s the scanning electron microscope provided the link between the magnification ranges offered by light microscopy and the higher resolving capability of the transmission electron microscope (TEM). Nowadays, following development of electron guns, electromagnetic lens systems and vacuum systems, scanning electron microscopes can have a resolution of 1 nm. Therefore, there is now considerable overlap between the resolving power of the two forms of electron microscope available, although the techniques are complementary and different types of microstructural information are obtained in each case.

Food and its ingredients have been examined by scanning electron microscopy (SEM) ever since the first instrument was available. In the early days the main applications were in studies on the microstructural characterization of dry foods, in particular powders. However, with the development of a range of different preparation techniques able to handle many different types of foods, almost every food material has now been examined in some way by SEM. (*See* **Analysis of Food**.)

Principles

When a fine beam of electrons is focused on to the surface of a specimen, different interactions occur, including the emission of secondary and backscattered primary electrons. If these are collected and amplified they can be used to create an image corresponding to the surface topography of the specimen. The electron beam is scanned across the specimen repeatedly in a raster pattern, which is synchronized with the scan of a cathode ray tube such that the image is presented in a digitized form built up on a TV monitor. Magnification is achieved through the electron beam scanning an increasing smaller area of the same specimen and most modern scanning electron microscopes have a magnification range of $\times$ 7 20, up to more than $\times$ 300 000, and resolution in the order of 2–4 nm or better. The great depth of focus of the microscope (> 500 $\times$ that of light microscopy) is achieved by the convergence angle of the primary electron beam and the relatively long working distance between the final lens and the specimen. This depth of focus enables production of images that appear to be three-dimensional.

As with transmission electron microscopes, conventional instruments must be operated under high vacuum in order that the electron beam can travel to the specimen surface without collision with gas molecules. However, the introduction of specialized vacuum systems with pressure-limiting apertures brings a new perspective to SEM and enables samples

to be examined at higher pressures. In conventional SEMs, the source of electrons is generally a heated tungsten filament, which provides ease of operation, low cost, and simplicity. More intense sources include lanthanum hexaboride (LaB6) tips and field emission guns and these are used where greater brightness is required. Accelerating voltages used typically range from less than 1 kV up to 40 kV. The higher voltages can provide greater resolving power, but at the risk of excessive penetration into many specimens and damage by the electron beam. Lower voltages are used to image fine structure on sample surfaces.

The generation of an image from secondary electrons remains the most frequently used form of imaging of biological samples within a conventional SEM (CSEM). However, the interaction of a primary electron beam with a specimen surface can also provide other information, for example, from backscattered or Auger electrons and X-rays.

Specimen Preparation

In its simplest form, preparation for SEM involves securing a specimen on to a metal support 'stub' and, if the sample material is nonconducting, coating the surface with a conducting thin layer of metal. The requirement for conductivity is to prevent the build-up of electrical charge on the specimen surface once it is bombarded with electrons within the instrument and also to enhance the secondary image. Many different procedures have been developed for securing dry food specimens on SEM stubs. These vary depending on the size, shape, and composition of the specimen and the type of information required. One of the most frequently used support media employs a colloidal silver cement (silver DAG), which not only holds the specimen firmly but improves conductivity. However, others include carbon cement (carbon mixed with an acrylic carrier), glues, gels, and adhesive tape.

Metal Coating

In the early days of SEM, surface metal coats were prepared by resistive evaporation in a high-vacuum coating unit. However, this procedure often caused localized heating of the specimen surface and, as the metal was applied unidirectionally, it did not always cover all the crevices in the specimen. It was soon superseded by the introduction of diode sputter coating, which is carried out under a lower vacuum. The coating material forms the cathode and the specimen the anode. Sputtering is carried out in an argon plasma generating a multidirectional spray of metal particles that carry into crevices and around corners. Relatively inexpensive sputter coaters are now available, which provide continuous, uniformly thin metal coats of controllable thickness, often in automated units. Such instruments deposit a metallic layer with a thickness typically of 10 nm and a grain size of approximately 2–5 nm to achieve a continuous film. Thicker films, up to 20 nm, are used for specimens with particularly irregular surfaces.

For conventional SEM, the most frequently used metal has been gold, although others used include silver, platinum, palladium, tungsten, chromium, or mixtures of two of these. Chromium is now being used increasingly with the requirement for thinner and finer layers which do not mask the fine detail of the specimen and provide ultrahigh-resolution images. It is deposited under a higher vacuum to achieve a finer grain size (0.5 nm) and a continuous, thin (< 5 nm) layer.

Drying Techniques

Many food products and ingredients contain relatively high levels of water. In the virgin state, such products are unsuitable for examination in a conventional SEM, as the high vacuum system causes rapid desiccation and consequential damage to the fine structure of the sample. For these types of specimens, examination by conventional SEM has been carried out successfully following some form of drying step. In many cases, preparation has involved a brief chemical fixation to stabilize the components of the sample *in situ* (for example, with glutaraldehyde, which cross-links proteins) before solvent dehydration and drying using critical-point drying. Alternatively freeze-drying has been used.

Water needs to be removed with great care in order to minimize shrinkage or other artifacts and a great deal of work has been undertaken to optimize the procedures. Critical-point drying involves the replacement of the organic dehydration fluid in the specimen with liquid carbon dioxide and subsequent conversion of the CO_2 into gas in a chamber pressurized to the critical point and temperature where liquid and gaseous CO_2 are in equilibrium. After gaseous CO_2 is released, the specimen is dry without having passed through any phase boundary. It has been shown to be a particularly useful technique for single-cell preparations (**Figure 1**) and food with high tissue contents such as meat, fish, and vegetables. However, the technique has now been shown to cause shrinkage of greater than 30% in some samples and to generate many surface distortions and is now losing favor as a routine SEM procedure. Furthermore, any solvent-extractable components are lost during the dehydration process.

In freeze-drying, wet samples are fast-frozen, transferred to a freeze-drying unit where a low temperature is maintained (typically $-80\,^{\circ}C$ to $-90\,^{\circ}C$) and the ice is sublimed slowly under low vacuum. Careful control over the different stages, including initial freezing, temperature, and vacuum of drying and, in particular, of the rate of rewarming, has proved to be important in retaining the microstructural features of food materials.

Unfortunately, these drying techniques are not readily adaptable to fatty foods, because solvent dehydration will remove the fat and freeze-drying will not adequately stabilize it. Many investigators, however, have found the techniques successful, for example, in the study of foods containing carbohydrate or protein gels and 'fully biological' tissues, including meat, vegetable, and fruit.

Low-temperature SEM (Cryo-SEM)

One way to overcome the problems of conventional drying techniques is to make use of low-temperature preparation procedures to examine frozen, fully hydrated food materials. If the temperature of the sample is sufficiently low (i.e., $< -130\,^{\circ}C$), there will be negligible freeze-drying in the vacuum system of the SEM; typically, samples are held at *c.* $-170\,^{\circ}C$ during imaging. No chemical fixation or solvent dehydration needs to be involved as the sample is 'cryofixed' (physically preserved). The technique has been used widely since the early 1980s in various biological applications, including in the examination of food.

The procedure involves rapid freezing of the specimen before transfer on to the precooled stage of a cryopreparation unit, which may be either dedicated (attached permanently to the SEM) or nondedicated (free-standing) vacuum equipment. The sample is often freeze-fractured in the unit to reveal internal structure. When particularly high levels of water are present, fractured and original surfaces can be 'etched' by raising the specimen temperature while it is still under vacuum so that a thin layer of surface ice is sublimed away to reveal more of the topographical detail.

As with low-temperature preparations for TEM, one of the most crucial stages is in the initial freezing of the specimen. It is desirable that the water present is solidified in a vitreous, noncrystalline state and the remaining components are preserved in the same form as they were originally. However, the relatively large size of samples typically used for SEM prevents vitrification of all but a very thin layer at the surface. In practice, the aim of the freezing process is to render the size of the resulting ice crystals as small as is practicable. Low-temperature SEM is particularly suitable for examination of liquid or semisolid materials such as margarines, low-fat spreads and dressings, as well as foods with high levels of crystalline fat such as chocolate (Figure 2) and frozen foods such as icecream.

Auxiliary Techniques

X-ray Microanalysis

The principle of X-ray microanalysis is related to the emission of X-rays from a specimen through

Figure 3 (see color plate 108) Digital X-ray map showing calcium distribution (of calcium phosphate) in frozen hydrated cheddar cheese.

interaction of the electron beam. When any material with an atomic number of four or more is examined in an electron microscope, X-rays are generated from just below the surface. As each element has a unique X-ray spectrum, the elemental composition can be determined on the basis of detected X-rays. X-ray microanalysis systems are of two types: energy-dispersive X-ray analysis (EDX) and wavelength-dispersive spectroscopy (WDS). EDX is the more frequently used technique for biological and food-type samples. This technique measures the energies of X-rays and provides analysis of all detectable elements simultaneously. By contrast, WDS measures the wavelengths of X-rays with individual crystals, each of which focuses on one element at a time. WDS has a better resolution than EDX but is less easy to use.

In the past, routine EDX detectors have been protected by beryllium windows that have excluded transmission of X-rays with an energy of less than *c.* 1 kV, i.e., the X-ray energies of elements with an atomic number below 11 (sodium) and, traditionally, for the detection of lighter elements, WDS has been used. However, improved detector design and the use of plastic windows has enabled the full range of elements to be detected by routine EDX systems and WDS is used for specialized analyses. Through computer interfacing, the X-ray microanalytical technique can be used to generate quantitative data and produce elemental distribution 'maps' of food materials. X-ray mapping techniques have already provided valuable information relating to chemical changes in food that have been associated with their processing, storage, and packaging (Figure 3).

Cathodoluminescence

Certain materials emit long-wavelength photons in the ultraviolet and visible regions of the spectrum when they are irradiated with a beam of high-energy electrons and this phenomenon is termed 'cathodoluminescence.' Although this technique is widely used for geological applications, with recent developments in detector design it has the potential to be applicable to a wider range of materials, possibly including foods. Novel treatments could include labeling specific structures with reagents that exhibit cathodoluminescence, much in the same way as fluorescent labeling is used for light microscopy.

Image Analysis

SEM produces electronic/digitized images and as such they are available for computer manipulation, for example, in image processing or analysis. Image processing involves computer filtration and enhancements to improve the final image quality from the microscope and this type of facility is often a standard feature on modern instruments. Image analysis is used to obtain quantitative data directly from the images, for example, relating to size and size distribution and shape of features as well as relative areas and coincidence measurements. Many purpose-built image analyzers are available commercially with which analysis of any image source, e.g., objects, photographs, light microscopy, and TEM images, as well as SEM images, can be undertaken. The basis for discrimination of features/areas of black and white images, such as SEM images, is the difference in gray levels (differences in black to white) across the image. SEM images often cause problems because of the very wide range of gray levels within any one image, although use of high-contrasting techniques, in particular backscattered imaging, can help eliminate the problem.

Applications of SEM

Many food laboratories have their own scanning electron microscope or have direct access to one and the use of the technique is commonplace in the majority of investigations on food. Applications are many and diverse, covering practically all of the different foodstuffs and their ingredients. The strength of SEM in food studies is its wide magnification range, large

depth of focus, and its ease of use. The relatively straightforward preparation of dry materials has led to the extensive use of SEM for the characterization of powders, for example, spray-dried ingredients (Figure 4), flour and sugars, as well as dried foods such as coffees and teas. Comparative information is obtained on the gross size and shape of the particles and, by breaking them open, details of the internal microstructure can be determined, for example the form and interaction of individual components, including crystalline inclusions and air bubbles.

SEM images often provide information that can be directly related to textural properties of food in a unique way and can also be related to processing information as well as sensory panel data. Examination of different types of bakery products, for example, can reveal the form of the starch, in particular the intactness of starch granules together with the levels of association of the protein strands (Figure 5). Such detail can often be related to the way in which the product is likely to break down in the mouth and explain terms such as 'crumbly' or 'brittle.' (*See* **Starch**: Structure, Properties, and Determination.)

Many food-manufacturing processes involve production of a number of relatively unstable, liquid, or semisolid intermediate products prior to the finished commercial sample. SEM, frequently in combination with low-temperature preparation techniques, provides a way of monitoring the changes taking place during the development of the final microstructure and helps to investigate the effects of different processing conditions and/or ingredients. Its use has been particularly valuable, for example, following crystallization of key food components such as sugar or fat in different foods, including changes in size and shape of individual crystalline regions.

Reproduced from Microscopy: Scanning Electron Microscopy. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

A significant area of food microscopy is concerned with the identification of contaminants in food, for example, fragments of glass, metal, paints or insects, which are introduced accidentally or deliberately during and after production. The use of SEM, in combination with EDX, provides a rapid way of identifying the composition of contaminants, which can be quite small (< 1 mm). The technique is noninvasive and thus the evidence is not destroyed. (*See* **Contamination of Food**.)

Recent Developments and Specialized SEM Techniques

Low-vacuum and Environmental SEM

Although conventional SEMs offering the best resolution operate at high vacuum, they suffer from limitations in that the specimens intended for examination have to be rendered stable, so that they are able to withstand the vacuum, and electrically conductive. Accomplishing this without altering the structure is difficult and, clearly, delicate hydrated or volatile samples often present in food systems are not vacuum-tolerant. Operation of an SEM at higher pressures opens up the possibilities of being able to examine a wide range of vacuum-intolerant specimens without prior preparation. Not

only can hydrated and semisolid samples be examined without prior preparation, the gas ionization that occurs with increasing pressure in the sample chamber effectively neutralizes charge that accumulates on the sample and eliminates charging artifact. The consequence of this is that a conductive layer of metal does not need to be applied to electrically nonconductive samples when they are examined at higher pressures.

SEMs that operate at higher pressures are now commercially available and are termed low-vacuum SEMs (LV-SEMs) or variable-pressure SEMs (VP-SEMs). A further category can provide (in addition to variable pressures) a saturated water vapor environment and this is termed environmental SEMs (ESEMs). All of these achieve their ability to produce a source of illuminating electrons from normal electron gun systems whilst maintaining a sample chamber at low (i.e., poor) vacuum by separating different regions of the instrument by small, pressure-limiting apertures.

Because they lend themselves to the examination of nonconductive samples without the need for coating, LV-SEMs, VP-SEMs, and ESEMs are now increasingly being used to examine different food systems. Examples of specimens suitable for examination with this type of instrument include finished products and samples taken from different stages of food processing as well as for the investigation of complex structures. Novel approaches to the preparation of samples can yield further information, e.g., exposing a lipid-containing matrix, such as a biscuit, to osmium vapor which will bind to the lipid phase preferentially and can then be contrasted by backscattered electron imaging. Further applications include samples immunolabeled with gold or silver probes and also dynamic experiments, such as following the crystallization of products in an ESEM.

Demonstration of elemental composition of unfixed, uncoated samples by X-ray microanalysis is possible, although (because of the higher pressure) the spatial resolution of the X-ray signal is reduced. However, mathematical corrections have been developed by some workers and at least one major manufacturer of X-ray microanalysis systems offers such algorithms in its software.

High-resolution and Low-voltage SEM

Resolution is largely dependent on the diameter of the scanning spot of electrons used to examine the specimen. However, with decreasing spot size there is decreasing signal and, with conventional SEMs, the signal-to-noise ratio becomes unacceptably poor at very high magnifications. With decreasing accelerating voltage there is a concomitant decrease in signal so, traditionally, relatively high (> 20 kV) accelerating voltages have been used for SEM examination of specimens. However, reducing the voltage has a number of advantages. There is a significant reduction in the build-up of charge and, with reduced beam penetration, fine detail on the surface of samples is revealed.

With the increasing availability of instruments equipped with a field emission gun (FEG) and advanced electron optics, the opportunity now exists for the examination of specimens with high-intensity electron beams with small spot sizes over a wide range of accelerating voltages (including very low voltage).

High-resolution cryo-stages have been developed to complement this range of FEG-SEMs so that frozen samples can be examined at high resolution. There is now considerable overlap between the information that can be obtained from fractured frozen samples examined by high-resolution SEM and that obtained from traditional freeze-fracture studies made by TEM. Often, larger areas of a sample are available for examination by SEM, when compared with complementary TEM freeze-fracture studies, and interpretation of the results can be less difficult. However, in both cases, the quality of freezing is paramount and normally it is only a small region close to the edge of a sample that will have been frozen sufficiently rapidly to be comparatively free of ice crystal artifact.

Applications that are particularly suitable for examination with such instrumentation include emulsions, foams, liposomes, microorganisms, and food systems where interfaces are of interest.

There is an additional category of instruments (ESEM-FEG) that exists that combines the ability to operate at high resolution and high gun intensity with the capability of operating at higher pressures and relative humidity. These instruments offer an enormous range of different operating modes to suit different sample types. However, this flexibility comes at a price and the principal limitation is the cost of purchase.

Specimen Preparation

Significant improvements have been made in both instrumentation and electronics in SEM over recent years. In applying the technique more widely to food studies, however, the limitations probably still lie in the area of presentation/preservation of the specimen to insure that the microstructure is retained in its original form when examined by SEM. It is

this area of the technique where most developments are likely, particularly in the use of environmental or LV-SEM or VP-SEM, low-temperature preparation procedures, and also in high-resolution cryogenic techniques.

When the first scanning electron microscopes were available commercially, the appeal of a three-dimensional image led to the rapid production of numerous micrographs of food materials with perhaps only limited scientific value. Now that this period is over, an increasing number of workers are using the fuller potential of SEM and it has emerged as an important research tool both in its own right and as a complementary technique to other microscopical techniques in microstructural investigations of food and food processing.

Transmission Electron Microscopy

J H Holgate and J Webb, Reading Scientific Services Ltd, Whiteknights, Reading, UK

Introduction

Many investigators have studied the textural behavior of numerous products using physical measurements and showed good correlation with sensory evaluations of texture and mouth feel. Microstructural analysis now seems to be playing a key role in explaining the type of data produced. It is being used increasingly in the study of a wide range of food products and ingredients, with the data obtained being related to a sample's textural properties and in some cases to its perceived flavor. Such studies can help in the overall understanding of the effects of food processing. (*See* **Analysis of Food**; **Sensory Evaluation**: Sensory Characteristics of Human Foods.)

The first commercial transmission electron microscope was available in the 1940s when it was recognized that significant improvements in resolution could be made over the light microscope through the use of an electron beam rather than a light beam. However, the instrument could only operate under vacuum and required ultrathin specimens for the beam to pass through. Thus, specialized preparation techniques had to be developed to insure that microstructural and ultrastructural details of specimens were adequately preserved during each of the preparative stages.

In the early years, the application of transmission electron microscopy (TEM) to the food industry lagged behind that in metallurgical and biological fields. This was partly due to problems in specimen preparation and handling that were specific to food materials, arising from the lack of homogeneity and often the presence of high levels of water, sugars, or fats.

Principles

A hairpin tungsten filament of an electron gun, encased in a column at high vacuum, is heated to generate a cloud of electrons, which is accelerated through a hole in an anode to produce a narrow beam that is directed towards the specimen. By using electromagnetic lenses to focus the resultant beam, an image can be formed by projecting the electron beam through a thin specimen. The first instruments produced magnifications up to $\times$ 10 000 but subsequent development of electromagnetic lens systems and guns capable of accelerating voltages exceeding 100 kV and up to 400 kV on standard TEMs has extended the magnification range up to $\times$ 1 000 000 or more, with resolutions of better than 0.2 nm possible on modern instruments. As the human eye is not sensitive to electrons, the final image is visualized by being focused on to a fluorescent screen or directly on to a photographic plate or film.

TEM operates under high vacuum ($< 10^{-5}$ mm Hg or $< 10^{-4}$ Pa) in order to minimize the scattering of the electron beam by gas molecules and allow it to

travel through the microscope without contamination. This brings with it the physical problems of having a specimen which must withstand exposure to high-vacuum as well as high-voltage electron beams.

Preparation Techniques

A number of different techniques are available for the preparation of specimens for TEM. The choice depends very much on the nature of the food, for example, whether it is liquid or solid or whether it contains high levels of water, fats, or sugars, which may make it difficult to handle during the various preparative stages. In all cases, however, the basic requirement is to produce an ultrathin preparation that allows an electron beam to pass through it, whilst at the same time being dry and resistant to the high vacuum and potential high temperature of a high-voltage beam.

Food often presents particular difficulties because of its heterogeneity and, in many cases, the presence of relatively high levels of fats and sugars, often in combination.

The most frequently used TEM preparation techniques that have been applied fairly successfully to different food materials are negative staining, thin sectioning, and freeze-fracture replication, with the latter two being used most often.

Negative Staining

Negative staining represents one of the easier and more rapid techniques in terms of specimen preparation but is limited in food applications to studies of dilute suspensions or dispersions, for example, food proteins, liposomes, cellular fragments, liquid crystals, or microorganisms. It cannot be used for large or more complex food systems.

In this technique the particulate or colloidal components are examined directly on a TEM specimen support grid after they have been surrounded or embedded in an electron-dense 'stain.' The technique relies on the metallic stain producing an outline of the structures, rather than reacting positively with them, thus providing information on overall size and shape and detail of features such as bacterial flagella. Phosphotungstic acid (PTA) is one of the negative stains used most commonly (**Figure 1**), although some success has been achieved with uranyl acetate, particularly for the examination of food protein macromolecules. A third reagent, ammonium molybdate, has been used, but with less predictable results, and has been shown to be particularly sensitive to localized pH changes.

There was a renewed interest in the use of negative staining in the mid 1980s as it became possible to use it in combination with low-temperature TEM preparation techniques. Fully hydrated, negatively stained preparations are fast-frozen and then examined by TEM on a low-temperature (below $-150\,^{\circ}C$) stage. This approach has been particularly successful in the examination of viruses and single-cell preparations, but has been of limited use to date in studying food components.

Thin Sectioning

Probably the most frequently used preparation procedure for TEM is thin sectioning, where the specimen is initially preserved chemically or 'fixed,' solvent-dehydrated, and then infiltrated and embedded in a resin or other polymeric material. On polymerization (usually by high-temperature curing), the resin hardens so that ultrathin slices or sections (< 100 nm) of the embedded material can be cut using an ultramicrotome.

Among the various chemical fixatives currently in use, glutaraldehyde, followed by osmium tetroxide (O_SO_4), remains one of the most effective. However, a number of different fixative regimes have been developed for different food systems, often involving alternative aldehydes or mixtures of aldehydes and using temperatures, osmolarities, pH values, and buffers appropriate to the food. Osmium textroxide has the advantage of being uniquely suitable for fats and thus has been used particularly for foods containing high levels of fat (e.g., oil seeds, emulsions, chocolate). It also functions in its vapor form and, therefore, is useful as a primary fixative to stabilize the specimen prior to further treatment. As well as fixing the sample, chemical bonding of the osmium to the unsaturated fats produces electron-dense 'stained' regions in the preparations. Extended fixation times are often employed for fatty foods, although these are often a compromise, as they have sometimes been shown to produce artifacts in the nonfat areas of the specimen.

Many different types of polymers have been used as embedding materials over recent years. Epoxy resins and methacrylates are perhaps used most frequently for food materials, particularly lower-viscosity polymers. A number of different resins were developed during the 1970s and 1980s. Initially they offered particular advantages of very low viscosity, and thus more rapid and efficient infiltration, and were thought to be safer to handle. Unfortunately, a number of the components of the resins were still found to be unsafe, having carcinogenic properties in particular. However, a range of new acrylates became available in the 1990s, which are not only considered safer to handle

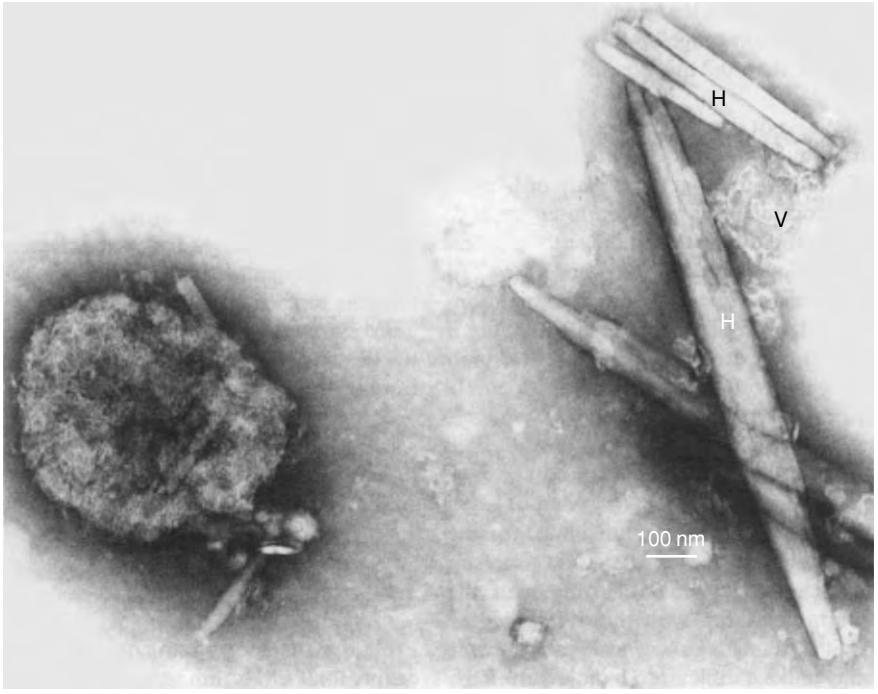

Figure 1 Negatively stained preparation of material isolated from a comminuted fruit drink showing the presence of hesperidin crystals (H), chromoplasts (C), and membraneous vesicles (V). Bar = 100 nm. Reproduced from Microscopy: Transmission Electron Microscopy, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

but have relatively low viscosities. Some of these can be polymerized at low temperatures by ultraviolet curing, though care has to be taken to prevent localized heat build-up as the accelerator is activated. Thus, the problems of exposing materials to high-temperature polymerization conditions are avoided. Other polymeric materials available are miscible with water and thus eliminate the solvent dehydration stages. However, these have been of only limited use as they often produce fairly brittle embedded blocks, which are difficult to section.

When food samples are in liquid or semisolid form, there is obviously a special requirement to keep the sample intact during the various preparative steps. This is achieved by some means of encapsulation and a number of workers have used a modification of the Salyaev technique with considerable success in preparing milks, fruit juices, cell suspensions, and other liquid food materials. The principle is to prepare a capillary tube of agar that is filled with the sample and sealed at both ends with further agar, before being put into liquid fixative and processed as for other materials.

The embedded materials, usually in the shape of small tubes or blocks, are sectioned using an ultramicrotome to produce ribbons of ultrathin sections measuring between 50 and 100 nm. Traditionally, freshly cleaved glass knives are used as they have very sharp cutting faces. However, diamond knives have increased in popularity over recent years, as they remain sharp for extended periods of time and thus are suited to hard materials, e.g., woody tissue, bone, and crystalline components. Their main disadvantage is price, including the high cost of resharpening.

Cut sections are collected on meshed support grids designed to fit the TEM holders and then examined in the microscope, usually after staining to enhance the contrast of the sample and specifically identify individual components. Contrast in a TEM image is a result of differential electron opacity and therefore the most effective stains are based on reaction with electron-dense materials, in particular those with the highest atomic numbers, e.g., inorganic stains containing heavy metals.

Traditionally, staining has involved an initial reaction with uranyl acetate followed by lead citrate to provide a fairly nonspecific staining of the whole sample. This approach is still used routinely for many food specimens, with subsequent identification of components based mainly on their characteristic morphological features rather than their reaction to

stain. However, many different staining regimes have been developed for specific components, e.g. proteins, carbohydrates, and polysaccharides, in a wide range of different foods. Frequently these have been based on traditional biochemical reactions, but for TEM the staining compound includes a heavy-metal salt rather than a chromophore (coloured moiety). (*See* **Carbohydrates**: Determination; **Protein**: Determination and Characterization.)

Low-Temperature Preparation Techniques

For specimens which contain high levels of water or which are liable to change significantly during fixation or embedding procedures, preservation of the ultrastructure can be achieved with a cryofixation step, i.e., rapid freezing of small samples. This preserves the natural three-dimensional structure and solidifies the material so that it can subsequently be sectioned or fractured to reveal its internal structure.

Cryosectioning

Cryosectioning (sectioning at low temperatures) of frozen materials can be used for biological and biomedical tissues. It involves the controlled sectioning of frozen material using an ultramicrotome at low temperatures. Sections can be examined directly on a low-temperature TEM stage or after freeze-drying. However, there are few published data on the successful application of this technique to foods because of the difficulty of cutting ultrathin frozen sections of food materials and handling them prior to examination.

Freeze-Fracture/Freeze-Etch Replication

The alternative to sectioning frozen material is to fracture the sample and reveal its internal structure. Combining freeze-fracture with metal shadowing/carbon replication techniques has proved a particularly useful procedure for preparing many different foods for TEM, including emulsions, foams, and fatty confectionery, as well as frozen products such as icecream (Figure 2). This procedure is referred to as freeze-fracture or freeze-etch replication. One of the critical stages in the procedure is achieving rapid and efficient freezing of the sample to prevent the formation of visible ice crystals or other artifacts and considerable efforts have been made to optimize this process. Nitrogen 'slush,' i.e., a mix of liquid and solid nitrogen ($-210\,^{\circ}C$), is probably the

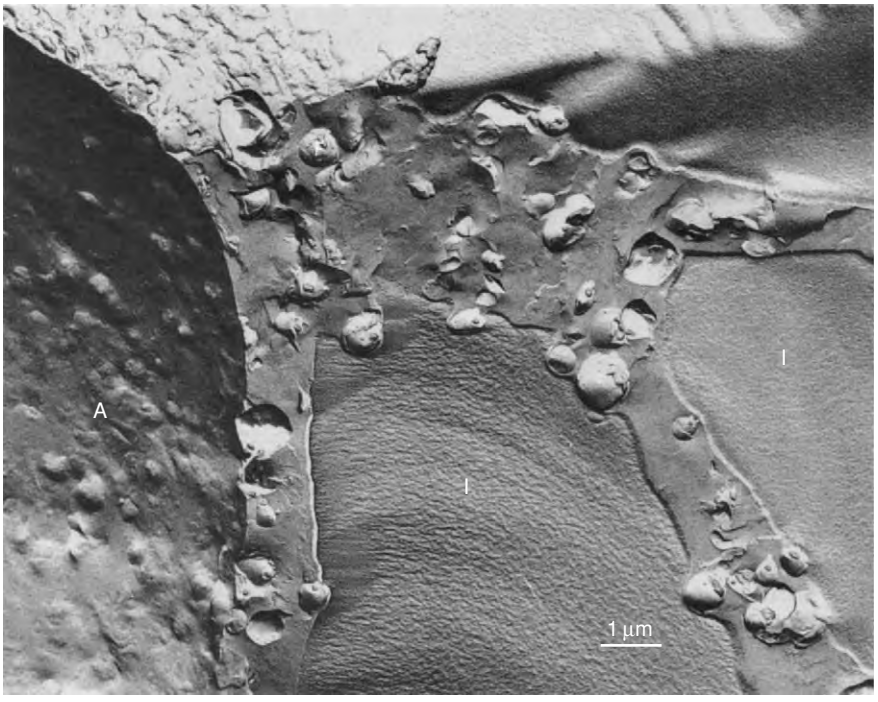

Figure 2 Freeze-etch preparation of icecream showing the presence of ice crystals (I), air bubbles (A), and fat droplets (F) within an aqueous sugar matrix. Bar = 1 µm. Reproduced from Microscopy: Transmission Electron Microscopy, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

most frequently used cryogen, as it is relatively easy to prepare and use. However, faster freezing rates are possible with liquid propane and hexane and these are now being used increasingly, particularly in combination with purpose-built freezing apparatus that are designed to enable safe handling of these flammable materials. Commercial developments in this field include specialized apparatus for cold metal block freezing ('slamming') and spray jet freezing. However, these are relatively expensive and have been of limited application in food microscopy.

Some success has been achieved with the use of cryoprotectants, for example glycerol, which can be used to infiltrate TEM specimens and inhibit the development of ice crystals on freezing. However, the interaction of the chemical has been shown to change the fine structure of samples and is now used more as a complementary technique in low-temperature preparations. Certain foods have been shown to offer an advantage in achieving fast freezing as they provide their own cryoprotection with the presence of high levels of sugars or salts.

Once the frozen samples are transferred on to the cold stage of a freeze-fracture/etch unit, they are fractured under vacuum and a carbon/platinum replica is prepared of the frozen fractured surface. Replication is achieved by the evaporation of a thin supporting layer of carbon followed by platinum deposited at an angle to produce a 'shadow' and hence reveal the topographical details of the surface.

For samples with high levels of water present, 'freeze-etched' replicas are made by the sublimation or 'etching' of a thin layer of surface ice before replication. After replication, samples are removed from the unit and the replicas are then cleaned in detergent and/or solvents to remove the food substrate before TEM examination. The choice of cleaning regime is important in order to clean the replica adequately whilst at the same time preserving its integrity. Strong caustic solutions have proved useful for many food materials, often combined with detergent or organic solvent washes to remove the fatty components.

Freeze Substitution

Freeze substitution involves the replacement of water (ice) in a frozen preparation with an organic solvent and subsequently with resin. There has been renewed interest in the technique recently because of its suitability for preparing biological tissues for immunolabeling. However, it is still of only limited application to food materials.

TEM Attachments

Scanning Unit

Many modern TEMs have the facility for attachment of a scanning unit to the main instrument. The unit allows the beam to be scanned across a selected area of the specimen and with the addition of suitable detectors the electron microscope can be used in a surface imaging mode or in a scanned transmission mode (STEM). In surface imaging mode, high-resolution images of the surface of samples can be obtained, although the small sample chamber restricts the size of sample that can be examined. The primary application of STEM is in imaging thicker samples. Since the images produced are electronic/digital, they have the advantage that they can be subjected to image processing and analysis to enhance the information further.

X-ray Microanalysis

Interaction of an electron beam with a specimen produces X-rays which are characteristic of its elemental composition. These X-rays can be collected to provide qualitative and quantitative chemical data from a sample. The technique is applicable to both transmission and scanning electron microscopes and is dealt with in more detail in the preceding article **Microscopy**: Scanning Electron Microscopy. In TEM its main application is in determining the distribution and changes in distribution of specific elements within thin-sectioned preparations. It has been of limited value for food samples to date, as the fixation and embedding techniques required for adequate preservation of microstructure frequently result in redistribution of elements within the material.

Applications of TEM

Many different food materials have now been examined using TEM. However, its main use has been in terms of characterizing the ultrastructure of different foods and relating this information to process changes and to textural and other physicochemical properties. Early studies involved the use of thin-sectioning techniques on foods with relatively high levels of plant or animal tissue, for example, meat, fruit, and vegetables. These studies were able to demonstrate the cellular changes associated with processing and cooking fresh tissue and included the use of specific staining regimes to monitor chemical changes such as the integrity of plant cell walls, meat fibrils, etc. More recent studies tend to use a combination of microscopy techniques to study the changes in more detail and to characterize more complex, composite materials, such as many confectionery products (Figure 3).

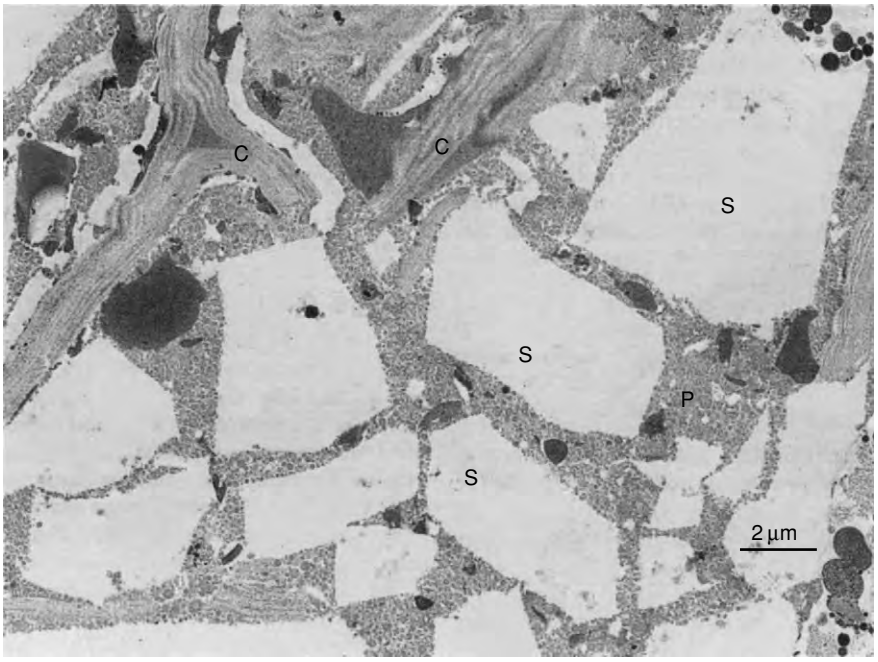

Figure 3 Thin section of milk chocolate showing the close association of milk protein (P), sugar (S), and cocoa tissue (C) within a chocolate particle. Bar = 2 μm. Reproduced from Microscopy: Transmission Electron Microscopy, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Studies on liquid or semisolid foods, for example, milk, emulsions, and fruit beverages, have increased significantly with the introduction of low-temperature techniques for handling and preparing these types of material. It has been possible, therefore, to identify and characterize the individual components present, for example, size and shape of fat droplets, form and level of aggregation of proteins (Figure 4), and to evaluate changes arising as a result of processes (heat, shear, pH changes, etc.), ingredients (different fats, protein source, etc.) or recipes.

The use of TEM for examining dry materials, for example milk powders, has been mainly superseded by the introduction of scanning electron microscopy techniques. However, it has been found that the use of thin sectioning, and more especially carbon replication techniques for TEM, has produced valuable information on the ultrastructural detail of these materials, in particular, the location and appearance of protein, which was not possible in any other way.

Future Developments in TEM of Food Materials

Immunolabeling

Colloidal gold immunolabeling is now probably the most highly acclaimed technique for electron immunocytochemistry. Gold spheres, bound to selected antibodies, are incubated with the relevant receptor to effect high-resolution and highly specific labeling. The technique is now enhanced by application of multiple labeling of different antigens using different-sized gold particles and quantitative techniques. However, it has yet to be used extensively for food materials. This is due to the problems of raising and isolating antibodies specific to food components, particularly after the foods have been processed, combined with the overall difficulties in handling food for TEM.

Low-Temperature Preparation Techniques

The use of low-temperature preparation procedures has increased significantly over the last few years. However, considerable advances have been made in faster freezing methods, alternative ways of handling frozen materials, e.g., sectioning, complementary fracturing techniques, and combinations of fracturing/sectioning/labeling, which have mainly been applied to nonfood materials. It is likely that these will be applied increasingly to studies on food.

Scanning Probe Microscopy (SPM)

This is a developing field and the techniques relevant to the microscopy of foods are centered on using scanning tunneling microscopes (STM) and atomic force microscopes (AFM). They provide high-resolution visualization of surface morphology and

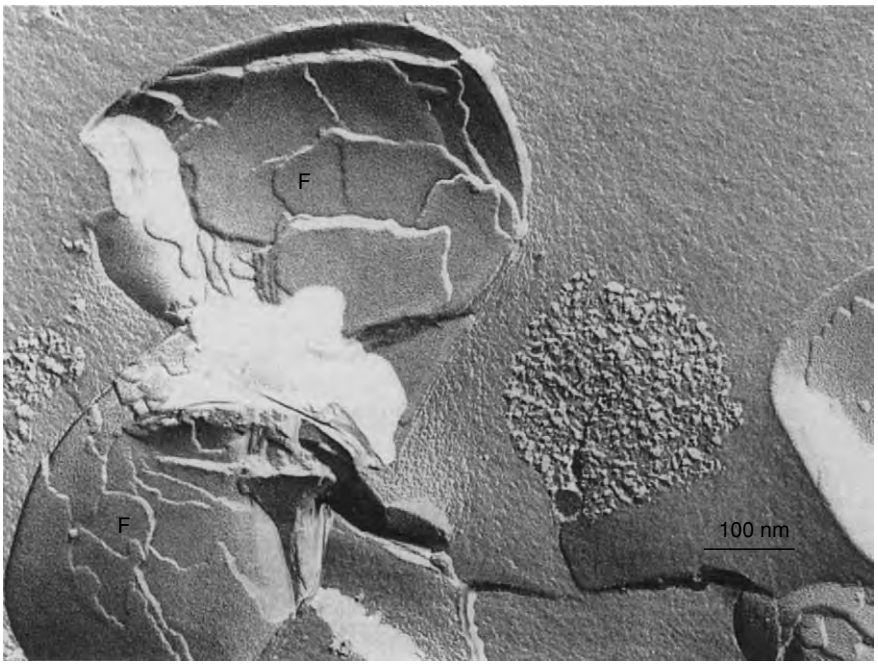

Figure 4 Freeze-fracture replica of a confectionery emulsion showing the fine emulsified fat droplets (F) and aggregated casein protein (P). Bar = 100 nm. the applications of the different microscopes in this family extend to provide information on physical as well as structural properties, including information on topography, hardness, capacitance, stiffness/adhesion, and microcalorimetry. For some sample types the resolutions quoted are to < 1 nm and applications have been demonstrated in biology, pharmaceutical, and metallurgical industries. The techniques have potential for applications for foods and have already been used to demonstrate the structures of proteins in some food gels and emulsions.

Image Analysis

A Flook, Bedford, UK

Introduction

Image analysis is a computer-based process of extracting quantitative information from images. The process begins with the input of an image and

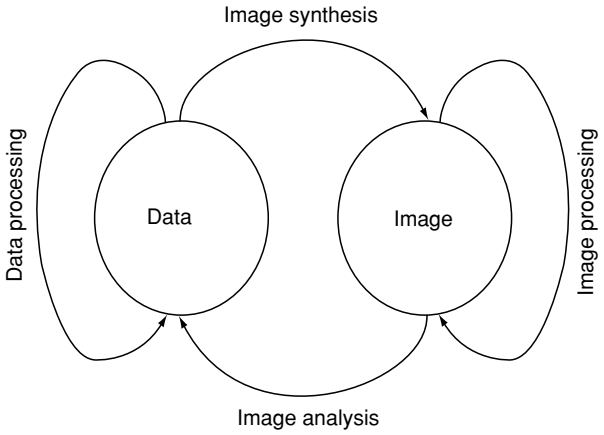

Figure 1 Conversion of information between data and image format.

ends with the output of numerical data (Figure 1). This distinguishes it from image processing where both input and output are in the form of an image.

Image processing is the means by which the input image is modified by one or more mathematical algorithms to generate an output image that is enhanced in some way. For example, edges may be enhanced or the noise reduced. Image processing is often used to prepare images prior to analysis.

Image analysis requires specialized computer equipment fitted with an imaging device, such as a television camera, coupled to a microscope or a macroviewer.

The first commercial image-analyzing computers were constructed in the early 1960s for grading steel by measuring nonmetallic inclusions. The value of using an automated method for the rapid, objective measurement of images was soon recognized for many different applications in life and materials sciences. Image analyzers with greater versatility have been developed but initially the application of the technique was limited by the high cost of the instrumentation. However, the price of computer hardware has steadily decreased over the years and now many manufacturers offer relatively inexpensive systems using a personal computer as the host processor. With the advent of more affordable equipment, applications have proliferated in many widely differing fields, including food science and technology.

Terminology and Nomenclature

Image-processing terminology is mainly derived from the mathematical functions used (e.g., Laplacian and Gaussian filters are used for image enhancement). These terms may not always be easy to understand but are used universally and can, in the main, be used without ambiguity. This cannot be said for image analysis. There are no internationally agreed standards and the terminology used can be specific to the manufacturer of the equipment. Indeed, in the early years of image analysis it seemed almost obligatory for each new analyzer on the market to come with its own set of terminology. For example, one manufacturer uses the term segmentation for the process of extracting a binary image by gray-level thresholding. Another calls this process detection and reserves the term segmentation for the process of separating touching regions. Also, the binary regions to be measured can be referred to as regions, objects, features, or even blobs, depending on the equipment used. This makes it difficult for newcomers to read research papers and relate the functions named to those installed on their own equipment.

This situation, although regrettable, is unlikely to change. The terms used in this article are those most commonly used but the reader should be aware that they are not unique.

The Hardware

There is a wide range of image analyzers commercially available. They all differ in detail but are broadly similar in design. A typical system consists of the following components.

Microscope

This is usually fitted with a trinocular head to allow direct viewing of the specimen and for the mounting of a television camera. (A macroviewer is an alternative optical input device for photographs or larger specimens.)

Television Camera

Most image analyzers use standard-format charge-coupled device (CCD) TV cameras, although an increasing number of systems are being fitted with color and high-definition cameras.

Analog-to-Digital Converter (ADC)

This is a device that converts the continuous voltage output signal from the camera into a sequence of numbers representing the voltage at timed sampling intervals. The lighter the region of the picture at the sampling point, the higher the voltage and hence the larger the numerical value. Most systems are fitted with an 8-bit converter, allowing $2^8 = 256$ different gray-levels. Three independent channels are used for color images – one each for the red, green, and blue images that constitute a conventional real-color image.

Image Store

The sampling interval of the ADC is chosen to give a discrete number of pixels (an abbreviated term for picture elements) for each scan line of the television signal. These are read into an image store. The format for the image store is a matrix of pixels corresponding to the CCD format of the camera. The store is usually large enough to accommodate several digitized images at once. Systems based on personal computers use buffers within the random access memory.

Monitor

This displays the images and provides a user interface for programming. Most image analyzers use a scripting language to build programs that control the processing of the images and the analysis of the data.

Image Processor

Digitized images are very large arrays of numerical data. Early instruments had specialized image processors to manipulate the images but modern personal computers have processors powerful enough to cope with the demands of image processing without using special processors.

Binary Image Store

In most applications the image will ultimately be reduced to a binary form where each pixel of the original image is converted to either a 1, representing a pixel within an area occupied by one of the objects to be measured, or a 0 representing a pixel in the background. Binary images are normally displayed either as bright pixels on a dark background or by the use of two distinct colors representing the 0s and 1s.

Early instruments had specialized memory stores for this type of data but these are now obsolete.

The Host Processor

This is often, but not necessarily, a personal computer. On older machines it is used to manage the data flow within the computer and issue instructions to the specialized processors. Now all the processing is usually done using the standard computer processor. The host processor also supervises peripheral devices such as printers and the automatic focus and x,y stage controls on the microscope (where fitted). Finally, it provides the means to process the data and provide any statistical, graphical, or other utility program that may be required for a particular application. The host processor will usually be fitted with disk drives for the storage of data and programs.

Output Device

This will commonly be a printer or plotter that will enable the results to be converted into hard copy in graphical or tabular form.

The Principles of Image Analysis

Image analysis often requires a greater degree of care in preparing the sample and setting up the microscope than is necessary for visual inspection. The human brain is well adapted to the recognition of objects of interest in an image and to ignore extraneous information. The computer, on the other hand, can only cope with relatively simple images. For this reason the image analysis process should be considered to start from the sample preparation onwards.

Measurements can only be made on a binary image. The ultimate goal of the image prepossessing is to simplify the image in such a way that will make it easy to convert it to this form. In the binary image the bright pixels should correspond to those areas in the original image that represent the objects or structures that are to be measured.

A typical sequence will include the following steps.

Sample Preparation

Small variations in the preparation protocol can determine whether or not a project is amenable to image analysis. The best images for analysis are those that show the objects that are to be measured in greatest contrast with respect to the rest of the image. Color contrast may be used with those instruments fitted with a color camera. Intensity contrast is used for monochrome images.

Image Capture

The analysis proceeds by setting up the input device to deliver the best possible image to the camera. When a suitable image is obtained, it is read into the computer memory via the ADC.

Image Processing

There are many methods of mathematically processing an image so that the output image is enhanced in a manner that renders it more suitable for image analysis. For example, the edges of structures may be sharpened or the image may be given enhanced contrast or reduced noise.

It is not always necessary to preprocess the image in this way, but shading correction is almost always used. Shading correction is the process by which the computer attempts to compensate for any uneven illumination of the specimen. This is usually achieved by storing the pattern of the variation in intensity

obtained from a blank image field. This image, called the shading pattern, is used to correct subsequent images.

Image processing can never increase the information content of an image. Any enhancement of one image attribute is obtained at the expense of another. For example, edge enhancement algorithms tend to increase the noise content of an image. Many algorithms have been developed over the years to enhance images with the minimum of unwelcome side-effects. There are, for example, methods of reducing noise without smoothing out the edges of objects. However, heavy processing can still introduce unwanted artifacts in the image. For this reason sample preparation and lighting conditions are best chosen to reduce the need for image enhancement to a minimum.

Segmentation

This is the process by which the digitized, gray, or color image is converted into a binary image representing the objects to be measured. This is the most important, and often the most difficult, step in image analysis. The computer needs a binary image to make measurements. There are several ways of defining the regions to be segmented. The simplest form is by setting a gray-level value below which (or above, for light objects) a pixel will be counted as being part of the object. All other pixels will be counted as belonging to the background. This form of segmentation is also referred to as thresholding or detection. Another method allows the operator to draw round or point to a typical region; the computer will sample the intensities of the pixels in the region and generate a binary image of all regions containing pixels with matching intensities. There are also methods that specifically detect the edges of objects.

Color discrimination provides an alternative method of segmentation for true color images. There are two main color models used in image analysis–the red, green, blue (RGB) model and the hue, luminance, saturation (HLS) model. Color images are separated into their three components (RGB or HLS) according to which color model is to be used for segmentation. Each component is held in memory as a separate image. These component images can be viewed separately as monochrome images but are normally displayed combined as a color image (Figure 2). Segmentation methods, similar to those used on monochrome images, are applied to each of these components and the resultant binary images combined. The resultant binary image will represent those regions in the original image that have a similar color composition.

Binary Image Processing

Often the segmentation process does not produce a perfect binary image of the objects of interest and many binary operations have been devised to amend the defects in the image. For example, there are operations for filling in holes and others that dilate or erode the binary image by adding or subtracting pixels from the perimeter of objects. Erosion and dilation can often be used to good effect by combining them to form new operations known as closing and opening. Closing is the process of dilation followed by an equal amount of erosion and is useful for joining up fragmented regions of an object. Opening is the converse operation and is often used to clean up ragged edges and remove small or thin artifacts from the image. Opening and closing operations leave the overall size of the objects relatively unchanged compared with erosion or dilation used on their own.

There are other more complex binary operations which can be used, for example, to separate touching objects, reduce objects to a skeletal representation, and erode objects to the point just before they would otherwise disappear. These tools allow the image analyst to automate much of the editing of binary images that would otherwise have to be done by time-consuming manual methods. They form an important part of image analysis and can make the difference between being able or otherwise to perform an analysis in a reasonable time. The theory behind these operations is known as mathematical morphology.

Editing

The binary image can be edited manually by using a hand-held device, such as a mouse or a light pen, which is interactive with the computer. By this means sections or lines can be cut out or drawn in at will. Although it is often necessary to do a little manual editing, this should always be regarded as a method of last resort since it is a slow operation and introduces a subjective element into the analysis.

Measurement

There are two distinct modes of measurement that can be made in image analysis: field-specific and object-specific. Before discussing these it is important to distinguish between the image and measurement frames. The total area of the specimen scanned by the TV camera and displayed on the monitor forms the image frame. The measurement frame is a subframe within the image frame over which the measurements are made. The area within the image frame that lies outside the measurement frame forms the guard region.

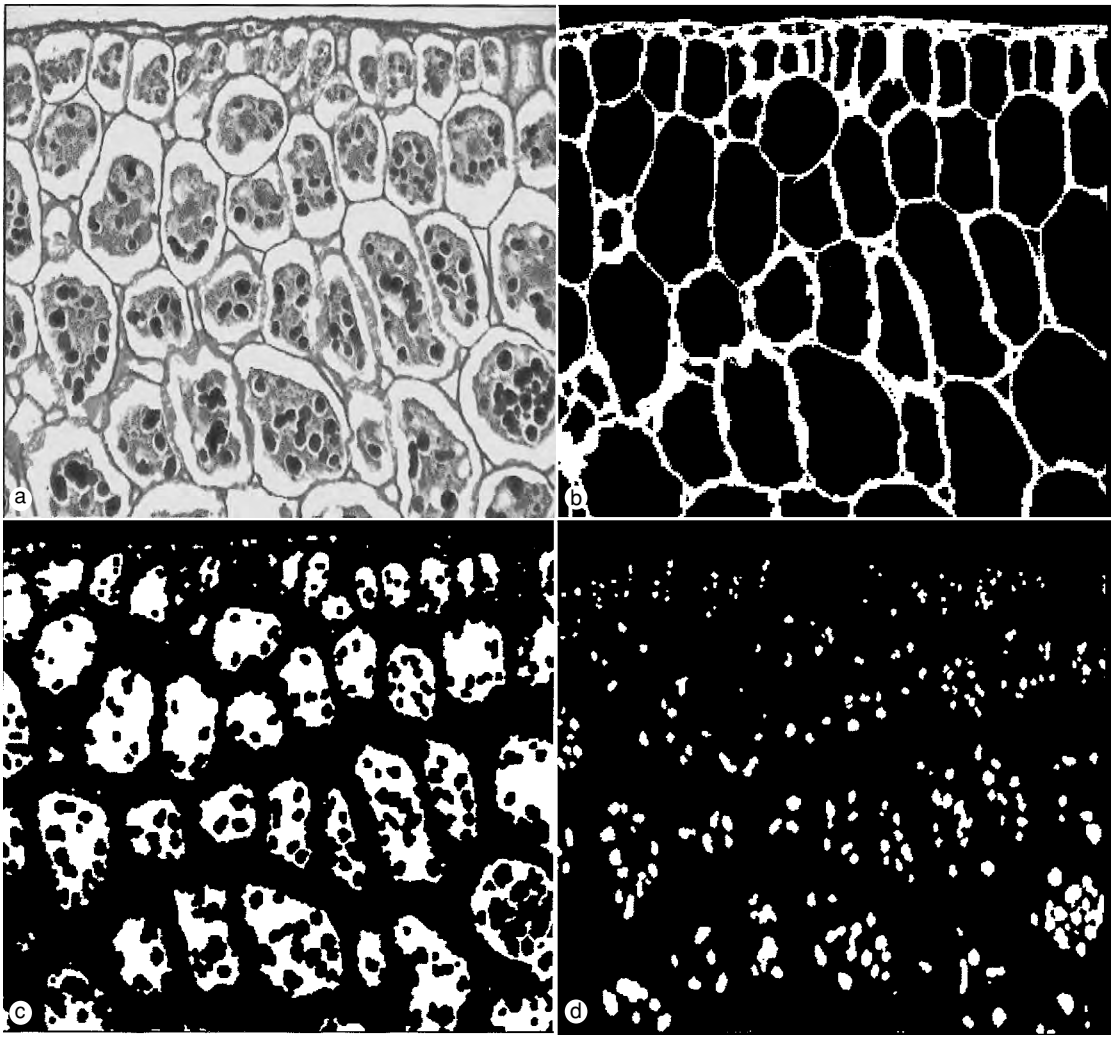

Figure 2 (see color plate 109) Color segmentation of a section from a pea cooked from frozen. (a) Original image; (b) cell walls; (c) cytoplasm; (d) gelatinized starch granules.

Field-Specific measurements Field-specific measurements are summed over all the objects and parts of objects lying within the measurement frame. In this mode, if an object is intersected by the edge of the measurement frame, only those parts of the object that project into the frame are measured. Field-specific measurements are used for stereological calculations of global parameters such as phase volume or count per unit volume.

Object-specific measurements Object-specific measurements are made on each individual object in the measurement field. In this mode, each object is associated with a unique object location reference point that is determined by the counting logic of the particular image analysis equipment used. The whole of an object is measured if its reference point is inside the measurement frame, even if much of it spills over the edge of the frame. Conversely, the object will not be measured at all if the reference point falls outside the frame. Any uniquely definable point may be chosen as the reference but, for practical reasons, the location of the last pixel visited within the object as the scan progresses down the screen is most commonly chosen. The measurement frame size is chosen so that the guard region, which surrounds it, is wide enough to insure that any object whose location point is within the measurement frame is wholly within the image frame.

Some primary measurement parameters for objects are defined below. Most of these measurements can also be made in field-specific mode:

- Area: the total number of pixels within an object
- Perimeter: the length of the boundary between an object and the background

- Horizontal intercept: the number of intersections of the TV scan line with an object
- Vertical intercept: the equivalent of the horizontal intercept but in a vertical direction
- Feret's diameters: These are equivalent to caliper diameters, i.e., the perpendicular distance between the parallel jaws of a caliper just touching the object. The magnitude of these measurements is dependent on orientation and the more advanced image analyzers are able to measure Feret's diameters at a large number of small angular increments.
- Integrated brightness: The gray-level values summed over the region corresponding to the binary image of the object. With suitable calibration, these measurements can be converted to optical density values.
- Count: In field-specific mode this gives the total number of objects in the field. It may also be possible, on some machines, to count objects within objects (e.g., the number of vacuoles within a cell membrane).

These primary measurements are often combined to create additional measurement parameters such as:

- Equivalent circle diameter: The diameter of a circle having the same area as the binary image of the object. Used as a size measurement that is insensitive to the orientation of the object.
- Form factors: The dimensionless ratios of primary measurements whose magnitude gives an indication of the morphology of an object. Dimensionless ratios are used to give values that are independent of size, e.g.:

$$\text{Circularity} = 4\pi \text{ area}/\text{perimeter}^2$$

A perfect circle will have a circularity value of one. All others shapes will give a lower value.

- Length: Usually taken to be the longest Feret's diameter.
- Breadth: This can be defined in a number of ways. For example, the shortest Feret's diameter may be used or it may be estimated by dividing the area by the largest Feret's diameter. There are other ways of defining breadth; the choice will depend on the application.

Three-Dimensional Imaging

One of the restrictions of image analysis has been the need to work on two-dimensional sections. Volumetric properties have to be derived from stereological computations. Whilst this approach is sufficient for most work, it does have significant drawbacks: care must be taken with anisotropic materials to avoid biasing the data and the sectioning process may mechanically distort the material. Furthermore, it is necessary to fix and embed soft or friable material specimens in order to section them. This may lead to further structural changes in the material, thus rendering any measurements of dubious relevance to its original state.

There is a number of methods for imaging beneath the surface of structures. Confocal microscopy, magnetic resonance imaging, and microfocus X-ray tomography can be used to provide series of two-dimensional, virtual sections. Many image analysis packages have software specifically designed to reconstruct three-dimensional images from a series of images representing two-dimensional slices generated by these methods (Figure 3). The reconstructed images can be used to create further virtual sections in any direction or to make direct volumetric measurements.

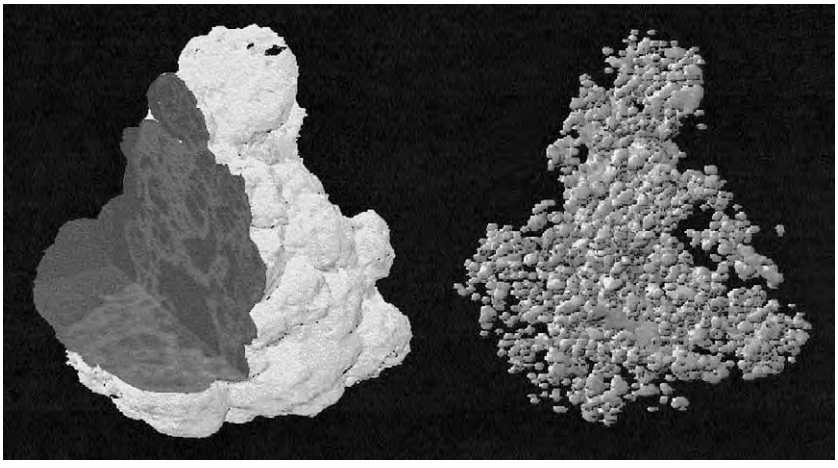

Figure 3 (see color plate 110) Reconstruction of puffed wheat from X-ray tomographic sections. Left, reconstruction with cut-out to show the internal structure; right, reconstruction of the voids inside the puffed wheat. Courtesy of Dr Paul Jenneson, Surrey University, UK.

Applications

The potential for applications of image analysis is enormous – anywhere where rapid, objective, quantitative measurements are required. Particle size and shape analysis can be used to monitor comminution or agglomeration processes. The technique has also been used to measure the air bubble size distribution in aerated products such as icecream, chocolate, and batters. Where objects have well-defined morphologies, shape discrimination can be used to count several components simultaneously, e.g., counting the population densities of lactobacilli and streptococci in yogurt.

The Future

The development of high-resolution scanners for computer document archiving and the advent of high-definition TV technology has provided a number of high-resolution image input devices. This, coupled with the relentless pursuit of even cheaper and faster computer memory chips, will provide the image analyst with access to much higher-resolution images; 1024×1024 pixel image matrices are already commonplace and larger formats will follow.

The latest image analyzers use standard computer components. The only specialized hardware is the frame-grabber board. New computer interfaces are being developed that will allow the fast transfer of data directly into the computer from a digital camera. This will reduce the cost of the equipment further and will make image analysis more available to cost-sensitive applications.

Three-dimensional analysis is already an option on many image analyzers. Its use is restricted due to the huge amount of memory required and the high demands made on the processor. These restrictions will become less relevant and this type of analysis will become more common in the future.

Most electron microscopes and all of the newer forms of microscopy (e.g., scanning tunneling, atomic force, and confocal) are controlled via an interface to a personal computer. These provide an ideal platform for image processing and analysis.

MIGRAINE AND DIET

M R Costa and M B A Glória, Federal University of Minas Gerais, Belo Horizonte, Minas Gerais, Brazil

Migraine Headache

'Migraine' is a French derivative of the Greek word for hemicrania, or half a head. The problem of migraine is of long standing. Aretaeus of Cappadocia, in the second century AD, defined migraine as 'a paroxysmal headache disorder that occurred on one side of the head and then the other, recurred at regular intervals, associated with vomiting and photophobia, and ameliorated by dark surroungings.'

Throughout the ages, migraine has been a problem to patients and an enigma to physicians. Migraine is a public health problem of enormous scope that has an impact on both individual sufferers and society. Several studies have indicated that 82–85% of individuals have some headache-related disability. About one-third of them are severely disabled or need bed rest. In addition, many live in fear, knowing that at any time an attack could disrupt their ability to work, care for their families, or meet social obligations. With regard to the impact on society, the costs in

human terms are overwhelming. The totals, in terms of lost production, medication, doctors' and hospital fees are huge.

Migraine may begin in childhood and usually starts before the age of 40. Its prevalence in childhood is about equal among girls and boys, but at puberty the two groups diverge sharply and females begin to outnumber males. Frequency tends to decrease with advancing age, and up to three-fourths of women note relief after menopause.

It is believed that sufferers from migraines may have an inherited predisposition for this disorder. It has been reported that 50–70% of patients with migraine have a positive family history. The precise mode of inheritance is not known, but current thought is that this predisposition is an autosomal dominant trait characterized by incomplete penetrance.

Symptoms of a Migraine Headache

The symptoms most frequently associated with migraine headache are indicated in Table 1. Migraine is characterized by throbbing head pain. Most of the time, it is unilateral in adults; pain may occur on either side of the head but rarely changes sides during an attack. In children, migraine is ordinarily bilateral. It is often accompanied by nausea and sensitivity to light and/or sound. Less frequently noted are abdominal bloating and diarrhea, pallor, sweating, chills, and cold extremities. Every individual is different and may experience some symptoms and not others, or in various combinations. Intensity varies from one attack to another.

The frequency of migraine ranges from every few days to less than once a year. However, most patients experience one to four attacks a month. These generally last from 4 h to 2 days, but severe episodes of prolonged migraine may persist for weeks. Proper management can significantly reduce the impact of this debilitating chronic disorder and improve both functioning and quality of life.

Table 1 Symptoms associated with migraine headache

Symptoms of migraine headache
Moderate to severe headache pain
Duration of 4–48 h, sometimes longer
Throbbing pain located on one side of the head
Nausea
Vomiting
Sensitivity to light, sound, or odors
Pain becomes worse when moving

Pathophysiology of Migraine

Migraine is a vascular headache believed to be caused by blood flow changes and certain chemical changes in the brain leading to a cascade of events, including constriction of arteries supplying blood to the brain and the release of certain brain chemicals.

Migraine has a number of forms, some of which may be confused with other diseases. It can be classified (Table 2) as migraine with aura (classic) and without aura (common).

The exact cause of migraine is uncertain, although various theories are being studied. The neurogenic theory emphasizes the significance of active substances acting upon the central nervous system and promoting intracerebral vasoconstriction and extracranial vasodilatation. According to many researchers, migraine is due to the vulnerability of the nervous system to sudden changes in either the body or the surrounding environment. They believe that migraine sufferers have inherited a more sensitive nervous system response than those without migraine. During a migraine attack, changes in brain activity produce inflamed blood vessels and nerves around the brain.

Another theory is that migraine represents a disorder of cerebrovascular regulation. In the typical migraine sequence, a trigger precipitates a cascade of events that includes release, activation, and production of active substances. When these substances

Table 2 Symptoms and signs of different forms of migraine

Types of migraine	*Characteristics*
Migraine with aura (classic)	Neurologic symptoms occur 15–60 min before headache: scotomas or blind spots are common; photopsia and teichopsia or fortification spectra occur frequently; diplopia, macropsia, and metamorphopsia are less common Headache begins as neurologic symptoms diminish
Migraine without aura (common or nonclassic)	Occurs in 85% of all patients No neurologic aura precedes the headache Premonitory disturbances of mood or appetite (craving for sweets, euphoria, fatigue, yawning) can happen 1–3 days before an attack Bilateral or generalized pain

concentrate in the tissue, vascular and nervous phenomena are enhanced. A fact of paramount importance is that some of these substances potentiate one another. In patients with regular attacks, each episode of migraine is followed by a phase of immunity and then by one of increasing reactivity, which can be divided into two stages. The first is called adrenergic, and is characterized by relatively mild symptoms, such as no pain, vasoconstriction, slight excitation, and sensory manifestations. In the second one, there is intense pain, marked vasodilatation, and pronounced psychic depression. During the reactive phase, migraine episodes may be triggered by stimuli that promote vasoconstriction (e.g., cold, anxiety) as well as vasodilatation (e.g., heat, alcohol, nitrites).

Triggers or Provokers of Migraine

Certain factors can provoke or trigger attacks more frequently in those susceptible to migraine headache. Some possible triggers include biochemical or environmental factors; hormonal changes in women; too much or too little sleep; stress (feeling overly tired); pharmacological precipitants; and diet. According to many studies (Table 3), the most commonly cited triggers are stress, change in sleep patterns, menstrual cycle, hunger, and diet or specific foods. Not all migraines have the same provoking factors, nor do all these factors necessarily provoke an attack. Migraine can also arise from a number of factors acting in unison.

Biochemical Factors

It has been postulated that there is a biochemical defect in migraine sufferers, especially with respect to their ability to metabolize amines and phenols when compared to controls. The monoamine oxidases (MAO) act as a barrier against the absorption of vasoactive substances contained in foods. MAO defect can prevent amine metabolism and, therefore, cause accumulation of monoamines. There could also be a deficiency of phenolsulfotransferase P, which is specific for the detoxification of dietary phenols.

Table 3 Major precipitating factors in migraine

Precipitating factors	*Frequency (%)*
Heredity	66
Stress, anxiety, and worry	43–88
Change in sleep patterns	77
Menstrual cycle	39–65
Oral contraceptive	31
Bright light	30
Diet or specific foods	13–74
Fasting	7–77

Environmental Triggers

Environmental triggers of migraine headache include weather or temperature changes, exposure to bright lights (glare from snow or fluorescent lights, computer screens), loud noises, and strong odors. High altitudes or the atmosphere of a pressurized cabin in a commercial airliner may also lead to migraine attacks or similar vascular headaches.

Menstrual Cycle

Many women with migraine have attacks linked to their menstrual cycles. Menstrual migraine occurs mainly between 2 days prior and 3 days following the onset of flow. It is usually related to changing levels of menstrual hormones during menstruation, puerperium, hysterectomy, and pill-taking. Migraine prevalence peaks in women in their early 40s and then declines steadily with age. Migraine may worsen in early pregnancy, but it generally improves in later pregnancy. Although some women find that their migraines worsen when taking oral contraceptives, the majority experience no change or improvement in their headache pattern.

Pharmacological Agents

Some pharmacological agents used to treat hypertension and coronary artery disease may increase migraine frequency. Reserpine may increase migraine frequency and exacerbate depression in some patients. Amyl nitrite, used for treatment of angina pectoris, may adversely affect the frequency of migraine. Migraine was observed after beginning 25 000 IU daily supplementation of vitamin A.

Headache potential is also increased in patients treated with MAO inhibitor drugs, such as phenylzine, isocarboxazid, pargyline and tranylcypromine for depression; iproniazid and isoniazid for tuberculosis; procarbazine hydrochloric for cancer; and furazolidone for antimicrobial use.

Emotional Stress and Anxiety

Stress is the most common migraine trigger. Emotional stress or response to life's daily pressure can trigger migraine attack in some individuals. Stress can cause alteration in adrenal hormone level. Stress, fear, and anger may liberate vasoactive substances from tissue stores.

Depression has been associated with migraine in both prospective and retrospective epidemiological studies, and psychological distress has been shown to be responsive to cognitive-behavioral headache interventions.

Sleep Patterns

An extra 1–2 h sleep can be enough to initiate a headache. The mechanism involved is not understood

but carbon dioxide retention with vasodilatation or delayed breakfast provide two possibilities. However, lack of sleep for social or work reasons, as well as psychological factors, can be a migraine precipitant.

Hunger and Hypoglycemia

Blood glucose levels have important effects on the tone of cerebral blood vessels. Marked cerebral vasodilatation may occur if blood glucose levels are reduced by insulin or other causes. Therefore, hunger headache can occur during fasting or food deprivation. It is provoked after stopping food intake for 5 h during the day or 13 h overnight. This condition may also be responsible for the weekend headache that develops when a person sleeps late and delays the morning meal. Since blood glucose levels do not fall below normal levels, it cannot be called hypoglycemia. However, hypoglycemia has also been associated with headache. It is a prominent symptom in a patient entering insulin shock. In addition, the reactive hypoglycemia that occurs after ingestion of a large simple-carbohydrate meal may also precipitate a similar headache in susceptible persons. Therefore, in order to reduce the number and severity of migraines, a patient should not skip meals, should have three or more well balanced meals a day and should avoid overabundance of carbohydrates at any single meal.

Cold Drinks or Icecream

Swallowing cold drinks or icecream can quickly cause a brief frontal icecream headache lasting a few minutes. The pain occurs either in the palate and throat or the forehead, temple, or ear. The cause is believed to be the sudden cooling of the oral pharynx. Icecream headache is an excessive vascular reaction to cold and a manifestation of erratic vasomotor regulation in patients with migraine.

Allergy

There is a very long medical history which attempts to relate migraine to allergy. However, the view of many researchers in the field of migraine appears to be that dietary migraine is not an allergic phenomenon. Recently, it has become evident that the immune system might be affected in migraine. Foods such as milk, wheat, eggs, and meat are usually involved. In patients with migraine, these foods induce formation of immune complexes which can release active substances. They may also react with mast cells, releasing histamine and serotonin.

Influence of Diet

Studies on the influence of diet on migraine are difficult to evaluate. A diet trial cannot be performed in a double-blind manner. Moreover, it is hard to reduce selectively one or a couple of components in the diet and yet preserve the original proportions of nutrients. Diet trials are also difficult to carry out with regard to compliance and practical inconvenience for the patients.

Although the relationship between diet and migraine has been a source of controversy for many years, certain relationships have become clear. Some specific foods, alcoholic beverages, and some food additives are possible triggers of diet-precipitated migraine, even though sensitivity varies with each patient.

Chocolate, cheese, and citrus fruits are the most frequently cited provoking factors to which patients ascribe their dietary migraine (Table 4). Fatty fried foods, vegetables, tea and coffee, pork, and seafood have also been cited. In 490 migraine patients attending the Princess Margaret Migraine Clinic at Charing Cross Hospital in 1984, 19% cited chocolate, 18% cheese, 11% citrus fruit, 29% reported alcohol, 7% coffee, 3% pork and dairy products, and 2% eggs as precipitants of their headaches. In another study with 429 migraine patients attending the same clinic from 1989 to 1991, 17% reported that headaches could be precipitated by cheese and chocolate, and nearly always by both; 18% reported sensitivity to all alcoholic drinks, while another 12% were sensitive to red wine but not to white wine; and 28% reported that beer would precipitate headaches.

Food-induced headaches are mediated by chemical constituents common to these foods (Table 5). Some are naturally occurring components, including tyramine, phenylethylamine, serotonin and other vasoactive amines, alcohol, flavonoid, caffeine, and copper. Additives added to foods, such as sodium nitrite and monosodium glutamate (MSG), may also elicit migraine headache. Some other food or food

Table 4 Major precipitating foods in migraine

Precipitating factors	*Patients with dietary migraine (%)*
Chocolate	17–75
Alcohol	11–67
Red wine	12
Beer	28
Cheese	17–50
Citrus fruits	11–30
Nuts	12–17
Fatty fried foods	18–19
Coffee	7–15
Ham	4
Pork	3–15
Dairy products	3–9
Seafood	6–10
Onion	18

Table 5 Causes of diet-precipitated headache or migraine and foods involved

Substances	*Foods*
Food components	
Vasoactive amines	
Tyramine	Aged cheeses (cheddar, Swiss, Gouda, Roquefort, Stilton, parmesan), sausages, pickled herring, red wine, beer
Phenylethylamine	Chocolate, cocoa
Serotonin	Banana, tomato, walnuts, tryptophan-rich protein
Ethanol	Wine, beer
Caffeine	Coffee, tea, cola, and candy withdrawal
Copper	Chocolate, cocoa, nuts, shellfish, distillates produced in copper stills, wheat germ
Additives	
Nitrites	Aged, canned, and cured meat such as hot dog, bacon, ham, salami, cheese (read labels)
Monosodium glutamate	Chinese food, soy sauce, instant soup, bouillon cubes, meat tenderizer, seasonings, ready-to-eat dishes, snacks (read labels)

components have been associated with migraine, such as food colorings (erytrosin), food flavorings, licorice extract, pesticides, boron, aspartame, vitamins (A, D, niacin), minerals (calcium, manganese), herbal tea, and seafood. However the prevalence is low, and further research is needed to ascertain their role in migraine.

Vasoactive Amines

A variety of amines have been implicated in the development of headache, most commonly the vasoactive monoamines tyramine, tryptamine, norepinephrine (noradrenaline), epinephrine (adrenaline), dopamine, beta-phenylethylamine, serotonin, and synephrine.

Ingested monoamines are normally inactivated by MAO, found in high amounts in the gut and which prevent monoamines from the diet to enter the general circulation in significant amounts. However, if large amounts of monoamines are present in foods or if the enzymes are inhibited by genetically deficient metabolism or by MAO inhibitor drugs, the metabolism is prevented. A MAO defect would act in precipitating migraine through the mechanism of increased absorption of vasoactive substances. Headaches have also been described in patients under treatment with MAO inhibitor drugs.

The monoamines that are not metabolized are free to act directly on blood vessels. They are also known to cause release of endogenous active substances, creating the potential for migraine and also for hypertensive crisis.

Tyramine Tyramine is a vasoactive amine that promotes blood pressure elevation, resulting in pain. Tyramine leads to cerebral vasoconstriction and subsequent rebound vasodilatation that causes a migraine attack in susceptible persons. Episodes can be accompanied by nausea and visual abnormalities. Symptoms are evident 1–12 h after ingestion of food containing tyramine. A dose of 10 mg tyramine has been associated with migraine onset; however, levels of 6 mg can cause migraine in patients under treatment with MAO inhibitors. Alcohol has been observed to facilitate tyramine absorption.

Tyramine is found in a number of foodstuffs, most notably aged and fermented foods and beverages. Cheeses (especially Camembert, Cheddar, Parmesan, and Emmental), overripe bananas, avocado, canned figs, peanuts, pickled herring, dried and fermented meat products and alcoholic beverages (wine, beer) are known to contain tyramine.

Phenylethylamine Similarly to tyramine, phenylethylamine causes headaches after 12 h of ingestion of 3 mg by susceptible individuals. Chocolate, a commonly cited trigger of headache, is specially rich in phenylethylamine. An ordinary chocolate bar may have at least 3 mg phenylethylamine per 56 g. Dark chocolate has been found to be more potent than milk chocolate in causing migraine.

Serotonin Chemically, serotonin is 5-hydroxytryptamine. It is a neurotransmitter that acts as a powerful constrictor of arteries, reducing blood supply to the brain, causing migraine. Because serotonin released from platelets has been suggested to initiate migraine, a decreased platelet serotonin content attained by a reduced intake of serotonin and the serotonin precursor tryptophan might be beneficial. Serotonin-rich foods include bananas, tomatoes, and walnuts. A protein-tryptophan-reduced diet decreased headache frequency and skin symptoms in patients with migraine-like headache. Therefore, the intake of foods with a high tryptophan-to-protein ratio should be restricted.

Other amines Dopamine is found in the pod of Italian broad green (fava) bean and bananas. Synefrine and octopamine are found in citrus fruits, including oranges, lemons, and grapefruit. Port, Chianti, and red wines, and some other alcoholic drinks contain histamine, which is also a vasoactive amine.

Ethanol

Alcoholic beverages may provoke migraine. Ethanol, which has both central and direct vasodilator properties, is a well-known potential trigger for migraine. The vasodilatation is assumed to be the result of depression or alteration of the central vasomotor centers, since the direct action of alcohol on blood vessels is insignificant. Ethanol can inhibit MAO, thus preventing amine metabolism and enhancing its activity. Ethanol can induce migraine in some persons regardless of the amount consumed. It generally occurs 7 h after drinking, usually starting in the following morning. Clinically, excessive dietary salt intake also appears to potentiate alcoholic migraine.

Some believe that congeners present in the majority of the alcoholic beverages are even more potent contributors to migraine than ethanol itself. Three troublesome chemicals associated with wine are histamine, tyramine, and phenylethylamine. Furthermore, compounds in the flavonoid fraction of wine have been observed to cause release of active substances.

In addition to the usual alcoholic beverages (wine, beer), many cough preparations, tonics, mouthwashes, liquid vitamins, and nonprescription drugs contain high concentrations of ethanol.

Copper

Foods that are high in copper have been responsible for the precipitation of migraine. Copper is involved in metabolic and enzymatic activities such as hemoglobin synthesis, bone and elastic tissue development, and normal function of the central nervous system. Copper is known to be necessary for the metabolism of vasoactive amines such as serotonin, tyramine, and catecholamines. Abnormal copper metabolism following ingestion of copper-containing foods would lead to decreased inactivation of amines and therefore the onset of migraine.

There are substances that can facilitate copper absorption causing migraine, among them citrate, glutamate, and histamine. Glutamate from MSG acts to transport significant amounts of copper to tissues, facilitating copper absorption. Histamine is known to bind and transport copper to tissues.

Foods containing high levels of copper include liver, cocoa, chocolate, nuts, shellfish, mushrooms, wheat germ, and certain cereals. Whiskies and distilled beverages that are produced in copper stills can also be a source of copper.

Caffeine

Caffeine is an ingredient of coffee, cola, tea, chocolate, and many over-the-counter and prescription analgesic compounds. It is a vasoconstrictor; however it does not cause headache as a primary manifestation. But rebound vasodilatation may occur, causing a migraine-like withdrawal headache when excessive caffeine consumption is suddenly interrupted. For example, a person who consumes large quantities of caffeine-containing beverages during the week may experience a headache on weekends if caffeine consumption is decreased. The headache is relieved by taking another dose.

Theobromine, a methylxanthine found in cocoa that is similar in chemical structure to caffeine, may act as the headache trigger.

Food Additives

Nitrates An aching headache often accompanied by facial flushing occurs in sensitive persons exposed to nitrites added to cured meats. As little as 5–10 mg sodium nitrite may provoke headache in a migraine-prone person. Headaches are noted to occur 35 min after sodium nitrite ingestion, and last approximately 1–2 h.

Up to 0.02% of nitrate and nitrite compounds are employed in meat products to create a pink color, to impact a cured flavor, and to prevent botulism. These foods include bologna, salami, sausage, pepperoni, bacon, frankfurters, corned beef, beef jerky, lunch meats, canned ham, and sausages. In some countries, nitrate can also be added to cheese to prevent late blowing. Migraine sufferers are advised to eliminate cured meats from their diets.

Monosodium glutamate MSG is another chemical that migraine patients are often advised to restrict. The amount of MSG added to food has increased enormously since its first introduction. It is a commonly used food additive that enhances the taste of meat in particular and is used in appreciable quantities in the preparation of food in Chinese restaurants. MSG is now found in varying amounts in many food products, among them bacon bits, baking mixtures, bouillon cubes, bread stuffing, breaded foods, canned meats, cheese dips, corn chips, dry roasted peanuts, frozen dinners and pizza, gelatins, oriental foods, potato chips, pot pies, salad dressings, salt substitutes, seasonings, soups, soy sauce, and meat tenderizers.

As little as 3–10 mg of this compound may provoke headache in a migraine-prone person. The Chinese restaurant syndrome is well documented and includes

Table 6 Dietary suggestions for migraine patients[a]

No alcoholic beverage, particularly red wines
No aged or strong cheese, particularly cheddar cheese
Avoid chicken livers, pickled herring, pods of broad beans
Use monosodium glutamate (MSG) sparingly. Avoid foods containing MSG
Avoid cured meats such as hot dogs, bacon, ham, and salami, if these can be demonstrated to evoke migraine. Avoid foods containing nitrate and nitrite
Eat three well-balanced meals per day. Avoid skipping meals, prolonged fasting, or excessive ingestion of carbohydrates at any single sitting
Avoid chocolate

[a]All of these foods have been demonstrated to contain vasoactive materials of varying types and all have, in specific circumstances, evoked migraine in predisposed patients.

symptoms of tightening of the muscles of the face and throat, constriction of muscles of the back and neck, paresthesia of the mucous membranes of the mouth and palate, nausea, giddiness and dizziness, flushing and sweating of the face, severe pain in jaws, and a band-like headache. The syndrome occurs within 20–30 min after eating foods with a significant amount of MSG.

Treating Migraine Headache

When having severe headaches, it is important to see a doctor for evaluation and diagnosis. Several therapeutic methods, both nonpharmacologic and pharmacologic, may prove useful. The approach to pharmacologic treatment is either abortive (acute) or prophylactic (preventive). The ergotamines remain the agents of choice for abortive therapy of migraine. For greatest benefit, these preparations must be taken either during the aura or as soon as possible after the headache starts. If a patient experiences more than two migraines a month or abortive agents are ineffective or contraindicated, prophylaxis should be considered. A variety of agents have been shown to be useful, but proptanolol is the safest and most effective. Patients on preventive medication still require acute treatment for breakthrough attacks.

Nonpharmacologic techniques are oriented primarily to reducing the frequency as well as the severity of migraine attacks. The first step in prevention is the elimination of triggering factors, which should be reviewed thoroughly with each patient. A detailed diary of when you have a headache (date, time, severity, possible triggering factors, time and amount of exposure, treatment used, the outcome) may help determine what may influence your headaches and could give you an idea of what triggers you may want to eliminate or avoid. It is important that time be taken to identify those sensitivities and eliminate only those foods related to the patient's migraine. Many times patients are given lists admonishing them to avoid all foods that have ever been implicated in migraine causation. This can create apprehension about eating, and the resultant avoidance of a variety of foods can lead to malnutrition and cachexia in the conscientious patient. An overconcern with diet can also be a psychological stressor that may further aggravate the headache problem. A diary can also help you see how well your medication and lifestyle changes are working.

Most experts in headache suggest that foods that have vasoactive properties should be avoided (Table 6). It is also important to eat a healthy diet, at regularly scheduled times, not skipping a meal. In addition, patients should be consistent in their sleeping patterns. There should be a regular bedtime and patients should wake up at the same time each morning. Stress and anxiety management strategies, such as regular exercise, relaxation techniques, biofeedback, or cognitive-behavioral therapy may also have a role in treatment.

MILK

Contents

Liquid Milk for the Consumer

J Manners, University of Melbourne, Parkville, Victoria, Australia
H Craven, Food Science Australia, Werribee, Victoria, Australia

Introduction

Historically, milk from cows and other mammals has been an important source of nutrients, especially protein for humans. Traditionally, villages and individual families tended one or two animals such as cows, goats, or buffalo, which provided milk for immediate consumption and then meat when the animal was slaughtered. Over time, the number of animals in a milking herd has increased from the one-animal situation to herds of tens and hundreds of animals. With this increase in size of herds, there have been developments in how the animals are milked and how the milk is handled from milking to receival at the milk factory.

Composition of Milk

Milk is a complex biological fluid consisting of fats, proteins, minerals, vitamins, enzymes, and sugar. The composition of milk varies according to the breed of the animal, the genetic background of the animal, the stage of lactation, the nutritional quality of the animal's feed, the frequency of milking, the incidence of disease such as mastitis, and general environmental conditions.

Animals from different species and breeds produce milk of varying fat, protein, and lactose content and volume. For example, Friesian or Holstein animals are more likely to produce larger quantities of milk with a lower percentage of fat compared to milk produced by a Jersey animal. Buffaloes produce milk with a higher fat and protein content than cows, while goats' milk has a lower lactose content compared to cows' milk. Within breed types, animals are largely selected for breeding on the basis of their performance as producers of milk measured in terms of fat, protein, and volume.

The greatest changes in composition occur during early lactation. Colostrum, the first milk after calving, has a high concentration of fat and protein, especially immunoglobulins, and a low concentration of lactose. Over the first weeks of lactation, the fat and protein levels decrease while the lactose levels increase. **Table 1** compares the composition of colostrum with that of milk produced 10 days later. The volume of milk produced by the cow increases during the early stages of lactation and after peaking slowly declines towards the latter stages of lactation. This decline usually coincides with the development of pregnancy in the animal.

Clinical or subclinical mastitis in the udder results in changed composition of the milk with decreased levels of lactose and potassium and increased levels of sodium, chloride, and serum proteins. In addition, a large number of somatic cells and bacteria are present. The higher number of somatic cells results in an increased concentration of the enzyme plasmin in the milk. Plasmin is a protease which is normally found in the blood stream. The industry commonly uses the

Table 1 Typical composition of milk at the start of lactation and 10 days later

Component	*Start of lactation concentration (g per 100 ml)*	*10 days after commencement of lactation: concentration (g per 100 ml)*
Fat	6.5	3.8
Protein		
Casein	5.0	2.6
Globulins	11.1	0.7
Lactose	2.9	4.9
Ash	1.2	0.8
Total solids	26.7	12.6

levels of somatic cells in milk as a screening test for the incidence of mastitis. A count of under 200 000 somatic cells per milliliter in bulk herd milk generally indicates an absence of mastitis, while levels above 400 000 per milliliter indicate a high incidence of mastitis in the herd.

The impact of feed consumed by the cow on the composition of milk is complex. Overall, animals on nutritionally superior feed will produce more milk with a higher level of fat and protein than animals on feed of lower nutritional quality. The quantity and type of fat and the composition of the nonlipid compounds in the feedstuffs affect the fat content and composition.

In cold climates, animals are generally housed indoors and the feed is bought to them. The volume of production and composition of milk from cows housed indoors is likely to be different to that produced by animals in temperate or tropical climates which are fed by range-grazing. The difference in composition and volume may also be related to the nutritional quality of the feed.

Milking

Historically, milk has been extracted from the udder by manual stimulation and expression of milk from the teats. The milk is collected in a small storage vessel such as a bucket or can. Manual milking is commonly carried out where the numbers of cows are small and there is plenty of available labor. As herds have grown in size, mechanical means of extracting milk have been introduced. These are generally called milking machines. The milk is extracted from the teat and udder by a pulsating vacuum in rubber liners called teat cups which fit around the teat. In most situations the milk is carried from the cow through pipelines to the milk storage vessel. These vessels may range from a bucket for milk from an individual cow to vats or silos of large capacity. The silos may be used for the storage of the milk from the several milkings.

Herds are generally milked twice a day during most of the lactation period: the frequency is reduced to once a day as the milk yield declines. Research work has demonstrated that more frequent milking, such as three times a day, can increase the total volume of milk, but this is not a common practice amongst dairy farmers.

Control of Microbial Contamination

Milk from the udder of a healthy cow contains very few microorganisms. However, addition of microorganisms during the milking process and growth of contaminating microorganisms will reduce the time required for milk to spoil. To minimize the addition of microbes to the milk, the farmer needs to prevent contamination of milk through the process of milking and transport to storage vessels.

The exterior of the teat and udder must be carefully washed to remove residues of manure and dirt, which contain large numbers of microorganisms. It has been demonstrated that the optimal treatment to minimize addition of bacteria to milk is to dry the udder carefully with a clean cloth after washing. In some situations such as large herds, strategic washing of udders is carried out. This involves a judgment about the level of visual contamination on the udder.

Another important source of microbial contamination is the hygienic condition of the rubbers and pipelines of the milking equipment. The materials used for the transport and storage of raw milk must be easy to clean and sanitize. Stainless steel and plastic are easy to clean and are more resistant to mechanical damage than rubber, wood, and other materials. Fat and protein deposits in the pipelines and storage vessels will prevent sanitizer solutions acting on bacteria. In addition, cracked rubberware is difficult to clean and sanitize effectively.

Other sources of contamination are water supplies used for washing udders and equipment, exposure of the milk to the air, dirty cloths used for cleaning udders, and the presence of mastitis in the udder. The total microbial count of milk can increase dramatically when an udder is infected with mastitis.

Care must be taken when milking to minimize the possible transfer of mastitis infection from one animal to another. Precautions used by farmers include dipping the rubber teat cups in a chemical sanitizer solution such as iodophor, dipping the teats after milking with a disinfectant such as iodophor, use of good-quality running water to wash udders, and single-use towels to dry udders after washing. The incidence of mastitis infection can be increased by the use of malfunctioning milking machines. Many

mastitis control programs include regular maintenance checks of rubberware and mechanical parts.

After milking, the major concern is to minimize the growth of microorganisms during the storage and transport of milk from the farm to the factory. The temperature of the milk from the cow is about 37 °C, or body temperature. To minimize the growth of microorganisms, it is necessary to reduce the temperature to less than 5 °C in a short period. In many situations, the temperature is lowered on the farm using a water cooling system based on plate or tubular heat exchange before the milk enters the milk storage vats.

Storage

Many storage vats or silos are now equipped with refrigeration units which are able to reduce the temperature to less than 5 °C. In some areas, the milk may be stored in cans in a large refrigerator for 1–2 days before dispatch to the factory. In areas where refrigeration is not common, the milk is collected once or twice per day from the farm or may be taken by the farmer to a milk collection depot. The milk is generally cooled at the milk collection depot before dispatch to the factory. The microbiological quality of milk received at the factory is dependent upon the initial contamination of the milk during the milking process and subsequent transport to storage vessels, the temperature of the milk during storage, and the length of time of storage. Table 2 shows the number of microorganisms in milk of varying quality stored at different temperatures.

Milk stored at low temperatures for extended periods is more likely to have large numbers of psychrotrophic bacteria present. Some of these bacteria may produce heat-stable enzymes (lipases and/or proteases) which will survive pasteurization and could therefore cause flavor defects in the finished product. Research work has demonstrated that enzymatic activity is unlikely if the numbers of microorganisms are less than 1 million per milliliter. Conversely, if milk is not cooled until hours after milking, the number of microorganisms may increase to in excess of 1 million per milliliter. Cooling of the milk after microbial numbers have increased significantly will increase the shelf-life only marginally.

Table 2 Influence of storing milk for 24 h at different temperatures on the bacterial content of three milk samples with varying numbers of bacteria

Time of storage (h)	*Storage temperature (°C)*	*Standard plate count at 30 °C (CFU ml^{-1})*		
		Sample A	*Sample B*	*Sample C*
0		1500	45 000	260 000
24	5	1600	46 000	660 000
24	10	10 500	126 000	8 900 000
24	15	220 000	860 000	32 000 000
24	20	580 000	1 570 000	128 000 000

It has been suggested that an alternative means for extending the shelf-life in regions without adequate refrigeration is to use the antibacterial activity of the lactoperoxidase enzyme system. Small quantities of hydrogen peroxide are added to milk to activate the lactoperoxidase system. The technique has been trialled successfully in Kenya, Sri Lanka, and Mexico.

Key factors in the successful use of the system to reduce the frequency of pick-up to once per day include relatively low numbers of microbes and reduction of the storage conditions for milk to less than 15 °C. Other techniques that have been demonstrated to extend the shelf-life of raw milk are thermization and addition of carbon dioxide.

One means of extending the shelf-life of milk on the farm is to separate the cream from the skim milk. The skim milk may be used to feed animals such as pigs while the cream is transported to the factory once or twice per week.

In countries that experience severe winters, steps must be taken to minimize the likelihood of the milk freezing. Freezing and thawing of milk in uncontrolled conditions may result in disruption of the fat globules and coagulation of protein, which will cause problems with subsequent processing and manufacture.

Transport of Milk from Farm to Milk Collection Depot

Milk sold by the farmer for manufacturing and processing is transported from the farm to the milk collection and receival depot in a number of ways. In countries with many small herds, the farmer or householder carries the milk to a milk collection center. Here the milk is graded for organoleptic quality, weighed, and then cooled before transport to the larger milk manufacturing factory. The number of milk collection centers will depend upon the density of the herds and the relative ease of transport from the farm. The milk collection center may be cooperatively owned by the farmers or owned by the milk factory. In some countries, the milk is purchased by a middleman from the farmers and transported to the factory.

In areas where farms produce large volumes of milk and the means of transport is more advanced, the factory may collect the milk from the farm on a twice-daily, daily, or alternate days basis. The frequency of collection will depend upon the storage conditions for the milk on the farm, the volume of

milk, and the distance from the factory. If the milk is not cooled on the farm it should be cooled immediately on arrival at the factory before storage. A road tanker of varying size may be used to pick the milk up or a tray truck able to carry cans or churns. Insulated tankers will be used for the transport of refrigerated milk. On arrival at the farm the driver usually measures the volume of milk and assesses whether the milk is organoleptically acceptable for pick-up. Samples of milk may also be taken for testing at the factory for composition and quality parameters.

Testing for Payment and Quality

A range of tests are carried out on raw milk supplies. A farmer may be paid for milk according to the volume of milk supplied, the quantity of fat, and other components such as protein and whether the milk is contaminated by added water, excessive numbers of bacteria, residues of antibiotic and other chemicals, somatic cells, and extraneous matter such as dirt. The payment systems vary around the world. In many countries, regulatory bodies or factories may establish minimum quality levels or standards for milk. The analytical techniques used to test for quality parameters will depend upon the quality standard, the number of suppliers, the accuracy required for results, and available technology. The use of automated instruments for measurement of milk composition, somatic cells, and bacterial numbers enables faster feedback of results to the farmer.

Payment

Historically, volume and fat content have been used for payment purposes. Where milk is used for consumption in a liquid form, the farmer is normally paid on volume basis provided the milk contains a minimum content of fat and solids-nonfat (SNF) and meets other defined quality standards. In some countries, where milk is used for manufacture of product, it is purchased on a fat content basis while other countries have introduced compositional payment based upon fat and protein content. Simple tests to determine the fat content of milk have been available for many years but development of instrumentation such as infrared equipment to determine SNF and protein has enabled companies to test for fat, protein, or SNF and volume on a daily basis. The frequency of testing milk for payment purposes depends upon the local situation.

Quality

Over the years, the quality parameters used to determine whether milk is fit for sale by a farmer have increased from simple sensory evaluations using sight and taste to complex analyses for the presence of chemical residues.

In developed dairy industries, where herds are large and the milk is used primarily for manufacturing purposes, the tests used to determine the quality of milk – apart from compositional analysis – include total bacterial numbers, presence of antibiotic residues, presence of added water, numbers of thermoduric bacteria, coliforms and other bacterial groups, presence of extraneous matter or sediment, number of somatic cells, residues of iodide, pesticides, and other chemicals. Table 3 summarizes typical standards for the different quality parameters.

Table 3 Typical standards for different quality parameters of raw milk

Plate count	*50 000–300 000 colonies ml^{-1}*
Freezing point	−0.548 to 0.520 °C
Antibiotic residues	0.0025–0.1 μg ml^{-1}[a]
Methylene blue reduction	> 5 h
Somatic cells	200 000–400 000 ml^{-1}
Thermoduric bacteria	1000–30 000 ml^{-1}

[a]Penicillin G-equivalent.

In other countries, milk quality tests, such as alcohol stability, methylene blue reduction, or resazurin, are used to determine the extent of microbial contamination while specific gravity determination may detect adulteration by water and other substances. Generally, failure to comply with quality standards results in a penalty such as rejection of the milk for a specified period or a payment discounted from the normal payment level.

Potential Public Health Risks

The consumption of unpasteurized milk by humans poses potential risks from the following factors: transmission of disease from the animal, transmission of disease from a human milker or handler of milk before consumption, or growth of undesirable organisms in the milk. Pathogenic bacteria which may be excreted in the milk by diseased animals include *Mycobacterium tuberculosis, Brucella abortus, Staphylococcus aureus, Streptococcus agalactiae, Escherichia coli, Listeria monoctyogenes, Leptospira* spp. and *Coxiella burnettii*. In many countries, stringent veterinary surveillance of herds has significantly reduced the risk of tuberculosis and brucellosis transmitted to humans by milk. With the exception of *C. burnettii*, which requires a higher heat treatment than normal pasteurization conditions, all other organisms are killed by effective pasteurization. A number of cases of food-poisoning

outbreaks caused by *Campylobacter* strains and *Listeria monoctyogenes* have been traced to the consumption of raw or improperly pasteurized milk.

Human handlers of milk may cause problems if they are clinically or subclinically infected with *Salmonella* spp., particularly *Salmonella typhi*, or *Streptococcus pyogenes*, and contaminate the milk during the milking, storage, and transport process. Heat treatment of the milk equivalent to pasteurization will eliminate milk as a likely vehicle for food poisoning by these organisms. Many health authorities recommend the scalding of raw milk by bringing milk to the boil before consumption in the home. This form of heat treatment kills microbes with the potential of causing disease and also increases the shelf-life by killing many bacteria which will spoil the milk.

Care needs to taken with the quality of feedstuffs, including grains, to prevent the possibility of contamination of the milk by aflatoxins.

Direct Sales from the Farm to the Public

The practice of direct sales of nonheat-treated milk from the farm to the public will depend upon the country. In some countries direct sales are prohibited while in other countries the practice may be permitted if the farmer has the herd regularly checked by a veterinarian for absence of specific diseases and carries out strict hygienic practices during milking, storage, and packaging. Some farmers may heat-treat the milk using a batch or high-temperature, short-time (HTST) pasteurization system, while other farmers sell raw or unpasteurized milk. The degree of surveillance by health authorities of farms that sell raw or heat-treated milk for human consumption varies from regular to no inspections or surveillance.

Processing of Liquid Milk

J Manners, University of Melbourne, Parkville, Victoria, Australia
H Craven, Food Science Australia, Werribee, Victoria, Australia

Background

Advances in technology and the demand by larger communities of people for a regular supply of various types of milk have led to the development and application of a range of processes for liquid milk. These include a defined heat treatment to minimize changes to the product while eliminating pathogenic bacteria and extending shelf-life, addition of supplements to improve nutritional value or flavor, and modification of composition to standardize consistency or improve dietary content.

Types of Products

Traditionally, the principal product sold as liquid milk was whole milk, heat-treated and packed in a

returnable container such as glass bottles. In recent years, changes in customer demands and technological advances have increased the range of liquid milk products available. Major types of liquid milk range from skim or nonfat milk, reduced- or low-fat milk, high-fat milk to reduced-fat, high-protein products. These may be sold as natural-flavored milk or with added flavors such as chocolate, coffee, and strawberry. The products may be heat-treated using conventional pasteurization or ultrahigh temperature (UHT) processing. Flavored milk products usually contain added sugar, coloring and flavoring agents and additives such as stabilizers. The range of flavors added to milk depend on the cultural background of the market. Chocolate-flavored milk is a popular product in many countries. Milks mixed with fruit juice or fruit pulp have been marketed successfully in some countries, while the consumption of drinking yogurt is growing. The typical compositions for different milk products are compared in Table 1. (*See* **Fermented Milks**: Types of Fermented Milks; **Heat Treatment**: Ultra-high Temperature (UHT) Treatments; **Stabilizers**: Types and Function.)

Milks may be sold with added vitamins, such as vitamins A and D, to increase the dietary intake of essential nutrients. In recent years, with increased awareness of the risks of osteoporosis, calcium has been added to some milk products. Low-lactose milk made by the addition of the enzyme, lactase, to milk before or after heat treatment is gaining a market share in markets with a large number of lactose-intolerant consumers. (*See* **Calcium**: Properties and Determination; **Cholecalciferol**: Physiology; **Dairy Products – Nutritional Contribution**; **Food Intolerance**: Lactose Intolerance; Milk Allergy; **Lactose**; **Osteoporosis**; **Retinol**: Physiology.)

Other new products incorporate *Lactobacillus acidophilus* and *Bifidobacterium* spp. in liquid milk to assist those with sensitive gastrointestinal tracts. In Australia, sales of pasteurized ultrafiltered low-fat milk have increased steadily since the initial market launch. (*See* ***Acidophilus*** **Milk**; ***Bifidobacteri*** **in Foods**; **Lactic Acid Bacteria**; **Membrane Techniques**: Principles of Ultrafiltration; **Probiotics**.)

In many countries, the new types of milk products have steadily eroded the market share of whole milk over time to the situation in Canada and The Netherlands, where reduced-fat milk accounts for more than half of the total milk sales.

Table 1 Typical chemical composition (g per 100 g of product) for different milk products[a]

Product	*Fat*	*Solids-nonfat*	*Total solids*
Whole milk	3.8–4.0	> 8.5	> 12.3
Skim milk	0.1	> 8.5	> 8.6
High-fat milk	5.0–6.9	> 8.5	> 13.5
Reduced-fat milk	1.0–2.0	> 8.5	> 9.5
Reduced-fat, high-protein milk	1.0–2.0	11.3	12.3–13.3

[a]Flavored milks may be made by adding sucrose, color, and flavors to the typical formulations described.

Collection and Storage of Raw Milk

As many milk-processing dairies are located near the market in urban areas, the milk is transported in large-capacity tankers to the processing dairy from milk collection depots in the farming areas. The milk is usually cooled at the depot before dispatch to the processing dairy. Some processing dairies may receive milk directly from farms.

On arrival at the milk-processing dairy, the milk is inspected for quality attributes such as temperature, flavor, smell, and presence of extraneous matter and volume. Samples of milk may be taken to determine fat and solids-nonfat content, numbers of bacteria, freezing point and presence of antibiotic residues. The actual tests performed on incoming supplies of milk depend on a company's quality program for inspection of raw materials and the requirements of regulatory authorities. (*See* **Milk**: Liquid Milk for the Consumer.)

After the tanker load has been accepted for use, the milk is pumped into a storage vessel designated for raw milk. The milk may be filtered during the pumping process to reduce the level of extraneous matter. It may be necessary to cool the incoming milk to 5 °C to minimize the growth of contaminating microorganisms. Plate heat exchangers are commonly used to cool the milk before storage. In many countries, the temperature of milk during storage and the allowed time for storage before pasteurization are limited by regulatory requirements. However, storage conditions of less than 5 °C and 48 h maximum are generally accepted as good manufacturing practice by the industry across the world. Storage of milk above 5 °C and extended times of storage encourage the growth of psychrotrophic bacteria, which may cause organoleptic defects.

The milk in the storage vessels must be agitated slowly to prevent the separation of fat. Mechanical agitation or passage of compressed air through the milk is commonly used by the dairy industry. Care must be taken during agitation to minimize the possibility of lipolysis caused by disruption of the milk fat globules.

Preparation

Before heat treatment and packaging, it may be necessary to prepare the raw milk for processing. Regulatory authorities in some countries permit the milk depot to standardize the milk to desired fat and solids level before dispatch to the processing dairies. In other countries, this form of preparation is not permitted. For skim milk, the fat is removed through the separation process while low-fat, high-solids products may require separation and the addition of milk solids in the form of skim milk powder or skim milk concentrate. In the preparation of flavored milk, sugar, flavors, colors, and other additives are added to the milk in the desired quantities. Often, these ingredients are purchased in a dry, premixed form, and blended with a small quantity of milk or water before mixing with the raw milk. Sometimes, the syrup mixture may be injected into the milk after pasteurization.

Recombination

Where the supply of raw milk fluctuates or is insufficient to meet the market needs, milk fat in the form of butter oil and milk solids in the form of full cream or skim milk powder may be used to prepare reconstituted or recombined milk. Recombination may also be used where the available milk supply has a high fat content. The butter, unsalted butter, and milk powders must be selected carefully and stored to ensure proper mixing of the materials and an absence of undesirable flavors in the finished product. The added water must be of a drinkable quality. In some countries, vegetable fats may be used instead of milk fat to prepare recombined milk. (*See* **Recombined and Filled Milks**.)

Heat Treatment

Milk is heat-treated to kill many of the microorganisms present in raw milk. The heat treatment makes the milk safe to drink and extends the potential shelf-life. Several different forms of heat treatment are used. These are pasteurization, UHT, and *in-container* sterilization. Pasteurization is the most commonly used form of heat treatment. The shelf-life of the milk depends on the heat treatment used in the process. (*See* **Heat Transfer Methods**; **Heat Treatment**: Ultra-high Temperature (UHT) Treatments; **Pasteurization**: Pasteurization of Liquid Products; **Sterilization of Foods**.)

Pasteurization

This form of heat treatment evolved from Pasteur's discovery that heating wines to 50–60 °C destroyed many of the organisms responsible for spoilage. With milk, a temperature–time combination sufficient to kill the organism, *Mycobacterium tuberculosis*, without adversely affecting the flavor, color, and nutritional value is used. (*See* ***Mycobacteria***.)

The two principal forms of pasteurization now used by industry throughout the world are *batch* pasteurization, where milk is held at a determined temperature for a long time, and *high-temperature, short-time* (HTST) pasteurization using a higher temperature for a relatively short period. Typical temperature–time combinations are 62–63 °C for 30–35 min for batch pasteurization and 72 °C for 15 s for HTST pasteurization. The temperature–time combination may need to be increased for effective pasteurization of products such as flavored milk with higher levels of solids, or reduced for skim milk to minimize damage to flavor and color. After heating, the milk is cooled immediately to 5 °C or lower.

The batch pasteurization process is carried out using slow agitation of milk in a jacketed vat, which can be heated and cooled. The cost of the equipment is relatively low, but the labor and energy costs are higher compared with the HTST system.

In the modern processing dairy with a large throughput, the HTST pasteurization process is favored, as the throughput can be as high as 50 000 l h^{-1}, and energy costs are reduced by using the heated milk to warm incoming milk in the regeneration section of the pasteurizer. The heated milk is cooled after pasteurization in the regeneration section.

The plate heat exchanger has historically been used for HTST pasteurization (Figure 1). The plate design offers a large surface area for heat transfer in a relatively compact area. Once the milk reaches the desired temperature of 72 °C, it enters a holding tube designed to ensure that all milk particles reside in the tube for at least 15 s. A temperature probe is located at the end of the holding tube. If the temperature falls below the desired temperature, a flow diversion valve is opened, which directs underprocessed milk back into the balance tank. The pasteurizers need to be checked regularly to ensure that there is no risk of raw milk contaminating the pasteurized product.

Heat exchangers designed using a tubular system have become increasingly popular in recent years. The heat is transferred from heated outer tubes to product in inner tubes. The tubular system is considered to be cheaper to maintain and can handle products with a higher viscosity compared with a plate heat exchanger.

In recent years, the design of pasteurizers and control systems used on pasteurizers has been improved in response to public health problems thought to be caused by inadequate pasteurization of milk.

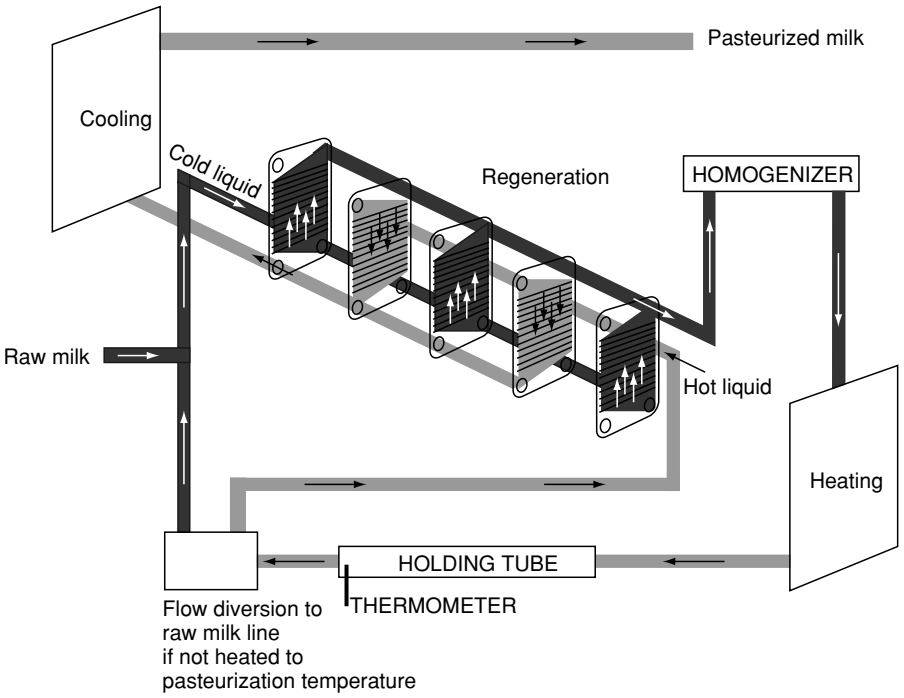

Figure 1 Schematic diagram of a plate heat exhanger pasteurizer showing milk flow.

Some processors use microfiltration in combination with pasteurization to extend milk shelf-life. The skim milk fraction is filtered to remove bacteria, sterile cream is added to adjust the fat content, and then the product is pasteurized. Microfiltration reduces levels of spoilage bacteria while avoiding flavor defects caused by high heat treatment of skim milk. Cream is not as susceptible to this problem. Canadian experience has demonstrated that the shelf-life of pasteurized milk can be extended from 12–18 to 32 days by using microfiltration.

UHT

The UHT treatment was developed to minimize damage to milk components caused by *in-container* sterilization while killing or inactivating all microorganisms, so there is little likelihood of microorganisms spoiling the product during storage and transport. The product is said to be 'commercially sterile.' The term 'UHT' may stand for ultraheat treatment or ultrahigh temperature.

UHT processing is being used increasingly for heat-treating milk, as the shelf-life is extended from days to months, and UHT milk can be stored and transported without refrigeration. The use of UHT treatment varies around the world. In Germany, France, and Spain, more than 50% of liquid milk is consumed in UHT form, whereas the process is rarely used in the USA.

The taste and appearance of UHT-treated milk are different from those of pasteurized milk. The milk may taste *cooked* or burnt to some consumers, because of the development of a sulfurous flavor during the heat treatment. The form of heat treatment used influences the intensity of the sulfurous flavor. However, the flavor has generally dissipated by the time of consumption, and the milk has a slightly brown color.

In some countries, the temperature and time conditions for UHT treatment are specified by regulation. Typical temperature–time conditions for UHT treatment of milk are 130–150 °C for 1–3 s. Products with increased solids will require a higher temperature or longer time to ensure effective heat treatment.

UHT treatment can be carried out using a number of different systems. These include direct means of heat treatment such as injection of steam into milk and infusion of milk into a steam chamber or indirect means using heat exchangers where the milk is separated from the heating medium. Scraped-surface heat exchangers may be necessary for UHT treatment of viscous products or products containing particulate matter. When steam is used for direct heat treatment, care must be taken to ensure that there is no dilution of the milk. The steam must also be suitable for contact with food products. All UHT equipment must be sterile to prevent recontamination of the milk with microorganisms. Products that have been UHT-treated must be packed aseptically to ensure optimum shelf-life.

The raw milk to be used for UHT treatment must be selected carefully to ensure that there is minimal

chance of heat-stable indigenous or microbial enzymes present causing gelation in the stored products.

Some dairies use equipment designed for UHT treatment to heat the product to 120–130 °C without a holding time. This is claimed to double the shelf-life of product packed under nonaseptic conditions compared with normal pasteurized milk.

In-container sterilization

The consumption of *in-container* sterilized milk has declined with the introduction of UHT processing and improved storage and distribution systems for pasteurized milk. The term 'sterilized' is used to describe milk that has been packed in airtight containers and subjected to temperatures in excess of 100 °C. The severe heat treatment of the milk results in a caramelized, burnt flavor and a brown color. The product is usually packed before heat treatment. If it is packed after heat treatment, the containers must be sterilized before use and then filled under aseptic conditions. Typical heating parameters for packaged sterlized milk are 115–120 °C for 10–20 min. The temperature–time conditions applied depend on the composition of the product, the type and dimensions of the package, and the desired degree of caramelization.

Homogenization

Many liquid milks need to be homogenized to prevent the separation of fat during storage and distribution. The large fat globules are broken up to form small globules that do not aggregate and rise to the surface. Homogenization also improves the mouth-feel of many products.

The homogenization step normally takes place after the preheat treatment in the pasteurizer. The normal temperature of milk required for effective homogenization is 60–70 °C. Heating the milk prior to homogenization helps to break up the fat globules and inactivates milk lipase that may act on the disrupted fat. The homogenization process is normally in two stages with 14 000–20 000 kPa pressure for the first stage to reduce the size of the fat globules and 3500 kPa for the second stage to disrupt and prevent the reformation of fat globules into large clumps. UHT milk may be homogenized before or after heating, although it is said that homogenization after UHT treatment gives a more stable product. (*See* **Homogenization**.)

Packaging

After heat treatment, liquid milk products are packed with minimal time delay. This helps reduce the likelihood of postpasteurization contamination that may affect the shelf-life.

Historically, returnable glass bottles were the containers commonly used, but technological advances have seen the introduction and regular use of cardboard cartons, plastic bottles and sachets, and laminates of foil, plastic, and cardboard. Many of these containers are *single-trip* and thus do not require specialized cleaning and sterilizing equipment in the dairy.

Selection of the type of package and packaging method requires consideration of many factors. The principal objective of packaging a product is to maintain the nutritional properties and quality of the product during storage, transport, and distribution to the consumer. Other factors to be considered when selecting packaging material include the safety of the packaging materials, compatibility of the product and package, hygiene, accuracy and mechanical efficiency of the packaging process, hygienic design of packaging equipment, marketing and promotion functions, consumer acceptance, energy consumption, environmental impact, and economics.

The sterilization of the packaging material and filling equipment for pasteurized products extends the shelf-life of the pasteurized milk product compared with the shelf-life of pasteurized milk packed under normal conditions.

When packaging UHT products, the equipment and packaging material must be sterilized to ensure that no microorganisms enter the product. This requires stringent cleaning and sanitation procedures and quality control checks. (*See* **Packaging**: Packaging of Liquids; **Plant Design**: Designing for Hygienic Operation.)

Storage and Distribution

This step is very important in the chain of events from raw materials to consumers, but its importance is often overlooked. In many countries, regulations may prescribe conditions for the temperature of the product during storage and distribution and for hygienic conditions in the storerooms and transport vehicles.

A major factor influencing the shelf-life of pasteurized milk is the temperature of the product after pasteurization. Many milk containers act as insulators; therefore, the temperature of the milk as it leaves the pasteurizer is critical to ensure that the pasteurized milk reaches the maximum shelf-life. The effective temperature of cool storage rooms is dependent upon factors such as the temperature of the external environment, the temperature of incoming product, the refrigeration capacity, and the isolation or separation of the cool room from the external environment. It is generally agreed that the temperature of milk should remain below 5 °C to ensure the maximum shelf-life. This

requires an efficient cold chain during the transport of milk from the pasteurizer to the customer.

In many countries, storage of milk at temperatures below 0 °C experienced during winter may result in freezing and subsequent damage to the milk during thawing. Steps must be taken to minimize the possible uncontrolled freezing and thawing of the product.

Care must be taken during storage and distribution to prevent possible contamination of milk with off-flavors caused by close contact with chemicals or other foods. Mechanical damage to the container may permit contamination by microbes and other material such as dust.

Factors that Influence Shelf-life

The shelf-life of milk products is defined as the period between manufacture or processing and when the consumer considers the product unsuitable for use. The product may be considered to be unsuitable for consumption, because of the presence of flavor defects and/or changes in physical appearance. (*See* **Storage Stability**: Shelf-life Testing.)

Factors determining the shelf-life of pasteurized milk include:

1. The presence of thermoduric bacteria in raw milk that are able to grow under refrigeration, e.g., *Bacillus cereus* and *B. circulans*. Processors using the extended shelf-life packaging technique often encounter problems with shelf-life owing to the presence of low numbers of *Bacillus* spp. in the raw milk. (*See* ***Bacillus***: Occurrence.)
2. The presence of psychrotrophic bacteria in the plant after the heat treatment step. These organisms grow under refrigeration and eventually cause spoilage as a result of their biochemical activity.
3. The temperature of the product after heat treatment. Ideally, milk should be stored between 1 and 2 °C to minimize the growth of psychrotrophic bacteria present in the milk from postpasteurization contamination. However, in many production situations, 1–2 °C is not practical, and the recommended temperature is 4–5 °C, with some countries permitting higher storage temperatures. Elevated temperatures allow bacteria to grow more quickly, thus reducing the time required for spoilage. (*See* **Spoilage**: Bacterial Spoilage.)
4. The presence of heat-stable enzymes produced by some species of psychrotrophic bacteria. Pasteurization and UHT treatments easily kill the bacteria, but the enzymes survive and are able to break down protein or fat. The problem is more pronounced in UHT products. Generally, a large number of bacteria must be present to produce the enzyme, and so low numbers of bacteria in raw milk will minimize this risk. (*See* **Spoilage**: Chemical and Enzymatic Spoilage.)
5. The action of lipase on damaged fat globules in raw milk results in rancid flavors in the finished products. Fat globules may be damaged during pumping and agitation. Maintaining the temperature of raw milk below 4 °C minimizes the lipolytic activity. The lipase is inactivated during pasteurization.
6. The general microbial growth in raw milk may result in damage to the milk solids as a result of metabolic activity. Subsequent handling of the milk may result in precipitation of the milk proteins or off-flavors. Numbers in excess of 5 million per milliliter are generally required for this to be a major concern.
7. Excessive temperatures (> 75 °C) during pasteurization are likely to induce the germination of microbial spores present in the raw milk; these microbes are then able to grow under low temperatures.
8. The action of heat-stable plasmin on proteins in milk. This causes flavor defects and age gelation in UHT products. Plasmin concentration increases with time during the lactation period, the degree of mastitic infection and the age of the cow.

Many consumer complaints relate to the presence of *off-flavors* in the milk. Frequently, these off-flavors may be caused by exposure of milk to sunlight or artificial light. One form of off-flavor, called *activated* flavor, occurs quickly on exposure to sunlight. The intensity of the off-flavor decreases over time. The light-induced oxidized flavor is very strong and objectionable, and does not decrease. Many dairies now use opaque packaging material to reduce the frequency of complaints from this problem.

Quality Assurance and Quality Control

Effective programs for the manufacture of safe, high-quality milk products are based on preventative systems for the control of microbial and other contamination. Many dairies now implement Hazard Analysis Critical Control Point-based programs to identify and manage points in the process where hazards can occur, including where pathogenic organisms can survive and proliferate. Key areas of hygienic control for the safe production of milk include raw material quality, adequate heat treatment, avoidance of postpasteurization contamination, and limiting the growth of microorganisms during storage prior to consumption. These practices will not only ensure the microbial safety of milk products but also assist in the prevention of milk spoilage.

Programs to ensure that the consumer receives milk with acceptable properties, including safety and shelf-life, include the following key elements:

1. Inspection of incoming raw materials for organoleptic and compositional properties, plus the presence of contaminants such as added water, extraneous matter, residues, and bacteria.
2. Monitoring of milk temperature during storage and heat treatment using chart recorders.
3. Monitoring of effectiveness of pasteurization heat treatment using the alkaline phosphatase test and operation of the diversion flow valve.
4. Monitoring of effectiveness of the homogenization process.
5. Testing of product to ensure compliance to specifications.
6. Monitoring the effectiveness of cleaning and sanitation programs. This may involve the application of tests to ensure that detergents and sanitizers are used at the correct strength, temperature, and time period, visual checks or swabs for the presence of milk residues, and tests for bacterial indicators such as Gram-negative psychrotrophs to determine the presence of postpasteurization contamination. (*See* **Sanitization**.)
7. Monitoring the volume of packed containers.
8. Monitoring the effectiveness of formation and sealing of containers, including the presentation of the pack.
9. Monitoring the control of temperature and housekeeping practices during the storage and distribution of the finished product.

A complete quality-management system will depend upon the processing requirements of individual dairies. The selection of process control tests should recognize the need for quick results to enable an operative to take corrective action, rather than for analytical precision. (*See* **Hazard Analysis Critical Control Point; Quality Assurance and Quality Control**.)

Physical and Chemical Properties

D Otter, New Zealand Dairy Research Institute, Palmerston North, New Zealand

Introduction

Milk comes from a wide variety of animal sources, e.g., human, cow, buffalo, goat, and sheep, and is an important source of nutritional and physiological components. The gross composition of milk from all these sources has some similarities and this article will discuss only bovine milk. It has a very complex

Table 1 Chemical composition of bovine milk

Component	*Concentration (gl^{-1})*
Lactose	36–55
Fat	
Triacylglycerols	36–38
Diacylglycerols	0.1–0.23
Monoacylglycerols	0.006–0.015

composition, comprised principally of water (88%), lactose (4.8%), fat (3.9%), protein (3.4%), and minerals (0.8%). These values however, can vary considerably depending on cow breed, and time of lactation, and between individual cows (Table 1).

Composition of Bovine Milk

Milk Fat

The fat (or lipid) in milk appears as an emulsion of globules dispersed in the milk serum that is held together by a very thin membrane derived from the plasma membrane of the mammary gland. The main functions of the fat are as an energy source for the neonate and a source of essential fatty acids (especially linoleic acid, $C_{18:2}$) and fat-soluble vitamins (A, D, E, K). Triglycerides typically make up approximately 98% of the total milk fat; the remainder consists of di- and monoglycerides, fatty acids, sterols, carotenoids, vitamins, and phospholipids. The membrane, in contrast, contains phospholipids, lipoproteins, cerebrosides, proteins, nucleic acids, enzymes, and trace elements (metals).

More than 400 distinct fatty acids have been detected in milk, with $C_{14:0}$ (myristic acid), $C_{16:0}$ (palmitic acid), $C_{18:0}$ (stearic acid), and $C_{18:1}$ (oleic acid) being the most abundant. The first three saturated fatty acids are solid at room temperature while the unsaturated oleic acid is liquid. The ratios of these fatty acids can therefore affect the hardness of the fat and any fat-based products. The fatty acids either come from the plasma lipids or are synthesized in the mammary gland. They therefore display marked patterns based on seasonal and dietary variations.

Esterification of fatty acids is not random, with the *sn*-1 and *sn*-2 positions on the glycerol comprising mainly myristic, palmitic, stearic, or oleic acid and the *sn*-3 principally butanoic ($C_{4:0}$), hexanoic ($C_{6:0}$) or oleic. The relative concentrations of C_4 and C_{18} fatty acids are important to keep the fat liquid at body temperature.

Proteins

Milk contains hundreds of different proteins, although most occur only in very small amounts. They are generally classified according to their chemical properties into caseins which is defined as those proteins, which precipitate from solution when the pH of milk is adjusted to 4.6, and whey proteins, which remain soluble under these conditions. In addition, milk contains the milk fat globule membrane proteins, which are found on the surface of the fat globules and are only released by mechanical action such as churning cream into butter; and a group of minor proteins/enzymes or protein-like material, i.e., the proteose-peptone and the nonprotein nitrogen (NPN) fraction. This last group is generally included in the whey proteins and includes casein fragments produced by posttranslational proteolysis or during casein processing.

Casein The caseins represent approximately 80% of the milk protein and consist of four subgroups: α_{s1}-, α_{s2}-, β-, and κ-casein. Each is heterogeneous and includes between two and eight genetic variants that differ from each other by one to 14 amino acids. The frequency of genetic polymorphism is breed-specific and can affect the processing properties of the milk proteins, e.g., cheese-making properties and the concentration of protein in milk. All the caseins are phosphorylated to varying degrees (between one and 13 phosphoserines) and κ-casein has up to nine glycosylated forms. α_{s2}- and κ-casein each contains two cysteines per molecule which form intermolecular disulfide bonds such that α_{s2}-casein exists as a dimer and κ-casein can exist as dimers through to decamers.

The α_{s1}-, α_{s2}-, β-, and κ-caseins contain 199, 207, 209, and 169 amino acids (mol. wt ~23.6 kDa, 25.4 kDa, 24 kDa, and 19 kDa, respectively), the composition of which is unusual in the following ways:

1. They contain high amounts of the apolar amino acids valine, leucine, isoleucine, phenylalanine, tyrosine, and proline (35–45%). The hydrophobic nature of these apolar amino acids is counteracted by the high content of phosphate and low content of sulfur-containing amino acids (methionine and cysteine) such that the caseins are reasonably soluble in water.
2. They all contain a high proline level that contributes to the low amounts of α-helix and β-sheet in their secondary structure and this makes them more vulnerable to proteolysis.
3. They have a very low sulfur amino acid content that lowers their nutritional and biological value to approximately 80% of the value for egg albumen.
4. They are rich in the essential amino acid lysine, and can therefore be used to supplement lysine-deficient food sources such as the cereal proteins and other plants. The high cationic lysine levels also make the caseins susceptible to nonenzymatic Maillard browning when exposed to heat and reducing sugars.

The high levels of polar and apolar amino acids in caseins manifest themselves as clusters in the primary structure, resulting in both hydrophobic and hydrophilic regions. This detergent-like arrangement, together with a high surface hydrophobicity and amphipathicity, gives the caseins good emulsification properties and helps with micelle stabilization.

The low amounts of α-helix and β-sheet give the caseins very little secondary or tertiary structure, resulting in 'an open, flexible, mobile conformation'. This lack of structure may give them stability against heat and other denaturing agents. It also renders them vulnerable to proteolytic attack and gives them high digestibility and hence nutritional value. They readily adsorb at air–water and oil–water interfaces, giving them good foaming and emulsifying properties that are used in the food industry.

There are also a number of minor caseins, the γ-caseins, which are produced from the C-terminal end of β-casein by proteolysis by plasmin, an indigenous proteinase. They occur at approximately 3% of the casein level but can be up to 10% depending on the stage of lactation and health of the cow. The remaining N-terminal segments of the β-casein comprise a large proportion of the proteose-peptone fraction. α_{s2}-Casein in milk and isolated α_{s1}-casein can also be hydrolyzed to a lesser degree by plasmin, although the degradation products have not been positively identified.

Micelle In milk the caseins interact with each other and with Ca^{2+} to form large colloidal complexes known as casein micelles. The micelle contains 63% water with a dry-matter composition of approximately 94% protein and 6% colloidal calcium phosphate (calcium, magnesium, phosphate, and citrate). Electron micrographs show that the micelles are roughly spherical, with a diameter between 50 and 500 nm, and evidence suggests that the micelles are made up of a large number of submicelles with diameters of less than 20 nm. The colloidal nature of the micelles results in light scattering that gives milk its whitish-blue tinge.

Whilst the definitive structure for the casein micelle has yet to be elucidated, there are a number of phenomena which help explain the stability of the micelle. Overall, calcium phosphate and hydrophobic interactions between the submicelles help form the micelles. The various caseins are distributed heterogeneously throughout the micelles, with κ-casein localized predominantly on the surface of the micelles. The solubility of the calcium salt of κ-casein thus helps to stabilize the calcium-sensitive α_{s1}-, α_{s2}-, and β-caseins. Micelle stability is further enhanced by the hydrophilic C-terminal of κ-casein that is situated outside the micelle complex, giving them a 'hairy' look under electron microscopy, and which contains the protein's carbohydrate moiety. The calcium ion concentration dictates the micelle size, with removal of colloidal calcium phosphate resulting in disintegration of the micelles.

The micelles are physically stable and can withstand all the processes to which milk is routinely subjected, such as heating (up to 140 °C for 15–20 min), compaction, homogenization, and high calcium ion concentrations (200 mmol l^{-1} for temperatures up to 50 °C). They are destabilized by alcohol (40% ethanol at pH 6.7) and freezing and aggregate and precipitate when the pH is reduced to 4.6 (the isoelectric point of the caseins), when the colloidal calcium phosphate concentration is reduced or when proteinases hydrolyze the C-terminal end of κ-casein.

Precipitation/Coagulation The precipitation of milk principally involves the precipitation of the casein proteins. It can be caused by a number of different mechanisms and is dependent on whether the casein is present in either the micellar or nonmicellar form.

The coagulation of micellar casein can be induced by lowering the natural pH of the milk using either an acid or by allowing the growth of an acid-producing

bacteria. As the pH is lowered to 4.9, the colloidal calcium phosphate in the casein micelle becomes soluble and forms calcium ions that can leave the micelle. As the pH is lowered further and reaches the isoelectric point of the casein proteins (approximately 4.6), the micelles aggregate and enlarge, creating a dense coagulum. This aggregation and precipitation is temperature-dependent.

Coagulation can also be caused by the hydrolysis of κ-casein by the acid proteinase, chymosin. This is the first step in the manufacture of most cheese. Chymosin is traditionally found in rennet that has been prepared from calf stomachs, although the calf chymosin gene has also been cloned into a number of microbial vectors for use in vegetarian cheeses. Chymosin specifically cleaves the peptide bond between the amino acids 105 (phenylalanine) and 106 (methionine), producing para-κ-casein (κ-CN f1-105) and glycomacropeptides (f106–169). Glycomacropeptides, which are soluble, hydrophilic, and contain the different carbohydrate moieties, diffuse into the whey, creating imbalances in the intermolecular forces in the micelles that then aggregate, forming a coagulum. Hydrophobic interactions then occur that lead, in the presence of calcium ions, to water expulsion from, and shrinkage of, the coagulum (syneresis).

The initial peptide bond cleavage is known as the primary phase of rennet action, coagulation is the secondary phase, and subsequent rennet action on the casein components during cheese-ripening is called the tertiary phase. The extent of the first two phases is governed by the pH and temperature and the secondary phase is calcium ion-dependent.

Micelle destabilization and coagulation also occur in the presence of approximately 40% ethanol at pH 6.7 and at lower ethanol concentrations when the pH is lowered.

Whey Proteins Whilst the caseins can be considered as a related family of proteins, the whey proteins are more diverse and encompass any protein or protein fragment, e.g., from casein degradation, not removed from skim milk by precipitation at pH 4.6 (i.e., not a casein). These soluble proteins (or milk serum proteins) have a well-ordered, globular structure and are generally not precipitated at their isoelectric points but are more heat-labile than the caseins.

β-Lactoglobulin, the major bovine whey protein, contains 162 amino acids with an approximate mol. wt of 18 kDa and is only found in ungulates, although a closely related protein occurs in other mammals. More than four genetic variants have been observed with the A and B variants being the most prevalent. β-Lactoglobulin is rich in sulfur amino acids, containing five cysteine residues, and has a high biological value of 110. At physiological pH it generally exists as a dimer of mol. wt approximately 36 kDa linked by up to three disulfide bonds.

At temperatures above 60 °C denaturation of β-lactoglobulin can lead to the exposure of the reactive sulfur amino acids that can then form disulfide bridges with κ-casein and/or α-lactalbumin. As the temperature is increased, other sulfurous compounds such as hydrogen sulfide are produced, leading to the 'cooked' flavor of heat-treated milk. β-Lactoglobulin also has a large number of lysine amino acids that can undergo lactosylation, which alters the physicochemical properties of β-lactoglobulin.

The principal biological function of β-lactoglobulin is presently unknown but it can act as a carrier for vitamin A (retinol). It can also stimulate lipolysis by binding the free fatty acids which inhibit lipases.

α-Lactalbumin is found in the milk of most mammals; it is the principal protein in human milk, and is thus considered to be the 'typical' whey protein. It is a compact globular protein of 123 residues (mol. wt ~14 kDa) and has three genetic variants, although the milk of western cattle contain only α-lactalbumin B. It is relatively rich in tryptophan and the sulfur amino acids cysteine and methionine. It contains four intramolecular disulfides, exists as a monomer and has 54 of its amino acids identical to the corresponding residues in lysozyme. Up to 15% of α-lactalbumin has been shown to be glycosylated to varying degrees. It is also a metalloprotein, binding one Ca^{2+} per mole (this increases its heat-stability).

α-Lactalbumin has an essential physiological role in lactose synthesis in the udder. Although it is not an enzyme, it acts as a 'specifier protein' with uridine diphosphate-galactosyl transferase to form lactose synthetase which catalyzes the transfer of galactose to glucose to form lactose.

The immunoglobulins are a very complex group of proteins that provide various types of immunity to the cow and its offspring. Immunoglobulin levels in colostrum (milk from the first 2–3 days postpartum) can be up to $100\,g\,l^{-1}$ as the colostrum provides passive immunity to the neonate prior to its own immune system functioning fully. This level falls rapidly over the first week postpartum to approximately $0.6–1\,g\,l^{-1}$ during normal lactation.

Bovine serum albumin is a large molecule (mol. wt ~ kDa) which is presumed to occur in milk as a result of leakage from the blood in the mammary gland during milk production. Although it can bind metals and fatty acids, it probably has little functional significance in bovine milk.

Lactotransferrin (or lactoferrin) occurs in trace amounts in bovine milk, although in human milk it represents up to 20% of the total nitrogen. It is

similar to serum transferrin, is involved in iron transport, and has an antibacterial role in the neonate gut.

Membrane Proteins The membrane proteins are a diverse group of proteins that, together with lipids, form the milk fat globule membrane. Some are lipoproteins and all tend to have varying degrees of hydrophobicity and hence align themselves in a gradient from the fat surface to the water. This attracts other hydrophobic molecules such as phospholipids and lipolytic enzymes that are adsorbed within the membrane structure.

Biologically Active Proteins and Peptides Milk contains a wide variety of biologically active substances. These include: (1) proteins such as lactoperoxidase, lactotransferrin, immunoglobulins, and vitamin-binding proteins (e.g., folate-binding protein); (2) growth factors such as insulin-like growth factors (IGF-1 and IGF-2), transforming growth factors ($TGF_{\alpha 1}$, $TGF_{\alpha 2}$ and TGF_{β}), mammary-derived growth factors (MDGF I and MDGF II), fibroblast growth factors, platelet-derived growth factors (PDGF), bombesin and bifidus factor; and (3) peptides from milk protein hydrolysates, e.g., glycomacropeptides from κ-casein, phosphopeptides from caseins, caseinomorphins, immunomodulating peptides, platelet-modifying peptide, angiotensin-converting enzyme (ACE) inhibitor, calmodulin-binding peptides, and bactericidal peptides from lactotransferrin.

Enzymes Milk contains both indigenous and endogenous enzymes. As many as 60 indigenous enzymes have been reported, with the majority derived from the milk fat globule membrane. Peroxidase and alkaline phosphatase are indicators of efficient pasteurization; catalase occurs naturally and also results from mastitic infection; lipase releases free fatty acids from milk fat, resulting in rancidity; plasmin degrades caseins; and lysozyme and lactoperoxidase possess antimicrobial activity.

The endogenous enzymes derive from microorganisms present in the milk and can cause both undesirable, e.g. rancidity, bitterness, or off-flavors, and desirable, e.g., ripe cheese flavors, properties.

Lactose

Lactose is the principal carbohydrate in milk and varies with the breed of cow, individuality factors, udder infection, and stage of lactation. It plays an important role in osmotic pressure maintenance in the mammary system and has an inverse relationship with chloride in milk. Lactose is a disaccharide consisting of galactose and glucose linked by a β1–4 glycosidic bond, with the glucose moiety being potentially free (i.e., a reducing sugar) and existing as either an α- or β-anomer.

Vitamins

Milk is a good source of the daily vitamin requirement of an adult person. It contains the fat-soluble vitamins A, D, E, and K, and the water soluble B-group vitamins B_1, B_2, niacin, biotin, panthothenic acid, B_6, folate and B_{12}, and ascorbic acid (vitamin C). The amount of each vitamin varies with stage of lactation and the animal's diet and health.

Minerals and Salts

The soluble and colloidal phases of milk contain varying amounts of different salts with the composition influenced by breed, individual cow, stage of lactation, feed, mastitic infection, and season. The most important cations are calcium, sodium, potassium, and magnesium that occur as phosphates, chlorides, citrates, and caseinates. Individual salt concentrations are dependent on the requirements to: (1) maintain electric neutrality; (2) maintain milk isotonic with blood, through lactose, sodium, potassium, and chloride ion concentrations; and (3) form casein micelles which constrain pH and calcium salt levels and require calcium phosphate to complex with casein. Variation in total calcium is due to changes in citrate and casein during lactation.

Approximately 20 trace elements are found in milk, including copper, iron, silicon, zinc, and iodine. The mineral (ash) content of milk is approximately 0.7–0.8%. Some trace minerals are essential for health, e.g., iron, zinc copper, and manganese, whilst others can be toxic, e.g., aluminum, arsenic, cadmium, and lead. Deficiencies or excesses in these minerals can result in a variety of physiological symptoms.

Other Constituents

Somatic cells (white blood corpuscles or leukocytes) are always present at low levels (200 000 cells ml^{-1}) in milk but increase, and are therefore a useful marker, in the diseased udders of unhealthy cows.

The gases carbon dioxide, nitrogen, and oxygen make up 5–6% by volume in fresh milk and exist dissolved in the milk, bound and nonseparable from the milk, or dispersed in the milk. They can represent a problem during processing, causing burning to heated surfaces.

Effects of Storage

Three chemical processes – oxidation, lipolysis, and hydrolysis – can affect the fat and protein in milk and

milk products during storage, generating either off-flavors (as in milk or butter) or 'mature' flavors (as in cheese).

Oxidation of fat, principally the unsaturated fatty acids, is a major cause of deterioration in milk and milk products, leading to a metallic flavor in milk or an oily tallow taste in butter. This oxidative rancidity can be accelerated by iron or copper salts, high dissolved oxygen levels, or exposure to light. The presence of reducing agents, e.g., from microorganisms, pasteurization, or added antioxidants, can help offset oxidation. With advanced oxidation the fatty acids can ultimately be degraded into aldehydes and ketones, resulting in oxidation rancidity in fat-containing dairy products.

Oxidation of protein by exposure to light results in the conversion of the amino acid methionine to methional. This can then react with riboflavin (vitamin B_2) and ascorbic acid (vitamin C) to form 3-mercapto-methylpropionaldehyde, the main component of 'sunlight flavor'. The overall dynamics of the reactions are factors such as the light intensity and duration, the condition of the milk, and the packaging of the milk.

Lipolysis, or degradation of fat into glycerol and free fatty acids, causes a rancid smell and taste due to the release of butyric and caproic acids. The degradation is due to the action of lipase, an indigenous enzyme normally associated with the casein micelle. This enzyme attacks the triglyceride in fat globules when the milk fat globule membrane is damaged. High storage temperatures and routine dairy processing (e.g., homogenization, pumping, and stirring) all contribute to the breakdown of the milk fat globule membrane and subsequent lipolysis. The lipases can be inactivated by high-temperature pasteurization.

Hydrolysis of milk proteins during storage can be caused by either indigenous proteinases, such as plasmin or cathepsin D, or enzymes derived from introduced sources, such as rennet or bacteria. Plasmin is fairly heat-stable, appears to be associated with the casein micelle during rennet coagulation and cheese manufacture, and preferentially attacks the β-casein to yield the γ-caseins and proteose-peptones. It contributes to the primary proteolysis of caseins in high-cook cheese and may affect the age gelation of ultra heat-treated milk. Introduced proteinases, e.g., from starter bacteria in cheese, are normally used in controlled conditions to produce a wide range of desired flavors or other properties in various milk products.

Effects of Heat

Milk and milk products are routinely subjected to various heat treatments during processing to eliminate any potentially pathogenic microorganisms (e.g., pasteurization). Specific heating regimes of time and temperature are required to destroy these microorganisms – regimes that can also result in detrimental or advantageous changes to other constituents in the milk.

Pasteurization (heating at 70–80 °C for 15 s) results in the 'cream plug phenomenon', where some fat gobules are ruptured, allowing the free fat to bind other intact fat globules to form the plug. This can be alleviated by homogenization. At high temperatures (above 135 °C), the proteins in the milk fat globule membrane partially aggregate, creating a denser, less permeable membrane.

Whilst the caseins are considered heat-stable within the normal pH, salt, and protein concentration ranges, the whey proteins, being globular proteins, are much more susceptible to heat denaturation. Denaturation starts between 60 and 65 °C and is characterized by an uncoiling of the proteins, in particular β-lactoglobulin, followed by the interchange of disulfide bonds to form binding of the β-lactoglobulin to the κ-casein of the casein micelle. Total denaturation is achieved with heating between 90 and 95 °C for 5 min. Alteration of the κ-casein in this way inhibits the renneting ability of milk, resulting in a softer coagulum. Thus, milk for cheese manufacture should not be subjected to heating regimes harsher than 72 °C for 15–20 s. In cultured milk products, such as yogurt, however, the whey protein–casein interactions result in reduced syneresis and improved viscosity, which improves the final product.

Of the other whey proteins, α-lactalbumin is more heat-stable than β-lactoglobulin, undergoing reversible denaturation up to approximately 95 °C. The immunoglobulins are denatured at temperatures above approximately 70 °C, resulting in the loss of their immune properties. Most of the indigenous enzymes in milk are also denatured and lose their activity on high heat treatments.

Above 100 °C, lactose reacts with the milk proteins in the Maillard reaction to cause nonenzymatic browning. A chain of reactions between the amino groups (principally the ε-NH_2 group of lysine) of the proteins and the carbonyl group of lactose produces brown-colored melanoidin polymers, off-flavors, a loss of nutritional value (through loss of lysine), and loss of solubility in milk powders.

Physical Properties

Appearance

The white-yellow color of milk is dependent on the amount of the hydrocarbon carotene. Its opaque appearance is caused by suspended particles of fat and

casein micelles. The greenish color of milk serum and whey is due to the presence of riboflavin.

Density

The density of milk is dependent on its composition and temperature and is generally between 1.028 and 1.038 g cm^{-3}. At 15.5 °C, the following formula can be used:

$$\text{Density (15.5°C)} = \frac{100}{\frac{\text{F}}{0.93} + \frac{\text{SNF}}{1.608} + \text{water}}$$

where F = % fat, SNF = % solids nonfat, and water % = 100 − [F + SNF].

Freezing Point

The freezing point of milk can vary from −0.53 to −0.59 °C and is used to check for adulteration of milk with water. After high-temperature processing, e.g., ultra heat treatment or sterilization, the freezing point will rise due to precipitation of some phosphates.

Acidity

Milk is usually slightly acidic, with a pH value between 6.5 and 6.7. A decrease in the pH is often an indication of bacterial activity and spoilage.

Viscosity

Under moderate shear rates (> 10 s^{-1}), fat contents below 40% and at temperatures above 40 °C (i.e., the fat is a liquid), milk displays Newtonian rheological properties. The coefficient of viscosity at 20 °C is approximately 2.127 mPa s^{-1}. Processing, such as homogenization, heating, and cold agglutination, all alter the viscosity to varying degrees.

Analysis

R J Marshall, Formerly of Asherton, Newbury, Berkshire, UK

Introduction

Milk is complex and the type of analysis to be undertaken depends on the needs of the analyst. Regulatory authorities routinely test milk for protein, fat, adulteration by dilution with water, antibiotics, and bacterial contamination. Determination of milk composition and comparison with milk products enables yields and losses to be measured. The exact composition of milk varies with the breed of cow, the stage of lactation, diet and with the season.

The major proteins of milk may be divided into the caseins (α_{s1}, α_{s2}, β, and κ) (organized into macromolecular units called casein micelles) and the whey proteins (β-lactoglobulin, α-lactalbumin, immunoglobulins, and bovine serum albumin), which are globular proteins. The fat in milk is in the form of droplets surrounded by a membrane, the milk fat globule membrane. It consists mainly of triacylglycerols of which most are composed of fatty acids $C_{4:0}$ to $C_{18:3}$. About 60 different enzymes have been identified in milk. The efficiency of pasteurization may be determined by measuring the activity of alkaline phosphatase. Under adverse conditions, others cause rancidity and proteolysis. Calcium, magnesium, inorganic phosphate, and citrate are essential for the stability of the casein micelles. Milk contains 14 vitamins important in human nutrition and many essential trace elements. It may also contain a large number of contaminants ranging from microorganisms to pesticide residues to radionuclides. (*See* **Contamination of Food**; **Fatty Acids**: Properties; **Pasteurization**: Principles; **Protein**: Chemistry; **Trace Elements**; **Triglycerides**: Structures and Properties; **Vitamins**: Overview.)

There are, then, numerous properties which may be determined. This article reviews the main methods used to characterize milk and to measure important contaminants. The methods are mostly those which are recommended jointly by the International Dairy

Federation (IDF), International Organization for Standardization (ISO), and Association of Official Analytical Chemists (AOAC). In most cases there are several other methods available for determining the properties and composition. A few of these are included where they are based on different principles from the standard methods.

Physical Properties

Physical properties include viscosity, specific gravity, freezing point, thermal conductivity and heat capacity, vapor pressure, surface and interfacial tension, electrical conductivity, refractive index, light absorption, and light scattering. Most of these are usually measured only for research purposes.

Specific Gravity

The specific gravity of milk varies with its composition and is usually measured by either a standard hydrometer (lactometer) or with a pycnometer (density bottle). A correction table for specific gravity at different temperatures has been calculated. If the fat content is known, the total solids content can be calculated using Richmond's formula:

$$\text{Total solids}, T(\%) = 0.25\text{G} + 1.2\text{F} + 0.14$$

where G = lactometer reading at 60 °F (1505 °C) and F = fat%.

Freezing Point

The freezing point of milk is used to detect the addition of water either accidentally during milking and processing or fraudulently. The standard method accepted by the World Health Organization (WHO) uses a thermostatically controlled water bath cooled by electrical refrigeration and a thermistor probe in place of the mercury-in-glass thermometer of the classical Hortvet method. Two types of instrument are available. The first determines a plateau in the freezing curve and the other, used for routine screening, reads at a fixed time from the start of freezing.

In the standard method, supercooled milk is induced to crystallize by mechanical vibration which causes the temperature to rise to a plateau corresponding to the freezing point. Standard solutions of sodium chloride are used for calibration. The method gives highly reproducible results – differences between laboratories testing the same sample of milk should not be greater than 0.005 °C. In general, 1% of additional water in milk raises the freezing point by about $T/100$, where T is base freezing point of authenticated samples. Although dietary, daily, and seasonal variations in the composition of milk affect the freezing point, the osmotic pressure does not change very much, so that the freezing point normally remains within the range −0.530 to −0.570 °C (mean −0.540 °C).

Viscosity

At all but the lowest shear rates, milk may be considered to be a Newtonian fluid, that is, shear stress is directly proportional to shear rate and the extrapolated line passes through the origin. Three main types of viscometer are used: capillary tube (e.g., Ostwald), coaxial cylinder (e.g., Brookfield, Couette) and falling sphere (e.g., Hoeppler). For research, a sophisticated controlled stress rheometer such as a Carrimed or Bohlin may be used. Measured values are dependent on the composition of the milk, temperature, and pH. Simple processing, for example homogenization, has relatively little effect. Viscosity may be measured for research into the effects of processing or chemical additions on the behavior of milk components.

Chemical Analysis

Proximates: Total Solids, Fat, Protein, and Ash

Individual methods are available for the determination of the proximates of milk. However, many laboratories use an infrared analyzer (e.g., Foss Electric) which measures the protein, fat, and lactose content of the milk simultaneously.

For fat, infrared analyzers measure the radiation absorbed by the carbonyl groups of ester bonds in the acylglycerols (at $\sim 5.73\,\mu$m) or by the CH groups (at $\sim 3.48\,\mu$m). For protein, the absorption at 6.46 μm by secondary amide groups is measured, and for lactose the absorption at 9.61 μm by the hydroxyl groups. To reduce errors the milk is first homogenized.

Total Solids

The total solids (TS) of milk is the mass remaining after complete removal of water and volatiles. In the standard method, accepted by WHO, a measured quantity of milk is dried under controlled conditions to constant weight. The TS is expressed as a percentage by mass.

Fat

The chemical method most often used to measure the fat content of milk is the Gerber method. A measured quantity of milk is added to a standard amount of concentrated sulfuric acid in a special test bottle (Butyrometer). Isoamyl alcohol is added to extract the fat and then the bottle is centrifuged to separate the aqueous and fat phases. The fat phase separates into the graduated neck of the bottle and the

percentage of the total volume may be read off. (*See* **Fatty Acids**: Analysis.)

The Rose–Gottlieb method is another which is used quite often. This method gives excellent results, but requires very careful attention to detail to achieve the best results. The milk is treated with concentrated ammonia and then the fat is extracted using organic solvents. Finally, the extract is dried, weighed, and expressed as a percentage of the original weight of milk.

Protein

A number of different methods are commonly used to determine the protein content of milk. (*See* **Protein**: Determination and Characterization.)

In the classical Kjeldahl method, the proteins are 'digested' in sulfuric acid with a catalyst (selenium, mercury, or copper salts). An acid deposit of ammonium sulfate is formed, which is then dissolved in water. The solution is made alkaline with NaOH and heated to distil off ammonia into excess standard acid (sulfuric). The excess acid is back-titrated with standard NaOH to determine the amount of ammonia and hence nitrogen.

$$\text{Casein protein} = \text{Casein N} \times 6.38$$

The total protein, casein protein, and noncasein protein are determined simultaneously by measuring total nitrogen (TN) and noncasein nitrogen (NCN), after precipitation of the casein fraction at its isoelectric point by acetic acid/sodium acetate:

$$\text{Casein N} = \text{TN} - \text{NCN}$$

Dye-binding methods use the ability of dyes to bind to charged amino acid residues of the proteins. The proteins may be separated as previously described and then treated with the dye. Dyes used include amido black and orange G. When they bind to the protein they form an insoluble complex which may be removed by centrifugation. The amount of residual color in the supernatant is then measured by spectrophotometry.

Individual Components

Lactose

Several methods may be used to measure lactose in milk. It can be measured enzymatically by hydrolysis of the lactose in the presence of nicotinamide adenine dinucleotide (NAD), which is reduced to NADH (eqns (1) and (2)). The amount formed is determined spectrophotometrically at 340 nm.

$$\text{Lactose} \xrightarrow{\beta\text{-Galactosidase}} \text{Glucose} + \beta\text{-Galactose} \quad (1)$$

$$\beta\text{-Galactose} + \text{NAD}+ \xrightarrow{\beta\text{-Galactose dehydrogenase}} \text{Galactonic acid} + \text{NADH} + \text{H}^+ \quad (2)$$

NADH has an absorption coefficient of 6.3 mmol^{-1} cm^{-1} at 340 nm, so that the exact amount of anhydrous lactose can be calculated. (*See* **Lactose**.)

Polarimetry may also be used if the proteins are removed first using phosphotungstic acid. The optically active lactose rotates the plane of polarized light in proportion to its concentration.

Ash

The salt content and ash content of milk are not identical. Ash is the residue after incineration at $< 550\,^{\circ}\text{C}$ and comes from both the organic and inorganic constituents of the milk. Chlorides are easily volatilized if the ashing temperature is too high, and citrate is lost completely.

Acidity

This is usually measured in milk at the start of cheesemaking as the baseline for the development of acidity by the starter bacteria which produce lactic acid. Phenolphthalein indicator is added to a measured quantity of milk diluted to twice its volume with carbon dioxide-free water. This is then titrated with 0·1111 mol l^{-1} sodium hydroxide (mol l^{-1}/9) to a first persistent pink color. (1 ml NaOH = 0.0010 g lactic acid). (*See* **Cheeses**: Starter Cultures Employed in Cheese-making.)

Lactic Acid

In the IDF/AOAC standard method for lactic acid in milk, the proteins are removed by precipitation with phosphotungstic acid and filtration. The filtrate is acidified with sulfuric acid and lactic acid is extracted in a special extractor using ether. After adding water, the ether is evaporated off and the remaining solution neutralized. After removal of the ethanol used to wash the solution, it is treated with ferric chloride in hydrochloric acid and a blue color develops which may be quantified at approximately 365 nm using a spectrophotometer.

Gas–liquid chromatography (GLC) and enzymatic methods are also used. (*See* **Chromatography**: Gas Chromatography; **Enzymes**: Use in Analysis.)

Individual Proteins

These are measured by electrophoresis of extracts of milk on polyacrylamide gels (PAGE) using standard protein solutions for quantitation. The caseins are solubilized with urea and separated by electrophoresis on polyacrylamide slab gels containing urea to

prevent aggregation. However, this method is not very satisfactory for the caseins. The whey proteins (β-lactoglobulin and α-lactalbumin) are determined in casein-free extracts by polyacrylamide slab or disk electrophoresis. Proteins in milk may also be analyzed by fast protein liquid chromatography (FPLC), in which they are separated on a column of ion exchange resin, eluted, and detected by their absorption of ultraviolet light.

Minerals

Metallic cations (including calcium and heavy-metal contamination) may be measured by atomic absorption spectrophotometry (AAS), in which the sample is atomized in the gas flame and the absorption is measured at the characteristic wavelength of each element.

Calcium

In the standard method for determining total calcium, the proteins are precipitated with trichloroacetic acid and filtrate obtained containing the soluble calcium. This is converted to the oxalate by adding saturated ammonium oxalate and precipitated by adding acetic acid. The calcium oxalate is washed into water, acidified with sulfuric acid, and heated over a boiling water-bath to dissolve it. The hot solution (> 60 °C) is titrated with potassium permanganate to a first permanent pink color. (*See* **Calcium**: Properties and Determination.)

To measure soluble and colloidal calcium separately, the milk must be separated into a milk serum fraction and a whole casein fraction by, for example, ultrafiltration. The soluble calcium is further subdivided into protein-bound and ionic. Ionic calcium may be determined in protein-free extracts by AAS.

Chloride, phosphate, and other salts in milk may be measured by various titrimetric and colorimetric methods. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Phosphatase Activity

The enzyme alkaline phosphatase is naturally present in milk and, because it is sensitive to heat, it is used to measure the effectiveness of pasteurization. Milk is diluted with a buffer (pH 10.6) containing disodium phenylphosphate which is hydrolyzed by the enzyme, releasing phenol. The phenol is reacted with 2,6-dibromoquinonechloroimide, producing a color which is measured spectrophotometrically at 610 nm.

Contaminants

Microorganisms

Microorganisms in milk (bacteria, yeasts, and molds) come from various sources: from the udder of the cow during milking, especially if the animal has mastitis, from contaminated equipment used to handle and transport the milk, or from personnel, whilst others come from the air. Hygiene control measures, such as use of antimicrobial washes and closed systems and keeping the milk cold, help to prevent microorganisms from entering the milk and growing. Heat treatment of processing equipment and of the milk reduces the levels of pathogenic organisms. The growth of most bacteria is reduced by the use of low temperatures, but certain types, called psychrotrophs will continue to grow at around 6 °C and cause problems when milk is stored for prolonged periods before use. (*See* **Adulteration of Foods**: Detection; **Pasteurization**: Principles.)

The same principle is used to measure most microbial contamination of milk. Dilutions of milk are carefully mixed into molten agar (40 °C) containing nutrients (purified meat extracts, salts, and a carbohydrate source such as glucose) – the growth medium. This is poured into sterile Petri dishes, cooled to set the agar into a gel, and incubated at a suitable temperature (e.g., 30 °C). Each microorganism which grows forms a small colony of cells in the agar. Colonies are counted by placing the dish over an indirect light source and marking each one on the outside of the dish with a felt-tip pen.

Total microorganisms are measured by culturing them in a complete growth medium that provides nutrients for all types. Specific types of microorganism are determined by using media which promote their growth but retard or inhibit others. For example, selective media are used to measure total coliforms (bacteria originating in the gut of animals) and fecal coliforms separately. To measure yeasts and molds, an antibiotic, usually chloramphenicol, is added to the growth medium to prevent bacteria growing. *Salmonella* species are measured by isolation in enrichment media before being grown, recognized, and confirmed.

With the need to prevent contaminated milk from being consumed or processed, rapid tests have been developed. The direct epifluorescence test (DEFT) is used routinely by some laboratories. A fluorescent marker is attained chemically to living cells. The marked microcolonies which grow in a short time fluoresce in ultraviolet-light and are counted automatically by an image analyzer.

Psychrotrophs

Psychrotrophs grow very slowly in milk at low temperatures. They are measured by using a growth medium similar to that described above but incubated at 6.5 °C for 10 days. A recent modification to the method allows the number of psychrotrophs to be

measured after 25 h at 21 °C, but other nonpsychrotrophs may interfere, reducing the accuracy of this method.

Antibiotics and Other Microbial Inhibitors

There are at least 40 antibiotics and sulphonamides which may occur in milk. They can be detected and identified by both microbial and chemical methods.

Microbial methods An inhibitory substance in the milk will prevent or retard the growth of test bacteria (*Bacillus stearothermophilus, Streptococcus thermophilus, B. subtilis, Sarcina lutea, Lactobacillus bulgaricus, B. megaterium*, etc.). In the disk-assay plate method, a disk of absorbent paper impregnated with the milk sample to be examined is placed on the surface of an agar plate preinoculated with a suitable test organism. When incubated, the growth of the bacteria causes the agar to become cloudy. The presence of inhibitory substances such as antibiotics which diffuse into the agar is indicated by a clear zone around the edge of the disk. The inhibitor may be identified by adding an agent that blocks its action. For example, the effect of penicillin is prevented by the addition of penicillinase; *p*-aminobenzoic acid blocks sulphonamides. With such substances in the growth medium, the antibiotic no longer prevents the test organism from growing.

Commercially available methods include Interest, Delvotest, and TTC.

On the farm, a Charm Farm Test kit may be used. The test organism is inoculated in tablet form into liquid medium in a testtube with a sample of the milk. An indicator in the buffer changes color if the bacteria are able to grow.

Chemical methods Inhibitory substances are extracted from the milk and then detected chemically by thin-layer chromatography (TLC), high-performance liquid chromatography (HPLC), fluorescence liquid chromatography, gas chromatography (GC), electrophoresis, bioautoradiography, enzyme-linked immunosorbent assay (ELISA), radioimmunoassay, enzymatic methods, and other forms of immunological methods. They are usually more specific than the microbiological methods. (*See* **Chromatography**: Thin-layer Chromatography; High-performance Liquid Chromatography; **Immunoassays**: Principles; Radioimmunoassay and Enzyme Immunoassay.)

Organic Residues

Organic residues occur in milk either through the diet or by contamination of the milk directly. Pesticide residues, polychlorinated biphenyls (PCBs), and dioxins are all toxic and tend to accumulate in the body. PCBs are used in a very wide range of industrial processes and products; dioxins are a byproduct of many chemical processes, including incineration of chlorine-containing materials at low temperatures.

Pesticide Residues

There is considerable difficulty in identifying pesticide residues in milk because they may be present in very low concentrations. To measure organochlorine (e.g., DDT) and organophosphorus (e.g., bromophos, malathion) residues, the fat is first extracted from the milk by a suitable solvent. The residues are then extracted from this into acetonitrile and diluted with water. The residues are extracted into petroleum ether, purified through a column of fluorosil, and eluted with petroleum ether and diethyl ether. The residues in the eluate are measured by GC and identified by a combination of GC and TLC. This is tending to be superseded by the more sensitive combination of GC with mass spectroscopy (GC-MS). (*See* **Pesticides and Herbicides**: Residue Determination.)

Polychlorinated Biphenyls

Two similar methods are used to measure PCBs in milk. In the first they are isolated by solvent extraction along with organochlorine pesticides and measured by GLC. In the second method they are extracted with solvents and purified on alumina or on fluorosil columns before determination by GC and GC-MS.

Dioxins

After treatment with ammonia and ethanol, the fat phase containing the dioxins is extracted into ether/pentane, then dried and concentrated. It is cleaned up by passing it through a series of columns of base silica, alumina, and activated carbon. The eluate is analyzed by high-resolution GC-MS. The method is calibrated by using standard dioxin labeled with carbon-13.

Radionuclides

Radionuclides which arise in milk are either naturally occurring or come from nuclear accidents such as the Chernobyl reactor disaster. Strontium-89 and strontium-90 (^{89}Sr, ^{90}Sr), cesium-137 (^{137}Cs), and iodine-131 (^{131}I) are probably the most important contaminants. Strontium is absorbed into bone, cesium mainly into muscle, and iodine only into the thyroid. These radionuclides are measured by scintillation counting of their radioactivity. Samples have to be enriched, unless the contamination is extremely high, to get counts which are significantly above background level. Scintillation counting consists of

placing a clarified sample into a special glass bottle with a reagent (scintillant) which absorbs the radiation and emits light in proportion. The light is detected by a sensitive photomultiplier and expressed as counts per unit time or time to standard count. (*See* **Radioactivity in Food**.)

Quaternary Ammonium Compounds (QACs)

These residues from cleaning agents and other fluids containing surfactants (e.g., cetylpyridinium chloraide (CPC) and cetyltrimethylammonium bromide (CTAB)) may have bacteriostatic effects or cause flavor taints. To determine QACs in milk, they are first extracted into solvent (1,1,2,2-tetrachloroethane) and then detected by the formation of a pink color with dioctyl sodium sulfosuccinate (Aerosol T) which is quantified by spectrophotometry.

Species Identification

Identification of the source of milk is generally used to detect the mixing of bovine milk into nonbovine milk and vice versa. Various methods have been tried, including TLC, GLC, and HPLC of the triacylglycerols. However, these methods are not very reliable because the identification of the species of milk present depends on measuring ratios of the fatty acids in the mixture. Improvements in HPLC methodology are helping to overcome some of these difficulties.

The proteins provide a better means of identifying the sources of the milks. The α_{s1}-casein in bovine milk has a higher electrophoretic mobility than the equivalent protein from other species. Therefore, in principle, simple electrophoresis on polyacrylamide gel should be sufficient to analyze the mixture. This is not very reliable, and better results can be obtained by more sophisticated electrophoretic methods such as isoelectric focusing and immunoelectrophoresis. The position and intensity of the electrophoretic bands gives a measure of the identity and amount of protein present. The availability of antisera to total milk proteins, and more recently the availability of monoclonal antibodies to specific proteins, means that exact identification of the origins of proteins in mixed milks is now relatively easy. Antibodies to particular proteins are allowed to react with the milk proteins. When the antibody binds to its antigen it normally forms a line or band of precipitation, the position and extent of which may be used to identify and quantify the protein present. Methods that combine electrophoresis with immunoreaction, such as rocket electrophoresis, give the most precise results.

Dietary Importance

J Buttriss, British Nutrition Foundation, London, UK

Introduction

Milk has been a component of the diet in many parts of the world for thousands of years. This article will review the nutritional value of milk, trends in milk consumption in the UK, and the role of milk in the diet of different population groups.

Nutrient Composition

Milk can be described as one of the most nutritionally complete foods. It provides a wide range of essential nutrients, in particular protein and a range of vitamins and minerals (**Table 1**). It is, however, a poor source of iron and vitamin D, and contains no starch

Table 1 Nutrient composition (per 100 g) of pasteurized milk in the UK

or dietary fiber. By volume, water is the major constituent of milk, comprising just over 87%. The remainder consists of milk fat and solids-nonfat (SNF).

Protein

The principal proteins found in milk are casein, lactalbumin, and lactoglobulin. Milk protein has a high biological value since it contains all of the eight essential amino acids, which need to be provided by diet. In addition, milk can improve the overall protein quality of a meal when consumed with foods of lower protein quality such as cereals and pulses. (*See* **Amino Acids: Metabolism.**)

Considerable interest has developed in a number of the peptides present in milk. It is now clear that cows' milk contains a number of biologically active peptide components that may prove to be of relevance to human health. Much of the research in this area has sought to identify and characterize components that influence the immune system.

Carbohydrate

Carbohydrate in milk is in the form of lactose, a disaccharide comprising a molecule of glucose and a molecule of galactose. This sugar is found naturally only in milk and is much less sweet than sucrose.

In the small intestine, lactose is digested by the enzyme lactase to its two component monosaccharides. This enzyme is present in babies and young children. In some adults, mainly noncaucasians, enzymatic activity can decrease, making milk in quantity less well tolerated. Such individuals are described as being lactose-intolerant. Most can tolerate small quantities of milk, and fermented milk products

appear to be better tolerated. In the UK, lactose intolerance is relatively rare in people of European descent but is more common in those of Asian, Far Eastern, and African descent, particularly first-generation members of these ethnic groups. (*See* **Carbohydrates**: Metabolism of Sugars; **Food Intolerance**: Lactose Intolerance.)

Fat

The fat in milk is in the form of minute droplets which rise to the top when milk is left to stand. The principal component of milk fat is triglyceride (triacylglycerol), three fatty acids joined to a glycerol backbone. All triglycerides contain mixtures of three types of fatty acids: saturated, monounsaturated, and polyunsaturated. The contribution of these three types of fatty acid to milk fat in the UK is 61% saturated, 28% monounsaturated, and 3% polyunsaturated. The percentages do not add up to 100% because milk fat is not composed totally of fatty acids. In the UK, whole cows' milk typically contains 3.9 g of fat in every 100 g of milk; semi-skimmed has 1.6 g per 100 g, and skimmed milk has less than 0.1 g per 100 g. The fatty acid profile remains the same. Milk fat contains small amounts of the two essential fatty acids, α-linoleic acid (1.4 g per 100 g fatty acids) and linolenic acid (1.5 g per 100 g fatty acids). (*See* **Fatty Acids**: Properties; **Triglycerides**: Structures and Properties.)

There is growing interest in a fatty acid found in milk known as conjugated linoleic acid (CLA). It is a polyunsaturated fatty acid with one *trans* bond, and is a product of rumen fermentation and so is present only in the meat and milk of ruminant animals. Work on rodents has provided evidence to support an inhibitory effect of CLA against mammary tumors, with some evidence for a similar effect against colon tumors. This work is supported by *in vitro* evidence using human tumor cell lines. CLA has also been shown to inhibit the accumulation of fat during growth in small and large animal models, and there is some evidence of a protective effect in cardiovascular disease. If the health benefits suggested in animal studies can be shown to apply to human populations, the consequences of advice to reduce fat intake may have important public health implications.

Vitamins

All of the known vitamins are present in whole milk (Table 1), although some are present in small quantities.

The fat-soluble vitamins – A, D, E, and K – are removed with the fat when milk is skimmed. Consequently, they are present in only trace amounts in skimmed milk and in reduced amounts in semi-skimmed milk. Whole milk is a good source of vitamin A, a pint (560 ml) providing 47% of the adult male and 55% of the adult female UK reference nutrient intake (RNI). Refer to individual nutrients.)

All of the three major types of cows' milk (whole, semi-skimmed, and skimmed) are good sources of riboflavin (vitamin B_2) and vitamin B_{12}. Where the overall diet is poor, milk can also provide useful amounts of thiamin (vitamin B_1), nicotinic acid, and ascorbic acid (vitamin C).

Heat treatment can have an effect on the vitamin content of milk. Of the heat-treated milks, fresh pasteurized milk has the highest vitamin levels. Milk which has undergone the ultraheat treatment (UHT) process keeps for longer but the higher temperature used in the processing results in lower levels of some vitamins, particularly vitamin B_6, vitamin C, and folate. The sterilization process used for milk has a somewhat greater effect and levels of riboflavin, vitamin B_{12}, and pantothenate will be lower than in milk heat-treated by the other processes. Vitamin C and folate are virtually absent from sterilized milk. (*See* **Heat Treatment**: Ultra-high Temperature (UHT) Treatments.)

Some loss of vitamins is inevitable when milk is stored. Milk exposed to bright sunlight on the doorstep for several hours can lose up to 70% of its riboflavin. Vitamin C levels also fall under these conditions, and measures should be taken to limit such exposure. There will also be gradual losses of folate and vitamin B_{12} from UHT and sterilized milks, even under ideal storage conditions, because of reactions with small amounts of oxygen remaining in the pack or bottle. Boiling milk also reduces its vitamin content, ranging from a 5% reduction in vitamin B_{12} to a 50% reduction in vitamin C.

Minerals

Milk makes a contribution to human needs for virtually all the minerals and trace elements known to be essential for health. These are often present in a form which is well absorbed and utilized by the body (high bioavailability), e.g., calcium and zinc. For most people in the western world, milk and milk products are a major source of calcium. In the UK, the National Food Survey, conducted by the Ministry of Agriculture, Fisheries and Food (now DEFRA), indicates that 55% of the calcium in the typical British diet is contributed by milk and milk products. Milk alone contributes about 40% of the total. Although the contribution to zinc requirements made by milk is relatively low compared with meat, the major contributor, the zinc is in a highly bioavailable form and there is evidence that the combination of milk (or meat) with vegetable foods, in which the zinc is less bioavailable, can enhance the bioavailability of zinc from the whole meal. (*See* **Bioavailability of Nutrients**.)

Seasonal and Breed Variations

Seasonal

The nutritional value of milk is influenced by the cow's diet. Milk produced in summer has a slightly different nutritional composition from that produced in winter. For most of the grazing season (spring), fresh grass can provide all the nutrients the cow needs. However, in some circumstances, e.g., where a cow has a high milk yield, additional food in the form of high-energy pellets is provided. When grazing, a cow may eat up to 70 kg (150 lb) of grass each day. The quality of grass is therefore an important factor in milk production.

The main diet during winter is grass conserved during the summer in the form of either hay (sun-dried grass) or silage ('pickled' grass). This is always less nutritious than fresh grass, so it is necessary to provide additional rations, sometimes in the form of concentrates, usually during milking. Alternative components of the winter diet include sugar beet pulp, maize gluten, or treated straw. Kale, cabbage, forage maize, or fodder beet are often specially grown for winter feeding.

As a result of the seasonal changes in diet, levels of vitamin A, β-carotene, and vitamin E are higher in summer milk. Iodine levels are higher in winter than in summer. Other nutrients remain the same.

The stage in the cow's lactation also has an effect on milk composition. Fifty days into the lactation, the lactose content of the milk starts to fall, and the fat and protein contents rise. However, since milk from individual cows at different stages of lactation is combined, these changes in composition are not reflected in seasonal changes in milk purchased.

Breed

Some breeds, such as Friesian and Holstein, are noted for producing large quantities of milk. Others, such as Guernsey and Jersey cows, are noted for the high fat content of their milk (5.1 g per 100 g compared with 3.9 g per 100 g). Other nutrients, including protein, calcium, phosphorus, carotene, and riboflavin, are also present in slightly higher concentrations in milk from Guernsey and Jersey cows, known as Channel Islands milk. Semiskimmed Channel Islands milk is also available in the UK and retains its slightly higher calcium content compared with ordinary whole milk.

As with milk from Friesian and Holstein cows, Channel Islands milk shows seasonal variations in retinol, carotene, and vitamin E content.

Health Implications of Raw Milk

The hygienic quality of raw (untreated) milk is very high in the UK. This is largely due to the introduction of a centralized testing scheme by the dairy industry in the early 1980s and a payment system to farmers based on the hygienic and compositional quality of raw milk produced on the farms.

Less than 1% of milk does not receive any form of heat treatment. In 1985, legislation reduced the availability of raw milk by prohibiting sales through shops, hotels, schools, and other catering establishments. Direct sales to the public are still allowed in England, Wales, and Northern Ireland. Raw milk has not been available in Scotland since 1983. It can be produced only by a farm holding a licence from OEFRA; it must be clearly labeled 'this milk has not been heat-treated and may therefore contain organisms harmful to health.' The address at which it was bottled or cartoned must appear on the container.

The Chief Medical Officer has advised that young children, pregnant women, elderly people, and those who are currently unwell or have a chronic illness should not consume raw cows' milk.

Trends in Milk Consumption

According to National Dairy Council figures, in 1990 weekly per capita consumption in the UK was 2.3 l (4.1 pints) per week, and had been falling steadily over the previous 10 years, as indicated in Table 2, which uses figures from a different source. The trends in the 1990s are shown in Figure 1.

Growth in Low-Fat Milks

There has been continued growth in purchases of low-fat milk in the UK. Most of this growth has arisen via increased sales of semiskimmed milk (Figure 2).

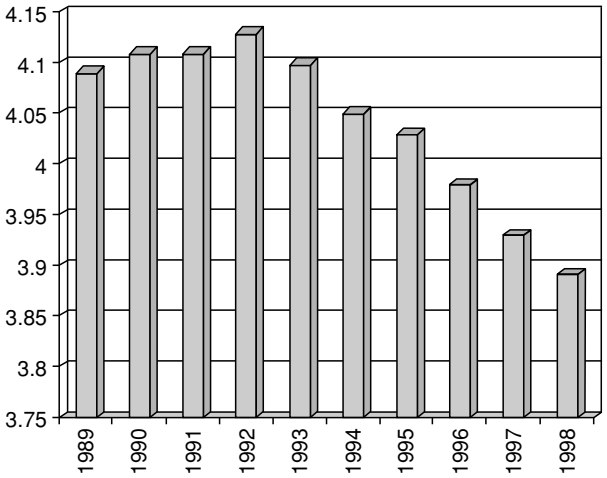

Figure 1 Estimated total liquid milk consumption in the UK from 1989 to 1998. Values given are pints per head per week. Reproduced from National Dairy Council (1999) *Dairy Facts and Figures*. London: NDC, with permission.

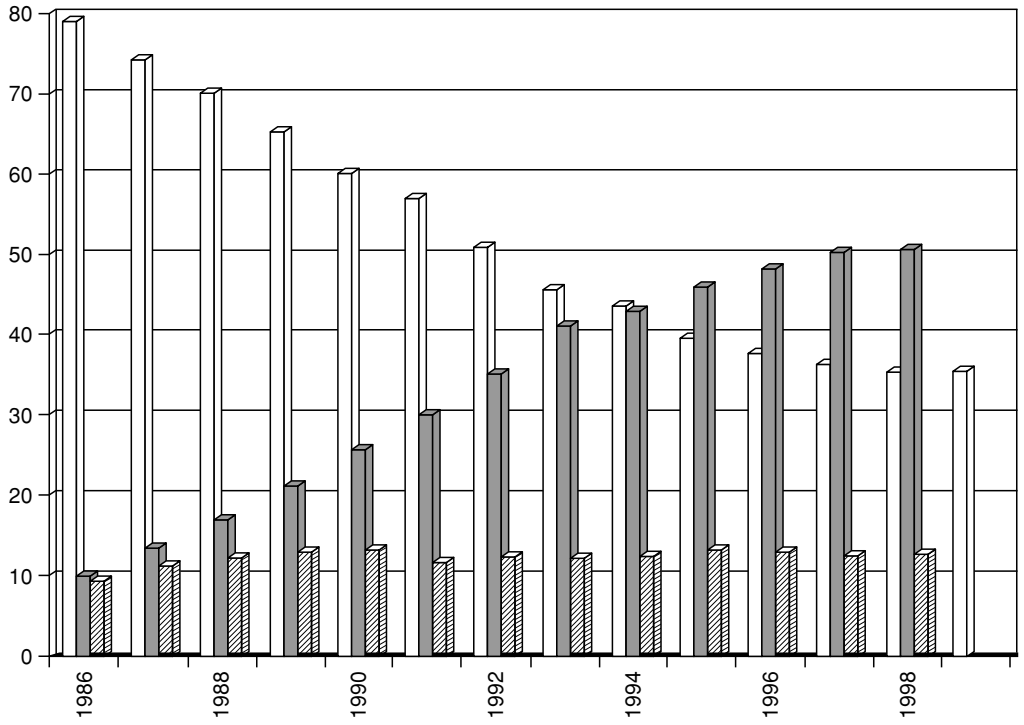

Figure 2 Percentage household milk purchases by fat content in England and Wales from 1986 to 1998. Open columns, whole milk; filled columns, semiskimmed milk; cross-hatched columns, skimmed milk. Reproduced from National Dairy Council (1999) *Dairy Facts and Figures*. London: NDC, with permission.

A similar pattern is seen in many other western countries.

Importance of Milk for Different Age Groups

As part of a balanced diet incorporating a variety of foods, milk can make a useful contribution to requirements for a number of nutrients. It is particularly valuable in the diets of certain groups of the population.

Infants and Preschool Children

In discussing milks suitable for children, the 1994 report, from the government's Committee on Medical Aspects of Food Policy, makes the following recommendations:

- There are advantages in continuing breast milk or infant formula during the first year. Cows' milk should not be introduced as the main drink during the first year of life. (*See* **Infants**: Breast- and Bottle-feeding.)
- However, from 6 months of age, whole cows' milk can be introduced in small quantities as part of the weaning diet, e.g., to mix cereals. It is important with all milks, but particularly with cows' milk, which is low in iron, that care is taken to insure that adequate iron-containing weaning foods are also provided. Suitable foods include those based on lean meat, fortified infant cereals, eggs, pulses, and green leafy vegetables. (*See* **Infants**: Weaning.)
- Skimmed milk is not suitable for children under 5 years, and semi-skimmed milk should not be given to children under 2 years of age because both milks are lower in energy and vitamin A.
- Semiskimmed milk can be introduced as the main drink at age 2 years, provided that the child has a good appetite and is eating a wide range of foods.
- A pint of milk per day is recommended by many health professionals for the under-fives. (*See* **Children**: Nutritional Requirements.)

Older Children

The report on Dietary Reference Values (1991), from the government's Committee on Medical Aspects of Food Policy, advises that children over 2 years and adults should make attempts to reduce their fat intake, especially intake of saturates, such that the proportion of food energy derived from fat is reduced from its current level of 42% to an average of 35% and intake of saturates is reduced to an average of 11% of food energy. At the same time, the reduction in fat intake should be compensated for by an increase in starchy, fiber-rich foods. Replacing whole milk with skimmed or semiskimmed milk is one of the ways in which fat intake can be reduced. Other ways include reduction in fried food, choosing leaner meat, using less spreading and cooking fat/oil, and cutting down on cakes, pastries, and fatty snack foods.

For children and teenagers, milk is a nutritious component of the diet and a major source of calcium, which is essential for the development of a strong skeleton.

School milk schemes exist in the UK and the rest of the European Community which enable primary schoolchildren to receive milk at a subsidized price whilst at school. A nursery school scheme also exists in the UK, providing free milk.

Pregnancy and Lactation

During pregnancy there is no increment in the advised daily calcium intake in the UK (700 mg) as the efficiency of absorption is known to increase. However, it is important that all pregnant women insure that they obtain an average of 700 mg per day (equivalent to a pint of milk). During lactation, calcium needs are covered by a daily intake of 1250 mg per day (1350 mg per day for pregnant teenagers). Milk and milk products are a useful way of obtaining the extra calcium. (*See* **Lactation**: Human Milk: Composition and Nutritional Value.)

Slimmers

Calcium intakes are frequently low among slimmers. This is avoided if skimmed milk, with its lower energy content, is included in the diet. A pint provides over 700 mg calcium, the reference daily intake for women.

Vegetarians

Milk is acceptable to most vegetarians and can make a useful contribution to protein quality. Whole milk is very important in the diet of young vegetarian children. Such diets can be bulky for the young child, and whole milk is a compact source of energy and nutrients in an easily absorbed form. Milk will also make a valuable contribution to vitamin B_{12} intake, which can be low in the diet of vegetarians who exclude eggs. (*See* **Vegetarian Diets**.)

Convalescents

During periods of illness and convalescence, appetite can be poor. Although energy requirement may be lower, essential nutrients are still required. Milk is a useful and versatile food at this time.

Elderly People

Milk is a valuable food for the elderly, who may also have a reduced appetite. Milk provides many essential nutrients in an easily assimilated form. Whole milk provides small amounts of vitamin D, which may be particularly beneficial for the housebound elderly who are unable to get out in the sunlight.

MILLETS

M I Gomez and S C Gupta, SDCC/ICRISAT, Bulawayo, Zimbabwe

Background

Millets comprise a number of small-grained, annual cereal grasses, which include several distinct botanical species. The most important types are pearl, finger, proso, and foxtail millets; other types of local significance include kodo, little, barnyard, and fonio millets, and teff. They differ in climatic and soil requirements, length of growing period, grain consistency, size, and taste. This article describes their common names, origin, geographical distribution, plant description, and crop utilization. The proximate composition of millets is summarized in **Table 1**. (*See* **Cereals**: Contribution to the Diet; **Cereals**: Dietary Importance.)

Pearl Millet

Pearl millet (*Pennisetum glaucum* (L.) R. Br.) is also known as bulrush, cattail, or spiked millet in English, bajra in Hindi, dukhn in Arabic, and mil à chandelles or petit mil in French, and as mhunga or mahango in parts of southern Africa.

Most botanists consider pearl millet to have originated in Africa and to have been subsequently introduced into India. Pearl millet originated in western Africa, where the grain developed by natural selection and acquired considerable resistance to a large number of diseases and insects.

[a]Figures in parentheses denote the number of samples.
dwb, dry-weight basis.
Data derived from several sources and different regions.

Pearl millet is the most widely cultivated of all millets and is one of the most drought-tolerant of all domesticated cereals. Soon after its domestication, it became widely distributed across the semiarid tropics of Africa and Asia. It is planted on some 15×10^6 ha in Africa and 12×10^6 ha in Asia. In Africa, major pearl millet-growing countries are Nigeria (3 133 000 t), Niger (1 227 000 t), Mali (695 000 t), Senegal (539 000 t), Burkina Faso (447 000 t), Sudan (355 000 t), Chad (161 000 t), and Tanzania (144 000 t). It is also grown in Cameroon, Ghana, Zimbabwe, Togo, Angola, Namibia, The Gambia, Ivory Coast, Zaire, Sierra Leone, Guinea Bissau, Kenya, Central African Republic, and Guinea where the production is above 10 000 t but less than 100 000 t per year. There are many other African countries, such as South Africa, Benin, Zambia, Ethiopia, Mozambique, Malawi, Libya, Mauritania, Morocco, and Botswana, where it is grown on small acreages. In Asia, it is the most important crop in India (5 625 000 t), followed by Pakistan (252 000 t) and Yemen (108 000 t). It is also grown in Syria, Myanmar, and Saudi Arabia. The average grain yield production is about 0.5 t ha^{-1}, but the improved varieties with good management under dry land conditions can produce up to 3 t ha^{-1}.

Pearl millet is a robust annual grass, usually 1.2–3.5 m tall. It is a staple cereal in India, and in some countries of west and southern Africa, such as Senegal and Namibia. The stems are 1–3 cm or more in diameter. The plant can tiller from few to as many as 20 culms based on spacing, management, and the cultivar. The tillering could be basal as well as nodal. Most of the cultivars have basal tillering. The internode is usually light green but sometimes purple. The nodes are often marked by a ring of long, white cilia pointing upward and bearing a ring of adventitious roots on the basal side. The leaves are long, scabrous, and rather slender; they may be smooth or have hairy surfaces, and they have hairy ligules. The blades are lanceolate, cordate, and sometimes 90–100 cm or more in length and 5–8 cm in width. The midrib color is white or green but sometimes brown. Leaves are upright or drooping, and the ligule is narrowly membranous with a fringe of hairs. The leaf sheaths are open and hairy, and the ligule is short, Leaves and culms may vary in color from light yellowish green to dark green and, sometimes, deep purple.

The ear head can be compact, semicompact or loose, cylindrical, conical, or spindle-shaped, 2–5 cm in thickness, and usually 15–45 cm long, although some Nigerian varieties can have ear head lengths over 100 cm. The rachis is straight, cylindrical, solid, often 8–9 mm thick, and unbranched. It extends the entire length of the inflorescence, tapering gradually from base to apex. The seeds are mostly gray but are sometimes grayish brown, grayish white, purple, yellowish brown, or white. Endosperm colors range from white to yellow and gray. The individual seed weight varies from 3 to 14 mg. The spikelets can be without bristles or with long bristles.

The aleurone layer is only one cell thick, and the endosperm consists of an outer hard or vitreous portion and an inner opaque region of soft endosperm. The hard endosperm consists of a tightly packed cellular structure containing no air spaces, whereas the soft endosperm is rather loosely packed and contains relatively large air spaces. The soft endosperm appears to contain no protein bodies, whereas large protein bodies constitute the protein matrix of the hard endosperm in which the starch is embedded. Proximate analysis of whole pearl millet grain shows it to have a relatively low protein content of about 10% but a high fat content of 3.8–4%, largely concentrated in the germ.

Processing and Food Uses

Pearl millets are used largely to prepare traditional, thick or thin, fermented or unfermented porridges in Africa. The second major use in Africa is malting for

the brewing of traditional beers and wines. In west African countries, e.g., Senegal, millet is used for making couscous, pap, and fritters. In Cameroon, pearl millet-based gruels and steamed cakes are prepared for feeding infants and preschool children. Malted pearl millet in combination with legumes has been used to prepare malted weaning foods. Pearl millet has also been used in composite flour with wheat for making bread. Up to 30% pearl millet was used successfully in making bread in Senegal. The nutritional advantages of pearl millet are its high fat content and a relatively high lysine content, comparable with that of high-lysine corn in some varieties. Antinutritional factors, however, have been reported in several studies. A thionamide-like substance has been identified that interferes with the formation of thyroid hormones, which in turn leads to undesirable goitrogenic effects. (*See* **Fermented Foods**: Beverages from Sorghum and Millet; **Goitrogens and Antithyroid Compounds**.)

Pearl millet is traditionally milled by hand-pounding in a wooden mortar, yielding a flour of about 85% extraction. Experimental milling systems, such as the Storamil process, have given 65–75% yields of fine flour. Pearling or debranning of pearl millet has also been achieved with a vertical cone polisher of the type normally used for polishing rice.

Pearl millet can be malted and used wholly or partially in place of sorghum malt in the traditional or industrial brewing of opaque beer. However, the small size of the grain is a disadvantage in large-scale industrial malting plants.

Pearl millet is also grown as a forage crop in the southeastern USA and in some parts of southern Africa.

Finger Millet

Finger millet (*Eleucine coracana* (L.) Gaertn, ssp. *coracana*) is commonly known as ragi in India and wimbe in East Africa; these are the major finger-millet-growing areas. Common English names are African millet, birdsfoot, and coracana.

Finger millet was developed in Africa from *E. coracana* ssp. *africana*, probably in the Ethiopian region. It was introduced to India perhaps more than 3000 years ago. It is a tropical crop grown from sea level to 3000 m above sea level.

The global production of finger millet is about 3.7×10^6 t of grain per year with an average of 0.6 t of grain per hectare. The improved varieties under good management can produce up to 4 t of grain per hectare. In Asia, the major finger-millet-producing country is India (2 613 000 t), followed by Nepal (122 000 t), China (79 000 t), and Afghanistan (38 000 t). In Africa, Uganda ranks first (451 000 t), followed by Ethiopia (198 000 t), Tanzania (95 000 t), and Zimbabwe (46 000 t). To a lesser extent, it is also grown in many other countries, such as Iran, Sri Lanka, Myanmar, Bhutan, Iraq, Pakistan, and Jordan, and (in Africa) Kenya, Burundi, Zambia, eastern Zaire, Sudan, Malawi, South Africa, and Rwanda.

Plants are annual, tufted, erect, or with geniculately ascending culms; they reach an average height of 103 cm and a maximum height of 165 cm, and they sometimes root from the lower nodes. Culms are commonly branched from the upper nodes to produce secondary inflorescences. Leaf blades are linear to linear-lanceolate, generally 35 cm but sometimes up to 70 cm in length, and 20 mm wide. Inflorescences are digitate, often with one or more racemes some distance below the main cluster of four to 19 branches. Inflorescence branches are slender, or incurved at the tip when robust, sometimes with secondary branches. Spikelets are six- to nine-flowered and 6–10 mm long, overlapping, and mostly arranged in two rows along one side of the rachis. Glumes are unequal and shorter than the spikelet. The inflorescence shape is variable. The digitately arranged branches may spread out and become reflexed, or they may be erect and incurved, often forming a fist-like structure.

Finger millet is largely a peasant crop. Seeds vary in color from light brown to dark brown or purple, and are small, up to 2 mm long, globose, and hard. The individual seed weight can vary from 1 to 3 mg. The small, flinty grains are highly resistant to both stored insect pests and molds, and thus have excellent storability. Some of the brown finger millet varieties contain high levels of tannin – 3–4% catechin equivalent. (*See* **Tannins and Polyphenols**.)

Processing and Food Use

Immature grain is roasted green and consumed in the dough stage. Traditionally, the grain is processed by wet grinding on stones. The resulting flour is dried and consumed as thick or thin porridge. Light-colored millets are particularly well suited for malting, the diastatic activity of millets (except pearl millet) being higher than that of sorghum. One of the major uses of finger millet in Africa is therefore in malting, prior to the brewing of traditional beers. To a limited extent, finger millet is reported to be grown in Japan and China, where its major use is the making of beer. In India, and Sri Lanka, finger millet flour is used in the preparation of unleavened bread (roti). (*See* **Sorghum**.)

Advantageous nutritional attributes of finger millet are its particularly high calcium and iron contents

(220–855 mg per 100 g and 64–15 mg per 100 g, respectively) and its high methionine content (83–226 mg per gram total N). In Nepal and India, farmers attach economic value to finger millet straw, since they use it as a livestock feed.

Processing of finger millet by dehusking or debranning was unsuccessful because of the small seed size, the relatively thick pericarp, and a highly friable endosperm. Roller milling of whole grain and sieving, however, produces a refined flour. Similarly, in traditional processing, finger millet is ground or pounded to a flour as whole grain, and particles of pericarp are sifted or winnowed out. (*See* **Flour**: Roller Milling Operations.)

In the preparation of unleavened breads such as roti or chapati, a cold-water dough does not hold together owing to the lack of gluten. Hot water is therefore used to pregelatinize the starch and to attain the required degree of cohesiveness for preparing the thin, flat, griddle breads. (*See* **Chapatis and Related Products**.)

Foxtail Millet

Foxtail millet (*Setaria italica* (L.) P. Beauv.) is also known as Italian millet and setaria. It is grown as a cereal in southern Europe, and in temperate, subtropical, and tropical Asia. It was domesticated in the highlands of central China around 5000 years ago, and spread to Europe and Asia soon after its domestication.

Total production of foxtail millet is around 5.7×10^6 t of grain per year, of which China alone produces 4.9×10^6 t, followed by India (500 000 t). It is also grown in Europe, particularly in Portugal, Turkey, Hungary, France and Spain, in Asia, primarily in Korea, Pakistan, Myanmar, Bhutan, Nepal, and South Africa. Each of these countries produces less than 10 000 t per year.

There are three morphologically distinct races: *moharia*, *maxima*, and *indica*. These differ in morphological characteristics, such as plant height and inflorescence, as well as in distribution. Race *moharia* is cultivated in southeastern Russia, Afghanistan, and Pakistan. Race *maxima* is cultivated in transcaucasian Russia, the Far East, and the USA for bird feed. Race *indica* is largely cultivated in India and southern Asia.

Cultivars from India are morphologically different from those of Europe and the Far East, and are typically robust with inflorescences bearing branches loosely arranged on the primary axis.

Variability has been reported for several characteristics such as plant height (20–175 cm), peduncle length (0–500 mm), inflorescence length (10–320 mm), exertion (10–360 mm), basal tillers (1–80), and in time to flowering (30–135 days) in germplasm accessions.

Uses

Foxtail millet is widely used as a food grain and as a forage crop in Asia, North Africa, and southeast Europe. It is used for brewing beer in Russia and is an important food crop in China, where it is used in gruels, for making cakes, and in beer and vinegar production. It is also used as a medicinal food in Chinese medicine, the beneficial effects being partly attributable to its high nutritional quality. The grain is also used as an animal feed, and the straw as forage.

Proso Millet

The millet with the botanical name of *Panicum miliaceum* (L.) is known as proso millet in Russia.

The common English names of this millet are hog millet, common millet, and broomcorn millet. The progenitor of proso millet is native to Manchuria. It was probably domesticated in central and eastern Asia, and was cultivated in Europe in Neolithic times. The species was introduced to Europe as a cereal at least 3000 years ago. This is essentially a crop of the temperature regions, but it is also grown in the subtropics and on high ground in tropical winters.

Proso ranks third after pearl millet and foxtail millet in terms of total global millet production, about 5×10^6 t of grain per year. The major proso-millet-producing countries are the Commonwealth of Independent States (2 330 000 t), China (1 600 000 t), India (500 000 t), Argentina (173 000 t), Myanmar (150 000 t), and the USA (110 000 t). It is also grown on small acreages in Korea, Australia, Turkey, Austria, Yugoslavia (Montenegro, Serbia), Pakistan, Greece, Bhutan, Nepal, Mongolia, and Japan.

Plant height varies from 25 to 133 cm. The inflorescence length varies from 2.2 to 40 cm. The flag leaf may cover as much as 5 cm of the inflorescence; however, the exertion of the inflorescence may be up to 32 cm. This is a highly tillering crop. It is early maturing, some of the accessions flower in 28 days, and a crop can be harvested in 50–55 days. However, most of the accessions flower in 30–35 days, and a few take up to 50 days. The individual seed weight can vary from 5 to 9 mg – similar to that of pearl millet. It is a self-pollinated crop, and hybridization can be achieved by hand emasculation.

Food Uses

In China, the grain is steamed or boiled like rice. It is also eaten flaked and sweetened with sugar. In the

USA, it is the largest millet crop and is largely used as a feed grain. Proso millet has been comilled in an experimental, semiindustrial process with wheat after individually conditioning the grains to 16% moisture. The flour can be used at up to 10% addition rates with no deleterious effects on the quality of bread.

Kodo Millet

Kodo millet (*Paspalum scorbiculatum* L.) is also known as ditch millet. It is grown only in India, although the wild grass is a widespread tropical weed that is harvested as a wild cereal in West Africa. The species was domesticated in India some 3000 years ago. It is grown in India from Kerala and Tamil Nadu in the south, to Rajasthan and Uttar Pradesh in the north, and West Bengal in the east, as a food grain.

The plant height can vary from 30 to 90 cm, with 10–48 basal tillers per plant. The length of the inflorescence varies from 2 to 12 cm. It is a relatively late-maturing crop compared to other small millets. The flowers are highly cleistogamous with a maximum opening of up to 50% only, i.e., this is a highly self-pollinated crop. Cytological studies have revealed the chromosome number as $2n = 40$.

The statistics for kodo, little, and barnyard millets are combined together, and these species are grown only in India, except barnyard millet, which is also grown in Japan (only 1000 t per year). The total production in India is around 386 000 t per year.

The crop is hardy and drought-resistant, and is capable of growing in marginal soils. The grain is enclosed in a hard, corneous husk, which makes debranning difficult. The grain is said to be poisonous after rain; this may be due to a fungal infection. Winnowed, clean, healthy grain seems to pose no health problem. Kodo millet is primarily cooked as rice.

Little Millet

Little millet (*Panicum sumatrense* Roth. ex Roem. & Schult.) is also known as miliare. It is widely cultivated as a cereal across India, Nepal, and western Myanmar. It is particularly important in the eastern ghats of India, where it forms an important part of tribal agriculture.

A comparative morphological study of accessions resulted in the recognition of two races. Race *nana* plants are small (60 cm) to large (170 cm) with decumbent culms that root at the lower nodes before becoming erect to produce flowering culms. Terminal inflorescences are 14–50 cm long, erect, open, and strongly branched, with the branches sometimes clumped at the time of maturity. Race *robusta* includes plants that are erect, or produce flowering culms from a shortly geniculate base. Flowering culms are 120–190 cm tall and robust. Terminal inflorescences are 20–46 cm long, open, or compact and strongly branched. Open inflorescences are essentially erect, and compact inflorescences become curved at maturity. It is largely a selfpollinated crop; natural cross-pollination can occur up to 3.5%.

The dehusked grain is cooked and consumed like rice, or is milled into flour. The crop thrives under conditions that will sustain no other edible plant and will mature in 2–5 months.

Barnyard Millet

Japanese barnyard millet (*Echinochloa crusgalli*) is native to temperate Eurasia and was domesticated in Japan some 4000 years ago. Barnyard (sawa) millet (*E. colona*) is widely distributed in the tropics and subtropics of the Old World, and was domesticated in India. The two species have different chromosome numbers ($2n = 54$ and $2n = 36$, respectively), and hybrids between them are sterile.

Cultivated plants of *E. colona* (L.) Link. are erect or geniculate ascending, often tufted, annual, and up to 242 cm tall. Culms are slender to robust. Slender plants are decumbent, with the culms strongly branched and rooting from the lower nodes. Stout plants are erect, with a few culm branches from the upper nodes. Inflorescences are variable; decumbent plants are characterized by short racemes that are appressed to the primary axis, whereas more robust plants have larger, pyramidal inflorescences with spreading lower racemes. Inflorescences are usually erect, rarely drooping, and can be up to 28 cm long. Spikelets are persistent at maturity, 2–4 mm long, acute but never awned. The grain is 2–3 mm long and 1–2 mm wide.

Cultivated plants of *E. crusgalli* (L.) P. Beauv. are erect, tufted, annual and up to 100 cm tall. Culms are mostly robust, simple, or branched from the upper nodes. Inflorescences are erect or slightly nodding, well exertion from the upper leaf sheath, with the spike-like racemes more or less erect and sometimes incurved at the tip. Spikelets are persistent at maturity, very crowded, 3–4 mm long, shortly cuspidate but rarely awned. The grain is 2–3 mm long and almost as wide.

Japanese barnyard millet is the fastest maturing of the millets and, under favorable temperature and moisture conditions, ripens within 45 days. The crop is grown for forage and food in India, and in the USA is said to produce two harvests within the cropping

season. *Echinochloa decompositum*, the Australian variety is used as food by aboriginal tribes.

Teff

Teff (*Eragrostis tef*) is the most important cereal crop in Ethiopia, particularly in the poorly drained, heavy soils that predominate in the Central Plateau. The total production is slightly above 1×10^6 t per year. Ethiopia is considered the center of origin of the crop, and domestication is thought to have started in the northern highlands. Teff grows in Australia, Kenya, and South Africa, but is cultivated as a major staple crop only in Ethiopia.

Teff is cultivated from sea level to 2800 m, on soils varying from waterlogged to well drained, and in areas that have less than 300 mm or more than 1000 mm seasonal rainfall.

Teff is a sexually propagated, self-pollinated annual tufted grass. It is an allotetraploid with $2n = 40$ chromosomes. The plants are short in stature (height varying from 45 to 150 cm) with loose, open panicles. The culm thickness varies from 1.2 to 3.1 cm. Teff can mature in 3–4 months, but a few early-maturing accessions can mature in 2 months. The average grain yield is 0.8 t ha^{-1}, but with improved management and cultivars, up to 2 t ha^{-1} can be obtained.

Two types of teff are found in Ethiopia – white- and brown-seeded varieties – and the white is preferred for food. The grain is very small, about 1–1.5 mm in length, and 1000 grains weigh approximately 0.3 g.

The flour of teff is used in Ethiopia for making a flat, fermented, griddle bread or pancake known as injera. It is also used for making porridge and the traditional alcoholic drinks, 'tella' and 'katikalla.'

Fonio

Fonio (*Digitaria exilis* Stapf) is also known as 'hungry millet,' 'hungry rice,' fundi, and acha. It is grown throughout the savanna areas of west Africa, notably in Guinea and Nigeria. The crop is not cultivated outside Africa and is capable of thriving in poor, rocky, and marginal soils. It is considered to be the oldest West African cereal, and its cultivation is thought to date back to 5000 BC. Black fonio (*D. iburua* Stapf) is grown by the Hausa of Nigeria (northern Nigeria), and in Guinea, Togo, and Benin, but the total production of black fonio is insignificant.

Total production of Fonio is 309 000 t per year, and about 70% of this is produced in Guinea (200 000 t). The other major producing areas are Nigeria (58 000 t) and Mali (36 000 t). To a lesser extent, it is also grown in Burkina Faso, Ivory Coast, Niger, and Gambia. It is grown on the plains as well as in the mountains, i.e., under annual rainfalls from 400 to 3000 mm.

Fonio is an annual plant with a plant height of 45–50 cm. The roots are well developed and attached firmly to the soil. The inflorescence is composed of two to six fingers of 5–12.5 cm length. The grains are small, and the individual grain weight is 0.5–0.6 mg. The grain yield varies from 0.2 to 0.5 t ha^{-1}. In low-rainfall areas, the crop matures in 2–4 months, whereas in high-rainfall areas, the maturity period varies from 4 to 5 months.

The seed is very small and is usually threshed and pounded to remove chaff; it is used alone or mixed with other cereals to make porridge. The grain can be added to stews, or boiled and eaten with palm oil. Fonio can also be used for brewing beer. In comparison with other cereals, fonio has a poor nutritional value in terms of total protein and amino-acid balance.

Principles Of Milling

E S Posner, ESP International, Savyon, Israel

Introduction

The wheat seed which is used for the manufacture of flour is an elongated structure 7–12 mm long and 2–4 mm wide (Figure 1). A crease along the kernel extends nearly to the center. Structurally, the wheat kernel consists of three main parts. The pericarp is the outer coat and is divided into several layers. The wheat germ is divided into the embryo and the scutellum. The endosperm is an accumulation of cells that makes up to 83% of the kernel. The endosperm cells, which are the 'flour' when reduced to small particles, contain many starch granules embedded in a proteinaceous matrix. (*See* **Wheat**: The Crop.)

Wheat is a living organism which varies in its quality as a result of genetic characteristics as well as a result of growing and storage conditions. Wheat-processing characteristics are related to its millability, protein quality and quantity, and baking results of the end product. Three main kinds of wheat can be recognized: hard, soft, and durum. Hard wheats tend to be higher in protein content (10–15%), usually have harder structured endosperm, and find their principal use in bread flour. Flour produced from internally softer wheats, with lower protein content (8–11%), are used in cake and cookie production. Durum wheats are processed to a granular or floury endosperm product for pasta. Distinctively different milling systems are designed to accommodate the differences in wheat that affect their millability. Although in the past mills were usually constructed to mill the locally harvested wheat, modern mills in any part of the world can be designed to process any desired wheat for a special end product.

The wheat flour-milling operation consists of the following functions: receiving, analyzing, wheat storage, blending, cleaning, conditioning, milling, product storage, and shipping. Table 1 indicates the various products and byproducts of the wheat-milling operation.

Wheat Quality for Milling

The determination of wheat milling quality is very complex. No single test has yet been devised to establish conclusively the milling quality of a wheat. Fluctuations in wheat characteristics and quality reduce the efficiency of the fully automated, high-capacity milling unit of today. High moisture replaces the amount of dry material in the wheat and is a significant economical quality factor. Larger wheat kernels are correlated with potential flour yield. Smaller kernels have a larger ratio between pericarp and endosperm, resulting in a lower amount of available endosperm. The weight of a thousand sound, whole wheat kernels, corrected to a fixed moisture level, is also a good indication of the flour yield and millability. Hardness of the kernel, especially after it has been tempered for milling, is an important quality characteristic. Harder wheats require longer tempering stages and produce more granular material, which flows and sieves better. Harder wheats also tend to give better extraction levels as a result of better separation of endosperm from bran. All the above-mentioned kernel characteristics affect the milling quality of wheat and require the appropriate design of a milling system and its adjustment. Recent development of the single-kernel characterization system (SKCS) can be calibrated to measure single-kernel hardness, protein, starch, internal insect infestation, color, disease, size, and moisture.

Wheat Storage and Blending

Wheat storage involves a substantial investment in facilities, equipment, and the value of the stored wheat. Different means of preservation are used, such as aeration with ambient air of the right characteristics or cooled air, fumigation, and control systems to monitor any physical or chemical changes in the wheat. Uncontrolled storage conditions could cause wheat deterioration, starting in 'pockets' in the bin as a result of high moisture. Live insects would also flourish if the temperature, humidity and grain fractions were readily available. There is an equilibrium between moisture content of the wheat, air

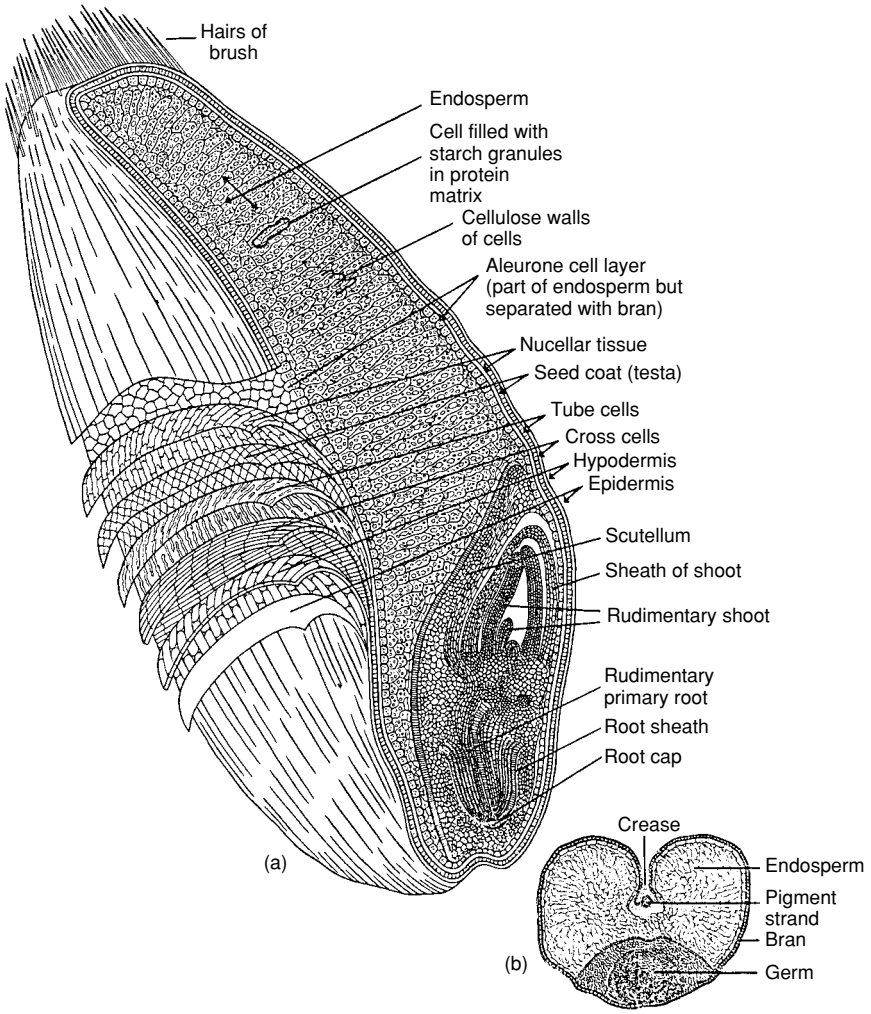

Figure 1 (a) Longitudinal section (enlarged about 33 times) and (b) cross-section of the wheat kernel. The endosperm makes up about 83% of the kernel, the bran about 14.5%, and the germ about 2.5%. Courtesy of the Wheat Flour Institute, Washington DC, USA.

Table 1 Products from a milling system[a]

Product	*Percentage of total*	*Primary end use*
Wheat screenings[b]	1–3	Feed
Flour I	60–65	Baked products
Flour II	10–17	Baking, industrial utilization
Farina	3–8	Breakfast foods
Semolina[c]	65–67	Pasta
Bran[d]	22–25	Feed, high-fiber
Germ	0.2–0.5	Food, cosmetics

[a]Based on wheat entering the mill.
[b]Screenings are impurities removed from wheat before grinding.
[c]In durum milling, only the rest (8–10%) of extracted endosperm is flour II.
[d]Bran is a distinct byproduct consisting of broad pericarp flakes, the aleurone layer, and some endosperm. Commercially, the term includes all offals from the process, such as the shorts (fine bran, germ, and endosperm particles) and red dog (very fine bran, germ, and endosperm particles).

temperature, and humidity. Accordingly, safe storage conditions include a moisture content below 12.5%, and temperature below 25 °C. Even under optimal conditions, stored wheat goes through a continuous change in its milling and baking characteristics by aging; this change is significant in the 3 months immediately after harvest. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs; **Insect Pests**: Problems Caused by Insects and Mites.)

One of the miller's main objectives is to be a supplier of uniform product to the customer. To accomplish this, there must be on hand wheats with such qualities that blending them will produce a mill-grist that is uniform in all its physical and chemical characteristics. To accommodate this need, it is important to evaluate wheat upon receipt and segregate it in bins according to quality.

Wheat Cleaning

The current methods of wheat harvesting make it impossible to obtain a pure product off the field. Foreign materials in the grain bulk have to be removed before milling, and this is accomplished in the wheat-cleaning section.

Separation of the unmillable fractions from wheat is based on differences in the following material characteristics: size, specific weight, shape, color, solubility, and response to magnetic forces. Many versions and combinations of those principles have been combined in cleaning machines. Modern equipment combines more than one principle so that, in many cases, the bulk of the grain in a certain range of size and specific weight is diverted to subsequent stages in the process, whereas only a small part of the load is cleaned intensively.

Wheat Conditioning

The clean wheat is subjected to the conditioning process, which is the addition of water followed by a time period of tempering it, allowing the water to be absorbed by the kernels. The objective in conditioning the wheat before milling is to reach a state at which the pericarp and germ parts are tough and plastic and do not splinter during the grinding process, because they absorb water very readily. On the other hand, the endosperm should be as friable as possible. Three variables effect the conditioning process, namely tempering time, temperature, and moisture.

Characteristics such as internal structure and level of pericarp damage of the wheat kernel exert different effects on the conditioning of wheat for milling. Wheat size significantly affects the water penetration rate because of its relationship to the specific surface area of the kernels. The relative best tempering time is the period that allows the bulk of the wheat to reach the optimum equilibrium of water penetration into all kernels. Uncontrolled moisture fluctuations in wheat fed to the fully automated mill might cause operational problems, as well as change in flour quality.

Wheat-Milling Process

The objective of the flour-milling process is initially to separate the major botanical parts of the wheat kernel – the endosperm, the pericarp, and the germ – from each other. Subsequently, it reduces the endosperm to finely ground flour, which passes through a sieve with an aperture of not larger than about 200 μm. From the technical aspect of flour milling, the efficiency is weighed mainly by the level of separation among those parts, and production of a high percentage of flour with a relatively low contamination with germ and pericarp parts. The miller's objective is to produce flour with good color, and products which have not deteriorated to an unexpected level during the milling process. The practical miller, for example, would count on about 1% reduction of protein between the whole wheat and the resulting flour, when using wheat in the range of 10–13% protein.

The current basic concept of the wheat-milling process was established at the end of the nineteenth century, when iron rollers were applied instead of grinding stones. The wheat is ground between two rollers which rotate against each other and are positioned horizontally in a rollermill machine. The commercial grinding rollers dimensions range from 180 to 350 mm in diameter and up to 1500 mm in length. From a performance point of view, smaller-diameter rollers are more fitted to those stages in which the objective is a shearing action to separate the endosperm from the bran. On the other hand, larger-diameter rollers create a longer grinding path that acts on the material, mainly through compression. Most modern wheat mills have rollers that are of the same length and diameter to achieve maximum uniformity and avoid keeping a large inventory of spare rollers. (*See* **Flour**: Roller Milling Operations.)

The outer layer of the cast-iron rollers, about 13 mm thick, is harder than the inner core; the casting process is responsible for this. Frequently, the rollers are called 'chills' because they undergo a cooling process. Fast cooling after casting will keep the carbon mixed evenly with the steel and create a hard surface. Slow cooling will allow the carbon in the steel to crystallize, which will result in a softer surface. To extend the duration of the corrugations' sharpness, the harder-surface rollers are used. In the smooth rollers, made out of softer steel, the carbon crystals that are dissipated during the wearing of the surface cause it to stay rough and grip the endosperm particles better, causing an effective reduction to flour.

Mill designers use a specific and cumulative roller length in the design of a certain milling process. As an example, a mill will be designed based on a total of 18 mm roller length per 100 kg wheat per 24 h. Recently, improved machine design has reduced substantially specific roller length. Automation and high-efficiency roll bearings contribute to the ability to run the rollermill machine at a speed higher than previously. The first grinding stages in the mill, known as 'breaks,' ideally open the kernel and scrape off the endosperm from the bran. Subsequently,

smooth 'sizing' and 'reduction' rollers are used to downsize endosperm granules to fine flour. The surface of the breaking rollers is corrugated along the axis. There are fewer corrugations per centimeter in the head breaks and they increase in number to the last break. The number of corrugations per centimeter ranges from four to 10 in the breaks. The corrugations are cut in spiral, relative to the axis of the roller, ranging from 8% to 18% (4°40′ to 10°20′). A large spiral is responsible for more flour, whereas a smaller spiral generates more granular endosperm particles. The spirals cross in a scissor-like fashion when the rollers are rotating against each other. A single corrugation has a front angle and a back angle, which creates a sharper edge and a duller edge respectively (Figure 2). By rotating the rolls at different speed (differential of 2.5:1) against each other, the main effect is a shearing action of the surfaces against each other. The front angle ('sharp' edge) or back angle ('dull' edge) of one roll acts against the 'sharp' or 'dull' edge of the other roller (Figure 3). There is also a compression effect, but it is very carefully controlled just to open the kernel and release the endosperm.

Between the reduction rollers, there is a differential of ratios 1.2:1 to 1.5:1. The lower differential is responsible for a larger compression effect on the material. Smooth rollers are set closer to reduce endosperm chunks to flour and, as a result, they require considerably more power than corrugated rollers. The miller controls the compression between the rollers to avoid extensive damage to the flour and prevent excessive flacking of the endosperm particles. Flacked endosperm might also cause flour extraction loss because the tailover from the top sieves in the reduction sieving sections end up in the tailover streams of the mill and, subsequently in the bran (stock that has gone over a sieve is known as 'overs').

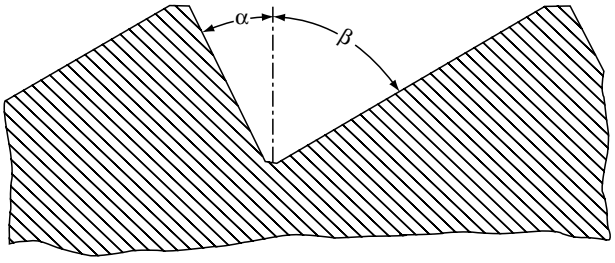

Figure 2 Roll corrugation: α front angle; β back angle.

The heterogeneous material after each stage of the grinding rollers is sent to a sieving machine called 'plansifter'. This is an enclosed unit in which up to 10 stacks or compartments, of up to 32 sieve frames, are placed. The exact number of frames depends on the materials sieved and on the manufacturer involved. The machine is centrifugally balanced and rotates at a certain prescribed number of rotations per minute and at a definite 'throw,' or radius. In a sifter compartment, sieves are arranged in groups which differ in their aperture size. Sieve aperture (measured in microns) is determined by the miller. The mill designer allocates a certain sieving surface area to each granulation of the material entering each sieving stack. Tailover materials from the sieves are directed to the next stage in the process for further grinding or purification. A certain percentage of flour is extracted from each of the sieving stages in the mill.

Purification is one of the three major processing principles in the flour milling process. The purifier is a machine in which air currents are drawn through one to three layers of sieves, and the sieves move simultaneously in a reciprocating motion (Figure 4). The material fed to the purifiers is made up of particles of about the same size range but differing in their content of endosperm and bran. The differences in relative density between pure endosperm (about 1.44 g cm^{-3}) and pure bran coat or pericarp (about 1.22 g cm^{-3}) are used in the purification process. Stratification with the help of the controlled air currents occurs between the heavier particles of relatively

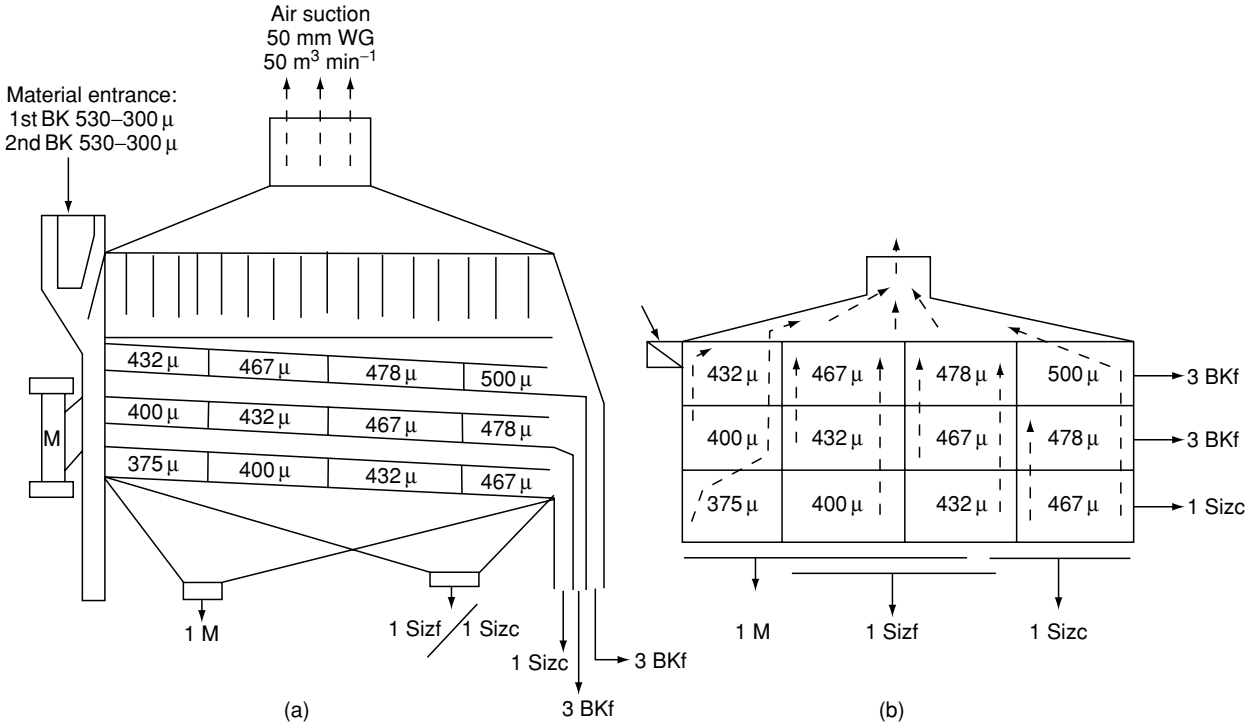

Figure 4 Schematic view of a purifier: (a) machine cross-section; (b) sieve arrangement. WG, water gauge; BK, break; M, middling; Sizc, coarse sizing; Sizf, fine sizing.

pure endosperm, which flow through the sieves, and the lighter ones of higher bran content, which tail over the sieves. The particles of pure endosperm will go through the sieves at the head-end of the machine, whereas the lighter ones will float over. Relatively pure endosperm particles of the head-end are sent to the reduction rollers for maximum production of flour. Tailover materials of the sieves are directed to sizing rollers or tail-end fine breaks.

Basically, the different stages of the process are grinding, sifting, separation, and regrinding, which are repeated again and again until the endosperm is reduced to an acceptable degree of fineness and no more flour can be separated from the bran (red dog fraction).

Each flour stream extracted under the sifter is of different quality, based on its origin within the kernel, equipment adjustment, and the stage in the milling process. The collected flours from under the sifter sections are mixed while transferred in screw conveyors (a screw conveyor uses a continuous helical attached to a drive shaft which runs the length of the conveyor) and sent to storage bins. Starting under the sifter, the miller is in position to blend those flour streams to the desired quality.

The miller also produces granular materials of relatively clean endosperm, which are coarser than flour. This type of product is called farina, when originated from hard or soft wheat, or semolina, when originated from durum wheat.

Experimental Milling

Experimental milling is an approach to determine milling quality of the wheat. The miller uses a small-scale system with which different settings can be tested to optimize the processing of the wheat in question. Results should reveal to the miller the relative expected performance of the wheat on the commercial mill. With the experimental milling system, the miller is in a position to learn about the separation of the bran, the disintegration of the endosperm, and characteristic qualities and quantities of the intermediate and final products from the wheat sample.

A milling system flowsheet, whether experimental or of a commercial unit, is the 'road map' of the process. The experimental milling flowsheet (Figure 5) describes the milling by indicating how, where, and what materials are distributed to the different machines and stages of the process. In a flowsheet, grinding rollers are designated by two adjacent circles. Some pairs are striped and some are clear, indicating corrugated and smooth rollers, respectively. A summary of roller characteristics in an experimental milling system is shown in Table 2. In the experimental milling process, after each

grinding stage, the material is sifted as a batch on a small-size sifter which includes a stack of sieves of different apertures.

Flour Handling and Control

Flour quality control is a very important function of the milling process. Flour color, starch damage, gluten denaturation, and particle size distribution can be affected by an uncontrolled milling operation. The quality of flour, if it is not affected by the milling process, is largely dependent on the quality of wheat used for grinding. For example, softer-structured wheat kernels with a lower protein level will generate less starch damage in the flour than vitreous kernels with higher protein content. The mill laboratory routinely checks different characteristics of raw materials and finished products to determine whether or not first, they meet specifications and second, there is any need to take appropriate measures in wheat blending or mill adjustments. The final adjustment of flour quality to customer needs is usually performed by the miller by blending different flours before shipping. In modern operations, batch-type mixers blend 3–5 t of different flours with optional additives in a few minutes before they are pneumatically transported to the customer's bulk truck. (*See* **Flour**: Analysis of Wheat Flours.)

To measure mill efficiency and control performance, the miller uses a variable called ash. Ash is the completely burned remains from a flour sample, or any other material from the process burned completely and expressed in percentages of the original weight. The pericarp and the aleurone layer, which technically end up in the bran, contain about six times more minerals than the inner endosperm. The percentage of ash residue from an intermediate material in the mill or the final flour will indicate the efficiency in separating the bran and germ from the endosperm. A comparison of flours cannot be based on ash if the flours are not milled from the same wheat.

In contrast to ash, which is mainly a parameter of the mill's technical efficiency, indicating the amount of bran in flour, color is a quality parameter, which is significant to the flour end user. Accurate wheat selection, blending, cleaning, conditioning, and mill

adjustment all affect the resulting color and baking characteristics of the flour.

Flours and other mill byproducts can be mechanically modified after the milling process to accentuate certain characteristics or qualities. One of those systems is air classification of flour. In the case of flour particle sizes ranging between 1 and 200 μm, sieving can be accomplished with sieves as fine as 75 μm. Below that size, the efficiency of sieving with a sieve becomes too low. It is of interest to the miller, in some cases, to separate endosperm particles below the range of 75 μm. It was determined that broken-down endosperm would end up with the fraction in the range of 1–17 μm, which contains a major part of the protein matrix in the endosperm. Particles in the range of 17–37 μm will contain different parts but, predominantly, whole starch granules. The usage of air to segregate between particles of endosperm below 75 μm is used in the flour-milling industry for two purposes – protein shifting and narrowing the range of particle size. The principles used in air classification are based on the differences in size, shape, and weight of particles, and the characteristic terminal or critical air velocities to segregate between them. Regrinding of flours on pin mills, before air classifying, separates more starch granules from the protein matrix and improves the efficiency of the system. (*See* **Air Classification**: Principles of Operation; Uses in the Food Industry.)

Important Landmarks in the Industry

The ancient milling process was very simple. Wheat was crushed between two stones, and then the pericarp was sifted out to a limited extent using reels. The reel is a rotating cylinder sieve, and a counterrotating internal rotor throws the product against the sieve to force the fine fraction through, while the coarse fraction tails over in the end. The same principle is currently applied in high performance sieves for hard-to-sieve materials in modern flour-milling systems. However, stone mills and reels are still assembled into commercial wheat mills to accommodate specific quality and taste demands.

Currently, machines are being built at a much better technical level than during the first half of the twentieth century. Up to four pairs of rollers are installed in one machine. High-precision bearings, better adjustable mechanisms, and higher velocities currently characterize mill machinery. The result has been a significant reduction in total roll length in the mill. Water cooling of the rollers has given the miller more flexibility in manufacturing desired final products.

In the past, silk screens were used to cover the sieve frames. Advances in synthetic threads replaced the silk with synthetic material inert to environmental conditions and with more stable sieve apertures.

In the 1980s, mill automation became the main concern of the industry, for control of the process as well as online monitoring of mill products.

During the 1990s a new approach to wheat flour milling technology was established in commercial mills, abrading and polishing off the bran layers before the grinding process. This approach causes a significant reduction in the number of grinding stages and roller length in the mill. The debranning process is responsible for an improvement in flour extraction and quality. The changes in flour quality can be attributed to the heat generated during the debranning stage of conditioned wheat.

One of the important mechanical means used in the process of flour milling is air as a tool in the process. In the modern milling industry, almost 10 times more air than wheat is moved through the operation. Pressure differences created by fans or blowers in pipes between two points and the movement of an air quantity at a certain velocity make it possibile to convey materials by air. The mill, which includes a large number of machines assembled on several floors, is an industrial unit in which intermediate products flow by gravity or are conveyed by air. Air also has a positive effect on the efficiency of machine performance and sanitation. Water evaporation off surfaces of particles improves sieving of the intermediate stocks in the mill.

Types of Mill and Their Uses

F Meuser, Technical University of Berlin, Berlin, Germany

Milling and Grinding

The term 'milling' covers a wide range of processes and businesses, including primarily the methods of processing cereal grains to flours and any other processing of metal, cloth, etc., to end products of the most diverse nature in plants or factories. The plants are very often described as mills. In the context of this article, the term 'milling' will mainly be limited to milling operations in the food industry. Emphasis will be laid on the milling of cereal grains and the grinding procedures used for this purpose. For this reason, it is necessary to differentiate between milling and grinding. Milling includes all operations which lead to defined end products, and grinding covers those processes which bring about a particle size reduction.

The grinding of cereal grains can be traced back to ancient times and is linked with some of the most important advances made by humankind which came about through the development of tools for this process. It all started with the use of stones to crush cereal grains (Figure 1). This type of crushing led to the development of the pestle and mortar, and other stamping tools. The next stage of development was to grind the grains under pressure between two stone slabs. This technique was the starting point for all modern milling processes as it opened up the possibility of being able to grind the various components selectively of the cereal grain. It had, of course, always been possible to use a sieve to separate the ground material from a pestle and mortar or stamping tool into a fine fraction containing mainly endosperm and a coarse fraction consisting principally of husk and bran. However, it was possible to achieve separation far more effectively for material obtained from grinding stones. The main disadvantage of oscillatorily moved grinding stones was that they could only be operated manually. The invention of the centrally holed grinding stone made it possible for the oscillatory grinding motion to be replaced by a circular one. This development meant that (1) the manual grinding performance could be increased considerably, and (2) the required work effort could be obtained at first from animals and later from wind and water energy.

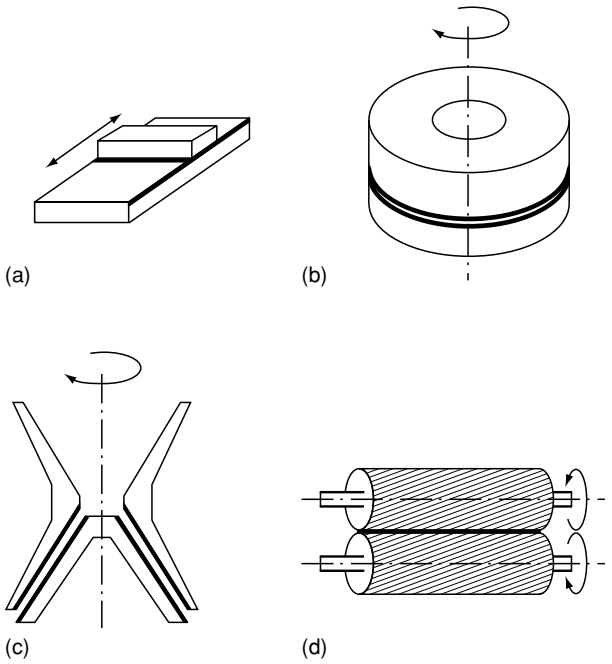

Figure 1 Historical development of grinding grain. (a) grinding slabs; (b) grinding stones; (c) grinding cones; (d) grinding rollers. Reproduced from Milling: Types of Mill and Their Uses, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The advantages of this development were that grinding could take place at a constant speed owing to the rotary motion of the stones, and that the latter provided a larger active surface area when compared with that of grinding stones. From the rotating grinding stone, the grinding cone was evolved, enabling the size of the grinding surface to be increased in comparison with that of the rotating grinding stones. However, flat milling stones again took the place of cone mills after the advent of power transmission by cogwheels, as these enabled wind and water energy to be used to drive the grinding stones. The resulting increase in available driving power was used mainly to boost the speed at which the grinding stones turned, thus improving the milling performance.

Grinding stones driven by wind and water power remained the most important means of grinding until the invention of the steam engine enabled the performance to be increased once more. This meant that grinding rollers (rolls), which had been invented centuries previously, could now be used for milling grain. The steam engine enabled two rollers to turn in opposite directions at speeds which – when the gap between them was multiplied by the distance covered by the surface of the roller – resulted in an acting surface comparable with that of a grinding stone. Grinding rollers had the advantage that they could be set according to the fineness of grinding required. This was a development of considerable importance when compared with the rather random degree of fineness obtained by using grinding stones, as the

grinding process could then be subdivided into any number of stages by altering the size of the gap between the rollers. Thus it became possible to combine grinding and grading stages in such a way that the endosperm could be separated almost entirely from the bran and the germ.

The operations described above, by which flour, the end product, is obtained and which consists of grinding cereal grain step by step, with interposed grading and sifting stages, are referred to as milling operations. These have assumed various forms as milling, sieving, and sifting technology has developed over the past 100 years. As the methods of sieving and sifting are described elsewhere in the *Encyclopedia*, only grinding – the theory behind it and the most important types of grinders (mills) used in the food industry – will be dealt with here. (*See* **Flour**: Roller Milling Operations.)

Grinding

Purpose and Aim

The purpose of grinding is to reduce a mass to a number of parts by the action of mechanical forces (energy). In the simplest case, the sole aim of the grinding actions is to achieve a size reduction. This applies, for example, to the grinding of masses which are homogeneous with regard to material and structure. The aim is to reduce the diameter of the mass concerned and increase its surface area. Size reductions can be carried out on solids (cereal grain, sugar, cocoa, spices), liquids (oil droplets in water), and gases (gas bubbles in liquids).

Grinding solid masses which are inhomogeneous in material and structure can result in a number of particles and groups of particles, the composition of which may differ considerably from the average composition of the original mass. One of the most important aims of grinding is to obtain particles of different sizes which can then be separated selectively by means of grading, sedimentation, and sifting. Essentially solid materials (cereal grain, oil seeds, spices) are first ground in preparation for these processing stages. It is the grinding of solid materials which will be dealt with in this article. (*See* **Ground Nut Oil; Palm Oil; Spices and Flavoring (Flavouring) Crops**: Fruits and Seeds; Leaf and Floral Structures; Tubers and Roots; **Vegetable Oils**: Oil Production and Processing.)

Range of Materials

The range of solid materials which may be ground covers both hard and soft materials (Table 1). In the food industry, it is mainly products up to 4 on the hardness scale which are subjected to grinding.

Table 1 Grinding classifications according to the hardness of the material to be ground

Hardness (Mohs scale)	*Material*
6–10	Quartz, cement
3–4	Salts, coal

Table 2 Grinding classifications according to the particle size of the ground material

Type of grinding	*Particle size of product (mm)*	*Surface area (m^2) of a mass of spherical particles with a volume of 1 m^3*
Crushing		
Coarse	> 50	< 120
Fine	5–50	120–1200
Grinding		
Coarse	0.5–5	1200–1.2×10^4
Fine	0.05–0.5	1.2×10^4–1.2×10^5
Ultrafine	0.005–0.05	1.2×10^5–1.2×10^6
Colloidal	< 0.005	> 1.2×10^6

Data from Zogg M (1987) *Einführung in die mechanische Verfahrenstechnik*, 2nd edn, pp. 13–76. Stuttgart: BG Teubner.

Grinding may also be broken down roughly into classes according to the particle size of the ground material (Table 2). Thus it is possible to distinguish among coarse crushing, fine crushing, coarse grinding, fine grinding, ultrafine grinding, and colloidal grinding. In relation to the volume per unit weight, the surface area of the particles increases as their diameter decreases when ground.

Grinding can take place either in a gaseous medium (air, gas, steam) or a liquid one (water, oil), giving rise to the terms dry and wet grinding (or milling). The type of grinding is selected in accordance with the desired result. Dry grinding is always preferable where dry end products (flour, cocoa, sugar) are required and where the products have to remain practically unaffected by the medium. Where grinding aims to separate out intermediate products, dry grinding has the disadvantage that it is impossible to set very high standards for the purity of the individual particles and groups of particles. In this case, wet grinding can meet far more stringent requirements as the medium can be used to refine the particles. (*See* **Cocoa**: Production, Products, and Use; **Sugar**: Refining of Sugarbeet and Sugarcane.)

Actions on the Material

The grinding process is influenced not only by the hardness of the material but also by its toughness,

inner tension, and surface structure. In addition to this, the heat capacity and conductivity of the material, the manner in which they vary according to temperature, and the type of mechanical action also affect grinding.

The material may be ground by subjecting it to various types of action. According to Rumpf, there are eight types of action which can be divided into four different groups (Figure 2):

1. Actions occurring between solid surfaces (compression, friction, shear stress, cutting) which can be either the surfaces of the grinding tools or those of an adjacent body. In both cases, the extent of the actions is limited either by the maximum amount of force which can be applied, or by the smallest gap which can be set between the surfaces of the grinding tools.
2. Actions occurring on contact with a single solid surface, which could be either that of a tool or of another particle. In this case, the actions are limited by the kinetic energy of the movement of the surfaces in relation to each other.
3. Action of the surrounding medium which results from the physical state of the medium, or from changes which occur within it.
4. Application of nonmechanical energy (electrical discharges). This type of action will not be given further consideration below.

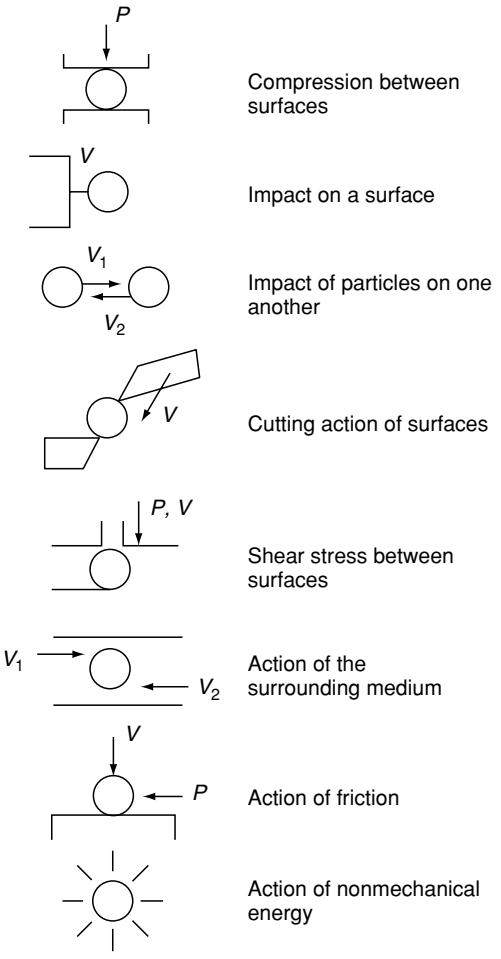

Figure 2 Types of grinding actions (according to Rumpf H (1954) Die Zerkleinerung unter besonderer Berücksichtigung lebensmitteltechnologischer Fragen I: Aufgabenstellungen. Zerkleinerungsaufgaben in der Lebensmittelindustrie. *Fette, Seifen, Anstrichmittel* 56: 404–408.

The various types of action are frequently combined during grinding operations carried out using grinding machinery. Many grinding machines are even designed to permit the combined application of several types of action. The best example of a machine of this type is the roller mill, in which compression and friction, as well as shear and cutting forces, are used in grinding.

The various types of action are combined in order to obtain the best possible grinding results. The aim is frequently to obtain a particular grinding result. Apart from the physical properties of the material and the type of action to which it is subjected, the degree of grinding also depends on the intensity of the action, which is limited by the type of grinding tool and the capacity of the material to absorb energy.

Grinding Result

The grinding result is a collection of particles which differ in size, shape, and surface structure. It is these distinctive features which provide the basis upon which the grinding result is assessed. They are determined by a variety of methods, of which those used to measure the particle size are of considerable importance. This may be determined as a function of the particular size range using various methods of analysis, for which special instruments exist (e.g., oscillating screen, air jet screen, sedimentation scales, optical particle spectrometer, laser diffraction spectrometer, image analyzer).

The methods of analysis yield different results for a single grinding result depending on the measuring technique used. Consequently, the assessment of the grinding result is affected by, amongst other things, the method by which particle size and particle size distribution are determined. Thus the choice of a particular method is always a compromise which must take account of the technical feasibility of the analyses on the one hand, and the conclusions to be drawn from the results on the other hand.

The means of measuring, e.g., in the case of the oscillating screen, are frequently smaller versions of actual sieving machines, so that it is possible to assess

the grinding results solely by analogy. In this case, the particle sizes are expressed in terms of a single linear dimension. The specific surface area of the material to be ground must, however, be determined where information on it is required for the purpose of calculating the energy needed for grinding, or in order to obtain data on those physical properties of the particles which are related to size and surface structure. It is usually obtained after first determining the particle size and is generally an approximate value. The calculation includes shape factors determined in separate tests.

Graphical Representation of Particle Size Distributions

Ground materials, such as flours, are frequently composed of particles of various sizes which cover a range of values extending over several orders of magnitude. The frequency with which particles of any one particular size occur as a result of grinding is random and follows no universally applicable distribution law. However, it is possible to describe the particle size distributions of many ground materials by means of empirically established function equations which provide a reasonable match with experimental size distribution data. A frequently used volume (mass) distribution function is the Rosin–Rammler–Sperling–Bennet (RRSB) function which describes skewed distributions of particle sizes, especially those of finely ground materials and dusts where significant quantities of particles exist above and below a predominant size.

The RRSB function may be expressed as follows:

$$F(d) = 1 - R(d) = 1 - \exp\left[-(d/d')^n\right] \qquad (1)$$

In this equation, $F(d)$ is the cumulative weight of particles passing size d, and $R(d)$ the cumulative weight of particles coarser than size d. The equation can be inverted as follows:

$$\begin{aligned}\log\log\{1/[1 - F(d)]\} &= n\log d - n\log d' + \log\log e \\ &= n\log d + \text{const.}\end{aligned} \qquad (2)$$

When this equation is applicable, a straight line, the RRSB line, results if $\log\log[1/(1-F)]$ is plotted versus $\log d$. The RRSB line is determined by the slope n (spread parameter) and the abscissa d' of the point at which $d = d'$. Where $d = d'$, $F(d) = 1 - e^{-1} = 0.632$ so that d' (position parameter) is the diameter of either the throughput of $0.632 = 63.2\%$ or the residue of $0.368 = 36.8\%$. The diameter is to be found at a point vertically below that at which the RRSB line intersects the parallel line at a distance $F = (0.632)$ from the abscissa. The slope of the RRSB line can be read from the specially devised scale at the side of the grid by parallel displacement of the line through the pole of the system of coordinates (Figure 3).

Determination of the Specific Surface Area of Particle Size Distributions

The graphical representation of particle size distributions, such as those according to the RRSB function, can also be used to obtain an approximate value of the specific surface area. To illustrate this, an approximation formula was developed for spherical particles:

$$S_m = (6.39/\rho\, d')\, \exp\,(1.795/n^2)\left(\mathrm{m^2\,kg^{-1}}\right) \qquad (3)$$

S_m ($\mathrm{m^2\ kg^{-1}}$) is the surface area as a function of the mass, and ρ ($\mathrm{kg\ m^{-3}}$) is the density of the mass.

As the specific surface area of a mass of spherical particles is, apart from the density, dependent only upon the spread parameter (n) which characterizes the RRSB line and the position parameter (d'), it is possible to place a scale at the side of the RRSB grid with which the specific surface area can be calculated as a function of the volume.

In Figure 3, the dimensionless characteristic value $S_v\, d'/\phi$ is given in the scale at the side of the grid. In this characteristic value, ϕ represents a form factor with which the deviation of the particles from the spherical form is taken into account. Nonspherical particles have larger surface areas than spherical ones and the form factors of these are therefore greater than 1. For example, the form factors for ground wheat, rye, barley, and oats are 1.2, 1.3, 1.5, and 1.8 respectively. (*See* **Barley**; **Oats**; **Rye**; **Wheat**: The Crop; Grain Structure of Wheat and Wheat-based Products.)

Using the outer scale at the side of the grid, the surface area is calculated by moving the RRSB line from the position parameter d' to the pole, keeping it parallel to its original position. The point at which the RRSB line intersects the outer scale is the characteristic value of the position and spread parameters. The specific surface area as a function of the volume S_v ($\mathrm{m^2\ m^{-3}}$) is determined by dividing the characteristic value obtained by the position parameter d' and then multiplying it by the form factor ϕ. The value thus obtained can be related to the mass by inserting the density (ρ):

$$S_m = S_v/\rho \quad \left(\mathrm{m^2\,kg^{-1}}\right) \qquad (4)$$

It should be pointed out that the data for the specific surface area thus obtained may frequently differ considerably from those determined by other methods

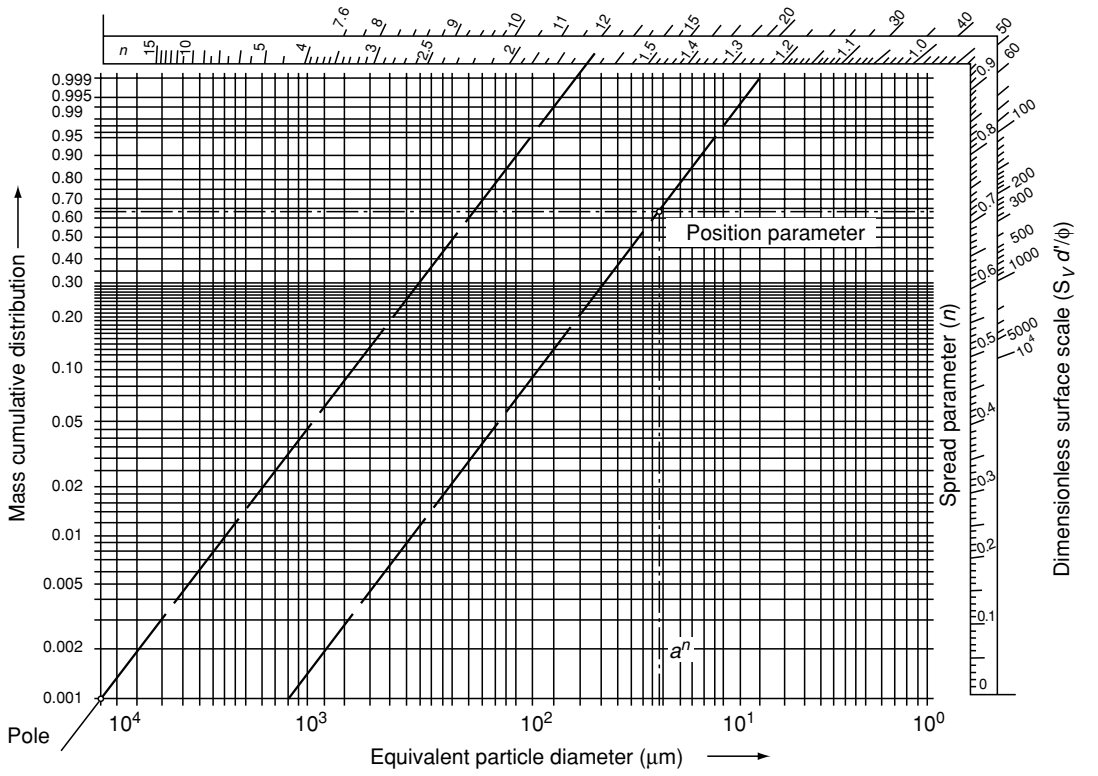

Figure 3 Graphical representation of particle size distribution, according to the Rosin–Rammler–Sperling–Bennet (RRSB) grid. Reproduced from Milling: Types of Mill and Their Uses, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

(e.g., adsorption and permeability methods). The values for specific areas obtained by calculation are therefore frequently of limited value only.

Energy Required for Grinding

Grinding requires energy which has to be applied to the material to be ground by means of tools. Part of the work applied is used to drive the tools and only the remaining, often much smaller part is used in the grinding process itself. Several equations have been developed to estimate the amount of energy required, based on different concepts of the grinding process. All formulae are based on model concepts in which it is assumed that separate particles are to be ground. They are therefore founded upon very rough simplifications compared with the actual grinding processes which take place in grinders. Thus the formulae yield results which are of value in certain areas of grinding only. For example, the energy required for grinding according to Rittinger's law is proportional to the sum of the newly created surfaces, irrespective of the type of mechanical action (tension, compression, shear stress).

Rittinger's law obeys the following function equation in which K_R is a proportionality factor (Rittinger's constant) which depends on the material and the grinder. Given the same material and grinder, it is independent of the degree of grinding. D_0 is the grain diameter prior to grinding and D_n the grain diameter after grinding. Rittinger's law is mainly used to estimate the energy A_R required to grind either fine or brittle materials.

$$A_R = K_R(1/D_n) - (1/D_0) \qquad (5)$$

By contrast, Kick's grinding law states that the energy A_K required for grinding consists entirely of the elastic and residual deformation of the particles to be ground, this energy being proportional to their volume. The function equation is written as follows:

$$A_K = K_K \log(D_0/D_n) \qquad (6)$$

K_K is also a proportionality factor (Kick's constant). Kick's law applies above all to coarse materials with fewer brittle and more elastic characteristics. In practice, however, it is impossible to obtain an exact result for the energy required for grinding by means of these formulae as it is influenced by too many factors, including the design of the grinder and its mode of operation. Neither is it possible to calculate the energy required from the particle size distributions before and after grinding or from

the mechanical strength of the material to be ground, as a considerable part of the energy applied is used not for grinding but for moving the material, or is absorbed by the material which has already been ground.

Grinders (or Mills) Used in the Food Industry

In view of the requirements which ground material has to meet and the large number of materials which must be ground to produce foodstuffs and similar goods, the differences in shape, size, composition, and strength characteristics have led to the development of grinders (or mills), the design of which is the result of the type of grinding operation to be performed. The grinders operate by applying compressive, shear, frictional, and cutting forces or, as is frequently the case, various combinations thereof can be applied to the material to be ground either simultaneously or consecutively, depending on the design of the grinder.

The application of mechanical energy to the material being ground can lead to the latter heating up considerably. The grinder parts are also heated by the energy conversion. Where the design and action of a grinder cannot contribute adequately both to dissipating the heat produced in the material in order to preserve its quality and to keeping the operating temperature of the machine within tolerable limits, it is necessary to cool the grinding tools, as a result of which the material is also cooled.

Coolant may therefore be pumped through the grinding tools and the surrounding sections of the housing. The rollers of roller mills or the rotor and stator of stirrer bead mills, for example, may be cooled in this way. In impact mills, the material being ground can be cooled by increasing the air flow through the impellers attached to the shaft of the mill.

Specially constructed impact mills, which are equipped with heat exchangers, enable the transfer of evaporable mass from the material being ground to the airstream. Thus a specific exchange of heat and mass occurs, during which the material being ground is dried. The machines in which grinding and drying take place simultaneously are referred to as drier-mills.

A few important examples of mills used in the food industry to process raw materials in order to obtain specific ground materials are described below. They have been selected in order to illustrate the most important principles of grinding and their applications by means of concrete examples. Hence the list of mills is not exhaustive, either with regard to the grinding principles or the design of the mills.

The majority of mills work continuously. The material to be ground is fed into them by means of conveyor equipment. The grinding of materials in air or gas is referred to as dry grinding (or milling) and that of suspensions as wet grinding (or milling). Some of the mills described below are designed to be operated in both dry and wet milling.

Roller Mills

Roller mills are used both for solely grinding and for selectively grinding and milling particles of granular shape. Their most important application is the selective grinding of cereal grain. In addition to this, roller mills are also used for fine grinding of cocoa and spices.

The great advantage of milling cereal grains by means of grinding rollers is that the process can be subdivided into many stages, the grinding forces acting on the material only once at each stage. A further advantage is that the mills can be set according to the material to be ground and the required grinding process, because not only can the distance between the rollers be freely selected, but also their diameter, surface structure, the speed at which they turn, and the differential speed.

Roller mills consist of a housing in which, as a general rule, several pairs of rollers in bearing rings are placed on either side on sliding bearings or on self-aligning roller bearings. Figure 4 shows a modern roller mill with four horizontal pairs of rollers which are used to grind cereal grains. The material to be ground is fed into the machine by two feed rollers which are located above the two upper pairs. The ground product passes, without sifting, directly from the upper pairs to the two lower pairs of rollers, where it is subjected to further coarse or fine grinding. In order to improve the supply of material to the grinding rollers, the machine is equipped with a fan to extract the air from the gap between the rollers. The latter can be set automatically, the automatic setting device being connected to a computer in which the optimum roller gap settings for all grinding phases of a grinding diagram are stored, thus insuring the maximum flour production for any given cereal or mixture of cereals.

The rollers of roller mills are driven by flat belts or, in the case of single rollers, by fan belts. The different roller speeds are produced by a cogwheel or chain drive. Driving the rollers by chains or stepped gears enables the distance between the axes of the pairs of rollers to be adjusted without changing the transmission wheels.

The rollers are made of centrifugally cast, chilled cast iron which is extremely dense and wear-resistant.

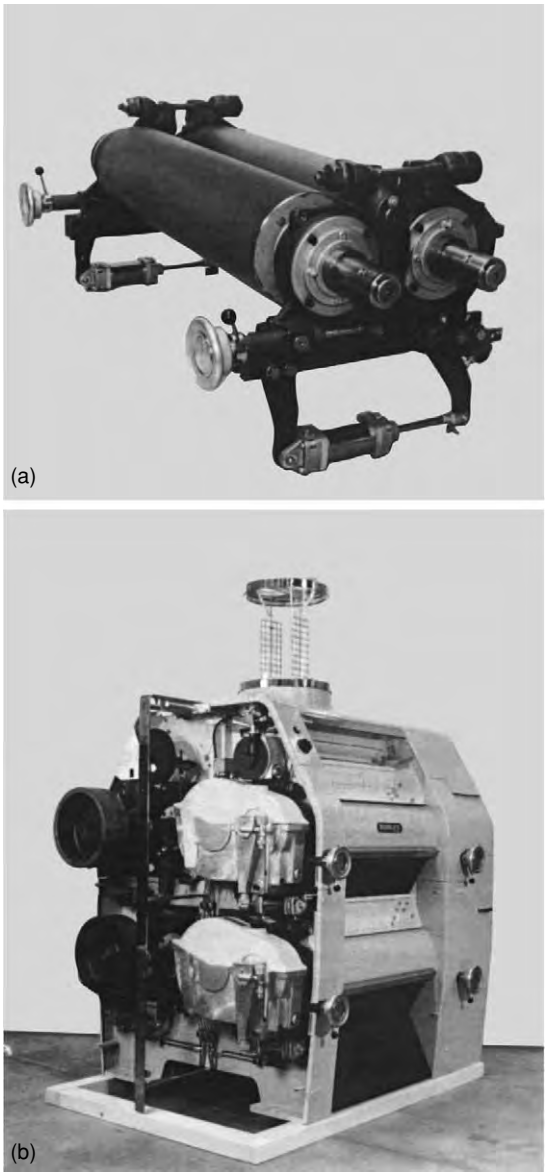

Figure 4 Roller mills: (a) pair of rollers; (b) eight-roller mill. Courtesy of Bühler AG, Uzwil, Switzerland.

Depending on the hardness of the cast iron, the rollers are either ground or corrugated by machine to produce either smooth or corrugated rollers.

The rollers, which are standardized, have a diameter of 220–315 mm, and a length of 315–1500 mm, and can be machined several times. They may also be made of porcelain. This type of roller has a working surface which comprises a porcelain sleeve with a wall thickness of approximately 50 mm. They are 220–350 mm in diameter and can be up to 1000 mm in length.

The grinding rollers can heat up considerably owing to the production of heat caused by friction, rendering it difficult to set the gap to a fixed distance, especially when subjected to a high degree of wear. As this can have a negative effect on the grinding result, water-cooled grinding rollers have been developed which are cooled by pumping water over the shaft through the hollow rollers. Cooling increases the specific grinding performance and leads to a more even grinding result.

As it is possible to change the working parameters, the material can be ground between the rollers by compressive, shear, and cutting forces. The length of time during which these forces act on the material depends on the radius of curvature and the absolute circumferential speed of the rollers as well as on the ratio between the gap between the rollers and the size of the material to be ground. In order for the material to be fed into the gap, the feed angle must be smaller than the angle of friction. This means that the ratio between the diameter of the rollers and that of the material must be large. The larger the diameter of the rollers, the slower the circumferential speed and the smaller the gap selected, the greater the forces acting on the material will be. The forces are limited by the hardness of the material being ground and its fracture.

Compressive forces only act on the material where the circumferential speed of the rollers is the same and the surface of the rollers is smooth. This results in the product being ground by being deformed to rolled plate-like particles, especially in the case of soft products such as cocoa. By comparison, different roller speeds give rise to shear forces which, combined with a corrugated surface and the finite distance between the rollers, results in a slicing action. This type of grinding occurs above all during the sharp-to-sharp grinding action of the corrugations, while the dull-to-dull grinding action grinds the product mainly by compression. Grinding predominantly follows the product's own fracture which can be deduced from its natural structure.

This is the case, for example, when grinding many types of cereal grains: the particle size distributions of the ground products exhibit characteristic differences which depend on the hardness of the material. Where the dull-to-dull grinding action of the corrugations is applied, it is possible to guide the grinding result towards the RRSB function. Combined with the slicing action of the rollers, it is also possible to impose a characteristic distribution deviating from the RRSB function on to the particle size of the ground product. The range of particle sizes and the shape of each particle are also influenced to a large extent by the design of the corrugations.

The corrugations are shown in section in Figure 5. The angle of the corrugations is composed of the cutting angle (α) and the rear angle (β). The slope of

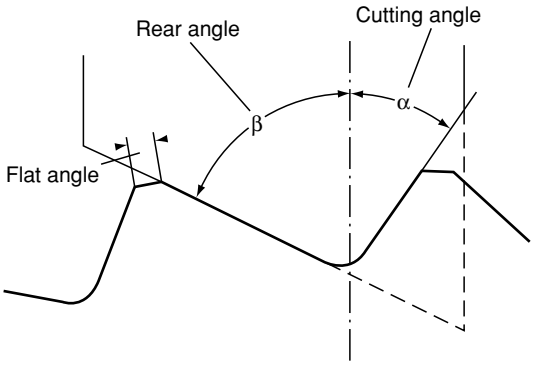

Figure 5 Corrugation of a grinding roller.

the corrugations, which runs parallel to the axis of the roller, is referred to as the twist. The cutting and rear angles, together with the position of the corrugations, and the absolute speed of the surface of the roller casing determine the efficiency of the grinding process. Where the cutting angle is small, the cutting effect of the corrugations predominates, favoring the production of grits. A larger cutting angle causes the material to be crushed instead, resulting in the production of flour.

The size of the cutting angle ranges from 15° to 45° and that of the rear angle from 60° to 75°, so that the angle of the corrugation usually lies in the region of 90–115°. The size of the slope of the corrugations, measured at the circumference, may range from 20 to 300 mm, given a twist of 5–20% with a roller length of between 400 and 1500 mm, for example. The flat angles of the corrugations have a lateral length of 0.05–0.30 mm, measured in the direction of the circumference of the roller. The depth of the corrugations (h) can be calculated using the formula given below, ignoring the fact that the root of the corrugation is rounded:

$$h = (T - S)/(\tan\alpha + \tan\beta) \qquad (7)$$

The efficiency of the roller mills depends on the amount of material fed on to the rollers, the type of corrugations, and the differential speed of the rollers as a function of the circumferential speed. The amount of material processed is limited by the air cushion which forms over the rollers owing to the parameters referred to above. The air cushion is therefore frequently reduced by means of special feed mechanisms in order to increase efficiency, either by compacting the material to be ground, for example, or by drawing off the air above the gap.

The differential speed can be as high as 1:15, depending on the product. For this ratio, the driven roller, which has a fixed position, is reduced to the circumferential speed of the movable roller. The upper limit of the circumferential speed is in the region of $6\,m\,s^{-1}$. For example, corrugated and smooth rollers with a standard diameter have a circumferential speed of $3.3–4.4\,m\,s^{-1}$ when grinding wheat and rye at a speed of 250–360 rpm.

Hammer Mills

Hammer mills are mainly used for coarse grinding of brittle and fibrous materials. The material is ground by beating, during which it may be partly broken down into its constituents. The disintegration of the material often serves to prepare it for subsequent processing stages, such as separating the constituents by sieving, squeezing, and extraction.

The mills consist of a rotor with suspended hammers which swing freely and which are then forced upwards and outwards radially by centrifugal force. The hammers strike a sieve casing fitted with impact ribs. The material, which is fed into the machine tangentially from above, is crushed by impact and rebound forces and expelled through the sieve casing. The fineness of grinding depends on the size of the sieve perforations, the circumferential speed, the number and width of the hammers, and the throughput.

Beater Mills

The structure of beater mills is similar to that of hammer mills. Their rotors are equipped with rigid ribs, plates, or arms, arranged in the shape of either a cross or a star. Such mills are suitable for finely grinding spices, for example. They may also operate as wet-milling colloidal mills, in which part of the energy used in grinding is applied by imploding cavitation bubbles which form on the backs of the rotor parts.

Slicing Mills

Slicing mills are mainly used to grind products which are resistant to compression, impact, and friction, such as fruits and vegetables. The rotors of slicing mills are fitted with removable blades with strike blades attached to the housing and a sieve casing. The knives slice the material which is fed into the mill from above, after which it passes through the slits in the sieve casing. The material is ground as a result of the shear stress which builds up between the stationary and rotating blades.

Toothed Disk Mills

Toothed disk mills are used for fine dry- or wet-grinding of soft, nonadhesive materials. They comprise

Figure 6 Toothed disk mill. Courtesy of Dorr-Oliver Deutschland GmbH, Grevenbroich, Germany.

a housing containing a stator and a rotor (Figure 6). The material to be ground is fed into the mill through an opening in the centre of the stator and falls on to the rotor. It is then transported by shear, compressive, and frictional forces through the teeth arranged in rows on the disk from the center to the outer rim, being ground in the process. The ground material passes into a collecting ring, from which it is transported into a radial outlet. The final fineness of the ground material is determined by the distance between the axes of the disks, the profile of the grinding tools, and the speed.

Pinned Disk Mills

Pinned disk mills are used to grind either oily materials or moderately hard to soft materials which are dry or contain little moisture. They comprise a housing containing a rotor and a stator, both of which are fitted with removable pins arranged in concentric circles such that they engage the opposite spaces. The material to be ground is fed into the mill through the center of the stator, falling on to the rotor. The radially increasing circumferential speed causes the rotor pins to press the material at high speed through the rows of pins, grinding it in the process by impact and rebound. The final fineness of the ground material depends on the distribution and shape of the pins, the circumferential speed of the rotors, the throughput, and the strength characteristics of the material.

Pinned disk mills may be used as either dry or wet mills. They are employed as wet mills in starch extraction, for example, where steeped maize is ground in order to remove the germ by disintegrating the maize kernels.

Underrunner Disk Huller

The underrunner disk huller is a corundum stone disk mill. It is used above all for dehulling rather than grinding, serving as the main huller in rice mills to separate the husk from the rice kernel. Other cereal grains and leguminous seeds, such as beans, peas, or lentils, may also be dehulled using this machine. (*See* **Legumes**: Legumes in the Diet; **Peas and Lentils**.)

The huller consists of a stator disk located above a rotor disk, both of which have abrasive coverings of corundum stone. The hulling process and its effectiveness are the result of the grains being rubbed between the disks and the distance between them. The grains describe a curved path between the disks, passing from the central opening to the outer rims. The disks are surrounded by a casing which is completely closed.

Stirrer Bead Mills

Stirrer bead mills are employed predominantly in the chocolate and confectionery industry, although they may also be used in the delicatessen industry. They are used for fine grinding (1–50 μm) of raw cocoa and chocolate, as well as in the production of peanut and hazelnut fillings and in the manufacture of mustard. (*See* **Mustard and Condiment Products**.)

Stirrer bead mills comprise a cylindrical or conical rotor body which moves in a corresponding stator body. In the example illustrated (Figure 7), a gap (2–25 mm) is formed between the conical rotor and the stator, and in this gap the beads move radially outwards from the centre. The material is thus ground uniformly, resulting in a close particle size distribution. The geometry of the grinding space insures that every single grain in the suspension passes

Figure 7 Coball mill. Courtesy of FRYMA-Maschinen AG, Rheinfelden, Switzerland.

along the prescribed path through the grinding /element. The suspension is fed into the mill through a central inlet and discharged through an outlet attachment near the shaft, the beads being separated from the ground material at the same time.

A large number of different settings is possible for this mill, depending on the fineness of grinding required, as not only the rotor speed may be freely selected but also the width of the gap between rotor and stator, the number of beads, the material of which they are made (glass, steel, ceramic, etc.), their diameter, and the rate of flow of the suspension. The rotor, stator, and cover of the mill can be cooled so that it is possible to maintain the suspension at a moderate temperature.

Drier-Mills

Among the mills which simultaneously grind and dry, particular attention is drawn here to one which is frequently used in the food industry, both as a grinder and as a drier-mill. It is known as the Ultra-Rotor mill and is used for fine grinding of materials such as starch derivatives, guar, and stearates. Furthermore, it is also employed in the selective grinding of various cereals which, when combined with subsequent sieving or sifting, serves to separate the endosperm fraction from the bran. As a drier-mill,

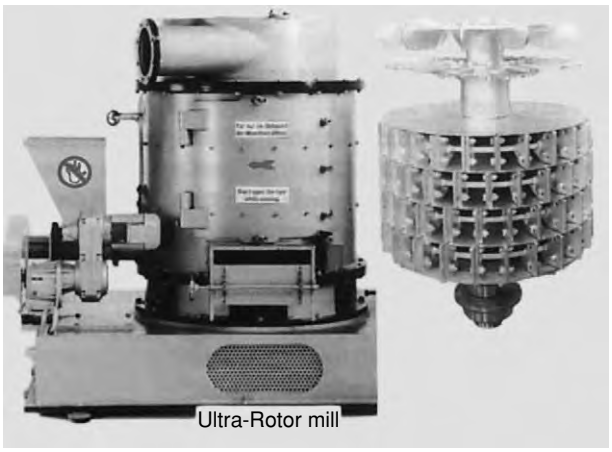

Figure 8 Drier-mill. Courtesy of Altenburger Maschinen, Jäckering GmbH, Hamm, Germany.

it is used above all in wheat starch plants to dry wheat gluten.

The mill consists of a specially designed rotor (Figure 8) mounted vertically in a housing which acts as a stator and is equipped with a removable corrugated inner casing. A fan disk is attached to each end of the rotor shaft. Disk-shaped grinding tools, arranged in a radial pattern, are fitted to plates between the fan disks. A second disk, on to which rod-shaped metal parts are screwed, is located below the upper fan disk. Between rotor and stator there is a narrow gap, through which the material to be ground passes at high speed.

The material is fed into the machine through an inlet in the wall of the housing at the level of the lowest grinding disk, being drawn into the grinding zone by the air stream produced there. The rotation of the rotor causes strong eddies of air to form in the chamberlike grinding tools which, together with the impact of the particles on the walls of the grinding tools and the stator casing, grind the material. Owing to the high throughput of air, a large part of the heat produced in the material during grinding is expelled with the air.

After leaving the grinding zone, the ground material passes into the space between the disk fitted with metal rods and the upper fan disk. The impact of the material on the rods produces a sifting effect. The rods cause the coarser particles to concentrate in the proximity of the wall of the housing, from which they are extracted through an adjustable opening placed at a tangent, and then recycled. The finer particles leave the mill as a finished ground product, being collected separately after passing through a sieve and subsequently through filters. The mill can be used to advantage to dry the ground material owing to the way in which the air flows and

the type of grinding. Only the air stream requires heating. This is best carried out by means of an interposed heat exchanger. The formation of eddies of air and the considerable increase in the surface area owing to grinding result in an intensive exchange of material and heat, so that the air outlet temperature does not need to exceed 70 °C even where the air inlet temperature is as high as 400 °C. The temperature of the product is normally in the range of 40–50 °C and the limiting dew point temperature is in the region of 38–45 °C. The thermal efficiency of the mill is approximately 90%. The average heat consumption for simultaneous grinding and drying is about 2800–3000 kJ kg^{-1} of evaporated water.

Characteristics of Milled Products

E S Posner, ESP International, Savyon, Israel

Background

The quality and characteristics of commercial mill products are a matter of geography and are set in commercial mills based on end users' expected demands. In addition to quality characteristics, specifications may include notes stating that products are untreated with chemicals during production, free from foreign matters, rancidity and/or other alimentary substances, suitable for human consumption and free from dead or alive insects in any developing stages. Nomenclature of wheat products such as 'All-Purpose Flour,' 'Type 00,' or 'Type 812' creates confusion, especially in a global trading environment. An international effort is required to set guidelines for wheat mill product specifications. In many cases, the flours originate from mixes of different kinds of wheat or blends of flours after processing. Following the description of the different wheat products, quality variables of products and milling methods that control the characteristics are dealt with.

Mill Products Description

Figure 1 shows a schematic diagram exemplifying products from a flour mill and their proximate analysis. Products in this case are referred to in typical USA nomenclature.

Flour Types from Milling Operations

Straight-grade flour This denotes all the flour streams generated in the mill combined to one final product. Depending on the wheat kind and mill design, in general, straight-grade flour would have a protein content about 1% below that of the wheat.

All-purpose flour This is medium-protein wheat flour made from hard wheat or a combination of soft and hard wheat. All-purpose flour is used mainly for a wide range of household baked products. The color and gluten characteristics are the important variables.

Patent flour This is the blend of flour streams from the front head of the mill. It is low in ash and protein, with a good color that is considered highest in economical value. Various blends of flour are named patent such as 'top patent' or 'baker's patent,' etc. They differ in the amount of clear or tail end streams that they contain.

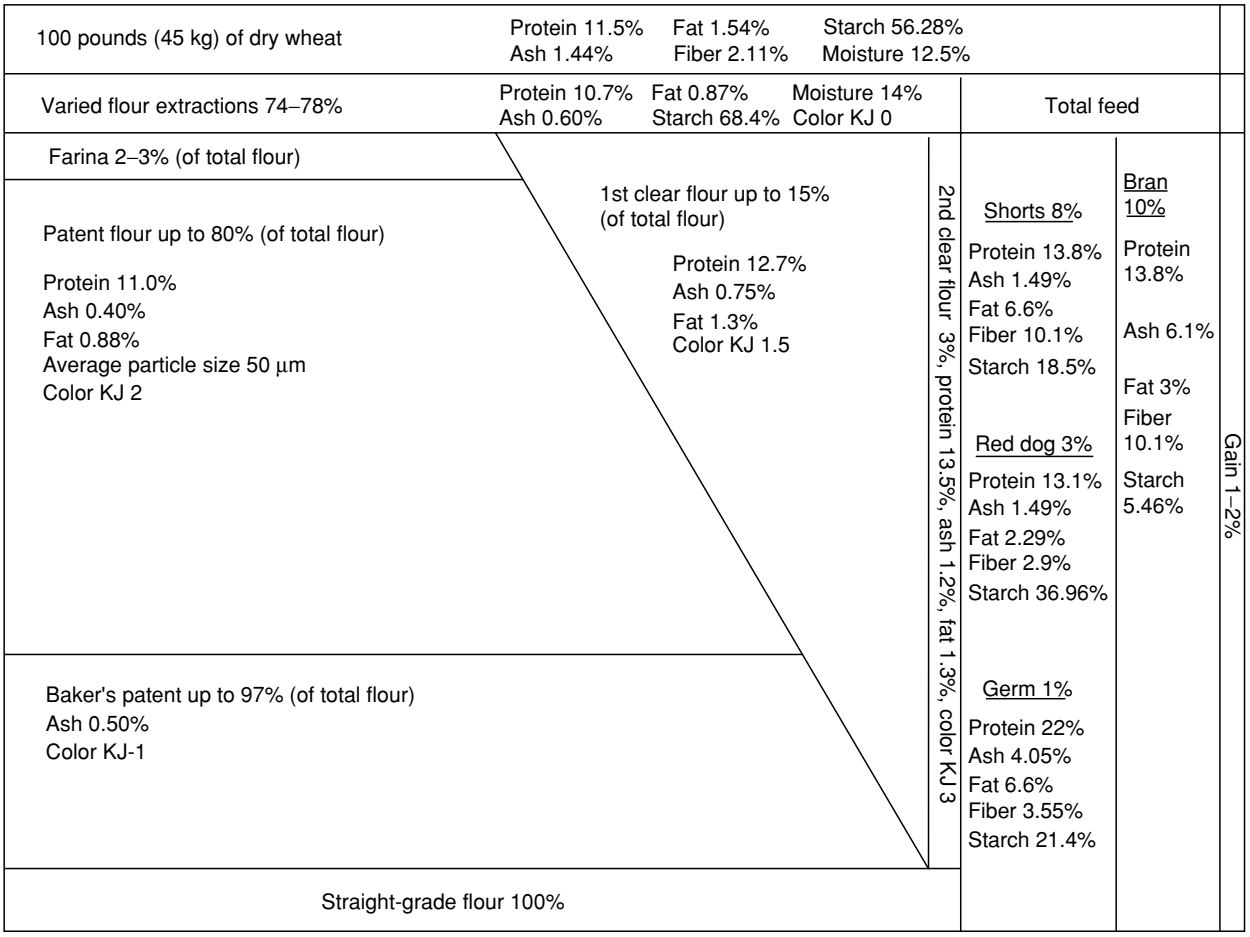

Figure 1 Products from a typical wheat-milling system. Adapted from Posner ES (2000) Wheat. In: Kulp K and Ponte JG, Jr. (eds) *Handbook of Cereal Science and Technology*. New York: Marcel Dekker, with permission.

Clear flour The portion of flour streams remaining after patent flour has been taken off. Clear flour normally contains a higher amount of bran particles, ash, and protein than patent and economically is secondary in value. The miller can produce more than one clear by further dividing the tail end flour streams.

Farina Regulations by the US Food and Drug Administration (FDA) define farina as a coarse granular separation of endosperm material extracted from wheat other than durum wheat and red durum wheat. Farina passes though a 841-μm (No. 20 US Standard) sieve, but no more than 3% passes through a 150-μm (No. 100 US Standard) sieve. It is separated from the bran coat, or bran coat and germ, to such an extent that the percentage of ash therein, calculated to a moisture free basis, is no more than 0.6%. Its moisture content is no more than 15%.

Semolina Semolina is defined in a similar way to farina, except that it is made only of durum wheat, and its maximum dry ash content is 0.92%. Durum wheat semolina is used for the production of pasta products. Coarse durum semolina, preferably between 550 and 1100 μm is used for the production of couscous, which is consumed mainly in North Africa. Semolina extraction can be up to 72% of the wheat kernel.

Durum flour Durum flour particles are such that 98% passes through a 212-μm (No. 70 USA) sieve. It is separated from the bran coat, or bran coat and germ, to such an extent that the percentage of ash therein, calculated on a moisture-free basis, is no more than 1.5%, and its moisture content is no more than 15%. 'Durum patent flour' is the re-ground semolina. 'Durum first clear flour' is Kaan, defined by the FDA as the through of a 150 μm (No. 100 USA) sieve. 'Durum second clear flour' is made during the milling of semolina, has a high amount of ash, is 'specky,' and has a dull color. It is used in the manufacture of pet foods. 'Durum granulars' is a combination of durum

semolina and durum flour containing no more than 15% durum flour. The ash content is normally about 0.72%. It is sometimes used as a substitute for durum semolina.

Atta flour This is high-extraction (92%) ground material from wheat, and is used mainly in the Indian subcontinent for baking chappati. The high degree of extraction leads to a darker shade and a maximum ash value of 2.0% (d.b.).

Wholewheat flour Wholewheat flour, also named 'Graham flour,' is a product that includes the endosperm, germ, and bran from cleaned kernels. The FDA indicates that 90% of ground wholewheat should pass through a 2.38-mm (No. 8 US Standard) sieve and no less than 50% through an 841-μm (No. 20 US Standard) sieve. Bran particles in the meal should pass through a 1.191-mm (3/64″) screen. However, meal granulation is subject to customer demand and depends on the grinding system. The product is used in some cases in different ratios with white flour. The bran particles in the meal interfere with the gluten structure of the dough causing a reduction in baked volume. Usually, to achieve an acceptable baked product from wholewheat flour, vital wheat gluten is added to improve the baking performance. The inclusion of the germ in the product limits its storability period.

Byproduct Characteristics

Mill products that do not coincide with flour are considered by the miller as byproducts and are usually diverted to feed. The total byproducts from the mill are named 'Mill Run' or 'Wheatfeed.' Different combinations of mill byproduct exist in the trade and vary in name and analysis. Proximate values of feed products are shown in Table 1.

Middlings These consist of fine particles of wheat bran, wheat shorts, wheat germ, wheat flour, and some of the offal from the tail of the mill.

Bran Bran consists of coarse outer layers of the wheat kernel. Large pieces of bran remain after the flour has been extracted from the wheat.

Shorts Shorts is a mixture of fine bran, endosperm, and some germ fragments that remain after flour extraction has been completed and used for animal feed.

Red dog This is a mixture of endosperm and bran powder, taken from the tail of the mill, that has a high ash and protein content, poor dress, and is dark in color. It is a product intermediate between a low-grade flour and feed.

Wheat germ products The germ of the wheat kernel consists of two parts, the scutellum and the embryo. The scutellum is softer (with a fat content of about 32%), and the embryo is relatively loosely attached to the scutellum and covered with the pericarp. In general, it is the embryo that is referred to in the trade as wheat germ. The 'wheat germ meal' consists of embryo together with some bran and shorts, and contains at least 25% protein. 'Pure wheat germ' is used for human consumption and contains at least 30% protein.

Effect of Wheat as the Raw Material

Flour quality depends about 75% on the quality of the raw wheat and about 25% on mill design procedures and adjustment. The different wheat kinds vary in the level of protein characteristics, which are mainly related to the quantity and quality of insoluble protein that forms the gluten. Wheat kernels vary in terms of the color of the pericarp. Accordingly, white wheat has an advantage over red wheat by allowing a higher flour extraction with a comparable color. Figure 2 shows the relation between wheat qualities of flours and their usage for different end products.

The objective of the milling process is to reduce the wheat kernel and deliver different products of consistent quality to bakers or other end users. To achieve this objective, the miller mixes wheat and blends final flours with particular specifications in mind. The reason is that wheat quality in commerce changes continuously as a result of variety, soil, and climate. Even in areas where only the local wheat is used by a mill, the miller adjusts the quality by mixing.

Table 1 Proximate analysis of mill feed products

Product	*Minimum protein (%)*	*Minimum fat (%)*	*Maximum fiber (%)*	*Maximum moisture (%)*	*Maximum ash (%)*	*kg m^{-3}*
Middlings	13.0	3.0	9.5	14.0	4.2	288–400
Bran	14.0	2.5	12.0	14.0	6.0	256
Shorts	13.0	3.0	7.0	14.0	4.1	160–256
Red dog	15.0	3.0	4.0	14.0	1.64–2.85	352–448

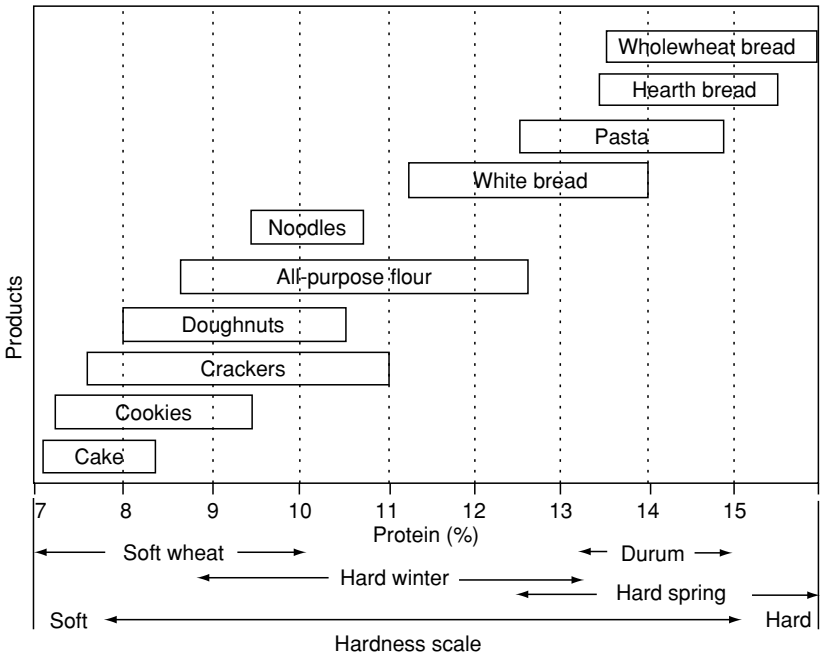

Figure 2 Schematic diagram of relationship between percentages of wheat protein, wheat type, hardness, and end-product utilization. Adapted from Posner ES (2000) Wheat. In: Kulp K and Ponte JG, Jr. (eds) *Handbook of Cereal Science and Technology*. New York: Marcel Dekker, with permission.

Definitions of Wheat Product Variables

The following explanation of milled wheat product variables that affect characteristics are arranged in alphabetical order. Different official methods and instruments exist to measure flour and other mill products. Flour analysis allows an approximation of the determined values. Flours with the same analysis have been found to show different baking characteristics or end-use performance. The interaction of a few or more characteristics, rather than one alone, affects the end-use qualities. (*See* **Wheat**: Grain Structure of Wheat and Wheat-based Products.)

Ash

Ash, or the mineral content of the wheat or its product, is determined by incinerating the sample and expressing the residue as a percentage of the original sample. The ash content of the wholewheat kernel depends on the wheat variety as well as the soil, irrigating water, and growing conditions. However, erroneously, flour ash is considered as a grading factor by some in the industry. A better expression of milling performance is where the whole kernel ash is considered. Accordingly, ash values of the wheat kernel products should not be taken as absolute numbers but expressed as a ratio of flour ash divided by wheat ash (FA/WA).

Where ash is considered as grading factor types 405, 550, 630, 812, and 1050, the ash range for each grade is quite wide. For example, flour could be considered as type 550 when the flour's ash content is between 0.490 and 0.580% (d.b.). Under regulations in the USA, the ash content added to flours as iron, or salts of irons, or calcium is excluded in calculating the ash of the shipped flour.

Baking Quality

The baking quality requirement of flour is a function of specific baking formulas, the baking process, and the final product requirements. Accordingly, millers adjust the flour characteristics to accommodate customers' specifications. The miller and the bakers test the baking qualities of flours in the laboratory. A scoring method should be developed in the laboratory to evaluate baked bread objectively.

Color

Flour color is one of the main production challenges to the miller, because it is directly related to the shade of the final baked product. Flour color evaluation is performed by the Kent Jones and Martin Color Grader, the comparison at a certain wavelength of light or the Tristimulus system and the image analysis of bran particles. All have their advantages and limitations. However, the miller usually uses the method that is acceptable to the majority of customers. The operative miller compares the flours every hour against an accepted standard. This test is the 'Pekar

test,' in which a flattened portion of flour is wet and dried to exaggerate the color differences.

Falling Number

The falling number value indicates the level of α-amylase activity in wheat and flours. Sprouting of wheat in a wet harvest period leads to a high α-amylase activity and, consequently, a low falling number. Depending on the amount of wheat germination, it weakens the gluten, shortens dough fermentation, and increases flour acidity and ash. Upon germination, the level of α-amylase enzyme activity increases many-fold. The enzyme breaks down large starch molecules and thereby reduces the starch viscosity. Germination increases the diastatic activity and sugar production during the baking process. Accordingly, flours that lack gassing power could show an improvement with some sprouted wheat in the mill mix. Testing instruments such as the falling number and amylograph are used to measure the relative viscosity of the starch in flour and, accordingly, the level of damage to the wheat.

Fragment Count

The actual number of particles of insect origin, regardless of size, in 50 g of flour or meal is determined by using a filth test method and by a microscopic count. FDA regulations for insect and rodent filth, consider as defective 75 or more insect fragments and one or more rodent hairs per 50 g of wheat flour.

Lipids

The lipid content of wheat flour depends on the rate of extraction. The lipid content ranges from about 0.88% in 60% flour extraction to about 2.5% in whole meal product. Lipids originate during the milling process mainly from germ particles that end up in the final flour. The oxidative deterioration of lipids is the factor limiting the prolonged storage of flour. (*See* **Fats**: Classification.)

Moisture

Moisture in mill products depends on variables such as the moisture content of the raw wheat, the conditioning process before milling, ambient conditions in the mill, the design of the milling process, and mill adjustment.

In general, there is an optimal range of moisture content in the wheat before milling to achieve optimal physical attributes such as kernel hardness for the process, milling performance, and final product moisture. The miller achieves this by conditioning of the wheat, which is also the main stage where physical and chemical changes occur in the raw material and, subsequently, the characteristics of end products.

All mill product values such as ash and protein content should be corrected and expressed on a fixed moisture basis that differs in different parts of the world. For example, in the USA, flour values are corrected to a 14% moisture basis, and in others, to a dry basis. Flour is corrected to that basis because at an average relative humidity of 70% the amount of 14% moisture in flour is in equilibrium. In addition, at about 14%, no significant chemical changes or proliferation of microflora would occur in stored flour.

Flour Particle-Size Distribution

The particle size of flour produced by a commercial mill ranges between 1 and 200 μm. Flour produced from soft wheat is finer, whereas that from hard wheat is coarser. The flour particle-size distribution is directly related to water absorption, during dough preparation, and baking performance. The coarsest fraction in flour is positively related to water absorption, loaf weight, and crumb quality. Finer fractions from any given flour absorb water more slowly, produce a sticky sponge, and show an inferior baking quality. It is the miller's objective to optimize the flour particle size distribution to accommodate end-use qualities.

Whereas the flour particle-size distribution is within a known range, durum semolina is a wheat product that is produced within significantly different particle size ranges. Depending on variables in the pasta production system, including semolina wetting, extrusion, and drying, an optimum particle size distribution is required.

pH

The pH levels of flour effect their baking performance, especially those from soft wheat used for cake baking. The optimum pH levels of some flours are as follows: bleached white bread flour, 5.7–5.9; cake flour, 4.9–5.8; cookie and pie, 4.9–5.8.

Protein

Mill product protein content is directly related to that of the wheat kernel protein. Accordingly, dividing the straight-grade flour into different products would result in less protein in the combination of head streams (patent) and more protein in the combination of tail-end flour streams (clear). The protein content of flour is the amount of nitrogen determined, multiplied by a factor of 5.7. A factor of 6.25 is used for wheat bran.

The gluten that amounts to about 85% of the total protein of white flour is made up of two components, glutenin and gliadin, which are normally present in roughly equal amounts. Gliadin is a soft, sticky substance that acts as a bond for the less coherent, but harder, glutenin. Gluten is insoluble in cold water and may be recovered from a weighted flour sample. One-third of the weight of wet gluten approximates the protein content of flour. Excessive temperatures during the wheat handling and grinding (above 55 °C) would affect the gluten characteristics and, as a result, the baking quality of the flour. Accordingly, millers are sensitive to any rise in grinding roll temperature and, in some designs, can cool them with internally flowing water.

Rheological Characteristics

Instruments that record rheological properties of dough made from a flour determine its development process, rising ability, elasticity, and the quality of the baked loaf of bread. The instruments generate curves that allow the quality to be interpreted from the shape of the curves.

Starch Damage

Mechanically damaged starch granules are susceptible to enzyme action. Starch damage at a desired level of flour is related to the effective water absorption and is reflected in an increase in the maltose value that is responsible for the gassing power during the baking process. To produce acceptable bread, an optimum relation should be maintained between the flour protein content and the level of starch damage. (*See* **Starch**: Functional Properties.)

Water Absorption

The weight of water per weight of flour, expressed as a percentage, is used to make dough with an optimal consistency. Various instruments are used to measure this characteristic of flour. Variation in the flour particle size distribution, protein, and starch damage content accounts positively for changes in the water absorption of flours. Damaged starch absorbs 100% of its weight in water. Undamaged starch absorbs only 30% of its weight in water.

Effect of the Mill Design and Adjustment on Product Characteristics

The design of the mill flow has a decisive effect on product characteristics. Mill design relates to sieve-cover aperture, the characteristics of grinding stages, and the direction of intermediate material flow. Long or a short mill diagram is characterized by the specific machine allocations for the milling process. It is based on a fixed quantity (100 kg of wheat) processed in 24 h. The longer mill flow that contains a larger number of grinding stages allows a higher degree of flour extraction and a relatively lower total amount of cumulative ash content in all flours. This is caused by a relatively less severe action at each of the grinding stages.

Starch Damage Effect

Setting of the grinding rolls, pressure exerted between them, the rate of feed to the rolls, the surface of the rolls, and the available sifting area in the mill affect the level of starch damage in the flour. In general, the smooth rolls in the mill that reduce the chunks of endosperm particles to fine flour are responsible for the main starch damage. Smooth rolls differ in their surface characteristics; they can be shiny smooth or matt. Higher starch damage levels can be achieved with matt surfaces and a greater differential between the grinding rolls. Rolls are more effective in generating damage to starch in flour that impact grinding.

Blending of Flour Stream in the Mill

The professional miller is familiar with the quantity and quality of the individual mill flour streams and blends them to generate the resulted final flours. Millers use different methods to achieve desired final commercial flours.

1. One method is to combine all the flour streams while grinding a certain wheat mix and subsequently make some adjustments in quality before shipment by blending flours from different wheat mixes.
2. A second method would be to divide the flour streams into two or three collecting conveyors. Those would be the final flours specified as patent, first clear, etc. Some blending would occur in the flour handling system before shipment.
3. The third method, named divide or split milling, would be to group flour streams into 'groups' of certain quality and blend those at the end of the process at different ratios, to generate required qualities.

A flour stream grouping in a typical spring wheat mill processing 13.7% protein wheat is shown in Table 2. The estimated percentage of each of the individual flour streams and their diversity vary from one mill to another.

The three main groups of flour streams are shown in Figure 3, which also shows the groups combined to produce the commercial grades.

Product Handling

Depending on the regulations and customer requirements, mill products are treated before shipment by the addition of different additives at specified levels, moisture adjustment, air classification, or modification by heat.

Table 2 Flour streams grouping in mill grinding 13.7% protein spring wheat

Stream	*Flour (%)*	*Ash (%)*	*Protein (%[a])*
1 M	35.0	0.37	11.9
2 M	12.0	0.39	11.8
3 M	8.0	0.39	11.6
Group I	**55.0**	**0.38**	**11.8**
2 Q	4.0	0.50	12.2
4 M	5.0	0.60	12.5
1 BK	5.0	0.58	14.6
2 BK	7.0	0.54	15.4
3 BK	4.5	0.68	18.0
Break redust	6.5	0.58	14.8
Group II	**32.0**	**0.58**	**14.7**
1 T	1.0	0.75	12.5
5 M	3.0	0.60	12.8
Exhaust	2.5	0.65	14.8
4 BK	2.5	0.95	18.5
Bran duster	1.0	1.20	18.7
Group III	**10.0**	**0.77**	**15.2**
6 M	1.0	1.30	13.2
7 M	0.5	1.50	13.0

Low Grade	**3.0**	**1.38**	**14.8**

[a]Adapted from Panter A (1988) Divide milling of Canadian spring wheat flour. *Association of Operative Millers Technical Bulletin* December: 5347–5353, with permission.

Nutritional Enrichment

Since 1940, all white wheat flour or semolina in the USA has been supplemented with vitamins and essential minerals that are natural to the wholewheat but are lost during the milling process (Table 3). Good manufacturing practices should insure that the required levels of added vitamins and minerals are maintained throughout the expected shelf-life of the food under customary conditions of distribution and storage. Prepared premixes are available that contain all the vitamins with added requirements of folic acid, vitamin A, calcium, and others.

Flour Improvers

Flour aging Following the milling process, the flour goes through an 'aging' or maturation process. Aging enhances the gas-retention properties of the gluten by oxidizing, among others, the –SH groups. In countries where additives are not permitted, millers store flours up to 12 days before shipment to allow the process to take place. Where permitted, oxidizing agents such as ascorbic acid (vitamin C), potassium bromate, azodicarbonamide, and chlorine dioxide are used to improve the bread-making qualities (Table 3).

Flour bleaching The yellowish shade of freshly milled flour is the result of the carotene present. Bleaching agents are added, where permitted, in the

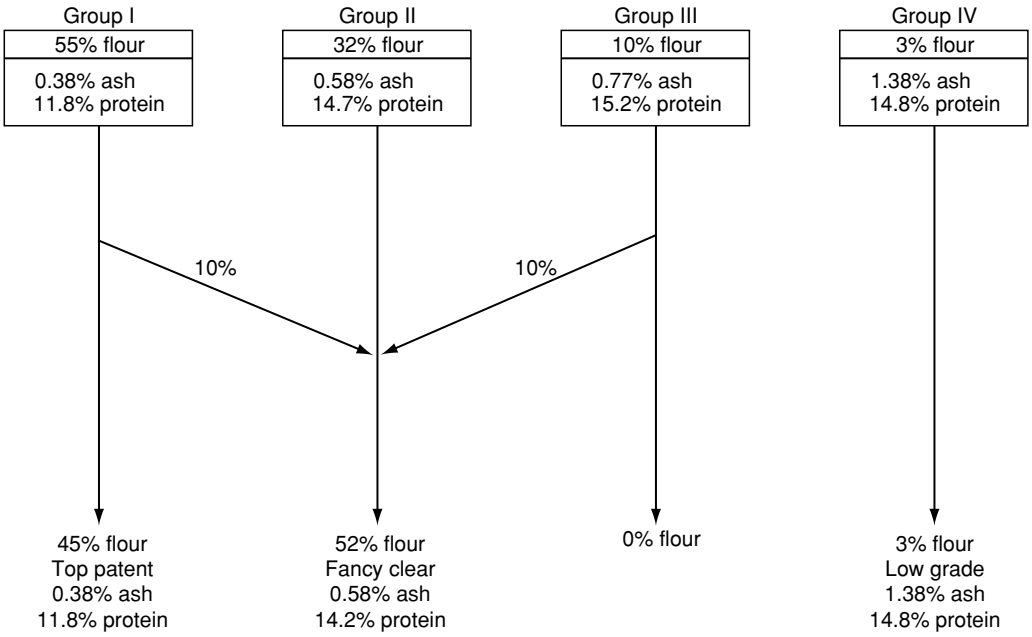

Figure 3 Schematic diagram of combining flour groups. Adapted from Panter A (1988) Divide milling of Canadian spring wheat flour. *Association of Operative Millers Technical Bulletin* December: 5347–5353, with permission.

Table 3 Additives to wheat flour

Flour additive	*Physical state*	*Rate (p.p.m.)*	*Effect*	*Maximum level (p.p.m.)*
Nutritional additives				
Thiamin	Premix	4.4–7.7	Prevents beriberi	Regulations
Riboflavin	Premix	3.7–4.8	Eye and mouth tissue health	Regulations
Niacin	Premix	35–64	Prevents pellagra	Regulations
Iron	Premix	29–43	Forms hemoglobin	Regulations
Folic acid	Premix	1–2	Prevents birth defects	Regulations
Calcium	Powder	2116	Counter phytic acid	Optional
Flour-improving additives				
Potassium bromate	Powder	10–20	Oxidation	50 p.p.m.
Azodicarbonamide	Powder	2–20	Aging	45 p.p.m.
Chlorine	Gas	1000–1400	Bleach/age	As required
Benzoyl peroxide	Powder	50	Bleach	150 p.p.m.
Ascorbic acid	Powder	70	Mix-time reduction	200 p.p.m.
L-Cysteine (hydrochloride)	Powder	30	Mix-time reduction	90 p.p.m.
Fungal α-amylase	Powder	30	Diastatic supplement	As required

mill to improve the flour color. One of the most commonly used bleaching agents is benzoylperoxide. Chlorine is another agent that is added as a gas mainly to soft wheat flour, where another objective is to control the flour pH level (Table 3).

Enzymatic activity To compensate for any natural deficiency of enzymes to convert starch to maltose, usually malted barley flour or enzymes are added. The treatment is approximately 0.25%, depending on the strength of the malt and the requirements of the flour treated.

Heat Treatment

Heat treatment of flour is used to change its physical and rheological properties. The heat reduces the elasticity and even denatures the gluten. The starch can be gelatinized and enzymatic activity reduced or eliminated. The heat also causes a reduction in the bacterial count of flour. In terms of amylograph values, a flour viscosity of about 300 Brabender units (BU) could be effected by heat treatment and reach 800 BU. The new characteristics improve the water-holding capacity of the treated flour. The heat-treated flour is used for special end uses such as soups, sausage filling material, infant foods, and other food and nonfood products.

New Developments and Their Effect on Product Characteristics

Debranning of Wheat Before Milling

The newly applied process of debranning the wheat outer layers from the kernels before milling yields products that are different from those produced by a conventional mill, in terms of quality and nutritional values. The finely adjusted debranning machine action on the wheat kernel allows the miller to remove by abrasion individually each of the seven bran layers before grinding the endosperm to flour. From the outer to inner layer, these are: cuticle, epicarp, endocarp, testa, nucellar layer, and aleurone layer. Each is significantly different in characteristics from the other. While the nutritous aleurone layer is high in protein content (28%), the epidermis, epicarp, and endocarp have a very high level of insoluble dietary fiber.

As mentioned earlier, the process of sprouting softens the wheat kernel, and accordingly, when milled on a conventional milling system, the bran is pulverized somewhat more than sound wheat, and the ash increases as a result of the fine bran particles. Wheat debranning before milling removes most of the kernel layers that contain high levels of α-amylase such that the resulting flours have a reduced enzymatic activity and are more suitable for bread-baking purposes.

MINERALS – DIETARY IMPORTANCE

J H Freeland-Graves, The University of Texas at Austin, Austin, TX, USA
P J Trotter, Augustana College, Rock Island, Illinois, USA

Introduction

Minerals are of critical importance in the diet even though they comprise only 4–6% of the human body. Major (macro-) minerals are those required in amounts greater than 100 mg day^{-1} and represent 1% or less of body weight (**Figure 1**). These include calcium, phosphorus, magnesium, sulfur, potassium, chloride, and sodium (**Table 1**). Trace (micro-) minerals are essential in much smaller amounts, less than 100 mg day^{-1}, and make up less than 0.01% of body weight. Essential trace elements are chromium, copper, fluoride, iodine, iron, manganese, silicon, and zinc (**Table 2**). Ultratrace minerals are a subcategory of trace minerals that are required in amounts less than 50 ng g^{-1} in the diets of animals. These include arsenic, boron, molybdenum, nickel, selenium, and vanadium (**Table 3**). Other inorganic elements which may contribute to biological processes, but which have not been established as essential, are barium, bromine, cadmium, lead, lithium, and tin. Nonnutritive metals such as aluminum, bismuth, gallium, gold, mercury, and silver may also be present in small amounts in foods. These metals have no known function and may contaminate wholesome food and create toxic symptoms. (*See* **Heavy Metal Toxicology**; **Trace Elements**; Refer to individual minerals.)

Food Sources

A mineral is an inorganic homogeneous substance. When food is burned, the organic portions oxidize; the ashes remaining are minerals. The ash can be analyzed to determine the specific quantity and type of minerals present. The level of some minerals, such as iodine and selenium, in foods is particularly dependent upon the amount of the mineral in the soil of the region where the food is produced. A variety of common food sources of minerals are listed in **Tables 1–3**.

The natural occurrence of minerals in food is not always desirable. In vegetable oils, miniscule amounts of iron and copper contribute to the development of rancidity. Sequestrants, such as ethylenediaminetetraacetic acid, are added to render them ineffective. Other foods are enriched by the addition of minerals. Some examples are the addition of iodine to salt, iron to flour and bread, calcium to orange juice, and iron and other minerals to breakfast cereals. (*See* **Food Fortification**.)

Figure 1 A portion of the periodic table of elements. Elements thought to be essential are shaded; fluoride may be beneficial rather than essential.

Table 1 Food sources, physiological functions, deficiency symptoms, and requirement of major minerals

Mineral	*Food source*	*Physiological functions*	*Deficiency symptoms*	*Toxicity symptoms*	*Requirements*
Calcium	Milk, cheese, yogurt, turnip, greens	Bone calcification, blood clotting, muscle contraction, nerve transmission	Rickets, osteoporosis, osteomalacia, tetany	Hypercalcemia, kidney stones, constipation, depression, confusion UL 2.5 g day^{-1}[a]	1000 mg[b]
Chloride	Salt, processed foods	Electrolyte in fluid balance, gastric acidity, acid–base balance	Hypochloremic metabolic alkalosis, hypotension	Hypertension (in conjunction with excess sodium)	750 mg[c]
Magnesium	Spices, nuts, coffee, cocoa, vegetables	Cellular metabolism, muscle relaxation, nerve transmission	Nervous disorders, muscle weakness, tetany, arrhythmia, hypertension	Diarrhea, UL 350 mg nonfood magnesium per day[a]	310–420 mg[b]
Phosphorus	Cheese, meats, peanuts, soft drinks	Bone calcification, energy release, membrane structure, acid–base balance	Fatigue, anorexia, bone demineralization, muscle weakness	Metastatic calcification and skeletal porosity (in animals) UL 4 g day^{-1}[a]	700 mg[b]
Potassium	Fresh foods, molasses, milk, legumes, bananas	Electrolyte in fluid balance, nerve transmission, muscle contraction, blood pressure	Weakness, anorexia, cardiac arrhythmia, irrational behavior	Muscle weakness and paralysis, cardiac arrhythmia or arrest	2000 mg[c]
Sodium	Salt, cured meats, processed foods	Electrolyte in fluid balance, membrane potential of cells, active transport, blood pressure	Hyponatremia, nausea, anorexia, weakness, confusion, convulsions	Edema, hypertension, congestive heart failure in elderly	500 mg[c]
Sulfur	Meat, fish, eggs, cheese, legumes	Energy transfer (constituent of sulfur-containing amino acids, insulin and some vitamins)	Unknown	Depressed growth (animals)	

[a]Tolerable upper intake level (UL) recommended for adults from the Institute of Medicine (1999): see Further Reading.
[b]Daily recommendation for an adult man from the Institute of Medicine (1999): see Further Reading.
[c]Daily recommendation for an adult man from the National Research Council (1989): see Further Reading.

Table 2 Food sources, physiological functions, deficiency symptoms, and requirement of essential trace minerals

Mineral	*Food sources*	*Physiological functions*	*Deficiency symptoms*	*Toxicity symptoms*	*Requirements*[a]
Chromium	Mushrooms, yeast, prunes, nuts	Glucose metabolism, enhanced insulin sensitivity, nucleic acid stability	Glucose intolerance, neuropathy, elevated serum insulin and lipids	Cancer (hexavalent form)	35 μg
Copper	Nuts, shellfish, liver, raisins, grains, chocolate	Iron utilization, nervous system, pigmentation, immune defense, neovascularization	Neutropenia, anemia, decreased pigmentation, neurological, skeletal, cardiovascular, and cartilage abnormalities	Gastrointestinal discomfort ($>5\,mg\,day^{-1}$), liver damage, weakness, nausea	900 μg
Fluoride[b]	Fluoridated water, seafood, tea	Precipitates calcium and phosphorus in bone and teeth	Increased dental caries	Mottled tooth enamel, joint stiffness UL $10\,mg\,day^{-1}$[c]	3.0 mg[d]
Iodine	Saltwater fish, iodized salt, bakery goods	Thyroid hormones in basal metabolism	Goiter, stunted growth, mental retardation, myxedema, cretinism, hypothyroidism	Goiter, hypothyroidism	150 μg
Iron	Liver, meats, molasses, prunes, nuts	Hemoglobin and myoglobin formation for oxygen transport, cellular oxidation	Anemia, poor body temperature regulation, impaired psychomotor/ intellectual performance	Liver damage, diabetes, increased risk of heart disease due to lipid oxidation	8 mg[e]
Manganese	Tea, nuts, oatmeal, bran, pineapple	Cartilage and bone equity, brain function, lipid and carbohydrate metabolism	Rash, nervous disorders, hypocholesterolemia, skeletal/mitochondrial abnormalities	Brain or neurological disorders resembling Parkinson's disease, schizophrenia	2.3 mg
Silicon	Pectin, grains, beer, cereals	Bone calcification and cartilage formation, growth	Depressed growth and skeletal development (chick)	Kidney stones; generally nontoxic	40 mg
Zinc	Meats, shellfish, liver, legumes	Reproduction, growth, skin integrity, wound healing, taste acuity, immune response	Impaired sexual development/growth, skin lesions, hair loss, anorexia, behavioral disturbances	Poor immune response, lower high-density lipoprotein-cholesterol, copper deficiency (chronic $>0.50\,mg\,day^{-1}$)	11 mg

[e]18 mg for adult female.

Bioavailability

The total amount of a mineral in a food does not necessarily reflect the amount that is available for absorption into the body. The presence of dietary fibers and mineral-binding ligands, such as phytates and oxalates, may substantially diminish the bioavailability of minerals. Phytates are abundant in bran, whole grains, and oil-seed legumes; oxalates are found in dark-green leafy vegetables, such as spinach. Diets rich in these compounds, found in strict vegetarian diets, may have the potential to affect mineral status adversely. (*See* **Bioavailability of Nutrients**; **Vegetarian Diets**.)

Polyphenolic compounds, formerly called tannins, are other dietary components that bind minerals. In tea, large concentrations of polyphenolic compounds can reduce the absorption of iron in a meal by as much as 87%. (*See* **Tannins and Polyphenols**.)

The amount of available mineral in a food may be further reduced by the large quantities of other minerals. For instance, the amount of oral manganese absorbed may be greatly decreased by the concomitant ingestion of calcium (Figure 2). Phosphates are known to diminish the absorption of zinc. Food sources that are high in fiber, phytates, oxalates, polyphenolic compounds, and other minerals should therefore be used in moderation in order to insure optimal mineral adequacy of the diet. (*See* **Dietary Fiber**: Effects of Fiber on Absorption; **Phytic Acid**: Nutritional Impact.)

In contrast, some dietary factors improve the bioavailability of minerals. Ascorbic acid, sugars, and amino acids enhance the absorption of iron and amino acids; citrate, phosphate, gluconate, and high

Table 3 Food sources, physiological functions, deficiency symptoms, and requirement of essential ultratrace minerals

Mineral	*Food sources*	*Physiological functions*	*Deficiency symptoms*	*Toxicity symptoms*	*Requirement*[a,b]
Arsenic	Fish, meat, poultry	Taurine and polyamine metabolism	Depressed growth, reproductive abnormalities, sudden death (animals), nervous disorders	Dermatosis, low hematopoiesis, sensory disturbances, skin cancer	2–29 μg
Boron	Milk and dairy products, fruits, nuts, vegetables	Energy utilization, development/ maintenance of bone	Elevated urinary calcium, aggravated arthritis (humans), poor bone development (chicks)	Nausea, anorexia, weight loss, decreased sexual activity and sperm count	1 mg
Molybdenum	Legumes, cereals, leafy green vegetables	Sulfur, pyrimidine, and purine metabolism	Low uric acid, tachycardia, tachypnea (humans), kidney stones (sheep)	Gout	45 μg
Nickel	Oatmeal, legumes, peas, nuts, chocolate	Production of hormones, membrane properties, oxidation/reduction	Low blood glucose, abnormal bone growth, poor iron absorption, altered calcium metabolism	Nasal and lung cancers, asthma, contact dermatitis, poor stress and immune response	< 100 μg
Selenium	Meats, fish, grains	Antioxidant, thyroid hormone metabolism, capillary integrity	Cardiomyopathy, liver damage, birth defects (wild fowl)	Skin lesions, brittle hair, nails, and hooves (animals) UL 400 μg	55 μg
Vanadium	Parsley, black pepper, mushroom, dill, shellfish	Iodine metabolism	Reduced growth, poor bone growth, impaired reproduction (animals), poor feathers (chicks)	Green tongue, intestinal upset, dehydration, breathing difficulty	6–18 μg

UL, upper intake level.

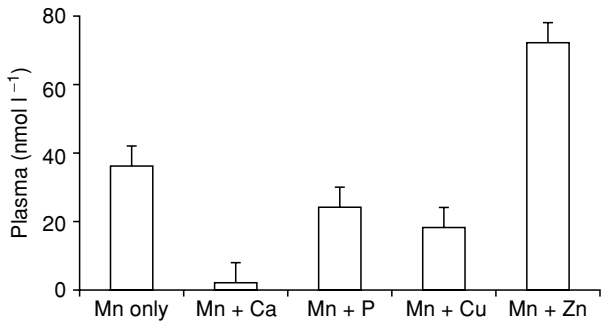

Figure 2 Plasma uptake of manganese as affected by oral loads of manganese (Mn), calcium (Ca), phosphorus (P), copper (Cu), and Zinc (Zn). Areas under the curve for response of plasma manganese when the following was administered: 40 mg Mn, 40 mg Mn plus 800 mg Ca, 40 mg Mn plus 800 mg P, 40 mg Mn plus 2 mg Cu, and 40 mg Mn plus 50 mg Zn.

dietary protein increase the absorption of copper. The milk sugar lactose increases the absorption of calcium by approximately 30%.

Requirements

The amount of a mineral required in the diet for optimal health and prevention of chronic disease is the basis for new dietary recommendations, dietary reference intakes (DRIs), that have been formulated in the USA in conjunction with the reference nutrient intakes (RNIs) from Canada. These have been set for major minerals (calcium, magnesium, and phosphorus) and trace elements (chromium, copper, fluoride, iodine, iron, manganese, molybdenum, selenium, and zinc). The DRIs consist of four standards:

1. Estimated average requirements (EAR), based on the median of a population;
2. Recommended dietary allowances (RDA), designed to meet nutrient needs of almost all (97.5%) healthy individuals;
3. Adequate intakes (AI) for minerals with insufficient data to establish an EAR;
4. Tolerable upper intake levels (UL) based on the maximum intake per day that appears to be safe for an individual over a long period of time (Figure 2).

No recommendations are made for other trace and ultratrace elements that participate in biological processes because of a lack of research.

In the UK, dietary reference values have been suggested for six minerals (calcium, phosphorus, magnesium, sodium, potassium, and chloride), and for five trace elements (iron, zinc, copper, iodine, and selenium). 'Safe' intakes have been set for molybdenum, manganese, chromium, and fluoride. (*See* **Dietary Reference Values**.)

Recommendations for minerals are more difficult to define than other nutrients as minerals can be

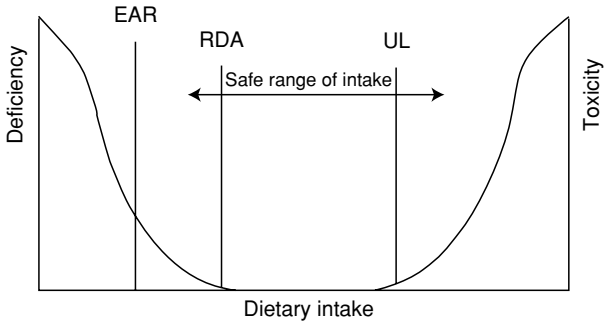

Figure 3 Dietary recommendations for minerals are located within a continuum between deficiency and toxicity. EAR, Estimated average requirements; RDA, recommended dietary allowances; UL, upper intake level.

both essential and toxic. The safe range of intake is somewhere between levels known to produce a deficiency and those that result in toxicity with continued exposure (Figure 3). Some minerals, such as zinc and copper, have a relatively large difference between the adequate and toxic doses, whereas others, such as iron and selenium, have a fairly narrow window of optimal intakes.

It should be emphasized that the recommendations mentioned above are for healthy persons as they consume their usual diets. The values may not be applicable to individuals receiving parenteral solutions, those with inborn errors that may influence absorption, transport, utilization, storage, or excretion, and during conditions of malnutrition, disease, and increased demand (pregnancy, lactation, growth, stress, injury).

Physiological Importance of Minerals

Minerals serve structural, catalytic, and regulatory functions in the body. The major minerals serve as structural components of tissues and function in cellular and basal metabolism, as well as water and acid–base balance (Table 1). Three of the major minerals – sodium, potassium and chloride – are called electrolytes. Although the functions of the trace and ultratrace minerals vary considerably, as shown in Tables 2 and 3, these minerals are primarily catalytic. These function as cofactors for enzymes or essential components of important biomolecules. For example, copper, manganese, and zinc are important components of enzymes, zinc is a component of some transcription factors (DNA-binding proteins) that regulate gene function, iron is an essential component of the heme portion of hemoglobin, iodine is an integral part of thyroid hormones, and cobalt is a necessary element in vitamin B_{12} (cobalamin). (*See* **Coenzymes**.)

It should be emphasized that the presence of a mineral in the body is not proof of essentiality. Metals that are toxic may enter the body via contaminated foods and nonfoods, inhalation of fumes, and absorption through the skin. They remain in the body since there is no mechanism for excretion. For example, strontium may be found in bones as a result of drinking contaminated milk; mercury may be deposited in the brain after inhalation of vapors; and lead may be present in the brain following ingestion of lead-containing paint.

The standard criteria of essentiality are as follows: (1) a deficiency or conditioned deficiency state is induced and prevented or cured by a mineral; (2) the mineral is required as a structural component by body tissues, regulators, or is a dietary essential; (3) biological fluids maintain a certain concentration of the mineral as a component electrolyte; and/or (4) a molecular process uses the mineral as a cofactor. For the ultratrace elements, another criteria for essentiality may be that (5) a deficiency state creates a suboptimal biological function, which can be circumvented or revoked by the addition of a usual dietary level of the mineral. (*See* **Coenzymes**.)

Minerals and their Interactions

Minerals act as cofactors in biochemical reactions since they have the ability to form stable chelates with nitrogen donor ligands in amino acids, peptides, and proteins. They can stabilize the structure and change the conformation (which may influence function), bind substrates or cofactors, activate an enzyme–substrate complex, and influence the enzyme's affinity for a substrate by the specificity of the metallic ion.

Binding to proteins can be beneficial as it limits the amount of free ions available. When some minerals (such as arsenic, chromium, copper, iron, nickel) are consumed in excess they may bind to DNA in a cross-link manner. This type of cross-link binding may create a dysfunctional or mutated DNA that may play a role in carcinogenesis (initiating cancer). Excess free ions of iron, for example, may stimulate the formation of free radicals which attack lipids or the free ions may bind to DNA in cells. Mutations in DNA may be related to the association between excess iron and colon cancer.

Some minerals, such as the cupric ion, bind strongly to proteins, and are not freed by dialysis. In contrast, zinc undergoes nonenzymatic chelation. Zinc ions are known to bind covalently with the nitrogen from the imidazole moiety of histidine and, possibly, glutamate. The binding of copper and zinc to metallothionein, a protein involved in the homeostasis of these minerals, confers resistance against the enzymatic degradation of this protein. Metallothionein chelates copper and zinc via the sulfhydryl groups (—SH) of its cysteine moieties. The affinity of this protein for copper is 105 times greater than for

zinc. (*See* **Protein**: Interactions and Reactions Involved in Food Processing.)

In calcium binding, coordination primarily involves oxygen atoms. A main-chain carbonyl (—COO—) is one ligand and each oxygen is the carboxyl group (—COOH) of glutamyl and aspartyl residues. Iron in nonheme proteins, such as transferrin, invariably binds to the sulfhydryl group of a cysteine residue or inorganic sulfur. In heme proteins, one ligand is the nitrogen of imidazole in histidine. A sulfhydryl group is a ligand for copper, zinc, cadmium, mercury, and other heavy metals. Some proteins have double metal sites (e.g., aspartate, glutamate) so that different metallic ions can have a site in common.

Mineral–Mineral Interactions

Minerals interact with each other according to their physicochemical properties, i.e., valence shell electronic structure, ionic radius, coordination number and geometric configuration, redox potential, spin transition state, and ligand exchange. Minerals with similarities in some of these properties can be predicted to develop antagonistic relationships. For example, both divalent iron and trivalent cobalt have a d^6 electronic configuration (six electrons of the *d* orbital), divalent copper (0.81) and divalent iron (0.83) have similar ionic radii, and vanadate and chromate have similar 3*d*-4*s* configurations. Thus antagonistic relationships can be predicted between iron and cobalt, copper and iron, and vanadate and chromate.

A calcium–phosphorus interaction occurs in the body when levels of serum calcium decline. Parathyroid hormone is secreted, which decreases the renal reabsorption and urinary excretion of phosphorus, resulting in lower serum phosphorus. This hormone also induces the active form of vitamin D which increases intestinal calcium absorption and renal phosphorus reabsorption, resulting in higher serum levels of calcium and phosphorus. This feedback mechanism maintains a homeostatic control of the serum levels of these minerals. During low dietary intake of calcium, zinc supplementation has an inhibitory effect. (*See* **Cholecalciferol**: Physiology.)

Magnesium also affects parathyroid hormone secretion and competes with calcium for intestinal absorption. At the cellular level, calcium transport by the sarcoplasmic reticulum is a magnesium-dependent process. When dietary magnesium is high, intestinal absorption of phosphorus is inhibited. It has been observed that both calcium and magnesium negatively influence fluoride uptake at the intestine.

Diets high in zinc have been shown to be detrimental to the status of both iron and copper. Excessive zinc results in iron-deficiency anemia via a direct effect on absorption. The opposite is true, i.e., high dietary iron reduces zinc absorption. The antagonism between zinc and copper is being exploited in the treatment of Wilson's disease, a genetic disease in which copper abnormally accumulates in the liver. The administration of 75 mg zinc day^{-1} blocks the intestinal absorption of copper and returns copper balance to normal quantities.

Iron-deficiency anemia is also produced by excessive quantities of manganese. During periods of low manganese intake, the absorption of iron greatly increases. (*See* **Anemia (Anaemia)**: Iron-deficiency Anemia.)

The significant interactions that can occur when excessive amounts of minerals are ingested suggest that mineral supplements be avoided under usual circumstances. High-dose supplements of one mineral can upset the delicate balance of other minerals in the body. Consumption of a varied, nutrient-dense diet is a better choice than supplements for achieving optimal mineral status.

Influence of Minerals on Food Processing and Food Quality

Minerals have the potential to affect the color, texture, flavor, pH, and nutritive value of foods and are often used as food additives.

Color

The brilliant colors of fruits and vegetables are due to a variety of plant pigments. Chlorophyll pigments, which contribute blue-green, yellow-green, and gray-green colors, react with both zinc and copper to produce a bright green color. The color change occurs when these minerals replace the central magnesium atom in the chlorophyll molecule. (*See* **Chlorophyl; Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Anthocyanins are red and blue pigments which turn red with acid, blue with an alkali, and are sometimes colorless with prolonged heating. When foods containing anthocyanins are processed in tin (actually tin-coated) cans, the tin must be lacquered to prevent the anthocyanins from forming greenish-blue pigments. A greenish-blue color is also created when rusted tin pans are used for fruit pies. Contact of a fruit filling, such as blueberry or raspberry, with the tin and iron salts may cause it to discolor.

Anthoxanthins (flavones) are pigments that are clear and white in acid, yellow in alkali, and pink with prolonged heating. Tin and aluminum react with these pigments and change the color to a bright yellow. This is illustrated by the bright-yellow cooking water produced when onions are cooked in an aluminum pan. When anthoxanthins react with

iron and copper, blue-black and reddish-brown colors appear, as seen in onions fried in such pans.

Sulfur prevents the darkening of foods which occurs when melanin is formed. This brown-black pigment is created via enzymatic browning in the presence of oxygen. Dried fruits, such as apricots and golden raisins, which might turn an unappetizing brown when drying, can be dipped in a sulfur solution or exposed to sulfur fumes to prevent discoloration. Pineapple juice is used as a dipping solution for cut fresh fruits, such as bananas, because its high sulfur content retards color changes. Cut lettuce for salad bars was once sprayed or dipped in a sulfite solution to retard browning, but this practice has been banned since over 100 people had allergic reactions (including one death) in response to the sulfur.

Chloride salts, such as chlorine dioxide and nitrosyl chloride, and chlorine are used to accelerate the natural aging and bleaching of flour.

Texture

When canned vegetables and fruits are cooked during processing, the tissue softens as cementing pectic substances in the cell walls of plant tissue degrade. This softening can be counteracted by the addition of calcium ions in the form of calcium hydroxide and calcium pectate. The calcium salts react with the pectic substances to form a firm material. Calcium salts are often added to canned tomatoes as a firming agent. The presence of phytates in vegetables, such as peas, decreases the firming effect of the calcium ions due to formation of a calcium–phytate complex.

In commercial baking, the texture and baking quality of bread dough are improved by the use of bromates and iodates which act as oxidizing agents. If the dough must wait for the oven, gas that is evolving may be lost before cooking and the baked goods will lose their characteristic light texture. To prevent the loss of gas, baking powders have been specially formulated to produce two reactions. In sodium aluminum sulfate–phosphate powder, monocalcium phosphate reacts first when moistened at room temperature to create a smooth, light batter; then sodium aluminum sulfate reacts when it is solubilized by hot water. In sodium acid pyrophosphate (SAPP)-baking powder, a pyrophosphate replaces the monocalcium phosphate because it has a slower reaction rate. An even slower reaction rate is seen with sodium acid aluminum phosphate (SALP) powder that contains sodium aluminum phosphate. SALP powder is used in cakes because it retains carbon dioxide until the gluten strands coagulate, thus preventing formation of tunnels. (*See* **Bread**: Chemistry of Baking.)

Mineral salts are also used as anticaking agents and flow conditioners for powdered foods that have a tendency to cake or form lumps, such as salt, confectioner's sugar, and baking powder. Some compounds used are tricalcium phosphate, silicon dioxide, calcium silicate, aluminum stearate, ferric ammonium citrate, and monocalcium phosphate.

Flavor and pH

The intensity of flavor and tartness in sherbets, carbonated beverages, and fruit drinks is enhanced by the addition of potassium citrate and phosphoric acid. The correct proportion of acidity and alkalinity is critical in controlling the correct flavor, texture, and keeping quality of several dairy products. Buffering agents such as sodium bicarbonate, calcium carbonate, hydrogen chloride, sodium citrate, sodium hydroxide, and calcium oxide may be used to control pH. (*See* **pH – Principles and Measurement**.)

Safety and Quality of Foods

Sulfur dioxide and sulfites are added to foods because of their ability to act as antioxidants, and to fermenting alcoholic beverages because it is more toxic to bacteria and molds than to yeast. Wine can have an exceptionally high sulfur concentration, as much as 200 mg per 0.5 l. This level far exceeds the acceptable daily intake of 0.7 mg kg^{-1}. In the USA, all foods containing detectable levels of 10 $\mu g\, g^{-1}$ sulfite or more are labeled. (*See* **Antioxidants**: Synthetic Antioxidants.)

Mold inhibitors, such as calcium and sodium propionate, monocalcium phosphate and sodium diacetate, are added to baked goods. These prevent ropiness in bread and increase the shelf-life. (*See* **Spoilage**: Molds in Spoilage.)

Sequestrants or chelating agents are added to foods to bind metals, such as calcium, iron, and copper. When the metals bound to the chelator are no longer in an ionized form, oxidative changes such as staleness, rancidity, and off-flavors are prevented from developing. These compounds are important in fruit juices, canned seafood, milk, and salad dressings. They are also used to clarify wine and other beverages of minerals.

The presence of minerals in foods may influence the cooking or processing time. Calcium ions, for example, have a firming effect, which prolongs the length of the cooking time. This may occur when hard water is used since it naturally contains calcium salts. If a long cooking period is desired for flavor development, as in preparing baked beans, calcium, as well as acids, can be added. In home cooking, molasses is used since it contains high concentrations of calcium as well as aconitic acid.

The use of soft water in food processing, however, may not always be desirable. In the formulation of

low-sodium foods, soft water derived from a water softener should be avoided because it may contain as much as 50 mg of sodium dl^{-1}. Sodium is also added when foods are brined, as in preparing pickles or preventing the discoloration of vegetables. When meats are processed according to kosher laws, large amounts of sodium are added as the blood is removed by salting.

MINERAL WATER

Contents

Types of Mineral Water

M Abdulla, M Bost and S Gamon, Trace Element – Institute for UNESCO, Lyon, Cedex, France

Background

The term 'mineral water' is currently applied to several types of drinking water originating from underground sources that is packaged and marketed for human consumption. Mineral water may be defined as drinking water containing naturally or artifically supplied minerals, trace elements, and gases. Natural mineral water is microbiologically wholesome water, originating from an underground formation and emerging from a spring tapped at one or more natural or bore exits. Natural mineral water can be distinguished from ordinary drinking water by its natural and original state.

Formation of Mineral Water

It takes a significant number of years for mineral water to accumulate in an underground formation. When rain and snow fall on the land, over a period of many decades, it percolates through layers of soil, sand, and clay. Successive layers filter out the

impurities while adding dissolved minerals and trace elements. Some trace elements such as arsenic can be found in significant quantities in certain geographical areas of our planet, which may contaminate the water. Finally, perhaps 100 years or more after it first touched the land, this mineral water settles on bedrock deep below the surface.

Classification of Mineral Waters

The packaged (bottled/canned/in carton or foil) water market comprises two main segments: still and sparkling water. The main difference between the two categories is in the carbon dioxide content. Still waters have no carbon dioxide, are often sold as an alternative to tap water, and are used for cooking and mixing with coffee, powdered mixes, concentrated juices, soft drinks, etc. Sparkling waters contain carbon dioxide and are generally used as an alternative to soft drinks or alcoholic beverages. There are several types of packaging (bottled/canned/in cartons and polyethylene bags), depending upon the source of water. The various types of water that are commercially available at present are shown in Table 1.

Regulations

The definition of mineral waters may differ in different countries. The rules and regulations for marketing the mineral water in the country of origin and outside that country may also differ. These differences in the rules and regulations may hinder the free movement of packaged mineral water outside the boundaries of the countries producing special brands. Efforts are being made, especially in the European Community, to eliminate these differences in order to promote the free movement of the packaged natural mineral waters. The producers of the natural mineral water, however, must fulfill the basic laws and regulations concerning foodstuffs and water intended for human consumption. From a global point of view, there is a standard set by the Food and Agricultural Organization and the World Health Organization of the United Nations (FAO/WHO codex standard). In the countries of the European Communities, in response to the opinion of the European Parliament delivered in October 1995 on the approximation of the laws of the member states relating to the exploitation and marketing of natural mineral waters, certain amendments have been made. These amendments, however, do not differ from those of the FAO/WHO codex standard. The following conditions apply to natural mineral waters packaged for human consumption, particularly in affluent industrialized countries.

1. Natural mineral water, in its state at source, may not be the subject of any treatment or addition other than the addition or elimination of carbon dioxide. It must contain a certain amount of dissolved mineral salts. In many industrialized countries, this amount is around $500\,mg\,l^{-1}$.
2. Natural mineral water, in its state of source, must meet the specified microbiological requirements. It must be free from all pathological organisms. After packaging, mineral water must not have more than a specified total colony count. In many countries, especially in industrialized countries, the figure may not exceed 100 per ml at 20–22 °C in 72 h on agar or agar–gelatine mixture and 20 per ml at 37 °C in 24 h on agar. The total colony count shall be measured within 12 h following packaging, the water being maintained at 4 ± 1 °C

Table 1 Types of water that are commonly available at present

Type of water	*Characteristics*
Natural mineral water	Originates from a geologically and physically protected and approved underground source. It must have a high quality and constant composition. It must naturally contain a certain amount of dissolved mineral salts and trace elements, and should not undergo any treatment. The amount of dissolved mineral salts is at least $500\,mg\,l^{-1}$. Nothing should be added or removed other than carbon dioxide. It must be tapped from the original source and pumped to the surface through stainless steel pipes for packaging in bottles, cans, or other approved packaging materials.
Spring water	Originates from an underground formation and flows naturally to the surface of the earth. It must have a high quality and constant composition.
Well water	Originates from a hole bored, drilled, or otherwise constructed in the ground that taps the water of an aquifer.
Mineral water	Originates from a protected underground formation that has a high quality and constant composition. It should not be modified other than by adding mineral salts, aroma-producing compounds and carbon dioxide.
Other packaged water	This applies to all other types of bottled, canned, or packaged table waters. Names such as table water, carbonated table water, soda water or other accepted names belong to this category. They may be treated and prepared in the same way as commercial drinking water according to the local public health regulations. Mineral salts, essential trace elements, aroma-producing substances, and carbon dioxide may be added.

during this 12-h period. At source, these values should not normally exceed 20 ml^{-1} at 20–22 °C in 72 h and 5 ml^{-1} at 37 °C in 24 h, respectively, on the understanding that they are to be considered as guide figures and not as maximum permitted concentrations. Further, the natural mineral water may not contain any organoleptic defects.

3. All containers used for packaging natural mineral water shall be fitted with closure designed to protect against any adulteration or contamination.
4. The labeling of the containers used for the packaging of mineral water must include certain mandatory information. The name should specify the type of water such as 'natural mineral water,' 'naturally carbonated mineral water,' and 'carbonated natural mineral water.' The label should also give the place where the spring is exploited and a statement of the analytical composition giving its characteristic constituents. It is not permitted to market natural mineral water from the same spring under more than one trade description. It is also prohibited to mention both on the packaging or labels a characteristic that the water does not possess, especially with regard to treatment or cure of human illness.
5. Exploitation of a natural mineral water spring shall be subject to permission from responsible authority of the country where the water has been extracted.
6. Equipment for exploiting the water must be so installed as to avoid any possibility of contamination and to preserve the properties of the water at source.
7. When the natural mineral water at source becomes polluted and no longer meets the microbiological criterion for human consumption, all operations leading to the commercial sale should be suspended. It is the responsibility of the local authority to undertake periodic checks to control the original characteristics of the natural mineral water.
8. In developing countries, the regulations concerning the marketing of natural mineral water vary significantly from country to country. Even for the export of natural mineral water from industrialized to developing countries, the directive above may not apply.

The last report of the FAO/WHO codex standard in 1997 did not deviate significantly from the above directive.

History of Consumption

Water has always been of vital importance to man's health and well-being. Water originating or flowing from hot or cold springs with a strong odor or taste has always excited the imagination of humans. The human race has used such spring waters in a variety of ways throughout history. Mineral wells and spas are found all over the world. From time immemorial, healing powers have been attributed to water from mineral springs, wells, and spas. Even at present, water from such sources in many parts of the world, especially in developing countries, is accredited with miraculous properties. Many of the well-known health resorts in the world became famous mainly because of the mineral springs originating there. Millions of people visit such resorts every year hoping to gain relief from many chronic diseases, such as arthritis and skin diseases. Large numbers of patients have subjectively benefited from visits to such health resorts. Except for a few elements such as sulfur and fluorine, the concentrations of other minerals and trace elements in many spa waters are very low. Scientifically, there is little evidence suggesting any physiological or pharmacological action resulting from mineral or trace element contents in spas, except, in some cases, laxation.

From the Middle Ages came herbal brewing, another forerunner of modern packaged drinks. Such brews, flavored with nettles or dandelions, were made by boiling the locally available water. Such brews continued as part of the housewife's art for many decades, and in the 1820s, brewed ginger beer first became commercially available. In 1772, Joseph Priestly, a British scientist, published a method of producing artificially carbonated water. This development ultimately resulted in the commercial production of artificial mineral water during the latter part of the eighteenth century. From a public health point of view, the introduction of this artificial mineral water might have been a turning point from a bactericidal point of view. Originally, these waters were taken primarily for medical reasons prescribed by doctors for their patients. When it was possible to analyze the mineral composition of spa waters, artifically carbonated waters were fortified with the same mineral and trace element concentrations and sold as copies of the original spa water in various parts of Europe until after World War II. Later on, the use of these artificially carbonated waters became common owing to the pollution of urban water supplies. At present, such is the situation in the urban regions of most developing countries.

Populations in many European countries have consumed mineral waters from ancient times. The best-known waters come from France and Germany. Packaged waters from underground formations in Perrier, Contrexeville, Vichy, Appollinaris, and Evian are exported on a large scale. In North America,

the tradition of drinking mineral water is not as old as that in Europe. However, the packaged water industry in the USA and Canada has experienced radical growth owing to consumer awareness about the quality and taste of drinking water. In a recent survey conducted in the USA, more than 60% of consumers of packaged mineral water cited taste and harmful chemicals in the tap water as the primary reasons for buying packaged mineral water. The case is much the same with other affluent countries. The consumption of packaged mineral water has increased significantly in many European countries during the last few decades. This can be attributed to environmental, demographic, and aggressive marketing strategies. Consumers, especially in urban areas, have become increasingly concerned with the pollution of water supplies. Packaged mineral water, however, allows the consumer to control the quality, appearance, and taste of the water. Demographically, well-educated families have moved into high-income brackets with high levels of income. This factor, coupled with the modern trend in health consciousness, has positioned packaged mineral water at the forefront of the beverage category. Additionally, the prestige value of well-known brand names with connotations of quality has become a status symbol of high-income families. Finally, the aggressive marketing efforts by manufacturers of packaged mineral water have accelerated the growth in consumption of mineral water. In certain affluent countries such as Sweden, drinking of alcoholic beverages and driving is strictly controlled, and this in turn has increased the consumption of mineral waters on social occasions.

Health Implications

From a nutritional point of view, water is an essential constituent of diet. The dissolved substances in water include traces of essential and toxic elements. Since the concentration of these dissolved substances in drinking water varies from place to place, the total quantity of water consumed during a 24-h period affects the amount of these substances in the diet. In certain tropical regions of the globe, the water consumed during a 24-h period can be substantial. Although fasting on water to cure disease has diminished greatly in Western countries during the last few decades, a great deal has been written lately in the popular medical literature about the relationship between the presence of mineral elements such as calcium and magnesium in water and certain diseases in man, especially cardiovascular diseases.

Drinking water in many parts of the world is a good source of trace elements. It is also an important source with regards to the intake of certain unwanted components such as toxic metals, nitrates, and a number of organic and inorganic substances from industrial discharges and fertilizers. Any beneficial health effect that may be attributed to mineral water is likely to be due to its mineral content and freedom from pathogenic organisms. Table 2 shows the concentration of a number of trace elements that are allowed in natural mineral water according to the FAO/WHO Codex Alimentarious Commission.

Table 2 Levels of certain trace elements allowed in natural mineral water (FAO/WHO)

Element	*Concentration (mg l^{-1})*
Antimony	0.005
Arsenic (total)	0.05
Barium	1.00
Boron (as borate)	5.00
Cadmium	0.003
Chromium (total)	0.05
Copper	1.00
Cyanide	0.07
Fluoride[a]	1.00
Lead	0.01
Manganese	2.00
Mercury	0.001
Nickel	0.02
Nitrate	50.00
Nitrite	0.02
Selenium	0.05

[a]The levels of fluoride should be declared in the labeling by a general warning 'contains fluorides' when the levels are higher than 1 mg l^{-1}, and when it contains more than 2 mg l^{-1}, it should be stated that this water is not suitable for infants and children under the age of 7 years.

The essential mineral and trace element content in commercially available mineral waters in most parts of the world is so low that it will hardly influence the overall mineral and trace-element metabolism. In a limited number of studies, it has been found that mineral water from certain areas in Europe and North America contains levels higher than the permitted levels of a few trace elements, particularly that of iodine and fluorine. A few cases of osteofluorosis have been reported in individuals consuming mineral water containing higher than the permitted levels of fluorine. Such cases were observed when the fluorine levels were around 8 mg or more per liter. The calcium content may also vary considerably between different brands of still and carbonated mineral waters. Increased consumption of such mineral waters may not be ideal for individuals who are susceptible to stone formation in the urinary tract. In certain areas of the former Soviet Union, the consumption of highly mineralized water is known to be very high, and a correlation has been noted between the amount of water consumed and the concentration of crystal-forming substances in the urine of

adults and children. The same is the case with radioactive elements. An increased content of radon has been found in some of the wells in the USA and Europe. In some European countries where radon mineral water is used for treatment of diseases, an increased incidence of lung cancer has been reported in employees working in the spas.

In comparison with the amount of mineral water consumed in different parts of the world, the incidence of adverse effects described in literature, is, however, negligible. When one takes into consideration the ill health caused by waterborne diseases in many parts of the world, the introduction of mineral water that is free from pathogenic organisms can play a role in protecting societies from such diseases. At the same time, the considerable increase in mineral water sales in developed countries during the last few decades has compelled the public health authorities to set up very strict regulations concerning the quality of mineral water. (*See* **Calcium**: Physiology; **Heavy Metal Toxicology**; **Iodine**: Physiology; **Nitrosamines**; **Trace Elements**; **Water Supplies**: Water Treatment.)

Commercially available mineral waters have no calories or alcohol. These two qualities make mineral water a suitable beverage for low-calorie diets. It is not uncommon for doctors to prescribe mineral water to pregnant women and infants, especially in areas where the drinking water contains high levels of nitrates and fluorides. In recent years, attention has been focused on the health hazard arising from the ingestion of nitrates and nitrites. Nitrate, when reduced to nitrite, is a precursor of the carcinogenic nitrosamine or nitrosamide. The extensive use of fertilizers in recent years has resulted in the contamination of drinking water with nitrates in many parts of the world. The situation is much worse in most developing countries. In such areas, mineral water can be an excellent substitute for drinking water for risk groups such as pregnant women, infants, and young children. Drinking water in some parts of the world may also contain significant amounts of toxic elements, including arsenic, cadmium, mercury, and lead. Contamination of ground water with arsenic, for example, in Bangladesh and West Bengal is currently a serious health problem in Bangladesh and India. Several million people are affected by this contamination. Mineral water, however, has only negligible amounts of these elements (see Table 2). During the last few decades, a number of investigations have reported an association between the calcium–magnesium (water hardness) contents of drinking water and mortality from ischemic heart disease. Most brands of mineral water that are commercially available at present do not have a high concentration of calcium or magnesium. Since mineral water contains no alcohol, it is an ideal beverage to drink before driving. Mineral water has become very common and popular as a healthy beverage during social gatherings in affluent countries owing to the low level of alcohol (in some countries like Sweden, almost zero level) that is permitted to be consumed before driving.

In conclusion, mineral water *per se* has no medicinal property other than being free from pathogenic organisms. The mineral salts and trace elements present in many of the well-known brands of mineral water are in such low concentration as to be virtually devoid of physiological or pharmacological action. The possible exceptions are with regards to the content of fluorine, calcium, and some toxic metals and metalloids such as arsenic. Mineral waters are usually free from chlorine, and the taste is often superior to treated water.

Trends in Consumption

In recent years, sales of commercially available mineral waters have rapidly expanded, transforming mineral water from a market niche to a sizeable mainstream market segment, in many countries. The reasons for this growth have already been described. People enjoy still and carbonated waters all over the world. Sales of packaged waters in Europe and North America have risen considerably in recent years. The consumption of packaged water in some countries such as the UK and the Netherlands is somewhat modest when compared with that of the other central European countries. The demand, however, is growing steadily in most countries. The per capita consumption of packaged mineral water a decade ago in the central European region was around 80 l. The corresponding figures in the UK and USA were 23 and 28 l, respectively. Even in East European countries, the per capita consumption of mineral water was significant during the last couple of decades. In the former Yugoslavia, the per capita consumption during the 1990s was around 20 l. Although the consumption of mineral water, especially still water, is fairly common in the former Soviet Union, consumption data are not currently available. The same applies to many countries in Asia where the consumption of packaged mineral water is significant mainly owing to the poor quality of public water and the increase in tourism. Generally speaking, the per capita consumption of packaged mineral water in most affluent countries has more than doubled during the last decade. This trend is likely to increase in future years as a result of a heightening of the consumer awareness of health and increasing concern about the quality and taste of public drinking water.

Sources and Analysis

H Kussmaul, Institut Fresenius, Taunusstein, Germany

Background

Mineral water is a special form of groundwater, from which it differs in its composition and properties. The criteria for differentiation can lie in increased mineral content, elevated carbon dioxide content, elevated spring (source) temperature, or the presence of higher concentrations of trace substances such as iron, iodine, sulfur, fluoride, or radon. Such mineral springs have been preferred by people from ancient times, whether for drinking or bathing, because mineral waters often have, or are associated with, beneficial health properties.

There is no generally applicable definition of mineral waters. They are often bottled or canned and marketed as beverages on account of their pleasant taste and their claimed beneficial properties. Most countries, however, have regulations concerning such mineral waters that define what is required of the product.

The countries of the European Community, for example, have guidelines for the production of, and trade in, natural mineral waters that have been adopted as national law by the individual member states. Here, it is required that natural mineral water shall differ appreciably from drinking water. Mineral water is water that meets the following special criteria:

- It has its origin in underground water resources that are protected from contamination and obtained from one or more natural or artificial sources.
- It is of original purity.
- It possesses particular nutritional–physiological effects on account of its content of minerals, trace elements, or other components.
- Its composition, temperature, and other characteristics remain constant within defined limits of natural variation.

Some countries (e.g., Germany) lay down maximum permissible concentrations for toxic substances (**Table 1**). The European Commission is currently discussing uniform limits for such substances, in some cases the limits will be more stringent.

The use of the product description 'natural mineral water' for such a packaged beverage requires that compliance with the defining characteristics has been checked officially and that the product has been recognized officially as a natural mineral water.

The natural purity requirement presumes that there is no microbiological or chemical danger of anthropogenic or environmental origin.

Once a source has been officially recognized for natural mineral water, it must be exploited in such a manner that all possibility of contamination is avoided and that the characteristics of the water

that justify its being a natural mineral water are maintained when it leaves the source.

It is forbidden to process the water or to add substances to it during the packaging, with the exceptions that unstable components such as iron or sulfur compounds may be removed, and carbon dioxide may be added to the water. In particular, it is forbidden to disinfect the water by any means or to add microbiological inhibitors. Any other treatment to change the microbial count of the natural mineral water is also forbidden.

In the USA, there are no uniform, special rules for mineral water. It is covered by the regulations of the bottled water standards. If the major components exceed the maximum contaminant level (MCL) for drinking water, this must be stated on the label, for instance; the following phrases are used in New York:

> This is a mineral water and should not be used as a sole source of drinking water

if bottled water products have received exemption from only the esthetic-related inorganic chemical MCL or

> This water contains levels of minerals in excess of standards for drinking water established by the New York State Commissioner of Health and, therefore, should not be used as a principal or sole source of drinking water.

if bottled water products have received exemption from the health-related MCL.

Furthermore, in the USA, all bottled water must be disinfected, which is forbidden in Europe. The standards in Florida allow, in this case, that imported water, which may not be disinfected in its land of origin, may be imported into Florida without being subjected to disinfection.

With certain exceptions, the rules for many other countries lie between these two extremes, of mineral water that differs appreciably from drinking water in the countries of the European Community and mineral water that is on the same footing as drinking water in the USA.

Sources

Natural mineral water is obtained either from free-flowing natural sources or from artificially constructed wells. Sources or wells are to be so constructed that microbiological or chemical contamination of the natural mineral water is prevented. The measures concerned involve securing the exit from free-flowing sources, and building a well-head and seal between bore and piping in the case of a well. The conveyance and transport of the water must be carried out using piping that does not contaminate the water and that is proof against corrosion by the mineral water, which is often aggressive against iron (not stainless steel) pipes.

Mineral and thermal waters often come from great depths. The temperature of the water increases with the depth from which it is drawn, the geothermal gradient normally amounts to 3 °C per 100-m depth. Water that is appreciably above average in temperature (for example, by more than 10 °C) is frequently referred to as 'thermal water.' The composition of the mineral water depends on the composition of the underground rocks through which it flows. Limestone and dolomite rocks produce calcium or calcium–magnesium–hydrogen carbonate (bicarbonate) waters; salt deposits yield sodium chloride water; and the rocks lying over salt deposits yield calcium sulfate waters. The amount of dissolved minerals is a function of the time spent underground and the solubility of the individual minerals. The solubility can be considerably increased by the influence of volcanic carbon dioxide or elevated temperatures. However, primary rocks, e.g., in Scandinavia, are very insoluble and yield very few minerals to the water obtained from them.

Since water often flows great distances through various rocky strata and remains underground for decades or centuries, the waters that are produced are frequently not pure simple water types, but mixtures of waters of various compositions that come together either underground or during extraction.

Analysis and Composition

The extent of a mineral water analysis depends on the purpose for which it is being made. Microbiological analysis and analysis of the major components and characteristic minor components are generally sufficient for the control of a mineral water. A basic investigation or an application for official recognition require a more comprehensive analysis that covers the inorganic and organic traces, as completely as possible, as well as including the microbiological status and the major components.

Sampling is simple when bottled mineral water is investigated. The product is sampled immediately after filling, or a sample is purchased from a retail outlet. However, proper sampling is essential if a representative analysis is to be obtained from the source. A range of measurements together with the variable parameters such as temperature, redox potential, oxygen content, carbon dioxide content, and radioactivity should be carried out on-site. Other constituents, e.g., iron(II) compounds, hydrogen sulfide, and cyanides, require stabilization in order to allow their determination in the laboratory without change.

Major Components

The major components of mineral waters are the cations of sodium, potassium, magnesium, and calcium, and the chloride, sulfate, and hydrogen carbonate (bicarbonate) anions. The amounts and proportions depend on the rocky strata that have been permeated. The composition of a well-known German mineral water is given as an example in Table 2. Refer to individual minerals.

The first column gives the named ion's mass concentration in milligrams per liter. The next column gives the equivalent concentration of the individual components in millimoles per liter. The sum of the equivalent concentrations of the cations must be identical to the sum of the equivalent concentrations of the anions. The last column reports the equivalent proportion of the individual ions with respect to the total number of equivalents. This provides a particularly clear indication of the characteristics of the water. In the present case, it is a sodium–magnesium–bicarbonate–chloride water. The slightly or completely nonionic undissociated components primarily consist of silicic acid, whose concentration depends on the temperature of the region from which the water is obtained, and boric acid. The sum of the mass concentrations of cations, anions, and undissociated components yields the total mineral content of the water.

In addition, it is important for the assessment of a mineral water to measure the content and composition of dissolved gases. Higher concentrations of carbon dioxide come primarily from water of volcanic origin. Groundwaters from great depths do not normally contain oxygen, as they are present in a reduced, anaerobic state. In addition to carbon dioxide, they contain nitrogen, increased concentrations of noble gases, and sometimes low-molecular-weight hydrocarbons such as methane and ethane. Apart from increased concentrations of carbon dioxide and radon, the composition of the gases in groundwaters from nearer the surface is broadly in agreement with the composition of air.

Inorganic Trace Substances

Deep waters with elevated mineral contents more frequently contain higher concentrations of trace substances than the groundwater from near the surface, which is often used to supply drinking water. However, these higher concentrations are natural and do not indicate anthropogenic contamination.

The EC guidelines are general and state only that heavy metals should be analyzed. The German mineral water regulation lays down which inorganic trace substances must be investigated. Some maximum permissible concentrations are laid down that are frequently equal to the limiting concentrations for drinking water (Table 1). (*See* **Heavy Metal Toxicology** and Refer to individual metals.)

Organic Compounds

The organic substances in mineral waters are characterized in summation by the coefficients of spectral absorbance at 254 and 436 nm, by the dissolved organic carbon, and by the amount oxidized with potassium permanganate. The extractable substances,

Table 2 Main components of 'Apollinaris' naturally sparkling mineral water

	Mass concentration (mg l^{-1})	*Equivalent concentration (meq l^{-1})*	*Equivalent percentage*
Cations			
Sodium (Na^+)	430	18.70	57.19

Total	1878	32.84	100
Undissociated substances			
Silicic acid (meta) (H_2SiO_3)	26.7		
Total	2561		

the organic nitrogen, the phenol index, and the concentration of surface-active substances, where raised levels can provide an indication of environmental pollution, are also determined. The same is also true of polycyclic aromatic hydrocarbons and phenols. Indicators of environmental pollution such as chlorinated solvents, chlorinated phenols, plant-protection agents and pesticides, high-boiling-point halogenated compounds and aromatics, plasticizers, and antioxidants are only determined with respect to the original purity. Their presence is of anthropogenic origin. In such a case, it is not possible to guarantee the original purity, which is a prerequisite for official recognition as a natural mineral water. (*See* **Contamination of Food; Pesticides and Herbicides**: Toxicology; **Phenolic Compounds; Polycyclic Aromatic Hydrocarbons**.)

Ratios of natural isotopes are frequently employed to determine the origin and age.

Microbiological Analysis

The legal regulations describe and lay down precisely the requirements and methods to be used in the microbiological investigations.

Methods of Chemical Analysis

Since the concentrations encountered are frequently higher than those occurring in drinking water, the methods used for the chemical analysis of mineral waters are often specially adapted and validated. The traditionally tested methods of water analysis still have their place, however. For example, gravimetry is the preferred method for high concentrations of alkaline earths (magnesium, calcium, strontium) and for sulfate concentrations; titrimetry is of importance for the determination of chloride and hydrogen carbonate. However, many of the modern instrumental methods of analysis must also be used. Atomic absorption spectroscopy, atomic-emission spectrometry with inductively coupled plasma, gas chromatography, gas chromatography–mass spectrometry, and high-performance liquid chromatography have established indispensable positions in the analysis of inorganic and organic trace substances. Ion chromatography finds its major application in the rapid determination of the major anions. (*See* **Chromatography**: Gas Chromatography; High-performance Liquid Chromatography; **Mass Spectrometry**: Principles and Instrumentation.)

Bottling and Storage

H Kussmaul, Institut Fresenius, Taunusstein, Germany

Introduction

As in the previous article concerning the definition of mineral waters, when discussing the processing of mineral waters from their extraction at the source to their filling into bottles or other types of packaging, it is necessary to distinguish between the requirements placed specifically on natural mineral waters by the European Community (EC) guidelines and international Codex Alimentarius Standard 108 and those for the filling of drinking water (bottled water).

The EC guidelines and the Codex Standard require that the extraction, storage, and filling be carried out in such a manner that impurities are avoided and that the properties the water possesses as it leaves the source, and which justify its character as a natural mineral water, are preserved. In particular, it is necessary to insure that:

1. The source and the exit from the source are protected from danger of contamination.
2. Attachments, piping and containers are made of materials suitable for mineral water and are so constructed that they do not cause any detrimental chemical, physical, or microbiological changes to the water.
3. The technical facilities, in particular the bottle-filling and cleansing plant, meet the hygiene requirements.
4. The containers are so treated or manufactured that they do not change the microbiological or chemical characteristics of the water.

Mineral Water Extraction and Storage

In accordance with the EC guidelines on the exploitation of mineral water sources, mineral water is mostly extracted through a stainless-steel riser by means of a submerged pump and transported to the filling facility in suitable piping (hard polyvinyl chloride (PVC) or high-density polyethylene (HDPE)). The piping must be constructed so that microbiological and chemical contamination cannot reach the water.

In some regions of the EC, e.g., Italy, the water may not be pumped but must travel to the filling plant and the packing line under natural pressure.

There are often storage facilities to form a buffer supply. This means that the water can be pumped continuously from the source at a moderate rate even though the filling facility is only operated on working days for one, two, or three shifts.

In order to avoid deleterious effects on the water as it passes through the piping or stands in the storage tank, the surfaces must be smooth and no growth of microorganisms should occur, otherwise reduction or oxidation processes might take place in the water. Ammonia could be oxidized to undesirable nitrite, or nitrate reduced to nitrite, depending on the conditions. Hence, the piping and storage vessels must be cleaned regularly. This can be done by means of chemical, thermal, or mechanical cleansing and disinfection measures. (*See* **Cleaning Procedures in the Factory**: Types of Detergent; Types of Disinfectant; Overall Approach.)

Water Preparation

In the USA all the water preparation measures applicable to drinking water may be used that are thought necessary. The standard for the state of New York reads:

> All bottled water facilities packaging water for distribution in New York State must provide satisfactory treatment of each water supply source used. Minimum treatment of each water supply source used shall be disinfection by chlorination, ozonation, ultraviolet radiation, or other disinfection methods as protective of the public health as the above.

Since drinking water in the USA is normally heavily chlorinated, ozone is frequently used to disinfect bottled water in order to avoid a chlorine flavor.

In the countries of the EC, on the other hand, mineral water may not be subjected to any processing at all; it is merely permitted to remove from natural mineral water unstable components which could alter the properties of the water as it is bottled or while in the bottle. These are primarily iron and sulfur compounds.

Iron often occurs in mineral waters that originate at great depth in reduced bivalent form. This is unstable in the presence of air and is oxidized to trivalent iron by oxygen in the air, causing the formation of yellowish or, in the presence of manganese, brownish floccules in the water. This is unattractive to the consumer. For this reason it is permissible to remove this naturally occurring iron from the water by oxidation and filtration.

Reduced mineral waters also often contain reduced sulfur compounds, usually hydrogen sulfide. As is well known, in such cases the water has a smell reminiscent of rotten eggs. This smell would also be unpleasant in the bottles and it is thus necessary to remove these naturally occurring sulfur compounds by aeration or oxidation, followed, if necessary, by filtration. In EC countries it is necessary to declare on the label that iron or sulfur has been removed.

Carbon dioxide may be removed from heavily carbonated waters if this is necessary for filling. There is also the possibility, frequently made use of in some countries, of adding carbon dioxide to the water, thus endowing it with a refreshing, tickling flavor.

Other treatment processes, such as the addition or removal of mineral substances, are forbidden for natural mineral water in the EC. The disinfection of the water is explicitly forbidden. Rather, the microbiological state of the water must always be satisfactory at the source, and deterioration must be avoided before the water is filled.

Filling and Packaging

In the countries of the EC, natural mineral water that is to be marketed must be filled at the source. Filling is carried out on high-speed filling machines, generally into bottles, which can be made of glass or plastic. Only limited quantities are filled into cans (aluminum

or tinned steel) and soft packagings (tetrapacks, combiblocks, etc.).

Disposable glass bottles are often used, which are purchased from glassmakers and are intended to be recycled to the glass works in a voluntary manner. Mineral water is mostly filled into reusable glass bottles in Germany. These are standard returnable bottles that can be refilled c. 40–70 times.

The plastic bottles that are usually or exclusively (e.g., in Arab countries) used in some countries, are primarily made from polyvinylchlorides (PVC), polyethylenes (PE), or polyethyleneterephthalats (PET); they are either bought-in ready for use or blown from blanks (preforms) on site. The plastic bottles in use at the present time are disposable bottles, while returnable PET plastic bottles are now in use for nonalcoholic beverages; these are still under test in the case of mineral water. However, for environmental reasons it will be impossible to avoid their use in so far as they allow unrestricted production of mineral water.

Complicated, multistage cleansing machines that supply acceptably cleaned bottles for filling are required for reusable glass or plastic bottles. The acceptable condition of the bottles must be monitored by an expensive bottle-checking system. The control of reusable plastic bottles has been found to be particularly expensive since it must also be insured that substances that may have been adsorbed on to the walls are completely removed. Expensive gas-sensitive detectors are necessary for this purpose.

The package used for filling of natural mineral water must be fitted with a cap that is suitable for preventing adulteration or contamination. This serves to protect the consumer, who can then establish whether the container is in its original state or whether it has been tampered with.

Labeling

For the labeling of all bottled waters in the USA, each label shall indicate:

- the type of source water: spring water, well water, public water supply, etc. (for distilled water, the type of source water does not need to be indicated)
- address and location of the bottling facility or corporate offices
- net contents and/or capacity of the container
- the certificate number

There can be individual differences from state to state. Mineral waters containing high concentrations of mineral substances must, if necessary, be labeled to point out that the drinking water standards are exceeded for certain substances.

In the countries of the EC there are special labeling rules for natural mineral water. The marketing name is always 'natural mineral water,' with a possible indication concerning the carbon dioxide content:

- 'naturally carbonated natural mineral water' means water whose carbon dioxide content from the spring after decanting, if any, and bottling is the same as at source, taking into account where appropriate the reintroduction of a quantity of carbon dioxide from the same water table or deposit equivalent to that released in the course of those operations and subject to the usual technical tolerances;
- 'natural mineral water fortified with gas from the spring' means water whose carbon dioxide content from the water table or deposit after decanting, if any, and bottling is greater than that established at source;
- 'carbonated natural mineral water' means water to which carbon dioxide has been added from a

Table 1 Labeling indications relating to the composition of mineral waters (EC)

Indications	*Stipulation*
Low mineral content	The inorganic constituents, calculated as dry residue, shall not be above 500 mg l^{-1}
Very low mineral content	The inorganic constituents, calculated as dry residue, shall not be above 50 mg l^{-1}
Rich in mineral salts	The inorganic constituents, calculated as dry residue, shall be above 1500 mg l^{-1}
Contains bicarbonate	The bicarbonate content shall be above 600 mg l^{-1}
Contains sulfate	The sulfate content shall be above 200 mg l^{-1}
Contains calcium	The calcium content shall be above 150 mg l^{-1}
Contains magnesium	The magnesium content shall be above 50 mg l^{-1}
Contains fluoride	The fluoride content shall be above 1 mg l^{-1}
Contains iron	The bivalent iron content shall be above 1 mg l^{-1}
Acidic	The free carbon dioxide content shall be above 250 mg l^{-1}
Contains sodium	The sodium content shall be above 200 mg l^{-1}
Suitable for the preparation of infant food	Different regulations apply in the various member states
Suitable for a sodium-reduced diet	The sodium content shall not be above 20 mg l^{-1}
May be laxative	–
May be diuretic	–

source other than the water table or deposit from which the water comes.

The label must also state the site and name of the source, the composition of the water, details of the mode of treatment (not every country), and minimum storage life. If the label provides information concerning particular components or special suitabilities, the requirements listed in Table 1 apply. For instance, statements concerning the diuretic or laxative properties of the water are not allowed in some EC countries, e.g., Germany, since such indications are reserved for medicinal mineral waters.

In general the various member states lay down their own regulations for labeling natural mineral waters that go beyond the EC requirements, and which cannot be reported in detail here. Sometimes the labels must be submitted for certification or authorization.

MINIMALLY PROCESSED FOODS

T Ohlsson, SIK–The Swedish Institute for Food and Biotechnology, Gothenburg, Sweden

Introduction

Minimal processing of foods covers a wide range of technologies and methods of preserving food during their transport from the agricultural production to the consumer. Minimal processing methods have in common that the processing changes the inherent fresh-like quality attributes of the food as little as possible (minimally), while the processing gives the food product sufficient shelf-life for transport from processing to consumers. Sometimes the term 'invisible (to the consumers) processing' is used for some of these methods.

Consumer Demand for Minimal Processing

Diet and Health

Diet and health are firmly established as long-term lifestyle, where healthy food is one of the important components of well-being.

Convenience and Simplicity

Convenience and simplicity are still very important, and must also now include the increasing health aspects.

Uncertainty

Uncertainty and the need for guarantees are signs of the increasing concerns for the impact of environmental pollution. There is a feeling that few foods are safe, and this results in reluctance to trust the traditional food supply and especially 'new' foods.

Food is Part of the Good Life

Interest in food and cooking is rising, with an emphasis on natural ingredients and cooking from scratch, including ethnic foods.

Market Trends

The trends in consumer values are strongly influencing the trends on the food markets. 'Low' and 'light' products are a major trend, oriented at lowering the caloric content of the food, often combined with lowering the content of ingredients such as fat, sugar, and salt. Additives (with E numbers) are removed from the foods and sometimes replaced by

natural ingredients with similar properties, if such are available. This trend goes hand in hand with the push towards more natural, more fresh-like products, evident from reviews of new product introductions on the UK market. The most active market segment is the chilled, ready-to-eat or ready-to-heat foods; typically in single-serving packages, designed to meet the needs of convenience and simplicity. But many of these products have short shelf-lives, typically a few days only, limiting the geographical area where they can be marketed. Technologies that allow for a two- or threefold prolongation of the shelf-life are much sought after, and increasingly applied.

It is not only the extended time of distribution and storage that is attractive. Added product safety is much in demand by producers and distributors.

The fresh-like products are highly perishable, and actions that add to the safety factors are important, e.g., in the light of the new legislation on product liability, and due diligence.

On the other side of the shelf-life spectrum, traditional long-life ambient storage products are also affected by the consumer trends. Long shelf-life is no longer an important selling point, with market trends towards more fresh-like products. Therefore, preservation technologies that prolong shelf-life but do not act detrimentally on the product quality attributes are in favor on the market. The push towards shorter shelf-lives for ambient shelf-life products is also supported by the demand for more rapid turnover of stock. This is due to the need to decrease capital costs and to the more rapid market changes pushed by improved communication between market and production, through electronic data identification (EDI) and computerized checkout counters.

Finally, an important packaging trend is to downsize material thickness and choose 'mono' material packaging. With the resulting lower barriers to oxygen of the packages, the product shelf-life is reduced.

In conclusion, products with a very short shelf-life will need preservation methods that will prolong the shelf-life, while long-shelf-life products need methods that give a shorter shelf-life but with improved quality. These methods are to be found in the group of technologies and methods called minimal processing.

Minimal Processing Technologies

In minimally processed foods, storage, processing, packaging, and distribution are accomplished in highly integrated systems. Each step must be considered in conjunction with the other steps. Different minimal processing methods can be applied at the various steps in the food distribution chain, from storage of agricultural products to packaging/processing of the ready-to-eat product. In this introduction and overview, different minimal processing technologies and methods will be presented following the food distribution chain. Detailed accounts of these methods can be found in the literature. A list of the methods reviewed here is given in Table 1.

Modified Atmosphere Storage

By modifying the composition and sometimes the overall pressure of the atmosphere in the storage environment, quality-and safety-degrading biological reactions can be slowed down or inhibited. For storage of fruits and vegetables, increased carbon dioxide concentration (up to 10%) and reduced oxygen concentration (3–5%) will retard respiration and prolong the shelf-life. Relative humidity is also an important factor, as is control of ethylene emission from the respiring fruits and vegetables.

A reduced pressure during storage is also used, often in combination with modified CO_2 and O_2 concentration levels. This method is often called hypobaric storage, using pressures of some hundreds of mmHg.

Postharvest Treatments

In order to add convenience to vegetables and other agricultural products, centralized cleaning, peeling, and cutting is common. The resulting products are often less stable after the treatment, due to enzymatic activity of cut cell walls and bacteriological contamination from the handling. Various postharvest treatment methods are employed to add biological stability and extend shelf-life. Chlorinated cleaning water is used. Soaking in solutions of reducing agents such as ascorbic acid or sulfite or preservatives such as sorbate or benzoate are used. Also, divalent ions, Ca^{2+}, are used to strengthen the texture. In all these treatments low temperature and good processing hygiene are essential to achieve the desired shelf-life, as treatments such as cutting instead reduce the shelf-life.

Clean-Room Technologies

The objective in clean-room technology is to eliminate microbiological contamination from humans or from the environment. The handling of the food is automated as much as possible. Equipment and the processing environment are presterilized before production. Air curtain and a positive air pressure are maintained in the processing line using sterile-filtered air. Production personnel use extensively protective clothing to reduce air- and human-borne microorganisms. Clean-room technologies are primarily

Table 1 Applications of minimal processing methods

Process	*Applications*	*Mechanisms*
Controlled-atmosphere storage	Bulk-stored fresh fruit and vegetables	Antimicrobial effect (inhibition of aerobic and anaerobic organisms); altered respiration rates
Postharvest treatments	Fresh vegetables	Antimicrobial effect
Chlorinated water soaking		
Reducing agents		Oxidation prevention
Preservatives		Antimicrobial effect
Divalent ions		Improved texture
Clean-room technologies	Fresh meat and fish	Reduced levels of environmental microorganisms
Protective microbes (lactic acid bacteria)	Dairy products; sausages	Release by the protective microbes of bacteriocins that reduce pH and microorganisms
Nonthermal processing methods		
High-pressure treatment	Many products, currently especially fruit products	Microorganisms ruptured under high pressure
Gamma irradiation	Many products, particularly fresh fruits, poultry, and spices	Ability of microorganisms to reproduce eliminated
High-electric-field pulses	Many products, particularly fruits	Microbial cell rupture due to uneven distribution of electrical charge across cell
Thermosonication	Drinks	Synergistic effect of ultrasound and heat
New thermal processing methods	Many products, especially finished meals	Optimized heating regime reduces levels of microorganisms while minimizing thermally induced quality losses (e.g., impaired flavor)
Ohmic heating		
High-frequency heating		
Microwave heating		
Sous-vide technology		
New packaging technologies		
Modified-atmosphere packaging and active packaging	Fresh meat and fish, prepared foods, baked goods, fresh fruit, and vegetables	Antimicrobial effect (inhibition of aerobic or anaerobic microorganisms); altered respiration rates in fruits and vegetables
Edible films	Dry, frozen, and semimoist foods	Protection against oxygen ingress, moisture loss, and flavor loss

developed for fresh prepared food and for dairy products. Clean-room technology is often an expensive method, which often means that the application is limited to high-value-added products and to a limited part of the production line. Also the hygiene classes used in the food industry are higher than in other industries using clean-room technology.

Protective Microbiological Treatment

It is well known that many microorganisms produce antimicrobial agents. Some lactic acid-producing bacteria produce bacteriocins that are efficient in stopping the growth of, in particular, Gram-positive spoilage bacteria. By adding selected lactic acid-producing strains to the surface of foods, controlled growth can create an antimicrobial condition at the food surface. The application of these methods is still in development. (*See* **Microbiology**: Classification of Microorganisms.)

Combination Methods: Hurdle Technology

Reducing the levels of salt, sugar, or acid in foods in order to improve consumers' acceptance often means increased perishability of the food. To attain sufficient shelf-life, a combination of preservation methods is often applied. The 'hurdle concept' is a simplified illustration of the principle for combination processing. By fine-tuning a preservation system with a number of methods, more knowledge is built into the product – an important step in product development.

Nonthermal Processing

High-pressure By applying pressures in the range of some thousand atmospheres on biological material, some enzymes and vegetative microorganisms can be inactivated. Cell membranes are broken. Very high pressures in combination with elevated temperatures are needed for the inactivation of bacterial spores. High-pressure treatment also changes the texture of food, e.g., coagulate proteins and swell starches. The method is commercialized in Japan and Europe for treatment to prolong the shelf-life of low-pH fruit products. In Spain, ham products are treated, with a resulting prolonged shelf-life. In the USA, avocado paste is treated at very high pressure. Extensive

research and development is now taking place to investigate the possibilities and limitations of the method.

Irradiation Very extensive research into the method in the 1950s and 1960s, particularly the wholesomeness of the irradiated products, demonstrated that the method is an efficient and safe preservation method. In spite of this, the commercial use has been very limited, due to consumer scepticism coupled with legislative limitation. Use of the method is gradually increasing in Europe and the USA, with applications for fresh fruits, poultry, and spices. The method is expensive, with typical processing costs of 0.1–0.2 Euro kg^{-1} product. Of course, this limits the application to high-value products. (*See* **Irradiation of Foods**: Applications.)

High-electric-field pulses When cells are subjected to electrical pulses with field strength of 15–35 $kV\,cm^{-1}$, cell membranes are broken due to an uneven distribution of electrical changes on both sides of the cell membranes. The broken cell walls cause inactivation of microorganisms. The method is more efficient the larger the cell, e.g., for yeast. Thus, the most interesting future application is for products where yeast growth is limiting the shelf-life, e.g., fruit products and other drinks. A number of active research programs are found in Europe and the USA, but the method is not commercial yet. (*See* **Heat Treatment**: Electrical Process Heating.)

Thermosonication By combining ultrasound treatment at 20–40 kHz with heat treatment at moderate temperatures, the inactivation of microorganisms can be strongly enhanced. It will thus enable pasteurization of drinks at lower temperatures with less thermally induced quality changes. Thermosonication is also efficient for enhancing enzyme inactivation. The method is not used commercially in the food industry. (*See* **Preservation of Food**.)

Thermal Processing

Mild heating methods There is much interest in mild heat treatment methods, which avoid excessive temperatures, resulting in thermally induced quality losses. Often a reduction of only a few degrees can have a dramatic influence on liquid losses of meat or fish. Yet the heat treatment needs to give microbiological safety to the product. With the help of modern process optimization and control methods, mild heat treatments that combine these objectives have been developed. Among these, most interest is found in direct heating methods such as microwave heating, that can be used to raise the temperature quickly and shorten the processing time. For industrial applications, the microwave equipment is designed by computerized methods to control the heating uniformity, by controlling the overheating of the edges and corners of the foods. The direct electric heating methods are typically two to five times more expensive than traditional heating methods. Thus their use is limited to processes with benefits in terms of better production yield or product quality.

Sous-vide cooking In sous-vide cooking, fresh food is vacuum (sous-vide)-packed, under hygienic conditions. The packed products are cooked at fairly low temperatures in water to internal temperatures determined by culinary objectives. The long cooking times give some tenderization effects. Excessive temperatures are avoided, allowing for high moisture retention and juiciness. As the microbiological safety of the sous-vide cooking can give rise to some concerns, depending on the processing temperature, the shelf-life is often limited to 6–20 days at temperatures of $+3\,^{\circ}C$.

Packaging

Modified-atmosphere The methods described above for controlled-atmosphere storage are also applied for individually packed food products. Fresh meat and fish, prepared foods, and baked foods are packed in modified atmosphere, with high concentrations of CO_2. Permeability of the packaging material to CO_2 is important to control.

Carbon dioxide is bacteriostatic and fungistatic. Increased CO_2 concentration will thus inhibit the growth of microorganisms as long as a sufficient concentration of dissolved CO_2 is maintained in the surface of the food. Refrigerated storage is required for CO_2 to be effective. A wide range of fresh and prepared foods are distributed and stored in the atmosphere with high CO_2 concentration (50–10%). Often O_2 concentration is reduced or essentially nil, except for fresh meat, where it is held at 20% oxygen in order to maintain the red meat color.

For vegetables, where the respiration is continuing and the CO_2 concentration would increase to levels that adversely affect the quality, microperforations in the packaging film allow the respired CO_2 gradually to escape from the package. (*See* **Packaging**: Packaging of Solids.)

Active packaging This term covers packaging methods and agents that actively influence the shelf-life of the food during storage. The best-known example is the oxygen absorbers or scavengers, which reduce the head space and permeating oxygen levels. The scavengers come as small sachets or tablets to be introduced into the package. It is predominantly

Fe^{2+} ions that are used. The reduced level of oxygen in the head space prevents development of rancidity, and is also effective in reducing growth of certain types of microorganisms, e.g., molds.

Other types of active packaging systems are ethanol vapor generators. The ethanol absorbed on silicon dioxide powder and contained in paper sachets prevents the growth of molds. They are mainly used for bakery products.

Edible Coatings

The rapid development of biodegradable films for food packaging has helped to strengthen the development of edible coating applied directly on food. Coatings are made from films of proteins, starches, or waxes. The coating will protect against oxygen, aroma components, and moisture to the product, reducing the requirements on packaging. Most films are sensitive to moisture, which limits their application to dry, frozen, and semimoist foods.

Minimal Processing in the Future

The minimal processing technologies represent a means of meeting the well-established, long-term trends in consumer demands for convenience, variety, and fresh-like quality. Such technology will allow the food industry the possibility of producing high-quality, high-value-added products to meet future consumer demands. The technologies require varying degrees of capital investment. But, most importantly, the technologies require investment into product and process know-how, not only of the minimal processing technology itself, but also of the integrated chain of food distribution, from agricultural production to the consumer.

An important future area is the understanding of the antimicrobial effects of enzymes and other biochemical agents. In addition, nonthermal processing methods need to be further investigated in terms of the mechanisms of preservation as well as engineering aspects of the industrialization of the methods.

Finally, future research into shelf-life treatments must include integrated approaches involving many different aspects along the production chain, such as hygienic design, and automated handling of products and packaging.

MIXING OF POWDERS

N Harnby, University of Bradford, Bradford, West Yorkshire, UK

Introduction

The mixing of dry or near-dry powders is a very common operation in the food industry. Powder mixing may be required prior to dispersing the powder into a dough, paste, or dispersion form, but an increasing number of products are now packaged and marketed directly to the customer in the dry form. In either case a poor understanding of the mixing process can result in a failure to mix consistently and effectively.

Many of the problems associated with powder mixing arise because it is assumed that powders behave in a similar way to the more familiar liquid and gaseous mixing processes. They do not! The major differences are that, in comparison to liquid and gaseous systems, the powder system has poor mobility and large primary particles. The poor mobility or flow leads to processing and packaging problems, while large particles lead to poor mixture quality. (*See* **Agitation**.)

The Influence of Powder Flow on the Mixing Process

Powder Flow Types

For all process fluids a high mobility is generally a desirable property. This speeds up the rate-controlling processes and facilitates both process control and the product-packaging process.

Visual examination of a variety of powders leads to a broad classification into free-flowing and cohesive categories. Free-flowing powders, such as granulated sugar, exhibit a smooth flow, an attractive nondusty appearance, and little adhesion to the container. Cohesive powders, such as flour, have an erratic stick–slip flow, are often very dusty, and stick to the walls of the container. Particle size is evidently an important determinant of flow type. If the mean particle size of a powder is greater than about 50 μm, it will tend to be free-flowing, whilst below that size it will tend to be cohesive. This boundary between flow types is dependent on more characteristics than particle size, but it is a very significant boundary in that it determines the philosophy of processing the powder and the type of mixer to be used.

Particularly for the large-tonnage industries, the attractions of a free-flowing powder from both a processing and a marketing point of view tend to outweigh the quality advantages of the cohesive powder. The attractions of free flow are often so strong that significant process costs will be incurred in order to aggregate an otherwise cohesive powder to achieve a free-flowing characteristic. Only when product quality becomes dominant does the finer texture of the cohesive powder become attractive. This is often the case for high-value-added applications, such as in the pharmaceutical and ceramics industries.

Free-flowing Powders

A single particle is the ultimate mobile element of a powder mixture and, in contrast to the uniform molecular nature of the gaseous and liquid systems, each of these elemental particles will have unique properties of size, shape, roughness, density, porosity, etc.

It is the uniqueness of individual particles that gives rise to the extremely dangerous process characteristic of segregation. If particles are subject to motion they will not randomize as in a molecular system, but will instead take preferred or segregating paths depending on their individual characteristics. This can lead to a gross loss of quality. If the constituent powder particles are chemically identical, then the segregation will only lead to physical variation between product packages. If there is also a chemical variation in a powder mixture then segregation can be much more dangerous, as the product will then have chemical as well as physical variation between packages.

Free-flowing powders are especially prone to segregation as individual particles are not subjected to any structuring restraints and have considerable freedom of movement.

All powder motion can potentially cause segregation, but the following are some of the more dangerous:

1. Projection. Coarser particles are generally projected farther than finer particles if projected at a constant velocity. Sources of projection in powder processing can be identified in pneumatic conveying, conveyor belt transport, chute flow, and higher-speed mixers.
2. Percolation. Smaller, denser particles have a greater ability and mobility to percolate through a loose mass of particles. One of the severest segregating mechanisms takes place when particles tumble or roll down an inclined plane.

When particles are poured into a heap the coarser particles roll to the edge of the heap and the fine particles percolate through the mobile face of the heap to form a central core. A rolling plane can also often be observed as hoppers, drums, sacks, and packages are being filled or emptied, or when a drum of powder is rolled. Another form of percolating segregation occurs when a loose powder is vibrated. Coarse particles tend to rise to the surface as fine particles percolate to the base of the container. Most product packages are vibrated in the transport operation between manufacture and receipt by the customer, and the product homogeneity can be destroyed in the process.

3. Elutriation. If a gas is passed through a loose powder mixture, the smaller particles will tend to be blown clear or elutriated from the mixture. This process commonly occurs when containers are filled. Powder displaces air as filling occurs, and the air elutriates out the finer particles, which are either blown clear or settle back on to the surface of the container.

As even small differences in particle size, shape, and density can produce significant segregation, the best way of eliminating or significantly reducing segregation is to build a structuring mechanism into the powder flow in some way. This can be done by reducing the mean particle size of the mixture, adding a fibrous or flake-like material, or adding some moisture to the system. This is to say, making the powder more cohesive. If this is not possible, then segregation has to be minimized by careful choice of mixer and mixture handling.

For a free-flowing mixture, the philosophy of mixer choice should be to minimize the opportunity of individual particles to choose their own path of motion and to impose a displacement on the particles by the mixer. A rolling, tumbling mixer gives individual particles freedom and is undesirable, whilst a ribbon or paddle mixer pushes and relocates groups of particles and is to be preferred (**Figure 1**). For this type of mixer, considerable thought should also be given to the method of emptying the mixer, as the emptying process can segregate an otherwise acceptable mixture as the mixture discharges.

Ideally, a free-flowing mixture should be packaged immediately on discharge from the mixer as any intermediate handling between discharge and packaging can potentially destroy the mixture quality.

Cohesive Powders

Cohesive powders have many unattractive properties. They flow badly and can disrupt a packaging line. They cannot easily be metered into the mixing process. They can be dusty and potentially hazardous. They are a potential source of contamination between batches. They have an unattractive appearance.

From a mixing point of view, however, cohesive powders have two very strong advantages. The cohesive structure inhibits segregation and the relatively small constituent particles provide a fine texture. Both these advantages can be overriding if the mixture quality and texture are the dominant requirements of the product.

Cohesive powders have poor mobility because individual particles are held in a structure with their neighbors and cannot easily move independently. If particles cannot move independently, they cannot segregate in the gross manner associated with free-flowing mixtures and the overall mixture quality is enhanced. Structuring is also promoted when the individual particles are small and lack the weight to fall free from the structure. Small particles also give a better statistical chance of achieving a high mixture quality.

A general comment would be that it is much more difficult to produce a bad mixture with a cohesive powder than with a free-flowing powder. With the reduced mobility associated with cohesivity, mixing will be a slower process but, unlike the free-flowing mixing process, it is irreversible.

The two main problems associated with cohesive powder mixing both relate to the structuring capabilities of the powder. It is very easy for cohesive powders to be held up in dead spaces in the mixer and be isolated from the mixing process, and efficient scraping or sweeping of the entire mixing volume is essential. The second problem concerns the strength of the structure between individual particles. If the mixer does not impose a breaking force larger than the structuring force, then aggregates of an ingredient can pass through the mixing process without being dispersed. The aggregates might be efficiently distributed throughout the bulk of the mixture, but on a localized scale they are not producing the same texture as individually dispersed particles.

Whilst the philosophy of mixing free-flowing powders was to suppress the free movement of individual particles, the philosophy for a cohesive powder must be to encourage individual particles repeatedly to break free from their structuring neighbors.

For many cohesive powders, the gentle rolling and breaking action of a tumbler mixer might be sufficient to cause restructuring. For strongly cohesive or aggregating systems it may be necessary to increase significantly the energy input to the process by the addition of high-speed impactors or intensifiers, or by creating a high-shear mixing zone within the mixer (**Figure 1**).

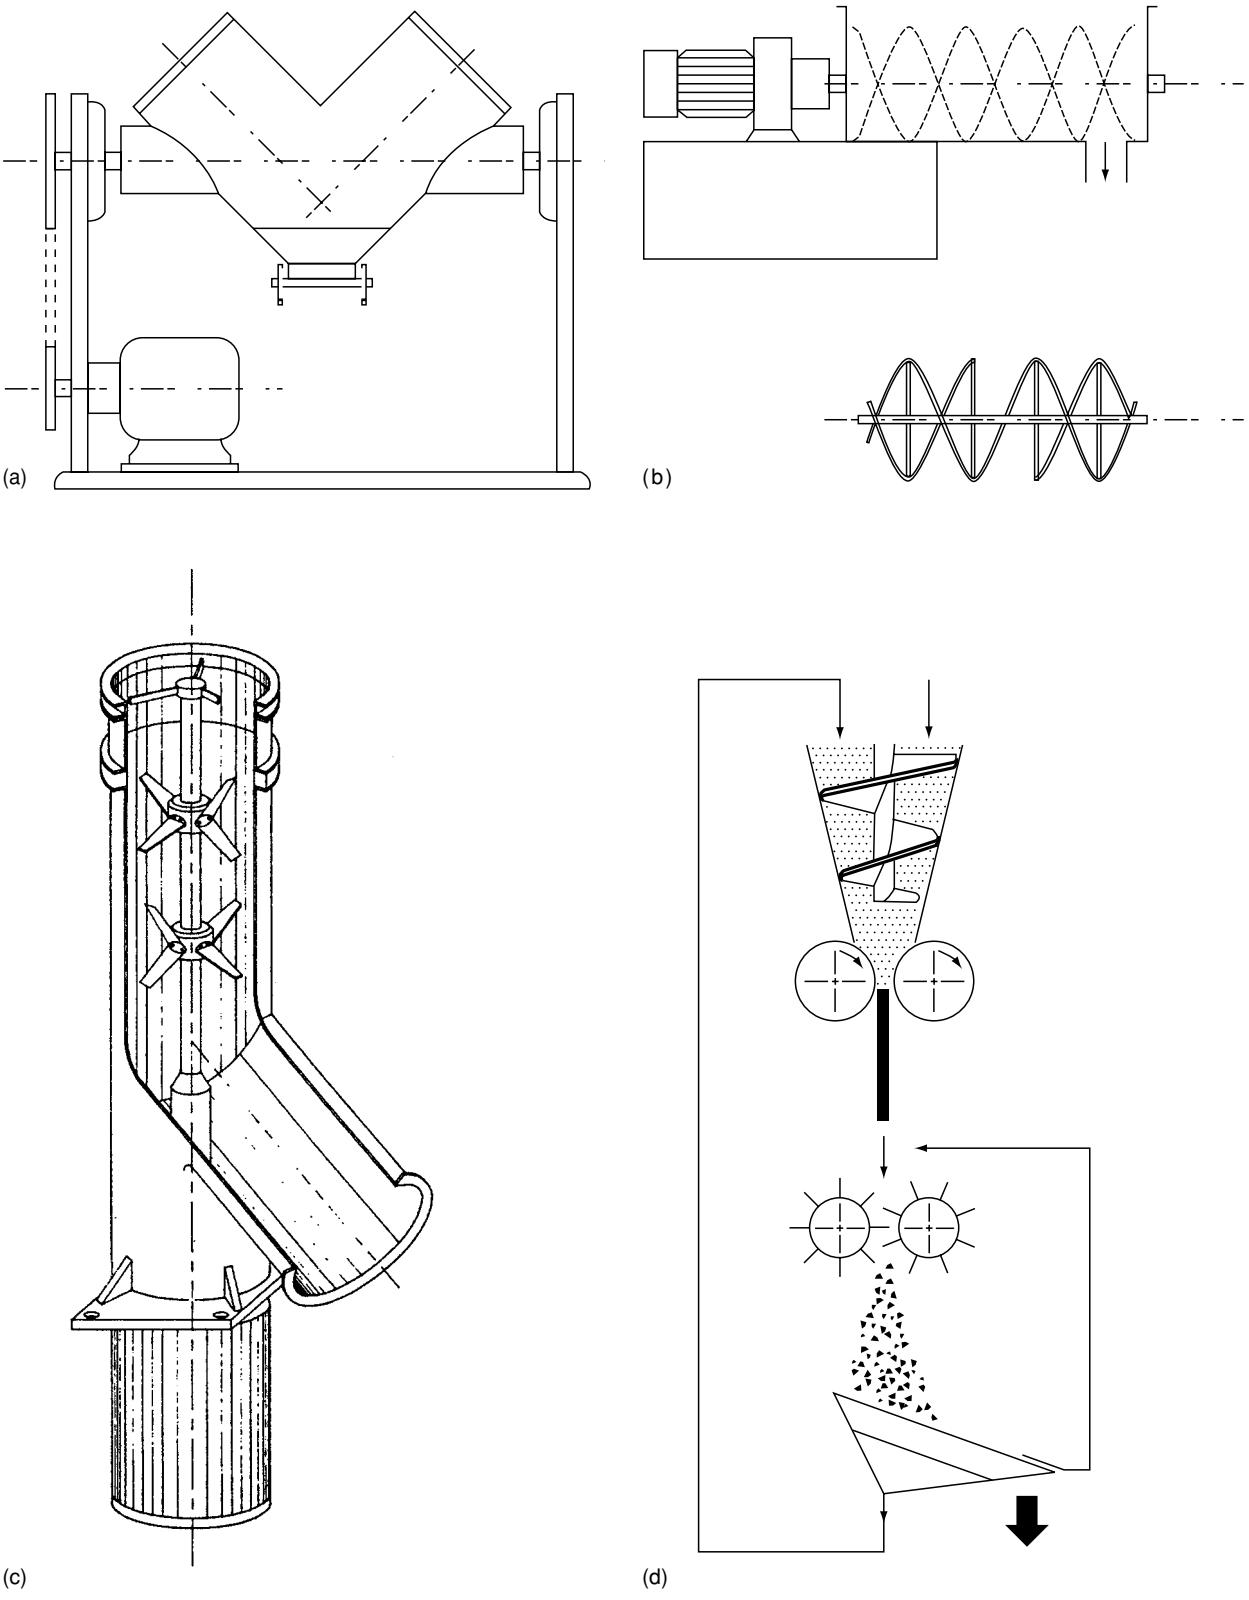

Figure 1 Typical powder mixers: (a) the tumbler mixer; (b) ribbon blender; (c) impactor; (d) high-shear rollers. Reproduced from Mixing of Powders. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The Texture of Powder Mixtures

What is well mixed? Very often a powder-mixing process is designed and installed without properly defining the quality requirements of the product. Mixture quality can be assessed on the basis of the number of letters of complaint received from disappointed customers, but usually a better and earlier quantitative assessment is required. To make this assessment it is essential first to identify the weight of mixture which will be judged for quality by the customer, and then to assess both the possible and attained statistical quality achieved in the mixing process.

Scale of Scrutiny

It is essential to identify the least weight of a powder mixture used by a customer in a single 'application.' This weight is frequently referred to as the required 'scale of scrutiny' for the mixture. Mixture quality is sensitive to the scale of scrutiny and the smaller the scale, the greater will be the difficulty of obtaining a satisfactory mixture quality.

Identifying the scale of scrutiny is often quite straightforward. Thus, if a sachet of dried soup powder is completely emptied into a pan of boiling water, the quality of the soup is determined by the weight and quality of powder delivered in one sachet, and this is then the scale of scrutiny. If marketing requirements decree that a cup rather than a pan of soup should be the package content requirement then the scale of scrutiny has been reduced, and it is possible that the mixer will no longer be able to meet the higher quality requirement.

A significant problem arises if the weight of package delivered to the customer is larger than the customer's scale of scrutiny. It could be, for example, that a customer makes two small pans of soup from a single sachet or takes many bowls of muesli from a single packet. The manufacturer fills the sachet or packet with a satisfactory mixture but, in the subsequent transporting and pouring operations, the contents may well segregate and the customer receives an unsatisfactory mixture when the original quantity is subdivided. It is evidently desirable to deliver the mixture to the customer in package quantities identical to the customer's scale of scrutiny.

As the scale of scrutiny is the weight of mixture assessed by the customer to determine quality, it is also the sample weight removed from the process by the manufacturer for a statistical assessment of quality.

The Statistical Assessment of Quality

If samples are withdrawn from a series of points in a mixture and analyzed separately for composition, then the variance, S^2_{ex}, of these samples can be estimated. A large variance indicates a poor mixture. In the form of the standard deviation, this experimental statistical value can be used to predict the number of product packages which would be outside the required composition tolerance.

When related to mixing data states, the experimental variance can also be used to predict the minimum mixing times or the presence of segregation. The process in Figure 2 illustrates three possible mixing states for a binary mixture of equal-sized particles. The unmixed state has the largest variance value S^2_0, and in most circumstances the best attainable mixture will be that of the randomized mixture, S^2_R. If segregation occurs, the variance S^2_R will not be attained and the product will have some higher variance value.

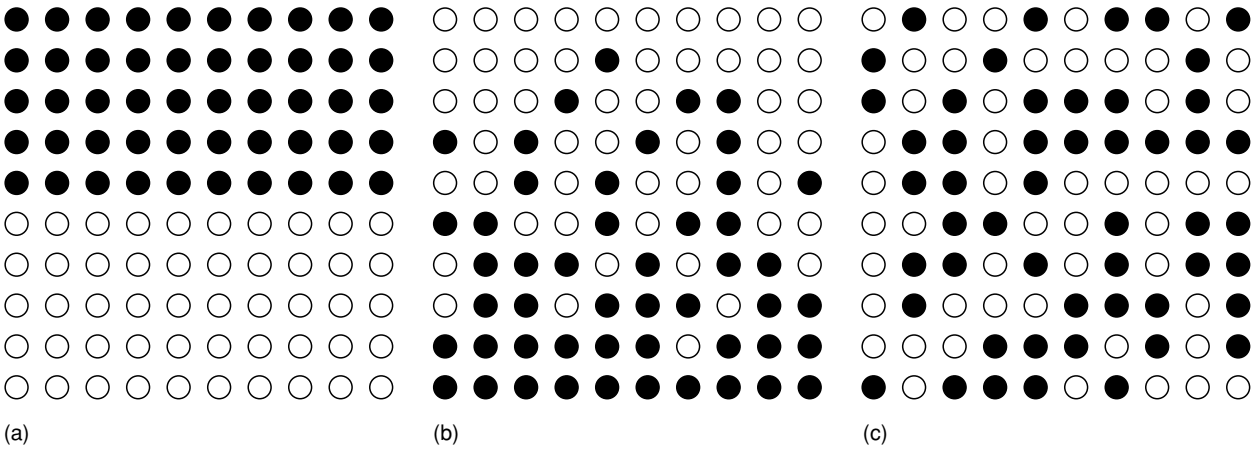

Figure 2 Possible mixing states for a binary mixture of equal-sized particles: (a) unmixed state; (b) segregated; (c) randomly mixed. Reproduced from Mixing of Powders. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

For the illustrated binary system of equal-sized particles, the limiting variance values can be predicted as

$$S_0^2 = pq \tag{1}$$

and

$$S_R^2 = pq/A \tag{2}$$

where p and q are the proportions of the two ingredients and A is the number of particles in a given sample size or scale of scrutiny.

Evidently, few 'real' mixtures fulfill the requirement of being binary systems of equal-sized particles, but the ideal form of eqns (1) and (2) enables us to derive some important mixing principles which will be applicable to multicomponent mixtures of multisized particles.

Eqn (2) illustrates the importance of the scale of scrutiny on mixture quality. A large scale of scrutiny gives a large value of A and a low potential variance, S_R^2. If the weight or the scale of scrutiny is fixed, then an alternative method of reducing the potential variance would be to reduce the particle size and hence increase the value of A. This is a quantitative assessment of the value of mixing cohesive particles as a means of improving texture. Whilst there is a definable relationship between the random mixing state and sample size, this relationship is not valid for other mixing states and, for completely unmixed systems, the variance value S_0^2 is independent of sample size. The inability to relate quality to sample size for intermediate mixing states makes it very difficult to predict the effect on the resultant mixture quality of scaling up or down a scale of scrutiny.

Eqns (1) and (2) can be used in conjunction with the experimentally determined variance S_{ex}^2, to give a mixing index (M). A common index is

$$M = \frac{(S_0^2 - S_{ex}^2)}{(S_0^2 - S_R^2)} = \frac{\text{How far the mixture has progressed}}{\text{How far the mixture could progress}}$$

In this case $M = 0$ for no mixing and $M = 1$ when the mixture is randomized. Evidently, a plot of M against time would indicate the minimum mixing time required.

Eqns (1) and (2) are available for multicomponent and multisized particulate systems. The equations are more complex but the principles are the same. When numbers are inserted for real systems some general conclusions become evident.

1. A few large particles in an ingredient have a significant effect on attainable mixture quality. This is a particularly important effect for minor ingredients and emphasizes the importance of keeping a tight control on any prior processes which affect the size distribution of mixture ingredients.
2. For a multicomponent mixture, the randomization of one ingredient does not insure that other ingredients will be randomly distributed. It is necessary to carry out separate statistical analyses for at least the key ingredients.
3. The derivatives of eqns (1) and (2) enable calculations to be carried out to insure that the mixing process is not attempting the impossible. When a product at its scale of scrutiny contains relatively few particles of one ingredient (say, less than 500), the spread of the number of particles per sample can be calculated and checked with the marketing requirement. Typical examples of this calculation would be the number of chocolate chips on a cookie, the number of sausages in a can of sausages and beans, or the number of mushrooms in a soup packet.

Given that a scale of scrutiny, the proportion by weight of the ingredients, the particle shape, density, and size distribution of the ingredients are known, then the possible attainable quality of the mixture can be calculated. This may not be reached because of segregation but it enables the potential quality of a range of formulations to be assessed and compared to a marketing requirement without carrying out any experimental testing.

The Testing of Mixers

If properly carried out, the testing of a mixer with a particular powder formulation is a long and expensive process and at best is to be avoided and at worst to be carried out with the most effective use of time and effort. One essential first step is to calculate the possible value of S_R^2 for a mixture formulation at a given scale of scrutiny, and check that the mixture quality required is attainable. A second essential is to test the quality of the mixture as it exits the mixer and is about to be packaged rather than in the mixer itself. This is especially important for free-flowing powder formulations. All testing procedures require that samples be taken from the mixture and subsequently assessed for the experimental variance value S_{ex}^2 or for some running statistical control. Especially for free-flowing powders, such sampling procedures are very prone to bias and, if this occurs, much expensive effort can be wasted.

Sampling of Mixtures

The quantity of sample removed from a point in the discharge of a mixture should be that of the scale of scrutiny. A larger sample will give an optimistic measure of quality and a smaller sample a pessimistic measure. It is important to retain the identity of

every point sample withdrawn from the mixture and to carry out a bulk analysis on each of the point samples taken. Many misunderstandings occur between production and quality assurance sections when the quantity of material required for analysis is less than the scale of scrutiny of the mixture. This reduces the effective scale of scrutiny, increases the variance between samples, and indicates a poor mixture quality. Ideally, analysis should be carried out on the entire point sample but, if this is not practically possible, then the sample should be riffled down to the required analytical quantity.

Poor decisions on where and how to take samples can result in significant bias of estimates of sample composition and quality of the mixture. This is especially so for free-flowing powders, which are prone to segregation.

If careful instructions are not given to the process operator on where to take a sample, then the most convenient sample will be taken. Typically this will be on the surface of a drum, adjacent to a valve, or nearest to the control room, and will almost certainly be nonrepresentative of the bulk material. A simple random selection using random numbers is statistically the best way of locating representative samples but, for a routine sampling procedure, it can be inconvenient. A systematic sampling process which locates samples at a fixed time interval is an easier selection process to apply, but care must be taken not to choose a sample frequency which coincides with a natural frequency of the process.

The thief or probe sampler is commonly used to retrieve samples from a selected location in a bulk powder. For a free-flowing powder, it can easily be demonstrated that this is a heavily biased retrieval. Rules to be followed to minimize the bias of sample retrieval are:

1. Retrieve the samples from a flowing stream and not from a bulk of powder. The mixture should ideally be sampled as it discharges from the mixer and not *in situ*.
2. Sample the entire section of flowing powder to allow for any segregation across the flowing stream.
3. Take as many samples at the required scale of scrutiny as possible, as this will improve the statistical precision of the quality estimates. The reader is referred to a standard text to determine the precision reward-to-sampling-effort ratio but, for an assessment of a batch mixture quality, there would be little point in taking fewer than 10 samples.

When samples are taken in a time sequence, considerable benefit can be obtained by plotting composition against time to produce a 'discharge profile' for the system. A mixture variance S_{ex}^2 can be calculated for the mixture but the discharge profile often reveals cyclical variations in the product, which can result in both process improvements and economy of sampling effort.

MULTIPLE SCLEROSIS – NUTRITIONAL MANAGEMENT

R Cichon and L Wadolowska, Warmia and Masuria University in Olsztyn, Olsztyn, Poland

Background

Multiple sclerosis (MS) belongs to the demyelinating diseases, which comprise a group of neurologic disorders. Demyelinating diseases have in common the pathologic feature of local or patchy destruction of myelin sheaths in the central nervous system accompanied by an inflammatory response. Destruction of the myelin sheaths leads to dysfunction of the central nervous system (CNS) in transmission of electrical nerve impulses.

The term 'sclerosis' is applied to the hardening of the CNS and is called 'multiple,' because multiple areas of optic nerves, brain and spinal cord undergo sclerosis, whereby myelin is replaced with sclera and/or scar tissue. The disease was first described by Cruveilhier in 1835 under the name 'sclerose en plaque,' in that the disease is marked by the appearance of hard patches throughout the brain and spinal cord. Its outstanding symptoms are weakness, muscular incoordination, jerky movements of the eyeballs, paralysis, and a curious, deliberate way of speaking, known commonly as 'scanning speech.' The condition has periodic remissions and on the whole tends to become worse, but is seldom an immediate threat to life. The disease most commonly strikes between the ages of 20 and 40 years, and females account for 60–70% of cases. The average age of onset of the first clinical episode of MS is in the third and fourth decades. It is rare for the disease to begin in childhood or beyond the sixth decade, but it is not unknown.

Features of Multiple Sclerosis

MS is pleomorphic in its presentation. The clinical picture is determined by the location of foci of demyelination within CNS. Classic features include impaired vision, nystagmus, dysarthria, decreased perception of vibration and position, ataxia and intension tremor, weakness or paralysis of one or more limbs, spasticity, and bladder problems. Diagnosis is based on the clinical presentation, neurological tests and magnetic resonance imaging (MRI, to reveal the presence of plaques). There are two main forms and two subtypes of the disease: relapsing-remitting MS (RRMS), chronic progressive MS (CPMS), and secondary progressive and benign MS. In RRMS, periods of acute worsening of symptoms are followed by spontaneous improvement. In CPMS, there are no clear-cut attacks, and the symptoms become steadily worse. This form of MS might progress rapidly,

causing severe disability and even premature death within a few years. Secondary progressive MS is described when RRMS becomes progressive, and benign MS when an initial attack is never followed by another. The criteria for the diagnosis of clinically definite MS include a reliable history of at least two episodes of neurologic deficit and objective clinical signs of lesions at more than one site within the CNS. Clinically probable MS is defined as either two attacks with clinical evidence of one lession or one attack with clinical evidence of two lesions. However, classifications of MS are based on clinical phenomenology, and the definitions of relapse, remission, and progression are still imprecise.

MS usually presents in the form of recurring attacks of focal or multifocal neurologic disfunction, reflecting lesions within the CNS. The disease begins most commonly in early adult life. The frequency of flare-ups is greatest during the first 3–4 years of the disease, but a first attack may be so mild as to escape medical attention, for example, blurred or double vision. Once the initial symptoms disappear, they may never recur, and a period of months or years may pass before other symptoms appear, such as weakness of certain muscles, unusual tiring of a limb, minor interference with walking, muscle stiffness, dizziness, loss of bladder control, and disturbances in the senses of touch, pain, and heat. Each symptom may appear and then disappear, only to be followed by another. The disease continues to progress, and eventually, the patient becomes crippled and even bedridden. However, the progression and remission of MS are different for every individual. Although occasional patients die within the first few years of disease onset, most do not, and the average survival from MS is more than 30 years after the onset of disease.

Pathology

In 1961, Swank proposed the hypothesis that a dysfunction of the blood–brain barrier is a primary damage defect in MS. Current opinion holds that autoimmunity or viral infection is likely to be implicated in their pathogenesis.

Many scattered, discrete areas of demyelination, termed plaques, are the pathologic hallmark of MS. Plaques vary in size and may be found anywhere in the white matter but typically occur in the paraventricular areas of the cerebrum and subpially, and within the brainstem and spinal cord. The peripheral nervous system is not affected. Many plaques are clinically silent. In fact, some autopsy studies indicate that 20% of MS cases are clinically silent during life.

Active MS lesions feature T-lymphocyte and monocyte–macrophage accumulations about venules and at plaque margins is being destroyed. The invasion of white matter by inflammatory cells is held responsible for the myelin breakdown. They also function as scavengers of myelin debris; fat-laden macrophages may persist for months, perhaps years, after the acute inflammatory response has subsided. Despite much research, viral inclusions have not been detected. Only limited regeneration of myelin occurs, and the reason is unclear. There are probably several mechanisms responsible for recovery from an MS attack. The pathologic features of MS fail to account for hour-to-hour and day-to-day waxings and wanings in function so characteristic of the disease. Conduction of impulses through demyelinated nerve is compromised and is further altered by transient changes in the internal milieu such as functuations in temperature and electrolyte balance or by stress.

Etiology

The causes of MS remain unknown. A role for immune-mediated or infectious factors has been proposed, but data to support these postulates are inconclusive. Epidemiological studies have implicated an interplay between genetic and environmental factors in the etiology of MS. It has been suggested that nutrition and food pattern, particularly high consumption of animal fat and low intake of fish products may play a role in the etiology of MS. Recently, studies have focused on long-chain polyunsaturated fatty acids (LCPUFA) and vitamin D.

Epidemiology

Epidemiologic studies have established several facts that ultimately will have to be incorporated into any coherent theory of the disease. Neuroepidemiology has played a fundamental role in the study of multiple sclerosis by providing some etiologic clues, although a definitive basis for the conclusive resolution of its enigma is still lacking. Epidemiologic and genetic studies have indicated that MS is probably caused by multiple factors, both genetic and environmental, none of which is individually sufficient, and appear to act before adolescence – or possibly later – in genetically susceptible individuals. This unifying hypothesis emphasizes the role of a genetic–racial susceptibility, the importance of environmental factors, a possible etiologic heterogeneity, and a lack of specificity of the unknown endogenous and exogenous agents. Situations or events with biological plausibility, such as childhood or adolescent infectious diseases, exposures to geographic and sociocultural factors,

nutritional habits, hypersensitivity, significant head and spinal trauma, and other factors may contribute, at different times, to the putative acquisition of MS, trigger its onset, and modify its subsequent course.

In general, the incidence in temperate climates exceeds that in tropical zones, but variations within regions with similar climates do exist; hence, the effect is not simply one of latitude or temperature. Geographically, MS describes three frequency zones. High-frequency areas (characterized by a prevalence of 30+ per 100 000) now comprise most of Europe, Israel, Canada, northern USA, southeastern Australia, New Zealand, and eastern Russia. Medium-frequency areas include the southern USA, most of Australia, South Africa, the southern Mediterranean basin, Russia into Siberia, the Ukraine and parts of Latin America. Prevalence rates of less than 5 per 100 000 are found in the rest of Asia, Africa, and northern South America. The incidence of MS in northern Europe, Canada, and the northern USA is approximately 10 new cases each year per 100 000 persons between the ages of 20 and 50, two to three times higher than that in Australia, New Zealand, and the southern USA. MS is rare in Japan, elsewhere in the Orient, and Africa. Some epidemiologic evidence also suggests that persons emigrating from high- to low-risk regions as children may be partially protected from MS. Immigrants from high- to lower-risk areas retain the MS risk of their birth place only if they are at least 15 years old at the time of emigration. Those from low- to high-risk areas increase their risk even beyond that of the natives, with susceptibility extending from about 11 to 45 years of age. MS occurred in epidemic form in the North Atlantic islands, particularly in the Faroe Islands, where the first symptom onset was in 1943, heralding the first of four successive epidemics at 13-year intervals. What was transmitted is thought to be a specific, widespread, persistent infection called primary multiple sclerosis affection (PMSA), which only rarely leads years later to clinical MS. The search for PMSA is best attempted on the Faroes, where there are regions still free of MS after 50 years. The data are consistent with the existence of an environmental factor, possibly a virus, and perhaps geographically restricted, that influences the development of MS. Immunologic, epidemiologic, and genetic data indicate that tissue injury in MS results from an abnormal immune response to one or more myelin antigens that develop in genetically susceptible individuals after exposure to an as-yet undefined causal agent.

There is some evidence for genetic factors in multiple sclerosis. The evidence comes from epidemiologic studies, racial predilection, risk in family members (sibs, half sibs, adoptees), and twin studies. MS is not a Mendelian inherited disease; only the susceptibility to the disease is inherited. MS seems to be an oligo- or multigenic disorder with an apparently similar phenotype for the different genes involved. A genetic component in MS is indicated by an increased relative risk to siblings compared with the general population and an increased concordance rate in monozygotic compared with dizygotic twins. Whole genome screens conducted in different populations have identified discrete chromosomal regions potentially harboring MS-susceptibility genes.

Nutrition and Multiple Sclerosis

Specific nutritional therapy has been advocated for a number of neurologic diseases of undetermined etiology. In some of the disorders, improper or inadequate nutrition is implicated. Therefore, dietary manipulation constitutes the main therapeutic mode. For instance, a low-fat diet has been recommended as an effective means of reducing the incidence of exacerbations in patients suffering from MS. However, objective evaluation of the efficacy of this treatment modality has not yet been possible. In MS, a combination of genetic and environmental factors, including dietary factors, underlies the symptoms and signs of neurologic dysfunction that can be ameliorated by changes in the diet and/or vitamin supplementation.

Epidemiologic studies relating MS to nutritional factors have revealed a possible link between the incidence of the disease, total fat intake, and percentage of calories (of animal origin) consumed. A long-term study carried out by Swank showed significantly less deterioration and much lower death rates among MS patients when they consumed less fat (20 g of fat per day).

The results of prospective case-control studies showed that some foods consumed at certain 'critical' ages could play a causal role in the oneset of MS. An association was suggested between MS and high consumption of bread and 'pasta,' butter and lard, legume soup, horse flesh, coffee and tea in the period from infancy to adolescence, and of eggs and wine during adulthood. A possible autoimmune demyelinating disease with lipid changes suggests a deficiency of PUFA.

MS tends to be more prevalent in countries where the use of animal fat is high. It has also been suggested that the administration of unsaturated fatty acids, such as linoleic or arachidonic acid, may reduce the number and severity of MS attacks. This idea is based on the observation that brain and spinal cord obtained from patients who have died of MS is deficient in unsaturated fatty acids and that linoleic and

arachidonic acids tend to inhibit the lymphocyte–antigen interaction, the cellular mechanism that may enhance demyelination. Sensitized lymphocytes probably interact with myelin components in the affected parts of the nervous system during an attack of MS. That the ingestion of unsaturated fatty acids, such as linoleic acid, affects the course of MS remains unproved.

Early epidemiological studies demonstrated a low incidence of atherosclerotic, inflammatory, and autoimmune diseases in Greenland Eskimos who consumed diets high in marine-derived (*n*-3) PUFA. Human studies have consistently demonstrated a decrease in production of pro-inflammatory cytokines when moderate to high levels of marine-derived (*n*-3) PUFA are taken orally. The decrease in production of pro-inflammatory cytokines and eicosanoids contributes to the beneficial effect of fish oil in reducing the pathogenesis of inflammatory and atherosclerotic diseases. Essential fatty acids (EFA) are necessary for normal immune function of humans and animals. EFA deficiency impairs B- and T-cell-mediated responses. These impairments can be ameriorated by the inclusion of EFA in the diet. The possibility that polyunsaturated fatty acids have an immunosuppressant effect has led to the evaluation of high-polyunsaturated fatty acids diets in MS, as neurologic disorders of immune-inflammatory etiology that affect CNS. α-Linolenic acid (C18:3 *n*-3) can be converted to EPA (C20:5 *n*-3), which can replace arachidonic acid in membrane phospholipids and can be preferentially used by cyclooxygenase. This results in the reduced production of prostaglandins (PG) of the 2 series and leukotrienes of the 4 series. Thus, the consumption of oils containing C18:3 *n*-3 might be associated with immunological changes. This opinion is supported by many studies that have shown immunological modulation following marine oil consumption.

Evidence on etiology in MS suggests that the prevalence depends on the interaction of two factors, diet and exposure to visible sunlight. The dietary features that may be beneficial include supplementation with fish oils, avoidance of saturated fats, and the associated intake of antioxidants with unsaturated fatty acids. Inhibition, by antioxidants, of the enzyme lipoxygenase inhibits leukotriene synthesis, and the presence of fish oils leads to the production of leukotrienes with less inflammatory properties. This is of particular importance in the retina, where leukotrienes might be the underlying cause of retrobulbar neuritis.

A significant protective effect has been observed with other nutrients, including vegetable protein, dietary fiber, vitamin C, thiamin, riboflavin, calcium, and potasium. With respect to specific foods (as opposed to nutrients), a higher intake of fruit juices was inversely associated with risk. A protective effect was also observed with cereal/bread intake; pork/hot dogs and sweets/candy were positively associated with risk. The study generally supports a protective role for components commonly found in plants (fruit/vegetable and grains) and increased risk with high-energy and animal food intake.

An epidemiologic study on the relationship between mortality rates from MS for the period 1983–1989 for 36 countries has shown that saturated fatty acids, animal fat, animal minus fish fat, and latitude correlated independently and positively with MS mortality. The ratio of polyunsaturated fatty acids to saturated fatty acids (P/S ratio) and the ratio of unsaturated to saturated fatty acids (U/S ratio) correlated independently and negatively with MS mortality. The results support the data, at least partially, on an association between certain dietary factors and MS.

For MS patients, good nutrition has the potential to enhance the quality of life and reduce the risk of lifestyle diseases and secondary conditions. Eating patterns in patients with MS showed the need for interventions to promote good nutrition among persons with MS. Usually, nutritional intake for MS patients is not optimal in many important areas.

Acute and chronic neurologic diseases of nonnutritional origin that impair consciousness of motor functions essential to adequate nutritional intake, such as paralysis or weakness of the facial muscles, the tongue, the pharynx, and the muscles of deglutition, frequently require the temporary or permanent use of a nasogastric tube or gastrostomy for the patient's well-being. These measures make possible proper enteral nutrition and may, in fact, prove to be life-saving. In most of these disorders, nutritional support does not affect the basic pathogenesis of the disease. The use of B-complex vitamin preparations for a variety of acute and chronic neurologic diseases of cryptic origin continues to be common medical practice. To date, however, there is no objective evidence that this practice has any effect on the speed of recovery of the afflicted nervous tissue.

Despite significant advances over previous decades in the field of nutrition, large gaps remain in our understanding of the role in the normal and abnormal activity of the nervous system. More sensitive and critical methods for the assessment of the nutritional status of the nervous system and for the evaluation of the dietary management of MS are essential for more rational and effective therapeutic manipulation (treatment).

Nutritional therapy consisting of vitamins and other nutrients continues to be used in neurologic

disorders of unknown cause, in spite of a total lack of scientific rationale. The popularity of administering large doses of vitamins (and other nutrients) as therapy for chronic neurologic diseases of uncertain etiology stems from the fact that experimentally induced deficiencies of this nutrients in animals frequently result in symptoms caused by reversible lesions of the CNS. In most instances, the far-advanced lesions show demyelination, a frequent finding in many human neurologic diseases. However, considering the large doses of vitamins consumed daily, for a variety of reasons, by an ever–increasing number of people, vitamin toxicity affecting the nervous system is relatively rare. Of all the vitamins, only two – vitamin A and pyridoxine – are known to produce adverse neurologic reactions when ingested in pharmacologic, rather than recommended, nutritional doses.

Patients who are being treated with drugs may incur a significant degree of vitamin deficiency (D, B_{12}, and folic acid). The prolonged administration of drugs may lead to a decrease in bone mineral content. The drugs interact with the vitamin D and its active forms, decreasing intestinal calcium absorption and redistribution. The severity of demineralization appears to be related to the dose of the drugs, a deficiency of physical activity, and a lack of exposure to sunlight. In general, the problem does not appear to be of sufficient clinical importance to warrant the routine vitamin D supplementation of patients with MS drugs; however, the possibility should be borne in mind, and vitamin D metabolites should be estimated periodically in long-term patients with poor intake or malabsorption.

Studies with animals, tissue cultures, as well as humans indicate that both the level and degree of saturation of dietary fats influence inflammatory and immunologic responses. Some of these immunologic changes are associated with beneficial clinical effects, for example, reduction in pro-inflammatory cytokine by marine-derived (*n*-3) PUFA. Others might not be desirable, for example, decreased T-cell-mediated function by marine-derived (*n*-3) PUFA in older people.

Recommendations to increase PUFA intake should be accompanied by appropiate recommendations for an increase in antioxidant intake, in particular vitamin E. Without adequate antioxidant protection, the substitution of membrane fatty acids with highly oxidizable (*n*-3) PUFA of fish oil, that is, EPA and DHA, may potentiate the peroxidation of cellular mambranes. Foods high in polyunsaturates should contain at least 0.6 mg of tocopherol equivalents per gram of polyunsaturated fatty acids. Higher levels may be necessary for fats rich in fatty acids containing more than two double bonds.

In general, for MS patients, recommendations to decrease dietary total fat intake, with the inclusion of moderate amounts of (*n*-6 and *n*-3) PUFA with adequate antioxidant nutrients should provide for a competent immune response. The *n*-6 and *n*-3 fatty acids have critical roles in the membrane structures and as precursors of eicosanoids, which are potent and highly reactive compounds. Various eicosanoids have widely divergent, and often opposing, effects on inflammatory processes and the immune system. Since they compete for the same enzymes and have different biological roles, the balance between the *n*-6 and *n*-3 fatty acids in the diet can be of considerable importance. The ratio of linoleic to α-linolenic acid in the diet should be between 5:1 and 10:1. Patients with a ratio in excess of 10:1 should be encouraged to consume more *n*-3 rich foods such as green leafy vegetables, legumes, fish, and other seafood.

Dietary Management of Multiple Sclerosis

Although there have not been any valid clinical trials supporting the efficacy of nutrition in delaying the progression of MS, it is imperative that the dietitian evaluates the nutritional health status and arranges a patient's diet. The nutritional management of patients with MS is primarily concerned with ensuring that their nutrient intake meets the requirements. The specific dietary modifications that are needed in some patients, mostly because of drug therapy, are of secondary importance. The principles of management have to take in consideration the individual needs, circumstances and difficulties. The current consensus is that extreme dietary change should have no place in the management of MS. Patients with MS should be encouraged to follow a varied, well-balanced diet based on good nutritional practice and principles for the population in general. In order to achieve the recommended dietary targets, considerable changes in the dietary habits of the MS patient will be required, usually necessitating:

- increased intake of micronutrient-rich foods such as fruits, vegetables, pulses, seeds, legumes, and cereals. Leafy green vegetables may contribute adequate amounts of antioxidative vitamins, e.g., vitamins E and C;
- use of low-fat alternatives for full-fat milk and dairy products;
- replacing saturated fat spreads and cooking fats with low-fat spreads and monounsaturated oils;
- avoiding sugar-rich/fat-rich food group, such as meat products, pastries, chips, snakes, cakes and biscuits;
- encouraging the consumption of all types of fish and seafood; two portions of fish or seafood per

week, including oily fish, are recommended to secure a moderate increase intake of *n*-6 and *n*-3 fatty acids, in particular LCPUFA.

An important consideration in the management of all patients is their hydration status. The consumption of at least six to eight glasses of fluid per day usually meets the adequate fluid intake of a patient.

Nutritional problems associated with MS vary according to the symptoms of illness and the degree of physical disability of patients. Dysphasia may occur as the disease progresses, and the diet consistency may need to be modified from solid to soft or puréed foods and even thick liquids. Other problems include impaired vision, dysarthria, and poor ambulation, thus making eating less enjoyable because meal preparation becomes a difficult task. In this situation, single-serving or convenience foods often permits independent preparation of meals. Given the chronic nature of this disease, patients may require enteral nutrition support.

Neurogenic bladder is common, causing urinary incontinence, urgency, and frequency. To minimize these problems, it is helpful to distribute fluids evenly throughout the waking hours and limit them before bed. Some patients limit fluid intake severely to decrease the frequency of urination, thus increasing the risk of urinary tract infection.

Neurogenic bowel can cause either constipation or diarrhea, and the incidence of fecal impaction is increased in MS. A diet that is high in fiber with additional prunes and adequate fluid intake can moderate these problems.

Supplement Usage

Patients may be taking combinations of different supplements in large doses, sometimes risking overdosage with fat-soluble vitamins. The types of supplements likely to be used include evening primrose oil, fish oil capsules, cod liver oil, and linseed oil. If a well-balanced diet containing dietary sources of *n*-3 and *n*-6 fatty acids is consumed, additional supplements of LC-PUFA sources, vitamins, and minerals are unlikely to be necessary or beneficial. Patients who wish to take supplements should be advised to restrict these to one multiple multivitamin/mineral preparation providing no more than the recommended dietary allowance, rather than taking several different types of supplement. In any case, it is best to do this after consultation with the dietitian.

MUSHROOMS AND TRUFFLES

Contents

Classification and Morphology

S Rajarathnam and M N Shashirekha, Central Food Technological Research Institute, Mysore, India

Background

Mushrooms constitute a specialized group of fungi and represent the fruiting bodies with a great diversity in shape, size, color, and texture, bearing the spores of sexual reproduction. In nature, they serve the function of production, maturation, and dissemination of spores, for the perpetuation of the species. Thus, these mushrooms as a group of fungi, are nonchlorophyllous organisms that cannot utilize solar energy to manufacture their own food as do green plants. However, mushrooms can produce a wide range of enzymes that can degrade the complex substrates on which they grow, following which they absorb the soluble substances for their own nutrition. This absorptive nutrition is a characteristic of fungi. Mushrooms as macrofungi can be either epigeous, as in 'morels' or 'field mushrooms,' or hypogeous, as in 'truffles,' and large enough to be seen with the naked eye and to be picked by hand. Mushrooms need not be aerial, or fleshy, or edible. Out of 69 000 described species of fungi, there are about 10 000 species of fleshy macrofungi, and only a handful of these are lethal. There are no simple ways of distinguishing between edible and poisonous mushrooms. This will be dealt with in a later section.

Classification

Mushrooms and truffles fall under the class Basidiomycetes and a few orders of Euascomycetes, respectively (Figure 1).

Euascomycetes

Euascomycetes include morels (species of *Morchella*) with epigeous fruiting bodies and truffles (species of *Tuber*) with hypogeous fruiting bodies and are characterized by the production of ascospores endogenously inside special club-shaped structures called asci.

Basidiomycetes

Basidiomycetes are considered the most highly evolved group of fungi and are characterized by the exogenous production of basidiospores borne over club-shaped structures called basidia.

Subclass: Hymenomycetes

This group includes all fungi composed of membranes, fleshy, woody, or gelatinous, whether growing on the ground or on wood. The spore-bearing surface, called the 'hymenium,' is external at an early stage in the life cycle. The spores are borne on basidia, and when the spores ripen, they fall to the ground or are carried by the wind to a host that presents all the conditions necessary for germination; there, they produce the thread-like structures called mycelia. Within these threads are small knots, which in time develop into full-grown mushrooms.

The subclass Hymenomycetes is generally classified in one large order, the Agaricales, which in turn is divided into six families:

1. Agaricaceae–hymenium with gills;
2. Polyporaceae–hymenium with pores;
3. Hydnaceae–hymenium with spines;
4. Thelephoraceae–hymenium horizontal and mostly on the under surface;
5. Clavariaceae–hymenium on a smooth club-shaped surface;
6. Tremellaceae–hymenium even and superior – gelatinous fungi.

Subclass: Gastromycetes

The word 'Gastromycetes' is derived from two Greek words, '*gaster*' (stomach) and '*mycetes*' (fungus). The hymenium is enclosed in the rind or peridium. The word 'peridium' comes from 'peridio' ('I wrap around'), because the peridium entirely envelopes the spore-bearing portion, which eventually sheds the enclosed spores formed inside the basidia and spicules. The cavity within the peridium consists of two parts: a threaded part, called the capillitium,

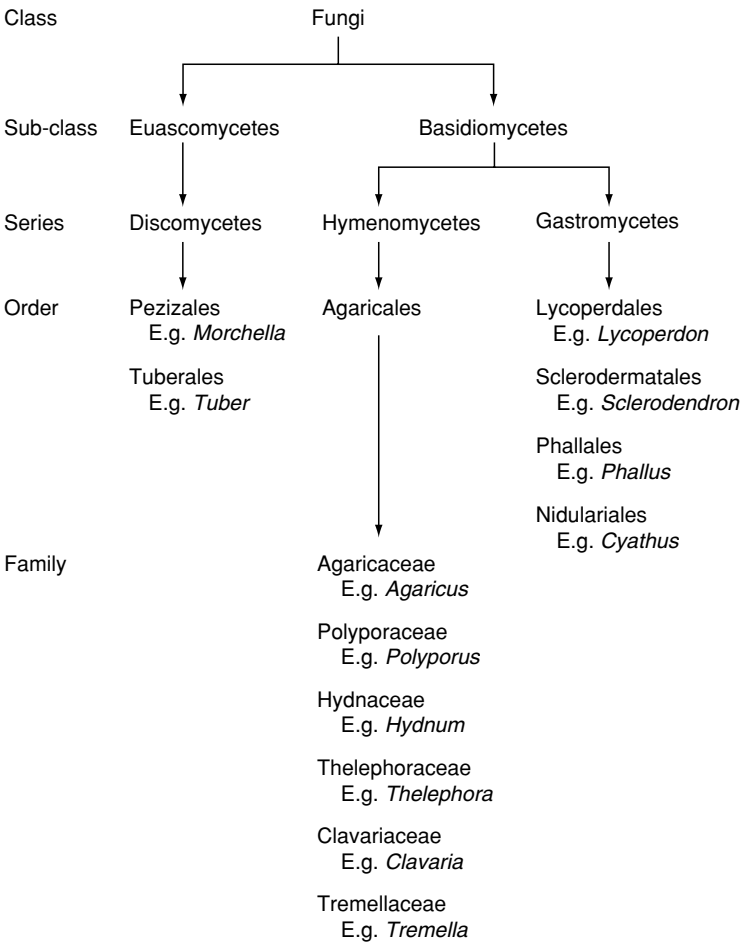

Figure 1 Location of mushrooms and truffles in the classification of fungi.

which can be seen in any dried puff ball, and a cellular part, called the gleba, which is the spore-bearing tissue, composed of minute chambers lined with the hymenium. The peridium breaks in various ways to permit the spores to escape. When children pinch a puff ball to 'see the smoke,' they are doing just what the puff ball would have them do, scattering its seeds to the winds.

Gastromycetes has four orders:

A. Glebal chambers usually not separating from the peridium or from each other;
B. Gleba powdery;
C. Hymenium present in early stages; spores mostly light-colored, small – *Lycoperdales*;
CC. Hymenium lacking or indistinct; spores mostly dark, large – *Sclerodermatales*;
BB. Gleba slimy and fetid; exposed on a receptacle – *Phallales*;
AA. Glebal chambers forming waxy peridioles, or entire gleba separating as a unit from the peridium – *Nidulariales*.

Distribution of Mushroom Species

Mushroom species are distributed throughout the world, some very specific to certain geographic areas, while others are universal and may occur in different seasons in the same region. Temperature plays a critical role in the distribution of mushroom species, and so their distribution can be categorized under tropical, subtropical, and temperate belts (Table 1). The reason for specific distribution of mushroom species in relation to temperature is to be

Table 1 Geographic distribution of various mushroom species

Climatic belt	*Mushroom species*
Tropical	*Volvariella* spp.
Subtropical	*Agaricus bitorquis*

	Tricholoma saponaceum
	Laccaria laccata
	Polyporus squamosus

viewed to the specific enzymes secreted and factors influencing these enzymes by the mushroom species under study, in relation to the geographic conditions of natural occurrence.

Morphology

Natural Habitat

Mushroom species can be found growing on dead and decaying plant material, humus soil, e.g., *Agaricus*, as saprophytes on the dead trunks of live trees, e.g., *Pleurotus*, as parasites on the living trees, e.g., *Armillaria*, or characteristically in symbiotic association with the roots of pine trees, e.g., *Morchella*. Species of *Termitomyces* grow on the ant hills, again an example of symbiosis. *Tuber* species grow underground in certain European climates and their flavour is often detectable by dogs.

Vegetative Phase

Mushrooms have two phases in their life cycle: a mycelium that is usually hidden and inconspicuous with a longer growth phase followed by short-lived fruiting bodies. The mycelium derives the nutrition for its growth (which, after a period of establishment, culminates in the production of fruiting bodies) under certain defined favorable conditions. The conditions for mycelial growth are not very specific, in contrast to the very specific growth conditions required by the fruiting bodies. The constraints and problems associated with the latter explain why several mushroom species have yet not been able to be cultivated artificially. Mycelia may be uninucleate (monokaryotic) or binucleate (dikaryotic) (Figure 2), depending on the species and stage in the life cycle. In nature, generally, the spore germinates under favorable conditions to produce the uninucleate mycelium.

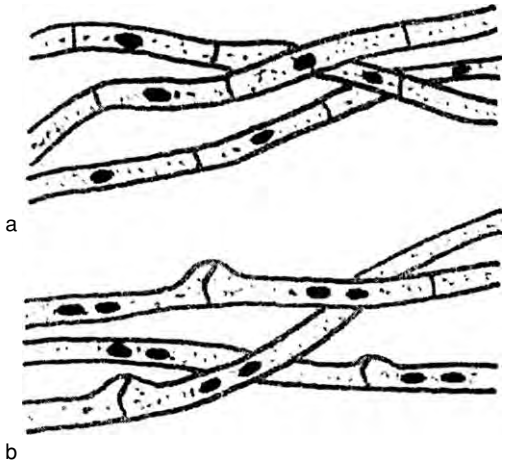

Figure 2 Mono- and dikaryotic mycelia. (a) septate without clamp connections; (b) septate with clamp connections.

Reproductive Phase

After a certain amount of vegetative growth depending on the availability of the compatible strain, the uninucleate mycelium reaches the dikaryotic phase, which in turn leads to the production of fruiting bodies, bearing spores. For clarity, the typical life cycles of three mushroom varieties are described below.

Primary homothallism Here, the basidiospore germinates to produce the mycelium, which in turn is self-fertile and ultimately can result in the production of fruiting bodies, which bear gills, basidia terminating with four basidiospores (per basidium), as a product of meiosis, e.g., *Volvariella volvacea* (Figure 3).

Secondary homothallism *Agaricus bisporus* is an example of this phenomenon, wherein the basidium by name itself bears only two spores, and each spore in turn is binucleate, carrying both the compatible factors in the same spore, so that the mycelium that results from germination of the basidium finally yields to the development of fruiting bodies (Figure 4).

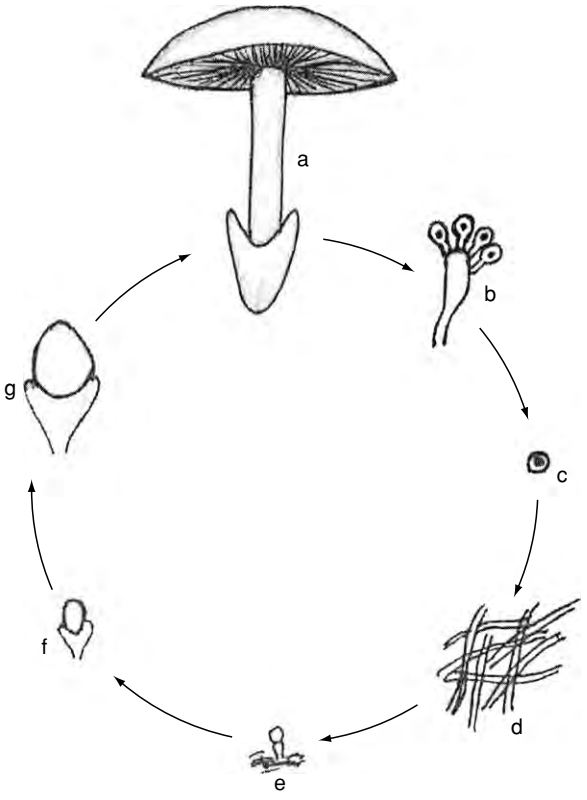

Figure 3 Primary homothallism in *Volvariella volvacea*. (a) fruiting body; (b) basidium; (c) basidiospore; (d) mycelium; (e) fruiting initial; (f and g) developing fruiting body.

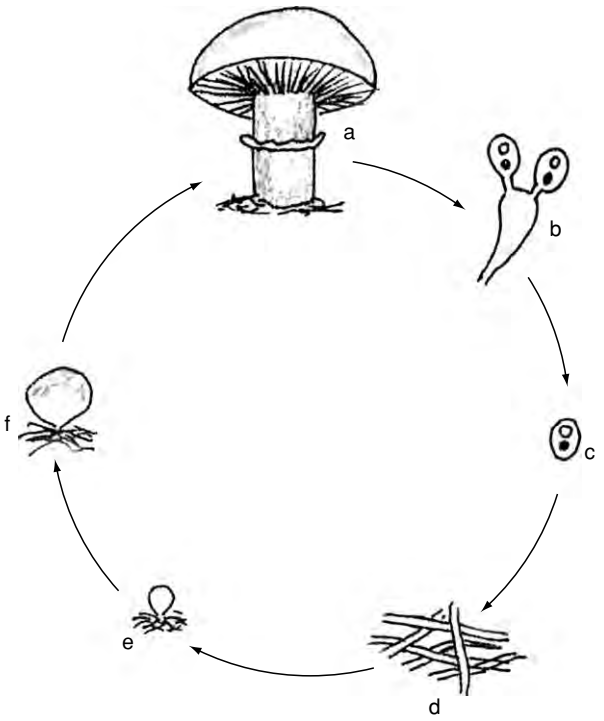

Figure 4 Secondary homothallism in *Agaricus bisporus*. (a) fruiting body; (b) basidium with two basidiospores; (c) basidiospore; (d) mycelium; (e and f) developing fruiting body.

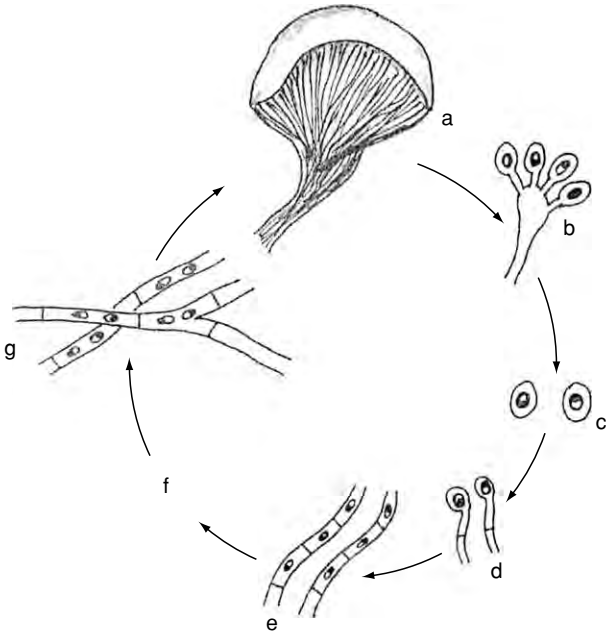

Figure 5 Heterothallic and tetrapolar life cycle in *Pleurotus sajor-caju*. (a) fruiting body; (b) basidium with four genetically different basidiospores; (c) basidiospores; (d) germinating basidiospores; (e) monokaryotic mycelia; (f) dikaryotization; (g) dikaryotic mycelia.

Heterothallism Species of *Pleurotus* are classic examples of heterothallism, in which each basidium bears four basidiospores, each genetically different from the other, so that the degree of inbreeding is reduced to 25%, with increased scope for outbreeding of 75%. This represents possibly the most highly evolved life-cycle system of the basidiomycetes and is strengthened further by the operation of multiple alleles at the two different loci (Figure 5).

Variations in Mushroom Morphology

The fruiting body is the net result of a certain minimum amount of vegetative growth, followed by the onset of conditions (physical, chemical, or biological) favoring reproduction. The fruiting body that develops typically has a stem/stalk called a 'stipe,' with or without a basal cup, called a 'volva,' and a ring on the stem known as an 'annulus' (Figure 6). The occurrence of an annulus/volva is dependent on the characteristic nature of development or morphogenesis of the fruiting body. The display of annulus and volva also varies depending on the species (Table 2). The stipe terminates with a cap, also called a 'pileus' varying in shape, size, texture, structure, and color, and constituting one of the most beautiful objects of nature on the earth. The great diversity in morphology of the mushroom species is depicted in Figure 7. The cap is variously colored, bright, or dull. However, the toxicity of a mushroom bears no relation to its coloration (Table 3). The cap consists of a fertile layer called a 'hymenium' (Figure 8) comprising gills, which in turn bear basidia with basidiospores at the distal end intercalated with sterile cysitidia. The fruiting body may collapse as a result of autodigestion, as in *Coprinus* (inky cap) or may even have latex-containing tissues as in *Lactarius* (milky mushroom).

Orientation of gills The morphology of gills contributes to valuable taxonomic criterion in *Agaricus*, when the gills are open from the genesis to the shedding of basidiospores. Their attachment to the stipe/stem varies and is specific to the species. Gills may be free and detached from the stipe. A mushroom is described as decurrent when the gills run down the stem (the usual situation in many funnel-shaped fruiting bodies), adnate when the gill is attached along its entire width, adnexed when attachment is along only a part of the total width, and sinuate when there is a notch where the gill joins the stem. The attachment of gills in the cap has a bearing on the confluency of the cap, and this interrelation is depicted in the Figure 9.

In Euascomycetes, ascospores are formed inside the club-shaped structures called 'asci,' whereas in

Basidiomycetes, the basidiospores are formed exogenously on the basidia (Figure 10).

Ornamentation of basidiospores The color of the spore print immediately after collection of a species may help to identify a species. Basidiospores are of various colors, shapes, sizes, and arrangements (Figure 11). In fact, they are one of the most useful features in mushroom taxonomy. They may be hyaline and thin-walled, as in *Agaricus* and *Pleurotus*, set for immediate germination; they cannot carry out the function of surviving to the next season. In some cases, they are thick-walled and variously ornamented to survive to the next season and also result in effective dissemination. Peridioles of *Cyathus* species exemplify a special mode of dissemination, that is effected by a drop of rain water. In fact, basidiospores of various mushroom species are microscopic objects of ornamentation on the earth (Table 4).

Vegetative reproduction Several mushroom species multiply using structures other than asco- or basidiospores (Table 5). Oidia represent thin-walled asexual spores that participate in germination. Chlamydospores are thick-walled spores produced vegetatively from mycelial cells, that resist the unfavorable conditions and germinate under the onset of favorable conditions. Sclerotia are thick-walled, conspicuous mycelial tufts of different sizes. These provide an easier means of producing the fruiting bodies in *Morchella*. In *Pleurotus tuber-regium*, the sclerotium carries out the function of sustaining during unfavorable weather conditions. Thus, mushroom species, as the mostly highly evolved of the fungi, have reminiscent characteristics of primitive fungi, which have served to prolong the life cycle and create alternative means of perpetuating the species.

Importance of Identification and Classification

Identification of mushrooms is a very difficult job in mycology, and the specimens collected, because of their delicacy, should be handled with care. Marking the characteristics of the species *in situ* in nature for shape, size, color, flavor, and latex, if any, and collecting spore print are essential in the field/forest or zone/area of collection. Further identification rests on the spore morphology and, to some extent, on the characteristics of the mycelium. It may be easy in some cases to assign the correct class, order, and family to mushrooms collected in the field, but assigning a genus and species requires more knowledge. If it is a new species, more interest would be evinced in understanding the edibility, life cycle, growth substrate, periodicity of fructification, enzymes secreted, and possibility of artificial culturing and any special feature in reducing environmental pollution by biodegradation of toxic compounds. Thus, the identification and classification of mushroom species may be difficult but sometimes rewarding.

The Royal Botanical Gardens, in Kew, London maintains records of all species discovered to date. Another dimension of natural collection of any mushroom species, its identification and characterization,

involves the maintenance of its culture in viable but importantly vigorous. Often, the culture may be viable but cannot yield to fructification on growth. In the American Type Culture Collection in Rockville, USA, identified mushroom cultures can be deposited and given a code number. This has led to a centralized system in which mushroom cultures from any area of the world can be deposited and made available for study, which would not otherwise be possible if species/cultures were lodged only with collectors.

Poisonous Mushrooms

It is very difficult to state whether a mushroom is poisonous or edible. Traditionally, mushroom species have been classed as 'poisonous,' nonfatal but causing stomach upset, termed 'inedible,' and 'edible.'

At present, animal-feeding trials are the best way to identify the poisonous varieties, but some of the characteristics relating to poisonous species are:

- bright-spored, with both annulus and volva – *Amanita* spp.;

Use of Wild Mushrooms

S Rajarathnam and M N Sashirekha, Central Food Technological Research Institute, Mysore, India

Background

Mushrooms were regarded by the early civilizations of Egypt and Rome as a special delicacy and were perceived by the Romans as the food of the gods. A clear indication of the high esteem in which mushrooms were held by different cultures is provided by the practice of restricting the use and consumption of many species to the rulers of the time. The medicinal and analeptic qualities of mushrooms, the scientific basis for which we are only just beginning to understand, have long been appreciated by the Chinese. Legend states that Chinese emperors consumed *Lentinus edodes* in large quantities to fend off old age. Other accounts tell us that the ancient Japanese courts valued these mushrooms for their aphrodisiac properties. 'The growing sites were well hidden and heavily guarded.' One species of mushroom, *Ganoderma*, is cultivated today strictly for its medicinal benefits. It is now realized that mushrooms have an important role to play in the recycling of organic wastes, thereby relieving environmental pollution.

Useful Chemical Constituents

Mushrooms are known for their characteristic biting texture and pleasant aroma. These properties have derived the meaning for mushrooms as items of food delicacy. In recent years, it has been well proven and documented in the world literature that mushrooms do provide definite nutrition and health benefits for humans. Significant compositional changes occur with a strain as a result of differences in age

or stage of development, lapse of time after harvest, study of different portions of a single fruiting body, the inaccuracies inherent in the methods of analysis, and the relative precision of the analyst. In order to insure universal comparison of the analytical values of different workers, it is worth expressing all the analytical data on dry weight of the fruiting bodies, since it is well known that mushrooms in general contain about 90% moisture in fresh form. Mushrooms on a dry-weight basis contain ~63% carbohydrates, 25% protein, 4% fat, and the remaining 8% is accounted by minerals represented by ash (Table 1). Most carbohydrates are in the polymeric form, glucan and hemicellulose types; starch as such is absent. Mannitol and trehalose represent the bulk of free sugars. Accordingly, the energy value is also relatively less. Mushrooms do contain considerable amounts of dietary fiber.

Protein represents the major fraction next to carbohydrates. The fraction 4.38 is used to convert nitrogen into mushroom protein (instead of the general factor 6.25), excluding nonprotein nitrogen in the form of chitin present in the cell walls. Albumins and globulins predominate in the protein fraction of *Boletus edulis* and *Cantharaellus cibarius*. Free amino acids account for nearly one-fifth of the total nitrogen. Protein is made up of most of the essential amino acids; however, some essential sulfur-containing and aromatic amino acids are lacking. Based on the amino acid analysis, several indices are used to predict the nutritional quality of the mushroom.

Mushrooms are relatively low in fat content. The fat includes representatives of all classes of lipid compounds, including free fatty acids, mono-, di-, and triglycerides, sterols, sterol esters, and phospholipids. There is a preponderance of unsaturated fatty acids, in particular linoleic acid (~78% of the total fatty acids). It is the degree of unsaturation of fatty acids in mushrooms that reflects on their safety in consumption without any danger of atherosclerosis.

The ash is mainly composed of calcium, potassium, phosphorus, and ferrous iron (Table 2). Some species also contain germanium, which is known for maintaining vitality in humans. Mushrooms have a special feature of bioaccumulation of minerals available in their growth medium. This property is useful in providing desired minerals in good quantities. When they accumulate toxic elements, they become dangerous for consumption.

	(30)	(0.9)	(14.5)	(1.3)	(0.2)

[a]*Report of a Joint FAO/WHO Expert Group* (1974) Rome: FAO.
Note: Figures in parentheses are values in mg recommended intake by FAO/WHO per person per day.

Mushrooms are a good source of several vitamins. Species of *Pleurotus* are estimated to contain predominantly vitamins of B-complex and folic acid. Relative to *Auricularia, Lentinus*, and *Volvariella*, the thiamin, niacin, and riboflavin content of *Pleurotus* species were higher (Table 3). Considering the amount of vitamins contributed by 100 g fresh *Pleurotus* mushrooms as a percentage of the requirement level indicated by the Food and Agriculture Organization/World Health Organization (FAO/WHO) per person per day and allowing for differences in moisture contents, *Pleurotus* mushrooms are a particularly good source for meeting the human requirements for riboflavin and folic acid (Table 4).

Mushrooms are known for their B-complex vitamins (niacin, thiamin, and B_{12}) and folic acid. Their ability to contain these vitamins, even during their growth on lignocellulosic wastes, eventually substantiates their biosynthetic capacities. In fact, folate synthetase and B_{12} synthetase enzyme systems have been demonstrated in mushroom cells.

Food Value

Determination or prediction of the nutritional value of mushrooms (Table 5) has been made possible based on their content of essential amino acids.

The amino acid score is the amount of the most limiting amino acid in the food protein expressed as a percentage of that amino acid present in a reference protein.

$$\text{Amino acid score} = \frac{\text{mg of amino acid in 1 g test protein}}{\text{mg of amino acid in 1 g reference protein}} \times 100$$

The essential amino acid (EAA) index evaluates the quality of dietary protein in terms of the ratio of the EAA contained in a food, relative to the EAA content of the reference protein, mostly egg.

$$\text{EAA} = \sqrt[n]{\frac{\text{Lysine}_p - \text{tryptophan}_p - \text{histidine}_p}{\text{Lysine}_s - \text{tryptophan}_s - \text{histidine}_s}}$$

where p = food protein, s = standard (egg), and n = the number of amino acids.

The biological value is a measure of the nitrogen retained by the body after consuming the test protein.

$$\text{Biological value} = 10.9\ (\text{EAA index}) - 11.7$$

In an attempt to resolve the difficulties inherent in comparisons between those mushrooms containing small amounts of high-quality protein with those containing larger amounts of a protein of lesser nutritional quality, the use of a nutritional index has been proposed:

$$\text{Nutritional index} = \frac{\text{EAA index} \times \text{percentage protein}}{100}$$

Amino acid scores and EAA indices of the most nutritive mushrooms (highest values) rank in potential nutritive value with those of meat and milk, and are significantly higher than those for most legumes and vegetables. The least nutritive mushrooms rank appreciably lower but are still comparable to some common/nutritious vegetables.

As Flavor Ingredients

In general, mushroom flavor substances are derivatives of fatty acids and nucleotides. Flavor is the most

Table 5 Estimated nutritive values of mushrooms

Mushroom species	*Essential amino acid index*	*Biological value*	*Nutritional index*	*Amino acid score*[a]
Agaricus bisporus	55.8	49.1	17.0	36
Boletus edulis	76.6	71.8	9.3	37

[a]Using egg as reference protein.

important inducement for past and present widespread consumption of wild and commercially grown edible mushrooms. As many as 150 volatile compounds have been identified in various mushroom species. A series of eight carbon (C_8) compounds are believed to be the most important volatile flavor compounds. It has been demonstrated that some of the C_8 and C_{10} compounds can be enzymatically formed from linoleic and linolenic acids, both of which are usually predominant in fruiting bodies. The gills were found to be the major compartment for the metabolic interconversion of fatty acids into aromatic compounds. 1-Octen-3-ol is the general fresh mushroom flavor, whereas 1-Octen-3-one represents the dried-mushroom flavor. Several alcohols, aldehydes, ketones, and phenols are known to be mushroom flavor components characteristic of each species.

Umami, the full, rounded taste (as defined by the Japanese) of a mushroom, is predominantly the result of the presence of monosodium glutamate, further improved with addition of minor amounts of nucleotides, such as guanidine monophosphate (GMP) and adenosine monophosphate (AMP). Tricholomic acid and ibotenic acid have been found in *Tricholoma muscarium* and *Amanita pantherina*, respectively. These amino acids have higher threshold values than that of glutamic acid in evoking the umami flavor. It is of great interest that these two amino acids are toxic to flies. A Japanese proverb states that the *Tricholoma matsutake* is noted for its aroma and *Lyophyllum shimeji* is noted for its taste. The aroma components of *T. matsutake* are matsutakeol and methyl cinnamate. A sulfur-containing compound, lenthinic acid, in fresh *Lentinus edodes* is flavorless, but it is converted by heat to lenthionin, which is responsible for the specific flavor, when *L. edodes* is dried.

As Source of Enzymes

Mushrooms are involved in the rotting of wood. Studies have been performed on many enzymes produced by cultured mushroom mycelia internally or externally. Mushrooms (basidiomycetes and a part of ascomycetes) are generally divided into lignin-hydrolyzing fungi (oxidoreductase producers) and cellulose-hydrolyzing fungi (hydrolase producers). In addition to phenol oxidase and cellulase, there are many reports on other mushroom enzymes, including protease, pectinase, chitinase, hemicellulase, amylase, and various glycosidases.

As Indicators of Toxic Elements

Mushrooms have a natural tendency to bioaccumulate the minerals from their growth substrates. *Agaricus campestris* finds use as a bioindicator species to trace the concentrations of silver. *Phanerochaetae chrysosporium* was most effective in sorption of lead compared with species of *Polyporus, Volvariella*, and *Pleurotus*. *Coprinus* species is shown to be able to methylate mercury after the transformation of mercury from the soil humus. The ability of several mushroom species to bioaccumulate cadmium, zinc, lead, copper, nickle, and manganese in their fruiting bodies is employed to monitor the intensity of environmental pollution. Several toxic metals are selectively sorbed from industrial waste waters by mushrooms. *Inonatus nikadol* is used to recover uranium selectively from the culture medium.

Biological Uses

Many mushrooms, such as *Ganoderma lucidum, Coriolus versicolor, Hericium erinaceus, Armillaria mellea, Marasmius androsaceus, Tremella fuciformis*, and *Lentinus edodes*, have traditionally been used as medicine and tonics in China, Korea, and Japan (Tables 6 and 7). Terpenoids, substances which inhibit growth of cancer cells such as He La cells *in vitro* (chemotherapeutic agents), have been found in *Ganoderma lucidum*. Steroids in *Coriolus versicolor* and *Agaricus blazei*, novel γ-pyrones, esinapyrones A and B, cytotoxic novel phenols hericenones A and B,

and novel fatty acid in *Hericium eriaceus*, as well as lampterol (illudin-S) in *Lampteromyces japonicus*, represent other inhibitors of growth of cancer cells. The germanium content of mushroom is involved in carcinostatic and analgesic functions. Many polysaccharides exhibiting remarkable antitumor activity *in vivo* have been isolated from various species of mushrooms belonging to Polyporaceae, Tricholomataceae, and Agaricaceae through screening studies using sarcoma-180 in mice (Table 8). These antitumor substances are regarded as a kind of biological response modifier (BRM) – immunotherapeutic agents, whose activities are based on the activation of immunological functions in a host.

Biological properties of several of the natural mushroom species due to the components present in them are presented in Table 9. This information reflects on the diverse manifestations of medicinal properties of these mushrooms.

'Mushroom nutraceuticals' represent the medicinal preparations from mushrooms. They are functional foods which are enriched or modified and consumed as normal diet to provide health-giving benefits. They are refined or partially defined extractives which are consumed in the form of capsules or tablets, as a dietary supplement (not a food) and which has potential therapeutic applications, increasing resistance to diseases and causing regression in disease state. Nutraceuticals are not to be confused with pharmaceuticals which are defined chemical preparations, specifications for which are listed in a pharmacopoeia, and are mainly used therapeutically; pharmaceuticals have high potency, so the chances of overdose and toxicity require regulation by the authorities. Mushrooms with little scope of toxicity and overdose do not require very strict regulation and can be sold as 'over-the-counter' medicines.

In the recent past, a variety of medicinal preparations in the form of tablets, capsules, and extracts from mushrooms have been produced and marketed. In 1991, the value of the world mushroom crop was estimated at $8.5 billion and in the same year $1.2 billion were estimated to have been generated from medicinal products of mushrooms. In 1987 PSK, a top selling anticancer drug from the mushroom *Coriolus versicolor*, had annual sales in Japan totalling $358 million and accounted for 25.5% of the country's total sales of anticancer drugs. It was not without reason that production of *Grifola, Lentinula*, and

Table 6 Use of mushrooms as drugs in China

Mushroom species	*Indication*
Agaricus bisporus	Stimulating digestion, curing hypertension
Auricularia polytricha	Strengthening health, helping blood circulation
Boletus edulis	Causing muscles and joints to relax
Coriolus versicolor	Curing chronic disease
Ganoderma lucidum	Rejuvenating effect, neurasthenia
Grifola frondosa	Strengthening health and resisting diseases
Hericium erinaceus	Beneficial to heart, kidneys, liver, lungs, spleen
Lentinus edodes	Strengthening health and resisting diseases
Pleurotus ostreatus	Causing muscles and joints to relax
Tremella fuciformis	Strength, health, and resisting diseases
Tricholoma mongolicum	Beneficial to stomach and intestine

Japanese name	*Mushroom*	*Medicinal effects*
Shiitake	*Lentinus edodes*	Antiinflammation, antitumorigenic, gastroenteropathy, headache, vertigo, hepatocirrhosis, arteriosclerosis
Fukurotake	*Volvariella volvacea*	Hypotensive, immunopotentiator, reduce cholesterol
Bukuryou	*Poria cocos*	Diuresis, edema, vertigo, dipsia, anxiety, neurosis, insomnia, antitumorigenic
Shirokikurage	*Tremella fuciformis*	Cough, sore throat, stethalgia, constipation, paramenia
Yamabushitake	*Hericium erinaceus*	Indigestion, neurasthenia, gastric ulcer, antitumorigenic
Tohtyukasoh	*Cordyceps sinensis*	Mild roborant, expectorant, antitussive, antiinflammation

Hypsizygus – three prominent medicinal mushrooms – registered a 102, 110, and 141% increase respectively during 1990–94.

Toxic Components in Poisonous Mushrooms

Mushroom poisoning accounts for approximately 70% of natural poisoning and often causes death. However, there are only 30–50 poisonous species among the thousands of species found on earth, and of these, no more than 10 are fatally poisonous. Nevertheless, many cases of mushroom poisoning are reported every year. There is no convenient way to distinguish edible mushrooms from poisonous ones. All the folklore about detecting poisonous mushrooms is not true. For example, poisonous mushrooms do not blacken silver spoons when cooked with mushrooms, as folklore claims. The best way to avoid risk is to learn the physical features of each species. If 10 of the most poisonous mushrooms were recognized by mushroom pickers, the number of cases of mushroom poisoning would decrease dramatically.

Amanita phalloides, the green death cap, is known as the most dangerous and poisonous mushroom. It is widely distributed in Europe and North America and is responsible for 90–95% of fatal mushroom poisonings. Cholera-like symptoms – nausea, vomiting, and diarrhea – of *Amanita* poisoning begin 10–20 h after ingestion; severe damage to the liver and kidney follows, and this damage finally leads to death. The cyclic peptides, the amatoxins, and the phallatoxins have been isolated as the toxic principles. *A. virosa* (Table 10), the 'destroying angel,' is as toxic as *A. phalloides* because it contains an amatoxin, amaninamide.

Amino acids structurally related to glutamic acid have been obtained as mushroom toxins. Some of them made significant contributions to neurobiological research because of the biological and clinical importance of glutamic acid. Acromelic acids isolated from *Clitocybe acromelalga* are neurotoxins showing highly potent activity as glutamate agonists. This mushroom, found only in Japan, has been known to induce unique symptoms. If ingested, it causes severe pain and reddish edema in the fingers and toes, which is similar to acromelalgia and erythromelalgia, and the symptoms persist for a month or so.

Amanita muscaria has a brilliant red cap flecked with white spots and is undoubtedly the best-known poisonous mushroom in the world. It is widely distributed throughout the world, except for tropical zones. The mushrooms belonging to the genus *Inocybe* contain far greater amounts of muscarine than do the *A. muscaria*, so that ingestion of *Inocybe* mushrooms induces typical symptoms of muscarine poisoning. Psilicybin and psilocin are well-known mushroom toxins with hallucinogenic effects detected in the majority of *Psilocybe* species. These alkaloids act on the central nervous system because the structure and activity are similar to those of the known hallucinogen, lysergic acid diethylamide (LSD).

Thus, mushrooms constitute a unique class of foods praised and priced because of their characteristic biting texture and pleasant aroma, and are aptly regarded as a food delicacy. They serve to complement and supplement the human diet with various chemical constituents not encountered in or deficient in food items of plant or animal origin. They have a tremendous potential to synthesize components and constituents not found in the nitrogen-poor, low-cost, lignocellulosic growth substrates. They can

Table 9 Biological properties of mushrooms

Mushroom species	*Compound*	*Biological property*
Agaricus blazei	Ergosterol derivatives	Uterus cervical cancer, He La and hepatoma cells
Armillariella tabescens	Armillarisia A	Increase secretion of bile
Coriolus versicolor	Ergosterol derivatives	Uterus cervical cancer, He La and hepatoma cells
Flammulina velutipes	Protein	Cardiotonic
Ganoderma lucidum	Adenosin, guanosin	Antithrombolytic
Ganoderma lucidum	Organic germanium	Pain reducer during final stages of cancer
Ganoderma lucidum	Two polysaccharide – protein complexes	Hypoglycemic activity
Ganoderma lucidum	Triterpenoids	Hypotensive
Ganoderma lucidum	Heterogalactan – protein complex	Antiinflammatory and antiallergic
Hericium erinaceus	Hericenones	Synthesis of nerve growth factor
Lentinus edodes	Adenine derivatives	Hypocholesterolemic
Lentinus edodes	RNA from the spores	Antiviral (influenza infection)
Marasmius androsaceus	Marasmic acid	Analgesic, sedative effect
Polyporus confluens	Polysaccharide	Peptic ulcers
Volvariella volvacea	Protein	Cardiotonic
Various mushroom species	Lectins	Agglutination of erythrocytes/precipitation of polysaccharide
Various mushroom species	Eritadenine, grifolin, neogrifolin	Reduction in cholesterol/neutral fat

Table 10 Mushroom poisoning

Mushroom species	*Compounds*	*Nature of compound*	*Symptoms*
Amanita phalloides	Phallotoxin		
Amanita phalloides	Amatoxin	Cyclopeptide	Fatal

be prepared in diverse recipes that can provide great satisfaction to human sensorials. Their unique chemical composition encourages the fight against diabetes, alimentary ulcers, tumors, blood cholesterol, and hypertension. As low-calorie foods, they are dietary items ideal for slimming. With the examples of mushroom species mentioned above, the chemical constituents described and their biological properties, it is clear that mushrooms, in addition to being an item of food delicacy, can claim value as 'health conditioner.' Probably within another decade, more research will further define more quantitatively the biomedicinal values of mushrooms.

MUSTARD AND CONDIMENT PRODUCTS

J S Hemingway, Brundall, UK

Introduction

The term 'mustard' is believed to be derived from the use of seeds as condiment, the sweet 'must' of old wine being mixed with crushed seeds into a paste – 'hot must' or 'mustum ardens'. Mustard seed has been known as a spice since the earliest recorded times; it is described in Sanksrit and Sumerian texts back to 3000 BC, Egyptian to 2000 BC, and Chinese before 1000 BC; seed fragments exist from the Indus Valley civilizations around 2000 BC and Egyptian tombs at Thebes of the same period. Records of mustard being traded as a manufactured condiment extend back to the days of the Avignon popes and Shakespeare.

In the present day, it is by far the largest volume spice in international trade, totalling over 170 000 $kg \times 10^3$ per year. Other particular features which make it unusual as a spice crop are that, for condiment purposes, the entire world supply is grown in temperate regions, as the crop needs long days; hence, its production is virtually all concentrated in the Northern Hemisphere, where it has necessarily been developed by plant breeding to suit full mechanization of every operation of its cropping and the bulk handling of mustard seed into trade (a further unusual aspect of a spice material).

Cropping

For use as spice, the predominant production is in North America, in the Canadian prairie provinces of Saskatchewan, Alberta, and Manitoba, and just southwards into Montana and North Dakota, USA. Annual crops of the order of 200 000 $m \times 10^3$ in those areas produce total quantities in excess of 150 000 $kg \times 10^3$ of export value US\$40 $\times 10^6$. Other important production centers are the Hungarian plain and the East Anglian counties of the UK, also Poland, the Czech Republic, and Slovakia. Smaller-scale cropping occurs in Argentina and Australasia for local use, but world manufacture effectively depends on the single annual crop of the Northern Hemisphere. The main manufacturing usage is in the USA, Canada, France, Germany, Japan, and the UK.

Botanically, two principal species of the Cruciferae family are involved: 'White' (or 'yellow') mustard, *Sinapis alba*; 'brown' and 'oriental' mustards, *Brassica juncea*. In condiments, *S. alba* contributes a hot (in terms of mouth feel) nonvolatile principle and *B. juncea* a pungent (i.e., olfactory) volatile principle, each from the hydrolysis of their respective glycosides. Until the 1950s, seed of *B. nigra* was almost the sole source of pungency, but with perhaps unparalleled rapidity in any industry, let alone in an area as traditional as the spice trade, *B. juncea* replaced *B. nigra* over a single decade. This change met the requirement for full mechanical harvesting, as the older type needed to be cut by hand.

Mustard species are also of great importance as oilseed crops, particularly *B. juncea* in the Indian subcontinent, China, and the Sarepta area of the southern Ukraine. In recent years, there has developed an increasing export trade from Canada to the Indian subcontinent, principally Bangladesh, of the order of 50 000 $kg \times 10^3$ per year. In all these countries, the growth is closely similar to that of rapeseeed. Mustards also find wide usage as salads, green manure, and fodder crops and as leaf and stem vegetables in the Far East.

The principal centers of plant breeding and agronomic research on mustard crops have long been Norwich, UK, and Saskatoon, Canada, where successions of varieties of improved habit, yield, and quality aspects (e.g., seed size and shape, lower oil contents, and higher essential principles, kernel and seed-coat mucilage contents, all being features of manufacturing importance) have been produced.

Mustard crops for condiment are all grown as spring-sown annuals. They show three marked periods of growth:

1. A rapid vegetative development of leaves and the branching framework.

2. Three to four weeks of characteristic intensive yellow flowering during June.
3. Six to eight weeks of seed filling and ripening.

The crops reach a full height of 1.5–2.0 m, with each plant branching to bear several racemes of pods, all in a clear 'podding zone' that forms the upper part of the crop canopy. The main differences between the two principal species are visible during growth: *S. alba* foliage and stem are bright green in color, with surface hairs on the hollow stems; *B. juncea* is more glaucous, with smooth, waxy, pith-filled stems. The pods of *S. alba* are 2–3 cm in length, with a pronounced 'beak' at the tip and with hairy rough surfaces, containing up to eight seeds, whereas pods of *B. juncea* are up to 5 cm in length, smooth and tubular, with up to 20 seeds.

Mustard crops are both easy and reliable to grow, and perform well on land of reasonable fertility, on which they need only nitrogen as an added fertilizer. *Brassica juncea* has considerable resistance to drought and can crop with limited rainfall but *S. alba* flourishes best with more regular precipitation. As neither species is affected by plant diseases to economic levels, and both suffer to only a limited degree from insect pests, they do not require repeated treatments from pesticides. The requirement for clean seed necessitates adequate weed control practices, for which well-proven and simple systems are available. The crops can tolerate reasonable extremes of weather, such as spring frosts, hail, or strong winds, without serious losses, standing well on stiff, erect stems. In cropping systems in which rotational practice is important, mustards form an excellent 'break crop' between cereals, especially as a preparation for wheat. As mentioned earlier, modern varieties have been developed that suit farming machinery used for other crops, and do not clash with them in the timing of harvesting, so that there is no need for special investment or any hand-labor operations.

Mustards are prolific yielders and can increase over 2000-fold in a season in optimum conditions. Current mean yields in UK cropping are of the order of 900–1000 kg of seed per acre (2220–2500 kg per $m \times 10^3$), ranging up to 1500 kg (3700 kg); in the North American prairie, expectations are lower, at some 400–700 kg per acre (990–1730 kg per $m \times 10^3$) for *B. juncea* and 275–550 kg per acre (680–1360 kg per $m \times 10^3$) for *S. alba*, with substantial variation according to soil moisture status. Yields in eastern European countries are intermediate.

Seed Handling and Storage

After harvest in Canada, the seed is usually below 10.5% moisture, at which level, it is safe for long-term storage; indeed, if thoroughly dry and clean, there is never any risk of infestation of mustard by stored product pests. In other countries, the seed may need to be dried gently to reduce it to safe storage levels; in such situations, it is important to act quickly, as the seed can deteriorate very rapidly, and to restrict the temperature of the drying airflow so that the seed temperature never exceeds 52 °C; otherwise, damage to its enzymes will result.

Cleaning operations are quite straightforward with mustards' round seeds of uniform size. Indented cylinders, perforated screens, and spiral separators are all effective, and surface dust can be removed by aspirated brush-conveyors. The presence of green or weathered seeds and of specific inseparable weed seeds is the main cause of downgrading within the official grades of the Canadian Board of Grain Commissioners, under which system the preponderance of world trading is operated. Storage is normally in bulk bins, with pneumatic or mechanical conveying, and carriage in bulk lorries or rail grain-cars, then bulk shipping holds. Smaller quantities are shipped in standard freight containers, occasionally in 100-lb (45-kg) bags if the customer so requires.

Anatomy of the Seed

The seed of *S. alba* is larger than that of *B. juncea*, averaging 148 000 seeds per kg, mean diameter 2.22 mm, against 408 000 and 1.63 mm. Features of the fine structure of the outside of the testa and the degree and type of surface reticulation and pitting are characteristic and of importance in differentiating the seed from that of other brassicas, e.g., rapeseed.

The seed coat consists of four or five layers of cells, including an outer layer of large cells and an inner palisade layer. Inside this lies the true endosperm, with an outer layer of cells that possess thickened walls and contain fat globules and small aleurone grains, and an inner, very narrow layer of compressed cells with no evident structure. The center of the seed is filled with two hemispherical cotyledons with the embryo lying between. There is only a small hilum and micropyle. The testa of *S. alba* contains a large number of mucilage glands opening to the surface; *B. juncea* has many fewer.

In *B. juncea*, the two distinct seed types are 'brown' and 'oriental.' The former has a darkly colored endosperm of more substantial cells, but such color is absent from the latter, leaving a golden-yellow shade. In this 'oriental' type, the testa occupies only 12–15% of the seed by weight, against 19–22% in brown; hence, the oriental type has a higher kernel content, of substantial economic value, provided that the testa is sufficiently robust to stand up to mechanical handling without rupture.

Seed Composition

General specifications for mustard seed and standard analytical methods are detailed under ISO 1237–1981 (E) UDS 633.844.004.1. The gross composition is shown in Table 1, the variation in content of common fatty acids in the oils of *S. alba* and *B. juncea* is shown in Table 2, and the principal amino acids in the protein fractions of these two species are shown in Table 3. (*See* **Amino Acids**: Properties and Occurrence; **Fatty Acids**: Properties.)

The organoleptic properties of mustards result from their contents of the essential mustard oils, which are colorless, irritating liquids; that of *S. alba* has little aroma, as it is nonvolatile, but a hot taste, whereas *B. juncea* gives a volatile oil with a pungent aroma. Within the seed, they exist as glycosides within intact cells of the cotyledons, and it is only on the rupture of the cells and in the presence of adequate moisture that the enzyme myrosinase can catalyze the reactions to produce the isothiocyanate principles.

In *S. alba*, the storage glycoside is sinalbin, which on breakdown gives *p*-hydroxybenzyl isothiocyanate; in *B. juncea*, the glycoside sinigin gives allyl-isothiocyanate. (Certain strains of *B. juncea*, all originating in the Indian subcontinent, give rise to a mixture of allyl and 3-butenyl isothiocyanates, the latter being an undesirable flavor, at least to the Western palate.)

Table 1 Gross composition of mustard seed

	Percentage of seed (dry weight)
Neutral oil	24–45 (*Sinapis alba* 25–30, *Brassica juncea* 35–45)
Polar lipids	6–12
Protein	20–30
Carbohydrate	12–18

Methionine	97	104
Cystine	124	159
Isoleucine	207	236
Leucine	412	395
Phenylalanine	233	240
Tyrosine	206	167
Threonine	171	251

Processing and Food Uses

The availability of these distinct flavor effects, heat and pungency, from the two mustard species allows the manufacture of a wide range of condiment products and food ingredients. A variety of processing techniques are used:

- wet milling of whole seeds;
- wet milling with husk separation;
- dry milling with husk separation;
- dry grinding of whole seeds;
- dry grinding after oil pressing.

A French (e.g., 'Dijon') mustard uses only brown-colored *B. juncea*, which, because it is wet-milled, loses much of its initial pungency. The extent of removal of the husk fragments by screening after milling governs the final color of the paste. Such mustards are commonly blended with wines and vinegars, and whole or split mustard grains, herbs, or other spices may be added. (*See* **Milling**: Characteristics of Milled Products.)

In contrast, an American 'cream-salad' mustard is made by wet milling only *S. alba* seed with water in a colloid-type mill. The viscosity of the product is greatly aided by the presence of mucilage in the seed coats. Turmeric is usually added to overlay the natural pale color to a rich yellow. The product has a sweet, tangy flavor and can be used in large amounts, almost as a ketchup.

Traditional German mustard is similarly made from *S. alba* alone, and is thus nonpungent. The texture of the paste can be varied by the degree of grinding, and admixtures of herbs, spices, and water or vinegar are used according to the product.

In contrast, traditional English mustard is a blend of the dry-milled flours of both *S. alba* and *B. juncea* and is both hot and pungent. This product is sold as a

dry fine powder, with no reaction until blended with water for the table, when the characteristic flavors develop very rapidly. However, as the pungency is volatile, and the hotness of the essential principle from *S. alba* breaks down within a day, the made condiment loses strength quite quickly. Its strength can only be maintained in a bottled paste ('hot English mustard') by the inclusion of fruit acids in its manufacture from milled flours.

The dry milling process to produce flour is broadly similar to the milling of wheat, with the difference that mustard seeds are very small and have 30–40% of oil in their cells. This needs great care, as the oil causes enormous problems if released by excess pressure or temperature. *Sinapis alba* and *B. juncea* are milled separately as they have distinct seed sizes. The seeds are first thoroughly cleaned, graded for size and shape, blended, and then dried to a very low level of moisture content. Their husks are then moistened (so that the kernel is dry and friable but the husk slightly elastic and less brittle) and metered steadily on to the 'break rolls,' of fluted surface, on which the seed is nipped to crack open the husk. This is separated from the kernels by sieving and currents of air in the 'purifiers': a remarkably clean separation can be achieved with little kernel adhering to the husks, and minimal presence of fine husk particles, which would show as specks in the flours milled from the kernel fractions.

The kernels then pass on to a series of smooth 'reduction rolls,' which progressively reduce them to a powder. After each pass through a roll, the fine particles are sieved off to ultrafine by the use of swirling sieves, their frames covered with silk bolting cloths of differing meshes; the coarse particles return to a further reduction roll. The resultant flours – the *S. alba* a deep creamy color and *B. juncea* a rich golden-yellow shade – are blended in varying proportions according to the product desired. Some products may be blended with stabilized wheat flour in small proportions to attain a standard flavor strength, and coloring may be enriched by the curcumin present in ground turmeric.

In Japan, the production of mustard powder is usually by the fine grinding and sifting of whole seeds, but after the extraction of some of the seed-oil content by pressing. The Japanese taste, like the Anglo-Saxon, is for very strongly flavored mustard products.

The grinding of whole mustard seeds is usually to obtain a coarser, granular product for use as an ingredient in sauces, pickles, or chutneys. An increasing usage of ground *S. alba* is in the North American meat products industry, where it adds flavor and protein, and its mucilage helps to absorb moisture. Some *S. alba* seed is now being heat-treated to inactivate its myrosinase, then pin-milled to coarse particles of no strength of flavor, thus allowing a higher and wider usage in such meat products.

The byproducts of dry milling are principally the husks. That of *S. alba* can be ground into a coarse meal used to impart viscosity to paste mustards or sauce products, but the husk of *B. juncea* has little value.

Beyond the ingredient usages of mustard already mentioned, based on its range of flavors and applications of the mucilage content of *S. alba*, the major usage is the inclusion of mustard flour – predominantly of *S. alba* – in the formulation of salad creams and mayonnaises. It provides some flavor and natural color, has natural bacteriostatic and antioxidant properties, and, most importantly, acts as an emulsifying agent, helping to bind the oil and fat phases of the recipe. This was perhaps a fundamental virtue within the original popularity of mustard as a spice, technically to 'enhance flavor' – or disguise the taste of salted meats or fish – but also to 'aid digestion' by its use with fatty meats or oily fish, attributes praised by early medical writers or gourmands. MUTAGENS

T J Schrader, Sir Frederick Banting Research Centre, Health Canada, Ottawa, Ontario, Canada

Background

Mutagens are chemical compounds or forms of radiation (such as ultraviolet (UV) light or X-rays) that cause irreversible and heritable changes (mutations) in the cellular genetic material, deoxyribonucleic acid (DNA). Mutagenic lesions persist when they escape detection by protective cellular DNA repair mechanisms, when mistakes occur in the repair process, or when repair mechanisms are overwhelmed by extensive damage. Upon subsequent cellular replication, these mutations become fixed in the genome and are inherited by all daughter cells. In this way, mutagenesis becomes a cumulative process, stretching over the lifetime of an organism.

The biological consequences of a mutation depend upon many critical factors such as the target loci, size of the mutation, timing during the cell cycle, and compounding effects of preexisting mutations. Thus, a mutagenic event occurring in a nonfunctional area of DNA will have no effect (*silent mutation*), whereas a similar change in an actively transcribed region may profoundly affect gene expression and phenotype or even lead to cell death (*lethal mutation*). The influence of mutations in human health is underscored by several human disease states caused by mutations that disrupt regulatory regions or gene coding sequences, resulting in altered gene expression and protein function. For example, mutations in genes that promote or inhibit growth and cellular replication (*protooncogenes* and *tumor suppressor genes*, respectively) or code for components of DNA repair pathways are important contributors to the multistage development of cancer. In addition, the accumulation of mutations over time, leading to gradually less efficient cellular repair capabilities, has been linked to the aging process and associated degenerative diseases. While the health of a particular individual can be affected by mutations in somatic cells, mutagenic events in germ cells (*germline mutations*) lead to the transmission of genetic diseases to subsequent generations. Genetic predispositions to certain breast and colon cancers, cystic fibrosis, and Huntington's disease are included among many examples of such inheritable diseases.

Although many dietary and environmental agents have been classified as mutagens, cells are constantly subjected to a barrage of spontaneous DNA damage. The spontaneous hydrolysis of DNA bases from the sugar–phosphate backbone, constant exposure of cellular DNA to oxygen-derived free radicals and low rates of miscopying during DNA replication all contribute towards the mutational burden. In addition to these sources, significant exposure to mutagenic compounds can occur through food and water, as well as through environmental and occupational sources. Many natural constituents of food are mutagenic and are produced by plants as defense agents. However, additional foodborne mutagens can be present as residues of compounds used during food production or leached from packaging materials. Mutagenic compounds can also be produced during food cooking and preparation. Foods also contain many compounds that can modulate the activity of mutagens. In order to minimize exposure to mutagens, the majority of developed countries have instituted regulatory protocols governing the introduction of new foods and food-associated chemicals before they are accepted into the marketplace. With advances in the understanding of mutagenic processes, existing foods and food contact items may also be reassessed for acceptability.

Molecular Mechanisms of Mutagenesis

DNA Damage

DNA is a double-helical structure composed of paired heterocyclic nitrogenous purine and pyrimidine bases attached to a backbone of deoxyribose and phosphoric acid. The purine bases (guanine and adenine) and pyrimidine bases (cytosine and thymine) form specific base pairs (guanine/cytosine, adenine/thymine) stabilized by hydrogen bonding. The specificity of base-pairing and sequence of bases along the DNA double helix forms the foundation of the genetic code, and any change can give rise to mutations, expressed as alterations in gene expression or in protein structure and function.

Spontaneous damage Instability of various parts of the DNA molecule in aqueous solution leads to spontaneous DNA damage and mutations. In addition to base deamination, the bonds between purines or pyrimidines and deoxyribose can spontaneously hydrolyze, creating apurinic/apyrimidinic (*AP*) sites, leaving the sugar–phosphate backbone susceptible to strand breakage. Also, the bases can exist in a number of slightly different (*tautomeric*) forms, several of

which lead to mispairing because of altered hydrogen bonding characteristics.

Chemical adducts DNA also comes under assault from a number of dietary and environmental factors that interact with several relatively reactive sites within the structure of DNA, leading to mutagenic events. Many chemical mutagens are electrophiles that are reactive, electron deficient species able to form covalent adducts with nucleophilic sites within DNA. Binding of chemical adducts to the purine/pyrimidine bases can stabilize alternative tautomeric structures or otherwise alter their structural and hydrogen bonding characteristics. These modifications not only alter the base pair coding properties and cause mistakes to be made during replication and transcription, but also can lead to increased base hydrolysis and AP site formation. In addition, some chemical agents produce inter- and intrastrand cross-linking of DNA, which prevents strand separation and causes particular difficulties for replication, transcription, and repair processes.

Oxidative damage Other mutagens can act through the induction of oxidative stress and cause oxygen or nitrogen radical formation. Radicals are highly reactive compounds that contain unpaired electrons and include hydroperoxides, hydroxyl, and superoxide radicals. Transition metal ions such as iron and copper can catalyze the formation of free radicals (*Fenton reaction*). The interaction of free radicals with DNA results in single- and double-strand breaks, hydroxylated derivatives of bases and several other lesions.

DNA intercalation Finally, some mutagens do not actually react with DNA but modify its structure by intercalating between the complementary strands of DNA, disrupting hydrogen bonding between base pairs. The presence of such compounds causes misreading during replication and transcription, leading to the generation of mutations.

Metabolic Activation

Some mutagenic compounds (*direct-acting*) are able to interact with DNA without any further modifications; however, many other compounds (*indirect-acting* mutagens), become mutagenic as unwanted byproducts of transformations carried out by cellular detoxification pathways. Several hydroxylation (*phase I*) and conjugation (*phase II*) pathways are available for detoxification to increase the water solubility of chemical compounds and aid in their excretion. Although the enzyme systems are generally most highly expressed in the liver, other tissue types maintain these capabilities to varying degrees. The phase I reactions are carried out by the cytochrome P450 enzyme system, which consists of a large family of related enzymes in which each isozyme shows specificity for particular chemical structures. During phase II reactions, more polar groups can be added by glutathione-*S*-transferase, glucuronide transferase, microsomal epoxide hydrase, or acetyltransferase. Generally, phase II reactions inactivate mutagens, but instances of the opposite outcome have been found. Several other enzymes, including flavin monooxygenase and prostaglandin H synthetase, are also known to activate mutagens.

DNA Repair

Several mechanisms have evolved to remove lesions in DNA and to restore the structural and coding properties of the base sequence in the damaged region.

Direct Reversal Direct reversal of damage is perhaps the simplest process, whereby a single gene product can repair a particular form of damage. In mammalian cells, mutagenic O^6-methyguanine residues are removed by a damage-reversal mechanism in which the O^6-alkyl group is removed by an O^6-methylguanine transferase in a 'suicide reaction,' resulting in inactivation of the enzyme. A second form of damage reversal is observed in the repair of simple strand breaks, which can be repaired by ligation in a process catalyzed by DNA ligase. Finally, a DNA purine insertase activity has been described by which apurinic sites in DNA are repaired by the direct insertion of purines.

Excision Repair The major and most versatile mechanism used by mammalian cells to remove altered bases or nucleotides within DNA is known as *excision repair*. Excision repair proceeds in several successive steps in a multiple enzyme process. Three major excision repair pathways using different sets of enzymes have been described: base excision repair, nucleotide excision repair and mismatch repair.

Classes of Mutations

Base excision repair removes misincorporated bases such as uracil as well as most methylated base damage. The majority of base damage is repaired by the replacement of a single damaged nucleotide with its normal counterpart, but base excision repair can also result in the synthesis of two to 10 nucleotide 'repair patches.' Initially, the damaged base is recognized and removed by a damage-specific glycosylase leaving an AP site in the DNA. For single nucleotide repair, the deoxyribose-phosphate residue in the DNA backbone is removed and a replacement nucleotide

inserted by activities associated with DNA polymerase β. Longer patches result when either polymerase β or another repair DNA polymerase synthesizes a stretch of DNA. In this process, a flap region of single stranded DNA is displaced and is then degraded by a deoxyribonuclease activity. Both types of base excision repair are completed when DNA ligase seals the final nick remaining in the DNA backbone.

The *nucleotide excision repair* pathway involves 20–30 gene products and is responsible for removing damage caused by agents that introduce bulky adducts into DNA. The initial recognition of DNA damage by a recognition complex recruits the entire multicomponent repair enzyme complex (*exinuclease*) to the lesion. The exinuclease nicks the damaged strand on either side of the damage site, releasing an oligonucleotide of approximately 30 base pairs in length. After the gap is filled in by a DNA polymerase using the opposite strand as a template, the nick at the end of the repair patch is sealed by ligase. Nucleotide excision repair has also been shown to be closely linked with transcription (*transcription-coupled repair*) by which actively transcribed genes are preferentially repaired compared to silent regions of the genome. A component of the nucleotide excision repair complex (TFIID) is shared with the complex involved in gene transcription and mediates the recruitment of DNA repair machinery to the damage site when RNA polymerase stalls at a lesion.

Mismatch repair is a form of excision repair that corrects mismatched base pairs resulting from replication errors and heteroduplexes formed during recombination. The interaction of various components involved in mismatch repair is less understood but results in repair patches of 100–1000 nucleotides. Mutations in mismatch repair genes have been linked to an increased risk for inherited forms of colon cancer.

Mutations can range in size from single base pair changes to the loss or duplication of entire chromosomes. Many factors, such as the mutagenic agent, particular region of DNA affected, preexisting damage, and timing during the cell cycle can influence the magnitude of a mutation. Mutations can be classified into four broad groups: extragenic, gene, chromosomal, and genomic mutations.

Extragenic Mutations Extragenic mutations occur outside of the gene coding sequence and are usually silent. However, if the mutation occurs in an important regulatory sequence, gene expression can be affected.

Gene Mutations Gene mutations occur within the coding sequence of a gene. *Point mutations* involve the substitution of bases, causing either transitions (the substitution of a purine for purine, or pyrimidine for pyrimidine) or transversions (the substitution of a purine for a pyrimidine or vice versa). If such a mutation occurs in the wobble position of a codon, the chance of a change occurring in the translated protein structure or function will be much reduced. However, a single base pair change elsewhere in the sequence can result in proteins with decreased or modified functions and can also affect protein synthesis and degradation. *Frameshift mutations* occur when bases are either lost or inserted, thus resulting in a shift of the reading frame by the transcriptional machinery. Frameshift mutations can result in the production of modified or inactive proteins and may be lethal to the cell. *Block mutations* occur when large sections of a gene are deleted, inverted, or duplicated, and can lead to defective proteins being produced.

Chromosomal Mutations Compared with gene mutations, chromosomal mutations represent a class of mutations that affect larger regions of DNA within chromosomes and may involve the deletion, translocation, duplication, or further amplification of whole genes. Chromosomal mutations may lead to either increased or decreased gene expression and can also result in the abnormal expression of normally silent parts of the genome.

Genomic Mutations Genomic mutations involve the duplication or loss of entire chromosomes. Such mutations can have far-reaching effects on gene expression and survival. Typically, the progression of a cancer is marked by cells that have developed progressively altered complements of chromosomes.

Mutagenicity Assays

Many assay systems have been developed to examine mutagenicity and induction of DNA damage (*See* **Carcinogens**: Carcinogenicity Tests). In many instances, mutagenicity assays are used as shorter term, more economical surrogates for the 2-year rat carcinogenesis bioassay. Although a high correlation exists between mutagenicity and carcinogenicity, neither this correlation nor that between results obtained with different mutagenicity tests is perfect. Therefore, test chemicals are generally subjected to a battery of three tests or more to gain a more balanced assessment. Widely used mutagenicity assays include both short-term bacterial, fungal, and mammalian cell-based (*in vitro*) and animal-based (*in vivo*) assay systems. Mutations within a target gene are detected as a loss of function (*forward mutations*) or as a reversal of the effect of a previous mutation (*reverse*

mutations). These assays generally rely upon a change in phenotype as an endpoint and therefore may miss some silent mutations. *In vitro* systems are generally conducted in the presence and absence of a source of metabolic activation, which can include rat liver homogenate (S9 microsomes) or liver cells. The application of molecular biology and biotechnology to many of these systems has led to further refinement and increased molecular characterization of the mutations induced.

The Ames *Salmonella* Test and the *E. coli* tryptophan assay are bacterial systems that measure reversions induced at genes responsible for the synthesis of histidine and tryptophan, respectively. Growth of the bacteria on minimal plates requires back mutations at the indicated loci, and therefore, test chemical mutagenicity is assessed according to colony formation. The Ames *Salmonella* Test has been widely accepted and validated as a bacterial assay with different strains available that respond to base pair and frameshift mutagens as well as oxidative damage. Various refinements to the Ames *Salmonella* Test have been developed, including a series of bacterial strains that are reverted at specific base pairs, allowing the spectrum of induced mutations to be assessed, as well as bacteria that express various mammalian Phase I and Phase II genes to examine the effects of particular types of activation. Several targets can be examined for the induction of forward mutations in mammalian cells, including gene loci encoding thymidine kinase in L51278Y mouse lymphoma cells, hypoxanthine guanine phosphoribosyl transferase (*HGPRT*) in Chinese hamster ovary or V-79 cells and Na^+/K^+ ATPase in V-79 cells. Mutagenesis at the HGPRT locus has also been examined in human lymphocytes and fibroblasts. Plasmid shuttle vectors have also been developed, which can be exposed to the test chemical, introduced into mammalian cells for repair, and then recovered and reintroduced into an indicator strain of *E. coli* for scoring of mutations. If needed, the plasmids can be recovered again and sequenced.

Germ-line mutations may be assessed in rodents using the specific locus test, dominant lethal assay, and heritable translocation test. Transgenic mice incorporating λ phage *LacI* or *LacZ* gene sequences have also been developed, which provide shorter-term, *in vivo* mutagenicity assays. DNA isolated from these animals is incorporated into λ-phage which is used to infect the proper *E. coli* host, forming either clear or colored plaques in the bacterial lawn. The transgenic assays allow mutations to be examined in all somatic tissues as well as germ-line tissues, and provide a well-characterized target for sequence analysis.

Chromosomal aberrations can be examined both *in vitro* using cell lines or *in vivo* using animal tissues, generally bone marrow. Stained metaphase chromosome spreads are examined microscopically for structural chromosomal aberrations. A newer variation of this technique, fluorescent *in situ* hybridization, uses fluorescent labeled DNA probes specific for particular chromosomal sequences to test for aberrations. Another chromosomal aberration assay is the micronucleus test using bone marrow and peripheral blood erythrocytes or lymphocytes. Micronuclei are small particles containing acentric fragments of chromosomes or entire chromosomes that are left behind in the cytoplasm after mutagen treatment. Micronuclei formation may be enumerated by microscopy or flow cytometry.

Sister chromatid exchange uses differential labeling techniques to measure the crossing over between each half of a replicated chromosome. The biological significance of sister chromatid exchange is not known, as the phenomenon does not appear to be related to the mechanisms involved in chromosomal aberration formation and is not directly related to mutagenesis. However, most alkylating agents and compounds that create adducts and single-strand breakage increase sister chromatid exchange. Therefore, the assay tends to be used as a complement to mutagenesis and chromosomal aberration assays.

Food-associated Mutagens

The investigation of mutagens in food is an important component of food-safety research. Mutagens found in food can be divided into three groups: naturally occurring compounds, those formed by heating or processing, and additives and contaminants, including pesticides.

Naturally Occurring Mutagens

Natural components of food account for over 99% of the carcinogenic and toxic chemicals to which humans are exposed. Most of these natural mutagens are produced by plants as natural pesticides. Many of these intrinsic chemicals are almost impossible to regulate or remove, although guidelines for acceptable exposure limits of some natural contaminants such as mycotoxins are enforced.

Flavonoids form a major group of natural plant compounds, and in a survey of mutagenesis using the Ames *Salmonella* Test, 33 out of 70 natural and synthetic flavonoids proved to be mutagenic, producing both base pair and frameshift mutations. Studies indicate that only the flavonol (3-hydroxyflavone) members of this group are mutagenic. Myricetin and quercetin are direct-acting mutagenic flavonoids, whereas kaempferol is indirect-acting. Norwogonin

and sexangularetin are two other indirect-acting flavonoids. The *pyrrolizidine alkaloids* represent another large group of widespread mutagenic plant compounds found in some herbal teas and medicines, and include compounds such as monocrotaline, dehydomonocrotaline, retrorsine, and isatidine. Pyrrolizidine alkaloids are indirect-acting mutagens, with some compounds inducing DNA-strand breakage, whereas others form DNA and DNA–protein cross-links. Another class of mutagenic compounds is the *glucosinolates*, which are found in cruciferous vegetables. Glucosinolates are broken down into isothiocyanates or nitriles, including the mutagenic allyl isothiocyanate glucoside (sinigrin). The mutagen aquilide A (ptaquiloside) from bracken fern (fiddleheads) is a related *glycoside* and can also be passed through cows' milk. *Catechol-type phenolics*, such as tannins and caffeic acid and its esters (chlorogenic and neochlorogenic acids), are more widespread than other natural pesticides and can induce chromosomal damage. Caffeic acid conjugates can be present in higher plants, with coffee, apple, and lettuce as major sources in the human diet. A class of chemicals known as *linear furanocoumarins*, found in parsley and celery, has several mutagenic members, including psoralen, 5-methoxypsoralen (bergapten), and 8-methoxypsoralen (xanthotoxin). Linear furanocoumarins intercalate into DNA and form mono- and di-adducts in the presence of long-wave UV light. A number of mutagenic *hydrazine* compounds such as hydrazinobenzoate are found in 30 species of mushrooms. Estragole and safrole are mutagenic *alkenylbenzenes* that are found in a number of spices such as black pepper, basil, fennel, and nutmeg. Other food-related mutagens, include ethyl acrylate from pineapple, sesamol from sesame seeds, and benzyl acetate from basil, jasmine tea, and honey.

Mycotoxins are an important source of mutagenic contamination resulting from mold growth in foodstuffs. Human exposure can occur through grain crops, meat products, milk and eggs, nuts and peanuts, fruits, and juice. *Aspergillus* spp. produce a family of aflatoxin mycotoxins (aflatoxins B1, B2, G1, G2), of which aflatoxin B1 is the most potent. Food products produced from livestock fed aflatoxin-contaminated feeds can also serve as a potential source of human exposure. Other mutagenic mycotoxins include vomitoxin and fusarin C produced by *Fusarium* sp., luteoskyrin (*Penicillium* sp.), sterigmatocystin (*Aspergillus* sp.), ochratoxin A, and patulin (*Aspergillus* and *Penicillium* spp.). *Alternaria* sp., of which *A. alternata* is primarily responsible for black spot on tomatoes and black head on grain, produce a number of mutagenic toxins such as altertoxins I, II, and III, and stemphyltoxin III (Figure 1).

Mutagens Formed During Processing, Preparation or Storage

Many very significant mutagens are formed during the processing and preparation of food. Mutagens that are formed as a result of heating and preparation are extremely difficult to avoid or regulate.

Grilling or charring of protein rich foods has been shown to produce some of the most potent mutagens described to date. *Polycyclic heterocyclic amines* are indirect mutagens formed during frying or grilling of meat and fish. This group includes several related amino imidazo-azaarene structures belonging to 3 major families: (1) imidazoquinolines (4-MeIQ), (2) imidazoquinoxalines (8-MeIQx, 4,8-DiMeIQx), and (3) imidazopyridines (PhIP). Grilling also produces a number of amino acid pyrolysis products (Trp-P-1, Trp-P-2, Lys-P-1, Phe-P-1, IQx) and oxygen containing heterocycles. Generally, PhIP is the predominant heterocyclic amine found and can be transferred to infants through breast milk.

Heterocyclic amines appear to be formed by a Maillard reaction between creatine or creatinine, an amino acid and a sugar such as glucose or fructose. The Maillard reaction is responsible for browning, which provides the improved appearance, flavoring, and aroma of heated foods. The reaction starts as a condensation between reducing sugars and the amino groups of amino acids, peptides, or proteins. The initial products may proceed through a very complex series of transformations resulting in the formation of thousands of compounds, including both mutagens and nonmutagens.

Polycyclic aromatic hydrocarbons are a second class of mutagenic compounds formed during the grilling or smoking of meat and fish. Polycyclic aromatic hydrocarbons are common pyrolysis products of most organic material, and include benzo[a]pyrene, 1-nitropyrene and 1, 6-dinitropyrene. The *furfurals*, another class of compounds, are produced during the heating of sugars. Hydroxymethylfurfural is a heat-induced decomposition product of hexoses that becomes mutagenic after sulfate conjugation.

Other processes can give rise to mutagens. *Urethane* (ethyl carbamate) is found in fermented foods and in beverages treated with the fungicide pyrocarbonate. *N-Nitrosodimethylamine* is a naturally occurring mutagen present in cheese, soybean oil, canned fruit, meat products, and alcoholic beverages, but is also formed from the use of elastic rubber nettings in cured pork products. Most nitrosamines cross the placental barrier or pass into the mother's milk, thereby leading to possible *in utero* and infant exposure.

Lipid peroxidation occurs with the storage of fats and oils, owing to the reaction of oxygen with sites of

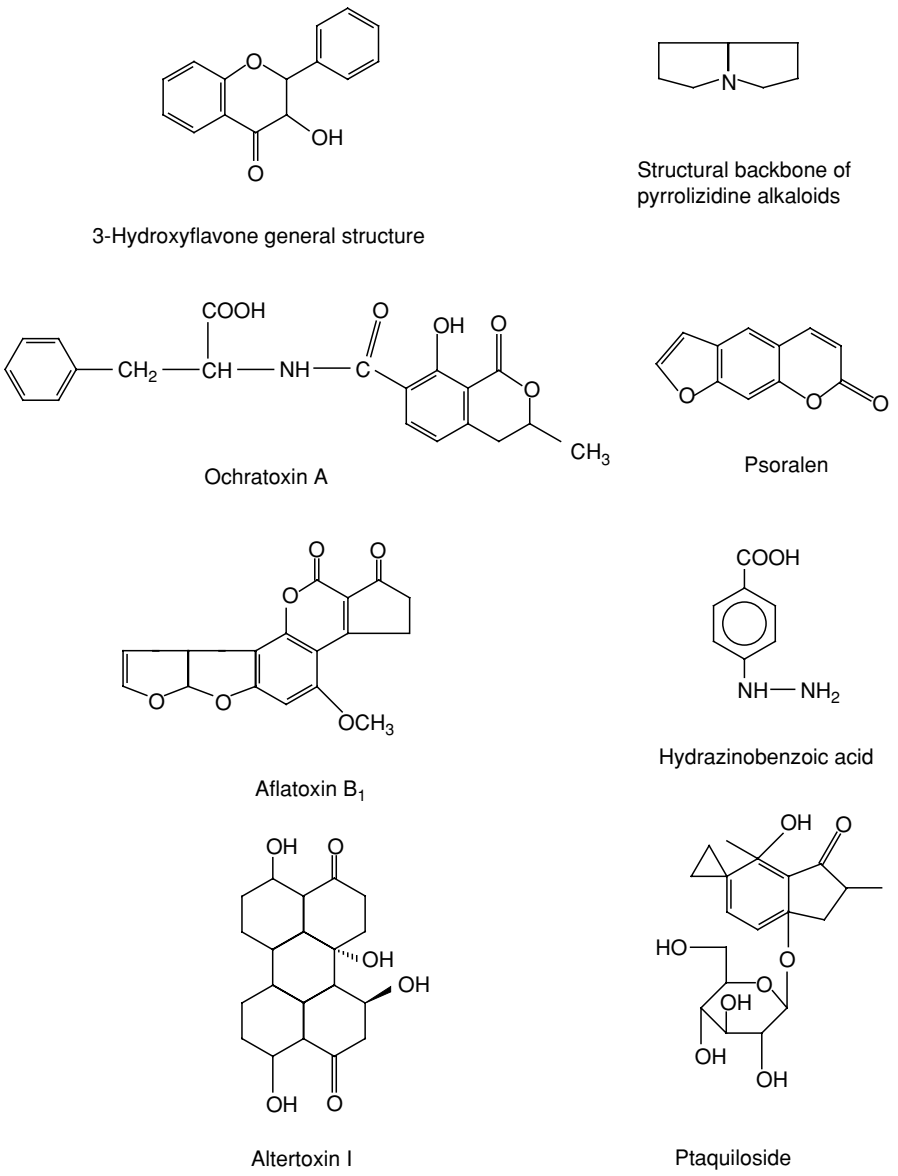

Figure 1 Structures of selected naturally occurring mutagens.

unsaturated bonds. The resulting lipid hydroperoxides, peroxy radicals, and hydroxyl radicals cause rancidity and are potential DNA-damaging agents. A variety of epoxides and aldehydes are also formed, including malondialdehyde, a potential mutagen (Figure 2).

Food Additives and Contaminants

Food additives and contaminants (including pesticide residues) are compounds that are added to food at some point during its production. Exposure to these substances can be controlled, and the introduction of new chemicals used in food manufacture falls under government regulation. Older additives or chemical contaminants are also reviewed periodically for exposure and health effects.

Use of the preservatives nitrite, butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT) as food preservatives has been controversial. *Nitrite* enters the diet both through its use as a common food preservative and through gut microbe-mediated reduction of nitrate from ingested vegetables. Nitrite cycles from the gut to the saliva and can react at acidic pH with amines, amino acids, phenols, and mercaptans, frequently resulting in the formation of mutagenic (nitroso) compounds. Mutagens can also be found in the smoke of nitrite-treated meat during frying. The formation of 2-chloro-4-methylthiobutanoic

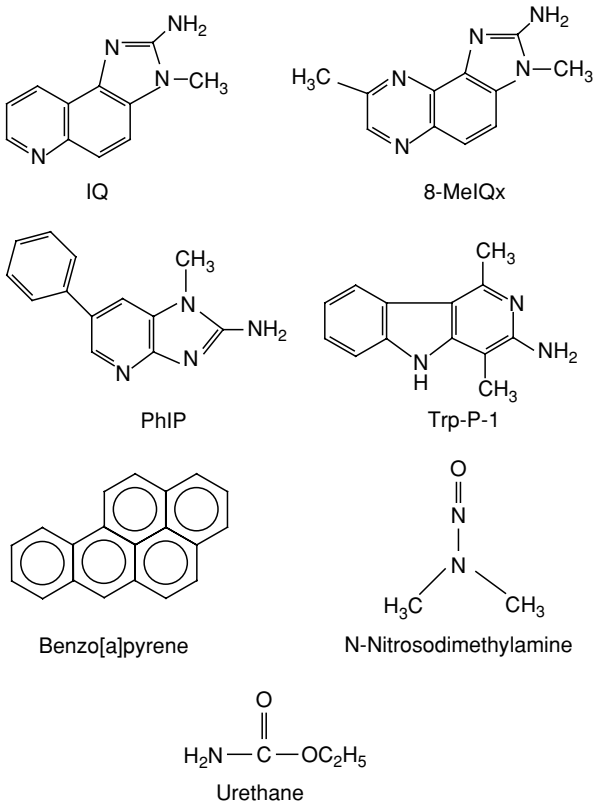

Figure 2 Structures of selected mutagens formed during grilling and processing.

acid, a mutagen in salted, pickled fish, has also been linked to nitrite. BHA and BHT have been added to foods and packaging as synthetic antioxidants. Previous concerns over BHA's carcinogenic risk to humans appear unwarranted and related to the large doses used in rodent-feeding studies. BHT increases the proliferation of pretumor liver cells in rodent models but has little effect on normal cells.

The artificial sweeteners saccharin and cyclamate have also been shown to have mutagenic properties, although saccharin-induced bladder carcinogenesis in rodents also appears to result from the large doses used. Also, the mutagenicity of some colors has led to their use being banned, although low levels of extractable mutagenic contaminants have been detected in others. Mutagenic heterocyclic amino acids have been found in some flavors.

Contaminants may occur in food as residues of pesticides and fungicides, solvents, or compounds, such as styrene leaching from packaging material. The persistent organochlorine pesticide toxaphene has been found in rural foods consumed by indigenous peoples in the Arctic region, having been carried and deposited through airborne transport from sites in the south.

Mutagens in Water

Drinking water provides another potential source of mutagenic compounds. Water disinfection by chlorination can produce many types of mutagenic chlorinated organic compounds, of which 3-chloro-4-(dichloromethyl)-5-hydroxy-2-(5H)-furanone (mucochloric acid, MX) is the most potent. Other mutagenic chlorinated butenoic acids, including EMX (the reduced form of MX), brominated trihalomethanes, and dichloroacetonitrile, are also produced. Dichloroacetonitrile is a direct-acting mutagen and induces DNA-strand breaks in cultured human lymphoblastic cells. Other less potent mutagenic disinfection byproducts include dichloroacetic acid, trichloroacetic acid, and chloral hydrate. Radioactive contamination can also contribute mutagenic activity in areas where water is contaminated with ^{40}K or uranium and thorium decay products (such as radon).

Mutagens in Feces

Human feces have been found to contain a class of mutagenic compounds known as fecapentaenes, the major forms of which are fecapentaene-12 and fecapentaene-14. These compounds appear to be synthesized by intestinal bacteria and are lipid-soluble, direct-acting base pair and frameshift mutagens. Fecapentaene-12 also causes increased sister chromatid exchanges, *HGPRT* mutagenesis, and oxidative damage. Bile salts have been shown to augment the ability of fecapentaenes-12 and -14 to induce DNA repair in bacteria, underscoring their possible role in colon carcinogenesis associated with high-fat, low-fiber diets.

Prevention and Modification of Mutagen Formation

A well-balanced diet also provides many compounds that can decrease exposure to mutagens. Studies consistently show that a greater consumption of fruits and vegetables is associated with a lowering of cancer incidence. These compounds can act at all levels of mutagenesis by: (1) preventing mutagen formation and acting as antioxidants, (2) deactivating mutagenic compounds, and (3) inducing detoxifying enzymes or inhibiting monoxygenase activity.

Several natural antioxidants, such as ascorbic acid, β-carotene, α-tocopherol, polyphenolic acids, flavonoids, and other plant phenolics have a direct mutagen-scavenging activity. For example, in addition to neutralizing oxygen radicals, many of these compounds inhibit the formation of nitrosamines by competing with the amine group. Mutagenic agents may

be inactivated through the formation of complexes with calcium, casein, chlorophyl and carbonyl compounds. Some evidence suggests that calcium can inhibit familial colon carcinogenesis through inhibition of lipid peroxidation. Both iron deficiency and excess have been associated with oxidative DNA damage, and zinc deficiency causes chromosome breaks. The activity of glutathione-dependent detoxification systems is increased by selenium and diallyl disulfide, from garlic, cysteamine, cysteine, as well as a variety of phenolic compounds. Monooxygenase activity and the formation of reactive compounds can be inhibited by phenolic acids, free fatty acids, flavonoids, and other polyphenols, methylxanthines, vitamins, and biogenic amines. Conjugated dienoic isomers of linoleic acid are antimutagenic compounds in extracts of fried ground beef and dairy products that appear to act through signal-transduction pathways and prostaglandin synthesis. Tannins or polyphenols in green tea have been found to be antimutagenic in some assays, but the effects appear to depend upon the dose and timing of exposure. Several other compounds have shown antimutagenic activity, including β-diketones, catechins, lignans, and isoflavones. Finally, dietary fiber can complex with mutagenic compounds and limit their uptake.

Mutagenic effects resulting from altered DNA metabolism can also be influenced by diet. Adequate intake of essential nutrients such as folate, vitamin B_{12} and vitamin B_6 aids nucleotide synthesis and prevents DNA-strand breakage. Niacin, methylxanthines, and some phenols have been attributed to promotion of DNA-damage repair (Figure 3).

Further Considerations

Much work remains to completely characterize the role of food-associated mutagens and antimutagens in human carcinogenesis. Despite the magnitude and frequency of exposure to these compounds, they

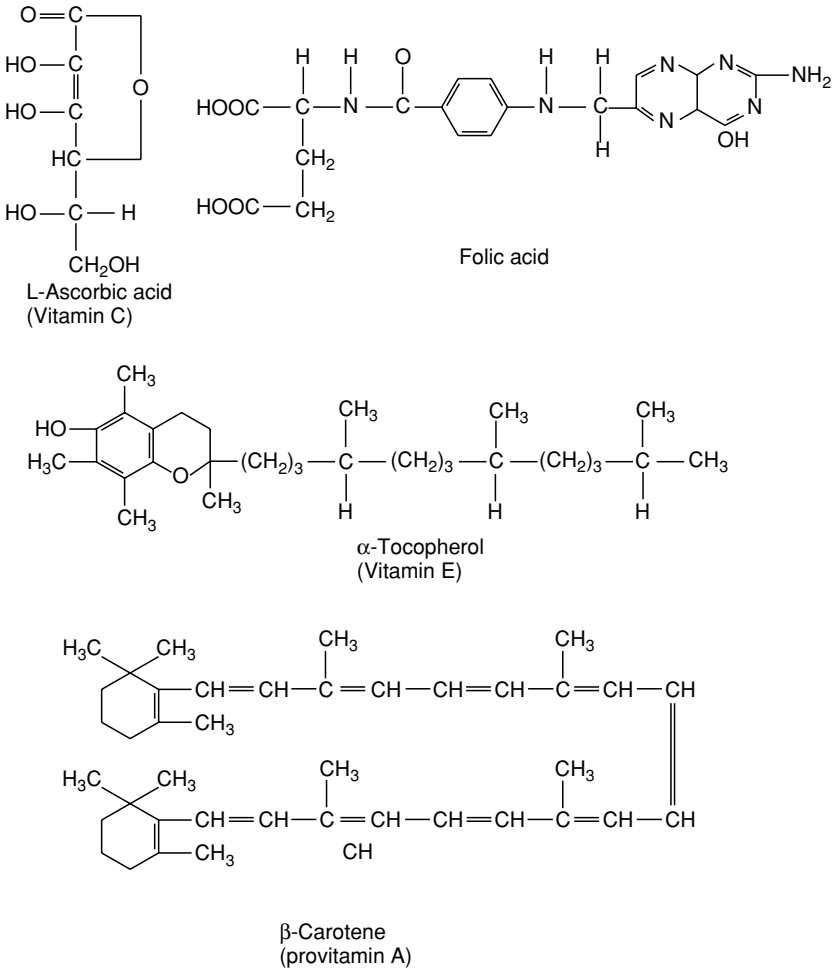

Figure 3 Structures of common dietary antioxidant antimutagens.

remain underrepresented in mutagenesis studies relative to synthetic chemicals. Additional characterization is needed of the human consequences of exposure to many antioxidants that appear to inhibit mutagenesis at low concentrations but have the opposite effect at high concentrations. Finally, more emphasis should be placed on the effects of chemical mixtures to study the effects of combinations of compounds encountered in the diet.

MYCOBACTERIA

C H Collins and J M Grange, National Heart and Lung Institute, London, UK

Introduction

The genus *Mycobacterium* contains over 60 species; these are divided into rapid-growers, slow-growers, and the human leprosy bacillus which has not been convincingly cultivated *in vitro*. A few of the species are obligate parasites, but most of them are environmental saprophytes. The latter are widely distributed in nature and have been isolated from natural waters, wet soil, mud, compost, grasses, vegetables, unpasteurized milk, and butter. They have also been isolated from domestic water pipes from which they readily enter drinking water. Mycobacteria are characterized by the possession of very thick, waxy, lipid-rich hydrophobic cell walls. Being hydrophobic, they tend to grow as fungus-like pellicles on liquid culture media: hence the name *Mycobacterium* – 'fungus bacterium.'

Even the rapidly growing mycobacteria grow slowly in comparison with most other bacteria. Mycobacteria may play a role in the decomposition of organic material, particularly in sphagnum

marshes, but there are no reports of mycobacteria causing spoilage in foods. They do not produce appreciable amounts of toxic substances and do not cause food poisoning. Pathogenic strains owe their virulence to their ability to resist immune defense mechanisms; they cause chronic infections.

The obligate parasites are *Mycobacterium tuberculosis* (the human tubercle bacillus), *M. bovis* (the bovine tubercle bacillus), and *M. africanum* (a species first described in equatorial Africa and having rather variable properties that are intermediate between the other two). Variants of these species are occasionally encountered and include *M. microti* (the vole tubercle bacillus) and biochemically and genetically distinct isolates from goats termed the caprine genotype or *M. tuberculosis* subsp. *caprae*. All these species, often grouped as the tuberculosis complex, are very closely related and should be regarded as variants of a single species. Other pathogens thought to be obligate parasites are *M. leprae* (the causative organism of leprosy), *M. paratuberculosis* (the cause of Johne's disease or hypertrophic enteritis in cattle and other ruminants) and *M. lepraemurium* (the cause of rat leprosy). As *M. leprae* is uncultivable and other two are very difficult to cultivate *in vitro*, the possibility that they can replicate in the inanimate environment cannot be excluded.

Some of the saprophytic species occasionally cause opportunistic infections of animals and humans. The principal opportunist species are *M. avium*, *M. intracellulare*, *M. scrofulaceum*, *M. kansasii*, *M. xenopi*, *M. malmoense*, and the rapidly growing species *M. chelonae* and *M. fortuitum*. The first two species are closely related and are often grouped together as the *M. avium* complex (MAC). Although essentially saprophytic, MAC are the most pathogenic of the opportunist mycobacteria. Members of this complex are a common cause of tuberculosis in birds and they also cause limited lesions, particularly cervical lymphadenopathy, in mammals, including pigs, cattle, and deer. Closely related to the MAC are *M. lepraemurium*, *M. paratuberculosis* and the wood pigeon bacillus (*M. avium* subsp. *sylvaticum*) which resembles *M. paratuberculosis* in requiring mycobactin, an iron-binding lipid extracted from mycobacterial cell walls, for its *in vitro* cultivation. A few other nutritionally very fastidious mycobacteria, requiring enriched media for their cultivation, have recently been described. These include *M. genavense*, which was originally detected in acquired immunodeficiency syndrome (AIDS) patients by means of DNA amplification techniques. This species has also been isolated from pet birds and a dog and infected pets may thus pose a health hazard to severely immunosuppressed persons.

Mycobacterial Disease

Although the human mycobacterial diseases differ enormously in their clinical features they have certain characteristics in common. They all commence with a local lesion, which may or may not be clinically evident, at the site of implantation of the causative organism. They may be in the lung in the case of inhaled bacilli, in the skin following trauma, or in the pharynx or intestinal tract following ingestion of the bacilli in contaminated food or water. In some cases, notably in tuberculosis, the local lymph nodes are also involved in the primary infection and the lymphatic lesion may be much more extensive than that at the site of implantation. Thus, ingestion of milk contaminated with *M. bovis* often leads to a cryptic tonsillar or pharyngeal lesion and gross enlargement of one or more of the lymph nodes in the neck – a condition known as scrofula. Bacilli may enter the blood stream from the primary lesion and then cause serious forms of primary tuberculosis, notably tuberculous meningitis and disease of the kidneys, bones, and joints. Thus, in countries where there is (or was) a high incidence of human tuberculosis of bovine origin, scrofula and associated nonpulmonary manifestations of the disease are (or were) commonly seen in children.

Unless one of the serious sequelae of primary tuberculosis develops, the primary complex usually resolves, but the disease reactivates in about 5% of infected persons to cause postprimary tuberculosis, years or even decades later. (The risk of reactivation is much higher in immunosuppressed persons and human immunodeficiency virus (HIV) infection has emerged as the most prevalent predisposing factor for the development of tuberculosis worldwide. A person dually infected by HIV and *M. tuberculosis* has a 8–10% chance of developing active tuberculosis annually.) Cases of tuberculosis due to late reactivation of *M. bovis* infection still therefore occur in countries that have virtually eradicated tuberculosis from cattle. In Europe and Australia, *M. bovis* accounts for around 1% of cases of tuberculosis.

The way in which residual mycobacteria persist in tissues for long periods is unknown. The reactivation may occur at the site of the primary lesion (such as cervical lymph nodes in the case of tuberculosis of bovine origin), but more often it reactivates, for unknown reasons, in the upper lobes of the lung. This leads to open or infectious tuberculosis and there have been reports of cattle being infected by such patients. Also, and for unknown reasons, some cases (about 25%) of postprimary human tuberculosis due to *M. bovis* in Europe involve the genitourinary tract. This rather insidious form of tuberculosis often passes

undiagnosed for long periods and farm workers with this condition are known to have transmitted tuberculosis to cattle by urinating in cowsheds.

In humans, some environmental mycobacteria are able to cause lymphadenopathy, particularly in young children; skin lesions following injections of contaminated material, superficial or penetrating injuries, and surgery involving implantation of contaminated prostheses such as porcine heart valves; pulmonary disease, particularly in patients with pneumoconiosis or other predisposing lung diseases; and disseminated disease. The last, once rare, is now a common AIDS-related condition and, for unknown reasons, is usually caused by the MAC, although some cases are due to the more recently described *M. genavense*, referred to above.

In recent years there has also been speculation that ingested mycobacteria, possibly from milk, might be responsible for Crohn's disease, a granulomatous disease of the human intestine. Normal forms and spheroplasts of mycobacteria have been isolated from tissue excised from a few patients with Crohn's disease and DNA supposedly specific for *M. paratuberculosis*, the cause of Johne's disease in cattle, has been detected by the polymerase chain reaction (PCR) in biopsies from patients with Crohn's disease. In some studies such DNA was detected in the majority of specimens but in other studies no such DNA was detected. These conflicting findings may be attributable to methodological problems and technological advances may resolve the issue but at present no firm conclusions can be drawn. Likewise, attempts to detect antibodies to *M. paratuberculosis* in serum and antigen in tissues, as well as trials of antimycobacterial drugs, have yielded unconvincing results.

Sources of Infection

The human tubercle bacillus, *M. tuberculosis*, is usually spread from person to person via expectorated aerosols and causes pulmonary tuberculosis. Individuals with open tuberculosis who work in the food industry may therefore transmit the organisms to other people and could possibly, in theory, contaminate food. The bovine bacillus, *M. bovis*, causes pulmonary tuberculosis in farm workers who inhale the bacilli in aerosols expectorated by diseased cattle while town dwellers usually become infected by drinking contaminated milk and predominantly develop nonpulmonary tuberculosis.

Although persons working with other animals with disease due to *M. bovis*, including seals, elk, and a rhinoceros with tuberculous rhinitis, have become tuberculin-positive, overt disease has seldom been reported. A few strains of the caprine genotype have, however, been isolated from humans with tuberculosis, including one isolate from a veterinary surgeon with a recent history of working with tuberculous goats, and a seal trainer contracted tuberculosis due to an *M. bovis*-like strain from a captive seal in Australia.

Mycobacterial disease may result from the inoculation of the bacilli into the skin. In areas where tuberculosis of cattle is common, food handlers are at risk of developing tuberculous lesions of the hands as a result of contamination of minor cuts and abrasions, the resulting condition being known as butcher's wart (it is also known as prosector's wart, as anatomists and pathologists were likewise exposed to this occupational hazard).

Food and drink may serve as vectors for the transmission of pathogenic mycobacteria. By far the most likely vehicle, leading to disease of the alimentary tract, is unpasteurized milk. Meat and water are also possible sources, but are much less important. (*See* **Milk**: Processing of Liquid Milk.)

Unpasteurized Milk

There is a long history of human infection resulting from the consumption of milk that contained *M. bovis*. In developed countries such as the UK these infections are now rare for two reasons: the eradication of tuberculosis among cattle by tuberculin testing and slaughter; and the pasteurization of milk for human consumption. Both have been the subject of legislation. Milk-borne tuberculosis is still a hazard, however, in developing countries.

The history of milk-borne tuberculosis in the UK illustrates this. The disease in cattle (and other animals) had been recognized as an economic problem for centuries. By the turn of the century it was known that tuberculosis in cattle was caused by *M. bovis*, but Robert Koch, who had discovered the tubercle bacillus in 1882 and was regarded as a world authority on the subject, told the British Congress on Tuberculosis in 1901 that the bovine organism did not cause the disease in humans and that measures to counteract infection with that organism were unnecessary. This was disputed by certain British bacteriologists and veterinarians and it was not until after the publications of the findings of a Royal Commission in 1911 that the bovine bacillus was accepted as the causative organism of many cases of nonpulmonary tuberculosis, notably cervical lymphadenopathy, abdominal and skeletal tuberculosis, particularly in children.

Official action was slow, however, and in the 1930s it was known that about 40% of all cattle slaughtered in public abattoirs had tuberculous lesions and that about 0.5% of all dairy cows produced milk that

contained the bovine tubercle bacillus. The eradication scheme that followed was initially voluntary and did not become compulsory until after World War II. By 1960 all dairy herds in the UK had been tested and by 1979 the reactor rate had fallen dramatically and only 0.18% of herds were infected. This may well represent an irreducible minimum, because reinfection, from humans and other animals (e.g., badgers) may still occur and therefore there is still a risk of infection from unpasteurized milk although, at present, as a result of more legislation, very little of this is sold for immediate consumption in this country.

Goats may also be infected, and tubercle bacilli have been recovered from their milk. The consumption of raw goats' milk is therefore not without risk.

Little is known about the role of milk in other mycobacterial infections. The possible link between milk-borne *M. paratuberculosis* and Crohn's disease has been referred to above. Members of the MAC and other saprophytic mycobacteria have been isolated from milk, but no direct link has been established between the presence of these organisms in milk and human disease, although contaminated milk is a possible source of *M. avium* causing disease in AIDS patients. Although DNA specific for *M. avium*, including the *sylvaticum* subspecies, has been detected in a few biopsies from patients with Crohn's disease, their role as primary pathogens remains, as in the case of *M. paratuberculosis*, highly speculative.

Meat

In most parts of the world meat is cooked before it is eaten, but there is nevertheless the possibility that there is insufficient heat penetration and that tubercle bacilli may remain viable in parts of the meat. Cross-contamination from infected meat to food ready for consumption is also a possibility. As indicated above, some infected cattle still reach slaughterhouses and the meat of some may be tuberculous. Five cases of tuberculosis due to *M. bovis* occurred over a 2-year period in abattoir workers in South Australia: four of the five cases involved the lung, suggesting that infection followed inhalation of aerosols. In addition, a DNA fingerprinting study of strains of *M. bovis* isolated from patients in Australia between 1970 and 1994 revealed that the majority of Australian-born patients had worked in the meat and livestock industries and had disease due to strains similar to those found in Australian cattle.

The incidence of tuberculosis among sheep is low, as it is among pigs, although members of the MAC have been responsible for outbreaks and single cases of tuberculous disease in piggeries. Bovine tubercle bacilli have been isolated from rabbits, wild and farmed, and along with the avian bacillus, from a variety of poultry. In the UK and New Zealand farmed, but not wild, deer are now known to suffer from tuberculosis. In the Middle East and India there is evidence that some of the camels that are slaughtered for their meat are tuberculous.

Fortunately, in developed countries, the systems of meat inspection, required by law, prevent the sale for human consumption of bovine, ovine, and porcine carcasses, or parts of them, that may be infected. There is still a trade, however, in carcasses, e.g., of goats, pigs, rabbits, and poultry, that escapes an official inspection and as yet in the UK carcasses of farmed deer are exempt from official inspection. All these animals offer a degree of hazard to the food handler and the consumer.

Fish are not normally a source of mycobacterial disease, although there have been a few cases of disease due to *M. marinum* infection, manifesting as warty skin lesions, in fishermen and fishmongers, presumably as a result of infection of dermal abrasions. Multiple regression analysis has shown that regular consumption of raw or partly cooked fish and shellfish is associated with an increased risk of disseminated disease due to the MAC in AIDS patients.

Water

Several species of mycobacteria, some of which are opportunist pathogens, have been isolated from piped, bottled, and natural waters. Tubercle bacilli, however, have never been recovered from water supplies.

There is adequate evidence that infections due to some opportunist mycobacteria result from the inhalation of aerosols containing the organisms. In the great majority of cases ingestion of these species does no harm (overt abdominal infection associated with them is extremely rare), but they may temporarily colonize the alimentary and upper respiratory tracts. There is evidence that they may cross the epithelial barrier (translocation) and persist for some time in the draining lymph nodes: thus they have been isolated from excised tonsils and abdominal lymph nodes. Water has been postulated as a source of infection in AIDS patients with disseminated mycobacterial disease due to the *M. avium*, although epidemiological evidence is conflicting, but *M. genevense* was detected in tap water at a hospital with an unusually high incidence of HIV-related disseminated disease due to this species.

Isolation of Mycobacteria from Milk, Meat, and Water

Tubercle bacilli and other pathogenic mycobacteria are in Hazard Group 3 of the Advisory Committee on

Dangerous Pathogens and other similar authorities. Such organisms may be dispersed as aerosols during laboratory manipulations, and individuals who inhale them may become infected. Any bacteriological procedure involving them or material that may contain them must be carried out under Containment Level 3 conditions in microbiological safety cabinets.

In some parts of the world the conventional techniques for isolating mycobacteria on solid media are being replaced by more rapid radiometric methods and more recent nonradiometric automated systems and also by the PCR and its derivatives. Originally evaluated in the field of human disease, they are increasingly being applied to veterinary microbiology, food hygiene, and environmental work. There have, for example, been reports of the use of PCR to detect and identify waterborne mycobacteria, *M. paratuberculosis* in pasteurized milk, and *M. bovis* in tissues obtained postmortem from various animals. Likewise, DNA fingerprinting techniques suitable for epidemiological studies on *M. bovis* from animal and human sources are now available.

The traditional methods for the isolation of mycobacteria are described below, but the final identification of tubercle bacilli and other mycobacteria is too detailed to be included. Alternatively, cultures of suspected mycobacteria may be sent to a reference laboratory, a regional tuberculosis laboratory, or a veterinary laboratory. For information on automated systems and nucleic acid-based technology, the rapidly changing primary literature should be consulted.

Milk

Direct microscopic examination of milk for acid-fast bacilli is unrewarding as saprophytic mycobacteria are often present, as are artifacts that retain the fuchsin stain.

A suitable method for recovering tubercle bacilli (and other mycobacteria) from the milk of individual cows or from small groups of cows is given below.

Centrifuge at least 50 ml of the milk at 3000 rpm for 20 min. Remove the cream to a small tube, add 4 ml of 4% sodium hydroxide and stand for 15 min; add 6 ml of 14% monopotassium phosphate containing phenol red indicator to indicate neutralization; centrifuge at 3000 rpm for 15 min; discard supernatant fluid and culture the deposit.

Discard the remaining supernatant fluid from the original centrifugation and add 2 ml of 4% sodium hydroxide to the deposit and stand for 15 min; add 3 ml of 14% monopotassium phosphate (3 ml) and proceed as above.

Divide the deposits between several tubes of Löwenstein–Jensen medium or Middlebrook medium containing antibiotics. Incubate at 37 °C for 6–8 weeks. Check the identity of any organisms that grow by Gram and Ziehl–Neelsen stains.

Identify acid-fast bacilli by the methods described in standard textbooks or send cultures to a specialist laboratory.

Meat

For full details, the World Health Organization guidelines for speciation within the *Mycobacterium tuberculosis* complex should be consulted. The recommended methods are briefly summarized here.

The material should be selected by a veterinarian or meat inspector familiar with the macroscopic appearance of tuberculous lesions. The usual specimens are lymph nodes from the respiratory and gastrointestinal tracts, lung, and liver tissue and these should be placed in wide-mouthed, hermetically sealed plastic or glass pots.

Cut about 10 g of the sample into small pieces with sterile instruments and further homogenize the pieces in a Griffith tube or mechanical blender.

Remove about 3 ml of homogenized tissue with a wide-bore pipette and add to an equal quantity of autoclaved 4% sodium hydroxide in a screw-capped tube, mix well and stand for 15–20 min, with occasional shaking.

Neutralize with a 14% w/v solution of monopotassium phosphate containing phenol red indicator (about 40 mg l^{-1}) and allow to stand until the indicator turns red, indicating that neutralization is complete. Centrifuge fluid at 3000 rpm for 20 min, decant the supernatant fluid, and inoculate the deposit on two slopes of Löwenstein–Jensen media and two slopes of a related medium, such as Stonebrink's medium, that contains sodium pyruvate instead of glycerol and which favors the growth of *M. bovis*.

Incubate slopes at 35–37 °C for up to 8 weeks. Read weekly, examine colonies for acid-fastness, and arrange for identification by a specialist laboratory.

Water

The sample should consist of at least 1 l of water and be delivered to the laboratory as soon as possible.

Pass separate 100-ml volumes of the whole sample through membrane filters. Place the membrane filters in 4% sodium hydroxide solution for 5 min (e.g., in a Petri dish), then in 14% monopotassium phosphate solution containing phenol red for several minutes.

Cut the membranes into strips 5 mm wide and place each strip on the surface of Löwenstein–Jensen or Middlebrook antibiotic medium in screw-capped tubes. Incubate at 35–37 °C. Examine every few days as some mycobacteria grow rapidly.

Examine colonies for acid-fastness and arrange for identification, if necessary.

In developed countries, foodborne mycobacteria do not offer a serious health hazard and routine laboratory examinations are not justified. In special circumstances attempts may be made to culture the organisms by the methods described above. However, the essential and expensive equipment requirements for Containment Level 3 preclude identification in most laboratories. The advice and services of reference and other specialized laboratories should be sought.

MYCOPROTEIN

M J Sadler, MJSR Associates, Ashford, UK

Background

Myco-protein is produced from microfungi, aerobic organisms that live in the soil and convert carbohydrate to protein. Research to produce food from microfungi began in the early 1960s. This was at a time when many projects were being set up to develop single-cell protein sources suitable for animal and human consumption in response to the predicted protein gap in developing countries. There are reports of three products produced form microfungi, but by far the most successful myco-protein product is sold under the trade name 'Quorn™.'

Myco-protein is the generic name of the major raw material used in the manufacture of Quorn™ products. It comprises the RNA-reduced biomass composed of the hyphae (cells) of the organism *Fusarium venenatum* A3/5 (deposited with the ATCC as PTA-2684) grown under axenic conditions in a continuous fermentation process. Quorn™ is the brand name of a range of meat-alternative products made from myco-protein. Quorn™ products include pieces and mince for use in home cooking in addition to a range of convenience products such as burgers, fillets, goujons, nuggets, and ready meals.

Quorn™ myco-protein is the first truly 'new' food product developed for humans. Introduced to the UK food market in 1984, Quorn™ products are the result of a development program, designed to produce single-cell protein, that was started in the 1960s. In addition to availability in all major UK and Irish food retailers, Quorn™ products are now available in an increasing number of retailers within Continental Europe, including Belgium, Luxembourg, Holland, Sweden, Switzerland and France, and in the USA.

This article covers the cultivation and harvesting of myco-protein, and its properties including acceptability, safety, and nutritional value. Known and other potential functional health effects of consuming myco-protein are also discussed.

It was predicted in the late 1950s that within three decades, there would be a shortage of protein across the world – the so-called 'protein gap.' In response to this, many projects were set up in the early 1960s to develop feeds or foods from single-cell protein sources that would be suitable for animal or human consumption.

Ranks Hovis McDougall (RHM) Research Centre in the UK undertook one such project, which started in 1964. The original aims were to convert starch into a protein-rich food that was highly nutritious, delicious, and safe to eat. The project focused on the potential of microfungi to produce a high-protein food (myco-protein). This resulted two decades later in the successful development of the Quorn™ (a registered trade mark of Marlow Foods Ltd, UK) range of products, which have been marketed as a human food for the past two decades.

It should be noted that the commercial development of myco-protein was a joint venture between RHM and ICI (Marlow Foods). In 1990, ICI assumed full control of the business. However, in 1993, ICI de-merged into ICI and Zeneca, and Marlow Foods became part of Zeneca. In 1998, Zeneca merged with Astra (Sweden) to become AstraZeneca.

Production

Cultivation

Cultivation of fungal mycelia has many factors in common with the production of yeast and bacteria, although because fungi are multicellular or coenzocytic, the term 'single-cell protein' cannot strictly be used to describe fungi produced by fermentation. The advantages of microfungi are that they can utilize a wide range of substrates, they have straightforward nutritional requirements, and they are relatively easy to harvest from culture broths on account of their particle size.

In addition, the whole microfungi can be consumed without any reported problems of toxicity and with only a very low level of adverse reactions. Fungal mycelia have a high nutritional value, desirable texture, and mild smell and flavour. Acceptability is less of a problem than for food from other lower organisms, since fungi already play a role in the human diet.

The microfungi *Fusarium venenatum* A3/5 (deposited with the ATCC as PTA-2684) was chosen by RHM for the production of the new myco-protein product, on account of its suitable organoleptic and nutritional properties.

Growth requirements and conditions Myco-protein is grown in an airlift or pressure-cycle fermenter in a liquid medium providing all the nutrients required for growth. In preference to a batch culture, a continuous-flow aerobic culture system is used in which the culture medium is continuously fed to the fermenter and the broth continuously drawn off for filtering such that the volume of the fermenter is displaced approximately every 5–6 h. This ensures that steady-state conditions are maintained and that optimal productivity is achieved. Optimizing the process conditions improves the yield, quality, and uniformity of the end product, and the efficiency of the process. The cell mass doubles every 4–5 h.

The carbon substrate used is glucose syrup, which is obtained from hydrolyzed corn. Ammonium is the source of nitrogen, and is also used to regulate the pH, which is maintained between 4.5 and 7.0. Salts of potassium, manganese, cobalt, calcium, magnesium, iron, copper, and biotin are supplied as a liquid feedstock from tanks adjacent to the fermenter. Compressed air is the source of oxygen, and its injection into the fermenter keeps the broth in continuous motion. All the ingredients of the culture medium are sterile and of food- or reagent quality. The temperature of the broth is maintained at 30 °C, and it is therefore necessary to cool the fermenter.

The fermentation must be conducted under monoseptic conditions, allowing only the specified culture to grow. To maintain the purity of the culture, industrial-scale continuous fermentations last up to a maximum of 6 weeks (1000 h).

Nucleic Acid Content

The nucleic acid content of myco-protein is mostly ribonucleic acid (RNA). There are potential clinical problems associated with the consumption of foods high in RNA, and the maximum intake recommended by the World Health Organization (WHO) is 2 g per day. If RNA consumption is too high, blood levels and urinary excretion of uric acid are increased, and uric acid crystals may precipitate out in the joints and soft tissues. This can lead to gout and stones in the urinary tract.

To remove the excess RNA in myco-protein (on average *c*. 10% w/w), the postfermentation broth (cell suspension) is subjected to a 'heat shock' treatment, a procedure specifically developed to reduce the RNA content. The broth is heated briefly to 64 °C to inactivate enzymes that convert cellular ribonucleic acids into monomer nucleotides, which can diffuse out of the cell. This process reduces the nucleic acid content to an acceptable level (< 2% w/w) and also causes the loss of some protein.

Harvesting

The cell suspension described above is then dewatered by centrifugation. The harvested cells, collectively known as myco-protein, are paste-like in consistency and contain around 75% moisture. This biomass has little, if any, intrinsic flavor or odor.

Quorn production process The harvested hyphae have a similar morphology to animal muscle cells, i.e., they are filamentous with a high length/diameter ratio. The product assembly process therefore seeks to reproduce in Quorn™ products the same structural organization as that in natural meats, where the muscle cells are held together by connective tissue. To establish a similar product texture in Quorn™ products, the hyphae are mixed with binders, flavorings, and other ingredients, depending on the final product format, and then heated. This causes the protein binder to gel and hence 'bind' the hyphae together.

The resulting structures are similar to those in meat products, and they also break down in the mouth during chewing in a manner similar to meat products, which accounts for their sensory textural properties.

Efficiency of Production

Animal flesh or fish is the most common source of high-quality protein for humans. However, animals are inefficient at converting proteinaceous vegetable material into meat in terms of both energy input and energy output. The organism described above converts 1 kg of glucose into 1 kg of wet cell mass, representing 136 g of pure protein. The efficiency of conversion is approximately 2:1 on a dry-weight basis, which is considerably higher than animal conversion rates. These may be as high as 10:1 for beef, calculated as dried feed intake against wet carcass weight. Only part of the animal carcass is eaten, whereas all of the myco-protein produced can be consumed.

Properties of Quorn™ Products

Acceptability

Since the microfilaments in Quorn™ myco-protein are almost identical in size to meat fibrils, Quorn™ products have a similar texture and eating quality to their meat equivalents. Table 1 details some of the physical characteristics of Quorn™ myco-protein.

Humans have a long tradition of consuming fungi. Truffles are an expensive delicacy in the Western world, and mushrooms and other cap fungi are eaten across the globe in a variety of forms. Foods such as Camembert cheese are mold-fermented, and in the Far East, microfungi are used to ferment soya beans in the production of miso and tempeh foods. In southern Africa, a variety of foodstuffs are produced from fermented cassava.

Safety

Myco-protein was safety tested according to the guidelines of the Protein Advisory Group of the United Nations. Purified diets were formulated containing myco-protein as the only source of protein at levels of up to 54% (w/w). Control diets contained casein in place of myco-protein, and a stock diet control was included in each trial.

The trials were started in 1970 and included teratology, carcinogenicity, toxicity, and multigeneration studies. Other studies looked at mineral balance, gastrointestinal effects, and estrogenic effects. There were no signs of toxicity or carcinogenicity from feeding myco-protein in any of these trials.

Table 1 Physical characteristics of Quorn™ myco-protein

Physical characteristics	*Typical dimensions*
Length	400–700 μm
Diameter	3–5 μm
Branch frequency	One per 250–300 μm

Data from Marlow Foods, Stokesley, UK.

Measurement of serum levels of uric acid was undertaken in trials conducted at the Massachusetts Institute of Technology in the USA. Eating 20 g of myco-protein per day did not significantly increase serum uric acid levels. Additional daily intake of nucleic acid from the myco-protein did not exceed 2 g. This confirmed that keeping within this limit maintains serum levels of uric acid within the acceptable range for normal subjects and minimizes the risk of deposition of uric acid crystals in kidneys, joints, and other tissues.

Low potential for allergenicity Adverse reactions to foods have been estimated to occur in 1–4% of the population. Feeding microbial proteins at a level of 10 g per day is associated with gastrointestinal symptoms and skin rashes. To test human tolerance to myco-protein, over 400 volunteers were involved in the initial trials conducted at Massachusetts Institute of Technology in the USA.

In a double-blind crossover trial lasting 67 days, the myco-protein was baked into experimental biscuits, each containing 5 g of myco-protein (2.7 g of protein). Identical biscuits were baked for the control group without myco-protein. One hundred volunteers ate two biscuits twice a day, the experimental biscuits providing 20 g myco-protein per day. After 30 days, subjects ate normal foods for 7 days, and then the alternative biscuits for the next 30 days.

No subjects had any gastrointestinal reactions or skin rashes that could be ascribed to ingesting the experimental material. Myco-protein was well tolerated, and the likelihood of adverse reactions was shown to be no greater than that to most common foods.

However, trading experience as the distribution of Quorn™ products increased suggested a need for further investigation. A small number of reactions had been reported, which equated to 1.5 complaints for every million Quorn™ products sold. Cross-reactivity studies showed that Quorn™ myco-protein shares common allergenic determinants with *Aspergillus fumigatus*, *Cladosporium herbarum*, and some with *Alternaria alternata*, suggesting the potential for some mold-allergic patients to react adversely to myco-protein when it is ingested or inhaled. Screening of 33 myco-protein production workers over a 2-year period, for whom any sensitization to myco-protein would occur via inhalation, suggested that two workers had increased RAST binding to myco-protein. However, specific IgE antibody to myco-protein was not significantly raised in any of the 10 consumers tested who had complained of reactions to Quorn™ products. Overall, these results are reassuring as they indicate that the potential for adverse reactions is extremely low. (*See* **Food Intolerance**: Food Allergies.)

Nutritional Value

On a dry-weight basis, myco-protein is 45% protein, 14% fat, and 26% dietary fiber, and on a wet-weight basis, it is 11% protein, 3% available carbohydrate, 6% fiber, 3% fat, 2% ash, and 75% water. Table 2 shows a comparison of the nutritional value of Quorn™ myco-protein with other protein-rich foods.

Quorn products are available as pieces and 'mince' for cooking, and also as a range of convenience products, in which the content of myco-protein may vary between 50 and 90% myco-protein.

Protein content The protein content of myco-protein is above average for fungal mycelia. However, myco-protein contains a significant proportion of nonamino-acid nitrogen, which is in the purine and pyrimidine bases of the nucleic acids and in the glucosamine and galactosamine residues of chitin, a structural component of the cell wall of the filaments and the form of fiber present in myco-protein. As this nitrogen is unavailable, it is more practical to express the protein content as amino-acid nitrogen $\times$ 6.25 rather than total nitrogen $\times$ 6.25. Nonamino-acid nitrogen accounts for about 20–30% of the total nitrogen. (*See* **Protein**: Food Sources.)

Net protein utilization (NPU) values before and after allowance for glucosamine nitrogen reflect the unavailable nitrogen present in chitin. The usual procedure for expressing amino acid content in grams per 16 g of total nitrogen underestimates the amino acid content of myco-protein. Amino acid values will increase after allowing for nonprotein nitrogen.

Although developed as a high-protein food initially, the protein content of Quorn™ myco-protein on a weight-for-weight basis is less than that of lean meat, fish, and poultry, but is comparable with egg (Table 2) and cottage cheese. The NPU is lower than these foods but higher than wheat and beans (Table 3). (*See* **Protein**: Quality.)

Myco-protein provides the complete range of essential amino acids (Table 4). The limiting amino acids are methionine and cystine, with a level of 2.9 g per 100 g of myco-protein. In the UK diet, for example, threonine is the limiting amino acid overall, of which Quorn™ myco-protein is a good source, in contrast to most cereals, which have a low content of lysine and threonine. The relatively high concentration of these amino acids in myco-protein indicates a potential value as a supplement to cereal-based diets.

Unusually, for a nonanimal food, the protein is of high biological value and compares favorably with that of casein. Studies on its biological availability

were carried out early in the development stages of myco-protein.

One way of assessing protein quality is to use the protein digestibility-corrected amino acid (PDCAA) scoring method, which is required by the US Food and Drug Administration (FDA) to be used for most nutritional labeling purposes. This method compares the essential amino acid profile of a food, corrected for digestibility, to the FAO/WHO requirements for 2–5 years olds. This age group is chosen because it has the most demanding pattern for amino acid use other than infants. The PDCAA score for myco-protein is compared with that of other foods in Table 5.

Table 5 Protein digestibility-corrected amino acid score of myco-protein, compared with other food proteins

Protein source	*PDCAA score*
Myco-protein[a]	0.91
Quorn™ pieces[a]	1.0
Roasted chicken (white meat)[b]	1.0
Cooked lentils (canned)[c]	0.52

[a]Calculated from Marlow Foods data, Stokesley, UK.
[b]Calculated from amino acid data in USDA Nutrient Database for Standard Reference, March 12, 1998 (assumes a digestibility equivalent to beef of 94%).
[c]FAO/WHO Joint Report (1989).

Quorn products typically contain between 11 and 15 g protein per 100 g. Most of this protein is from the myco-protein content, but egg albumen and milk proteins, added in product manufacture, also contribute some additional protein.

Fat content The fat content of myco-protein is approximately 3%, which is generally lower than that of most meat and poultry. The cells of the microfungi do not store fat because of their rapid growth rate, and the fats present come mainly from the cell membranes.

The content of saturated fat (0.7%) is particularly low, and no cholesterol is present (Table 6). The ratio of polyunsaturated to saturated fats (3.5) is also favorable when compared with braised beef (0.1) and lean roast chicken meat (0.5). Myco-protein contains no *trans* fatty acids and no cholesterol. In Quorn™ products, small quantities of fat may be added to improve the taste and texture, and these generally contain between 1.5 and 11 g fat per 100 g. (*See* **Fats**: Classification.)

Energy content On account of its low fat content, myco-protein is low in calories. It has fewer calories

Table 6 Typical fatty acid composition of harvested Quorn™ myco-protein

Fatty acid	*Grams per 100 g of myco-protein*

than lean chicken (Table 2), making it a useful food to include in calorie-controlled diets and in weight-regulating diets. Quorn™ products generally have a significantly lower energy density than their equivalent meat products.

Fiber content In contrast to animal sources of protein, myco-protein contains nonstarch polysaccharides or dietary fiber (Table 2). The content of fiber (6%) is higher than that in most vegetables, and the amount per serving compares favorably with plant protein foods such as grains, beans, peas, lentils, nuts, and seeds. (*See* **Dietary Fiber**: Properties and Sources.)

The types of fiber present are chitin (35%) and β-glucan (65%), which are present in the cell walls. The fiber is 88% insoluble and 12% soluble.

Vitamins and minerals Myco-protein provides some minerals and some B vitamins, although it is lacking in B_{12} (Table 7). The content of iron is approximately 50% that of chicken and 25% that of beef. The iron is present in an inorganic form, and is therefore not as bioavailable as heme iron. Myco-protein is rich in zinc, containing higher levels than meat, making it a particularly useful source for vegetarians, who generally tend to have low zinc intakes.

Experimentation has shown that the type of fiber in myco-protein is unlikely to cause interference with mineral absorption since it does not contain phytic acid or phytic salts. Research conducted at the Dunn Nutrition Laboratory in Cambridge, England, demonstrated that myco-protein had no significant effect on the absorption of calcium, magnesium, zinc, iron or phosphorus when compared with a polysaccharide-free diet. (*See* **Vitamins**: Overview.)

Known and Potential Functional Health Effects

Lipid-lowering Effects

Studies have demonstrated, under both controlled and free-living conditions, that myco-protein significantly reduces serum total and low-density lipoprotein (LDL) cholesterol levels, and that it may raise high-density lipoprotein (HDL) cholesterol levels. This suggests that myco-protein consumption has a beneficial influence on serum lipid variables, in relation to protection against coronary heart disease. (*See* **Cholesterol**: Factors Determining Blood Cholesterol Levels; Role of Cholesterol in Heart Disease.)

In a metabolic study, nine subjects with mildly raised blood cholesterol levels ate myco-protein–based products in place of meat (control diet – eight subjects) for 3 weeks. The diets were similar in fatty acid and cholesterol content, and in polyunsaturated: saturated ratio. The only significant difference was a 29% higher dietary fiber content in the experimental diet, on account of the high fiber content of the myco-protein products. The experimental diet produced a 13% decrease in total cholesterol compared with no change in the controls. LDL cholesterol fell by 9% in the experimental group compared with a 12% increase in controls. HDL cholesterol rose by 11% in the experimental group compared with an 11% decrease in controls.

Favorable effects of myco-protein products on blood lipid levels in subjects with slightly raised

serum cholesterol concentrations have been confirmed in free-living subjects over an 8-week study period. The experimental group ate biscuits containing myco-protein, and the control group ate a nutrient-balanced biscuit without myco-protein. Total cholesterol was reduced by 0.46 mmol l^{-1} and LDL cholesterol by 0.35 mmol l^{-1} in the control group, compared with reductions of 0.95 mmol l^{-1} and 0.84 mmol l^{-1} in the myco-protein group, respectively.

This suggests that myco-protein has a beneficial effect on dyslipidemia and may be a useful dietary means of improving unfavorable blood lipid profiles. A potential mechanism for this effect is likely to involve the high dietary fiber content of myco-protein.

Blood Glucose Regulation

Myco-protein has also been investigated for potentially beneficial effects on blood glucose and insulin levels, which may benefit diabetics. A study consisting of two single-meals in a crossover design investigated the effects of myco-protein on acute glycemia and insulinemia in 19 healthy individuals. Glycemia was significantly reduced after the meal containing myco-protein (13% at 60 min) compared with the control meal. Insulinemia was also significantly reduced in the experimental group (19% at 30 min and 36% at 60 min) compared with the control.

These preliminary data suggest a potentially beneficial effect of myco-protein for diabetics, although further studies are needed before firm conclusions can be drawn. However the high fiber and low saturated fat content of myco-protein makes it a suitable component of the diabetic diet for other reasons.

Satiety

Several studies have suggested that myco-protein may help to induce feelings of satiety and to reduce hunger and calorie intake at subsequent meals following myco-protein consumption.

In a study (two 3-day study periods), 13 female subjects, all nonrestrained eaters, ate either an isoenergetic meal containing myco-protein or chicken. Energy intake was significantly reduced on the day of the study (by 24%) and the following day (by 16.5%) in those consuming the myco-protein meal compared with the chicken meal. In a further crossover design study, 18 male and female subjects ate an isocaloric lunch containing either myco-protein-based products or chicken, which were similar apart from their dietary fiber content (11 g vs. 3 g, respectively). At the evening *ad libitum* test meal, the energy intake was reduced by 18% in those who had eaten the myco-protein product-based lunch compared with the chicken-based lunch. These studies suggest that myco-protein may play a useful role in weight-reducing diets.

Other Potential Health Effects

Myco-protein has a number of other attributes that may produce beneficial health effects, and these warrant scientific investigation.

Provision of α-linolenic acid Myco-protein is a useful source of α-linolenic acid (ALA), an essential fatty acid belonging to the *n*-3 family. ALA is a precursor of the very-long-chain *n*-3 eicosapentaenoic (EPA) and docosahexaenoic acids (DHA) in the body. EPA and DHA are associated with protection against coronary heart disease through antithrombotic effects in addition to other potential mechanisms. Research suggests a protective effect of ALA itself against CHD, through lowering blood cholesterol concentrations, and beneficial effects on hemostatic factors and heart arrhythmias.

Provision of β-glucans The sources of dietary fiber in Quorn™ myco-protein are chitin (35%) and β-glucan (65%). β-Glucan occurs in three main forms, characterized by linkages that are designated as β 1–3, β 1–4 and β 1–6 linked. Myco-protein contains 16% β 1–3 and β 1–6 glucans on a dry-weight basis, such that a typical Quorn™ product delivers 2–3 g of β glucans per serving. β 1–4 Glucans are present in certain cereal products such as oats, and are associated with lowering blood lipids for which an FDA-approved health claim is permitted. There is less evidence for beneficial effects of β 1–3 and β 1–6 glucans, but reports to date have suggested possible immune-stimulating properties and a cholesterol-lowering effect from these forms of β-glucans present in yeast.

Provision of chitin Chitin is also being investigated for potential cholesterol-lowering effects. Chitin is a type of dietary fiber that is found in mushrooms, fungi, and yeast, as well as in the exoskeleton of insects and in the hard shells of shellfish. Myco-protein contains 8% chitin on a dry-weight basis with a typical serving of a Quorn™ product providing 1–1.5 g of chitin.

Provision of prebiotics β-Glucan and chitin are both being investigated as potential prebiotics, which can be defined as 'nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and activity of a limited number of

Table 8 The developing role of food

Time period	*Context*
Early to mid-1900s	Focus on adequate vitamin intakes to cure deficiency diseases
1960s–1990s	Eat less of what is bad for you
1990s	Eat more of what is nutritionally good for you
2000s	Foods that are positively good for health beyond their nutrient content

bacteria in the colon that have the potential to improve health.'

Provision of glucosamine Research suggests a potential role for glucosamine in the alleviation of joint pain arising from osteoarthritis. Free glucosamine is not present in any food sources, but polymeric glucosamine is present in chitin. Myco-protein therefore contains 8% glucosamine in polymeric form (chitin). There is preliminary evidence that polymeric glucosamine may also have a beneficial role, as it can potentially provide sustained release of glucosamine, but this requires further investigation.

Potential of Myco-protein

Though originally researched and developed as a high-protein food, the predicted protein gap did not materialize. However, the ever-changing climate of consumer demands for food products meant that the Quorn™ range of products could be successfully marketed in a climate where demand for acceptable meat-alternatives was growing. This was a response to an increasing emphasis on healthy eating, for which, in the 1980s, the context was on removing elements from the diet considered to be 'bad' for health (Table 8).

However, as we have entered the new millennium, and the role of food has developed further, there has been a shift in emphasis towards eating products that are positively good for health (Table 8). Within the context of this focus on the functional properties of foods beyond their nutritional value (so-called 'functional foods'), Quorn™ products would appear to potentially have a number of positive attributes that may be of functional value in this context, and these warrant further investigation.

MYCOTOXINS

Contents

Classifications

L B Bullerman, University of Nebraska-Lincoln, Lincoln, NE, USA

Introduction

Mycotoxins are a group of structurally diverse, naturally occurring chemical substances produced by molds (microfungi). The term 'mycotoxin' is derived from the Greek word '*Mykes*', which means fungus, and the Latin word '*toxicum*,' which means toxin or poison. Thus, mycotoxin literally means 'fungus toxin' or 'fungus poison,' and its use is restricted to describing the metabolites of microfungi, as opposed to the toxic principles of certain macrofungi, i.e., mushrooms.

Toxicity and Biological Effects of Mycotoxins

In general, mycotoxins produce a number of adverse effects in a range of biological systems, including microorganisms, plants, animals, and humans. The toxic effects of mycotoxins in humans and animals, depending upon dose, may include (1) acute toxicity and death as a result of exposure to high amounts of a mycotoxin, (2) reduced milk and egg production and lack of weight gain in food-producing animals from subchronic exposure, (3) impairment, stimulation, or suppression of immune functions and reduced resistance to infections from chronic exposures to low levels of toxins, and (4) tumor formation, cancers, and other chronic diseases from prolonged exposure to very low levels of a toxin. In addition, mycotoxins may be mutagenic, capable of inducing mutations in susceptible cells and organisms, and teratogenic, capable of causing deformities in developing embryos. Other manifestations of mycotoxins that can affect the food supply in economic terms are reduced growth rates and increased reproductive problems in food-producing animals and livestock. (*See* **Carcinogens**: Carcinogenic Substances in Food: Mechanisms; **Mutagens**.)

Mycotoxin-producing Molds

Most molds that produce the mycotoxins of greater concern can be found in three main genera, *Aspergillus*, *Penicillium*, and *Fusarium*. Organisms of the *Aspergillus* and *Penicillium* genera tend to be saprophytic and often attack commodities while in storage, though some aspergilli can also invade in the field. The genus *Fusarium* contains a number of plant pathogenic species as well as saprophytic types. A number of factors affect mycotoxin production by molds, including moisture, relative humidity, temperature, substrate, pH, competitive and associate growth of other fungi and microorganisms, and stress on the plant such as drought and damage to seed coats from hail, insects, and mechanical harvesting equipment. The major commodities that are susceptible to contamination with mycotoxins include corn (maize), wheat, barley, peanuts, cottonseed, and some tree nuts (Table 1). Dairy products, primarily milk, can become contaminated as a result of feeding contaminated feed to dairy animals. Cheese made from contaminated milk will also be contaminated. (*See* **Cereals**: Dietary Importance; **Spoilage**: Molds in Spoilage.)

Specific Mycotoxins

Aflatoxins

Aflatoxins are produced primarily by some strains of *Aspergillus flavus* and most, if not all, strains of *A. parasiticus* and *A. nomius*. There are four main aflatoxins B_1, B_2, G_1, and G_2, plus two additional aflatoxins that are of significance, M_1 and M_2 (Figure 1). The M toxins were first isolated from the milk of lactating animals fed aflatoxin preparations; hence the M designation.

Aflatoxins are potent liver toxins, in all animals in which they have been tested, and carcinogens in some species. Aflatoxin B_1 is the most toxic of the group. Effects of aflatoxins in animal tests vary with dose, length of exposure, species, breed, and diet or nutritional status. These toxins may be lethal when consumed in large doses; sublethal doses produce a

Sterigmatocystin	Green coffee, moldy wheat, Dutch cheeses	Mouse, rat	Carcinogenesis Hepatotoxin
Trichothecenes (T-2 toxin, diacetoxyscirpenol, neosolaniol, nivalenol, diacetylnivalenol, deoxynivalenol, HT-2 toxin, fusarenon X)	Corn (maize), wheat, commercial cattle feed, mixed feed	Swine, cattle, chicken, turkey, horse, rat, dog, mouse, cat, human	Digestive disorders (emesis, diarrhea, refusal to eat) Hemorrhage (stomach, heart, intestines, lungs, bladder, kidney) Edema Oral lesions Dermatitis Blood disorders (leucopenia) Food-borne illness (nausea, vomiting, abdominal pain, diarrhea) Immune disfunction (suppression and stimulation)
Zearalenone	Corn (maize), moldy hay, pelleted commercial feed	Swine, dairy cattle, chicken, turkey, lamb, rat, mouse, guinea-pig	Estrogenic effects (edema of vulva, prolapse of vagina, enlargement of uterus) Atrophy of testicles Atrophy of ovaries, enlargement of mammary glands Abortion

chronic toxicity, and low levels of chronic exposure result in cancers, primarily liver cancer in a number of animal species. In general, young animals of any species are more susceptible to the acute toxic effects of aflatoxins than are older animals of the same species. Susceptibility also varies between species. Of all the mycotoxins, the aflatoxins are of greatest concern because they are highly toxic and potently carcinogenic. Mold growth and aflatoxin production are favored by warm temperatures and high humidity, typical of tropical and subtropical regions. (*See* **Aflatoxins**.)

Sterigmatocystin

Sterigmatocystin is produced by several species of *Aspergillus*, *Penicillium luteum*, and a *Bipolaris* species. Chemically, sterigmatocystin resembles aflatoxins and is thought to be a precursor in the biosynthesis of aflatoxin. The acute toxicity of sterigmatocystin is low, and the main concern is that it is carcinogenic, about one-tenth as potent a carcinogen as aflatoxin B_1. Sterigmatocystin has been detected at lower levels in green coffee, moldy wheat, and rind of hard Dutch cheese.

Ochratoxins

Ochratoxins are a group of related compounds that are produced by *Aspergillus ochraceus* and related species, *Aspergillus niger*, as well as *Penicillium verrucosum* and certain other *Penicillium* species. The main mycotoxin in this group, ochratoxin A, is a potent toxin that causes kidney damage in rats, dogs and swine (Figure 2). Ochratoxin is thought to be involved in a disease of swine known as porcine nephropathy, which has been associated with the feeding of moldy barley. Ochratoxin has also been

reported to be teratogenic to mice, rats and chicken embryos, and has been suggested as a possible causative factor, though never proven, in a human disease known as 'Balkan endemic nephropathy'.

Citrinin

Citrinin is a yellow-colored compound that is produced by several *Penicillium* species as well as *Aspergillus* species (Figure 3). Like ochratoxin A, citrinin causes kidney damage in laboratory animals similar to swine nephropathy. Citrinin may be involved with ochratoxin A in cases of swine nephropathy in Denmark. However, the toxicity of citrinin is low compared with ochratoxin, although possible synergistic activity with ochratoxin A cannot be ruled out.

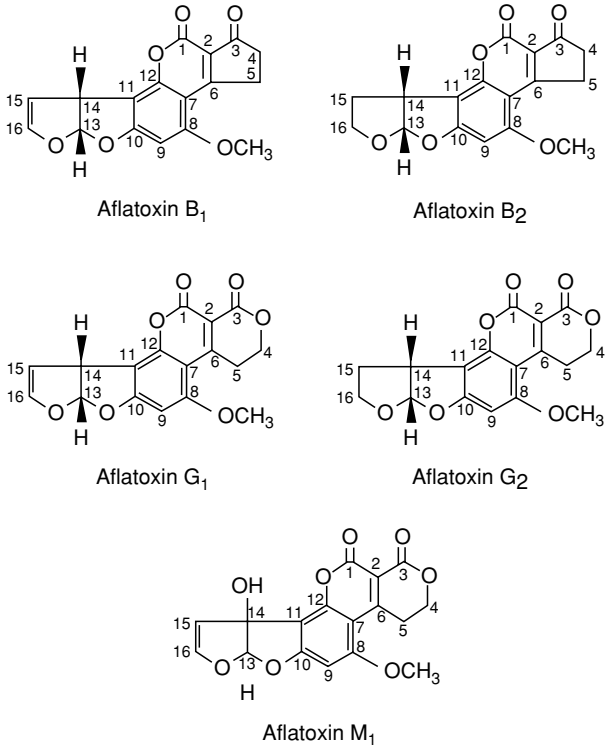

Figure 1 Chemical structures of aflatoxins.

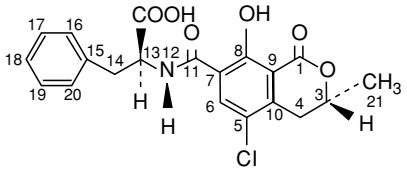

Figure 2 Chemical structure of ochratoxin A.

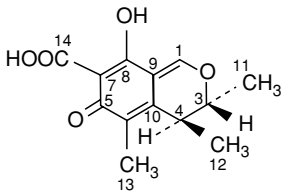

Figure 3 Chemical structure of citrinin.

Patulin

Patulin is toxic to many biological systems, including bacteria, mammalian cell cultures, higher plants, and animals, but its role in causing animal and human disease is unclear. Patulin has a lactone structure and is carcinogenic when injected intradermally into mice (Figure 4). Patulin is produced by numerous *Penicillium* and *Aspergillus* species and *Byssochlamys nivea*. *Penicillium expansum*, which commonly occurs in rotting apples, produces patulin. Patulin is of some public health concern because of its potential carcinogenic properties, and because it has been found in commercial apple juice and other apple products. Patulin appears to be unstable in grains, cured meats, and cheese. When administered orally to rats, patulin showed no toxicity or carcinogenicity.

Penicillic Acid

Penicillic acid has a low oral toxicity. The concern about penicillic acid in foods is based on the fact that the compound bears structural similarity to known carcinogens such as patulin, and has in fact been shown to be carcinogenic to rats when injected subcutaneously (Figure 5). However, the potencies of penicillic acid and patulin as carcinogens are much lower than aflatoxins. When given in lethal doses, penicillic acid caused fatty-liver degeneration in quail and liver-cell necrosis in mice. Mixtures of penicillic acid with ochratoxin A are synergistic and cause

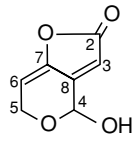

Figure 4 Chemical structure of patulin.

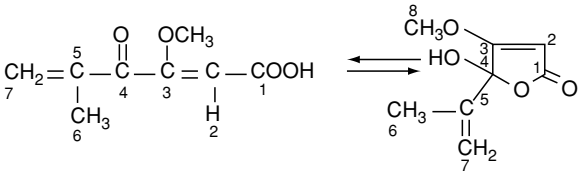

Figure 5 Chemical structure of penicillic acid as the straight-chain acid and the lactone configuration.

death in mice. Pharmacologically, penicillic acid dilates blood vessels and has antidiuretic effects. However, penicillic acid is similar to patulin in its rapid reaction with sulfhydryl-containing compounds in foods to form nontoxic products. Penicillic acid is produced by strains of *A. ochraceus* and related species and *Penicillium aurantiogriseum* and other species. Some strains of *A. ochraceus* are capable of producing penicillic acid along with ochratoxin A. Penicillic acid has been found in large quantities in corn with a high moisture content stored at low temperatures.

Cyclopiazonic Acid

Cyclopiazonic acid (CPA) is produced by several molds that commonly occur on agricultural commodities or are used in certain food fermentations (Figure 6). CPA has been reported to be produced by *A. flavus*, *A. versicolor*, and *A. tamarii* as well as several *Penicillium* species, some of which are used in the production of fermented sausages in Europe. Other molds used in the food fermentations that have been reported to produce CPA are *Penicillium camemberti*, used to produce Camembert cheese, and *Aspergillus oryzae*, used to produce fermented soy sauces. CPA has been reported naturally occurring in corn and peanuts, and a type of millet (kodo) that reportedly caused a human intoxication in India. It is also possible that CPA was involved along with aflatoxins in 'turkey X' disease in England in 1960, since some isolates of *A. flavus* produced both aflatoxins and CPA. CPA has been shown to affect rats, dogs, pigs, and chickens. Clinical signs of intoxication include anorexia, diarrhea, pyrexia, dehydration, weight loss, ataxia, immobility, and extensor spasm at time of death. Histopathological changes in CPA-exposed animals include alimentary tract hyperemia, hemorrhage, and focal ulceration. Focal necrosis can be found in liver, spleen, kidneys, pancreas, and myocardium. In broiler chicks given CPA, skeletal muscle degeneration characterized by myofibular swelling and fragmentation has been observed. About 50% of a dose of CPA given orally or intraperitoneally to rats or chickens is distributed to skeletal muscle within 3 h. CPA has the ability to chelate metal cations. Chelation of such cations as calcium, magnesium, and iron may be an important mechanism of toxicity of CPA.

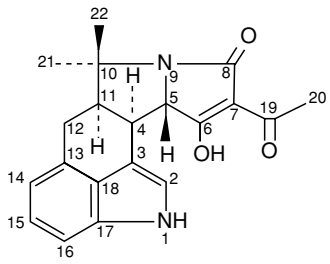

Figure 6 Chemical structure of cyclopiazonic acid.

Mycophenolic Acid, β-Nitropropionic Acid, Tremorgens (Penitrem), and Rubratoxin

Many toxic compounds have been obtained from mold cultures; however, not all have been shown to cause disease in humans or animals. Other mycotoxins such as mycophenolic acid, β-nitropropionic acid, and tremorgens have been reported but have not been studied extensively. Tremorgenic mycotoxins called penitrems have been reported to have caused poisonings of dogs that consumed moldy cream cheese, moldy walnuts, and other moldy debris (Figure 7). The toxins caused severe muscle tremors, uncoordinated movements, and generalized seizures and weakness in the dogs. The disease can also occur in cattle, where it is called staggers. Tremorgenic mycotoxins can be produced by fungi in the genera *Aspergillus*, *Penicillium*, *Claviceps*, and *Acremonium*. Mycophenolic acid (Figure 8) and β-nitropropionic acid have been associated with cheeses produced in Europe and are believed to be antibiotic substances of low oral toxicity. Rubratoxin B (Figure 9) produced hepatic degeneration, centrilobular necrosis, and hemorrhage of the liver and intestine when given to experimental animals. However, no natural occurrence of disease caused by this toxin has been documented, though it is suspected of causing a hepatotoxic, hemorrhagic disease of cattle and pigs fed

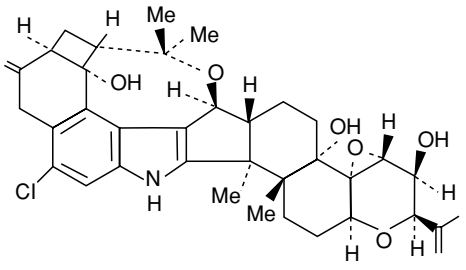

Figure 7 Chemical structure of penitrem A.

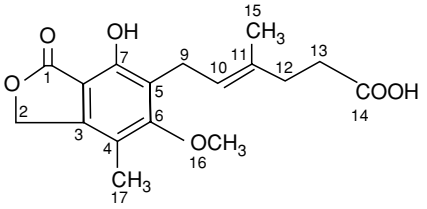

Figure 8 Chemical structure of mycophenolic acid.

moldy corn. Rubratoxin is produced by *Penicillium rubrum* and may exert a synergistic effect with aflatoxins.

Zearalenone

Zearalenone (Figure 10), an estrogenic compound also known as F-2 toxin, causes vulvovaginitis and estrogenic responses in swine. Zearalenone is produced by *Fusarium* species. Zearalenone has been found to occur naturally in corn with a high moisture content in late autumn and winter, primarily from the growth of *Fusarium graminearum* and *Fusarium culmorum*. Although the compound is not especially toxic, 1–5 p.p.m. is sufficient to cause physiological responses in swine. Zearalenone can be transmitted to piglets in sows' milk and cause estrogenism in the young pigs. Zearalenone has been found in moldy hay, high-moisture corn, corn infected before harvest, and pelleted feed rations. The involvement of zearalenone in human toxicoses has not been confirmed, but it is classified as an endocrine disrupter and is considered potentially hazardous for humans. The formation of zearalenone is favored by high humidity and fluctuating temperatures, followed by low temperatures. These conditions often occur in temperate regions during autumn harvest.

Trichothecenes

Trichothecenes (Figure 11) are a family of closely related compounds produced by several *Fusarium* species. There are more than 20 naturally occurring compounds produced by *Fusarium* species, which have similar structures, including T-2 toxin, diacetoxyscirpenol, neosolaniol, nivalenol, diacetylnivalenol, deoxynivalenol (DON, vomitoxin), HT-2 toxin, and fusarenon X. DON has been implicated in a disease known as moldy corn toxicosis of swine, symptoms of which include refusal to eat (refusal factor), lack of weight gain, digestive disorders, and diarrhea, ultimately leading to death. T-2 toxin is quite toxic to rats, trout, and calves. Large doses of T-2 toxin fed to chickens result in severe edema of the body cavity and hemorrhage of the large intestine, along with neurotoxic effects, oral lesions, and, finally, death. T-2 toxin is also thought to be one of the toxins involved in the human disease alimentary toxic aleukia (ATA) and has been implicated as a component of the so-called 'yellow rain' samples collected from South East Asia in the early 1980s. T-2 toxin causes severe dermal responses in rabbits, rats, and other animals, including humans, when applied to the skin. However, it is not thought to be carcinogenic. Although T-2 toxin is very toxic, its natural contamination in foods and feeds appears to be low. Deoxynivalenol causes vomiting in animals and has been suspected as a cause of foodborne illness in India in which nausea, vomiting, and diarrhea were the symptoms. Short-term feeding trials with animals suggest low acute toxicity, but other evidence indicates that deoxynivalenol may have a teratogenic potential. Unlike T-2 toxin, deoxynivalenol contamination in commodities, especially wheat and corn, is significant in certain years. Deoxynivalenol is produced by *F. graminearum* and *F. culmorum* and is the most commonly occurring trichothecene. The trichothecenes are also of concern because chronic exposure to low levels of these compounds may cause immunosuppression or immunostimulation-like illnesses in humans and animals.

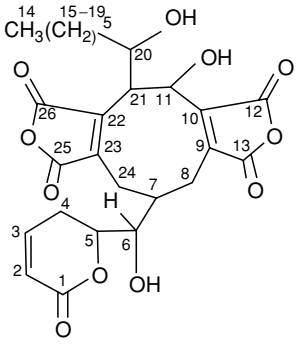

Figure 9 Chemical structure of rubratoxin B.

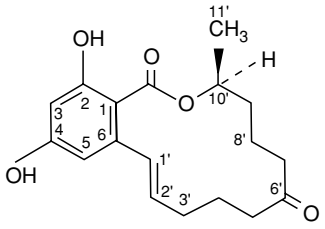

Figure 10 Chemical structure of zearalenone.

Fumonisins

Fumonisins (Figure 12) are a group of compounds produced primarily by *Fusarium verticillioides* (formerly known as *Fusarium moniliforme*) and *F. proliferatum*. In animals, fumonisins have been shown to cause several diseases such as equine leucoencephalomalacia, porcine pulmonary edema, and liver cancer in rats. While not as potent a liver carcinogen as aflatoxins, it has been suggested that the lifetime carcinogenic potential of fumonisin B_1 in the rat falls somewhere between carbon tetrachloride and dimethylnitrosamine. In terms of human disease, fumonisins are of concern because they have been linked to esophageal cancer. It has been shown that there is a significant correlation between the

consumption of corn contaminated with *F. verticillioides* and fumonisins and esophageal cancer in humans in the Transkei region of South Africa. Fumonisins and *F. verticillioides* have also been linked to corn (maize) consumption and a high incidence of esophageal cancer in certain provinces of northern China. *F. verticillioides* commonly occurs in corn-growing regions of the world and has been said to be found virtually everywhere that corn is grown. *F. verticillioides* invades the corn plant and can exist there as an endophyte, and may not be evident as a surface contaminant or infestation. Infection of the corn kernel by *F. verticillioides* may occur by invasion through the silk, fissures in the kernel pericarp and/or through systemic infection of the plant.

Moniliformin

Moniliformin (Figure 13) was first reported to be produced by *F. moniliforme* isolated from corn. While the toxin apparently was named after this organism, the name has turned out to be a misnomer, since subsequent work has shown that most strains of *F. moniliforme* (now called *F. verticillioides*) do not produce moniliformin, or are only weak producers. The toxin is produced by *F. proliferatum* and *F. subglutinans*, as well as other *Fusarium* species. Moniliformin is highly toxic when given orally to experimental animals, causing rapid death without severe cellular damage. One-day-old cockerels and mice have been shown to be quite sensitive to the toxin. Clinical lesions observed include acute degenerative lesions in the myocardium and other tissues. Moniliformin has also been suggested as a possible cause of Keshan disease, a human myocardial impairment occurring in rural areas of China and South Africa where there is a high consumption of corn (maize) that has been shown to be contaminated with moniliformin.

Potential Toxicity of *Penicillium roqueforti*

Penicillium roqueforti has been shown to produce several toxic compounds, including roquefortine, PR toxin, and festuclavine (Figure 14). Toxicities of PR toxin and roquefortine are low. Roquefortine is a neurotoxin that reportedly causes convulsive seizures, liver damage, and hemorrhage in the digestive tract in mice. However, repeated studies have failed to reproduce these results. Roquefortine has been recovered from blue cheese and was associated with the mold mycelia rather than the nonmoldy areas of the cheese. A toxic factor in the fat of Roquefort cheese that caused severe injury to the liver and other organs of rats has been reported. Atypical, wild strains of *P. roqueforti* have been shown to produce patulin and penicillic acid simultaneously, patulin alone, patulin plus citrinin, and mycophenolic acid. The significance of the various toxins produced by *P. roqueforti* to public health is not clear. Patulin, penicillic acid, and citrinin have been observed only in wild-type isolates of the organism and not in commercial strains, nor in any cheese produced by commercial strains. As such, the wild isolates represent no greater significance than any other toxinogenic isolates of other species. The significance of PR toxin, mycophenolic acid, the roquefortines, and related alkaloids to human health is likewise unclear,

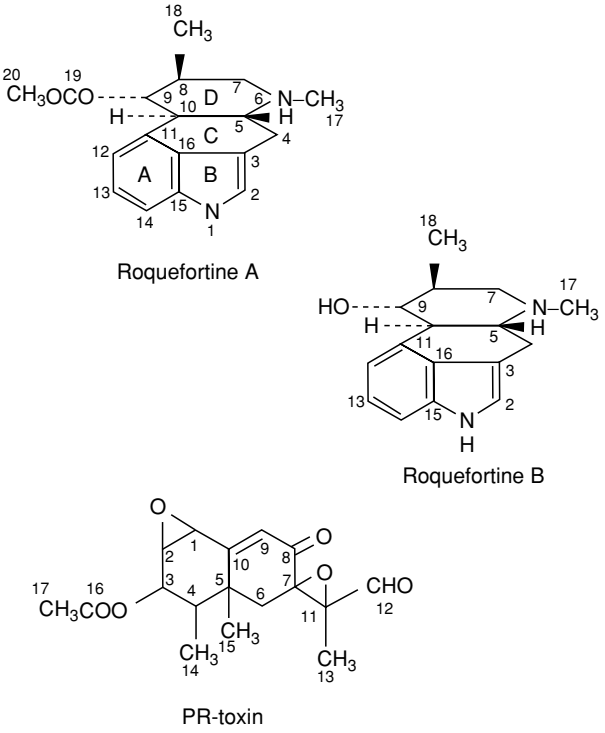

Figure 14 Chemical structures of some *P. roqueforti* toxins.

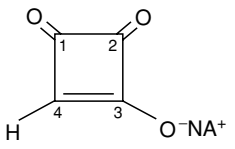

Figure 13 Chemical structure of moniliformin.

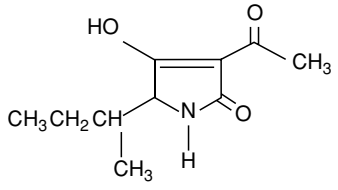

Figure 15 Chemical structure of tenuazonic acid.

particularly in view of the limited toxicological information available on these compounds. PR toxin apparently reacts with cheese components and is neutralized. The fact that blue-veined cheeses have been consumed for centuries without any apparent ill effect suggests that the hazard to human health is minimal or nonexistent. (*See* **Alkaloids**: Properties and Determination.)

Alternaria Toxins

Alternaria species, including *A. alternata, A. citrii, A. tenuissima*, and others produce several toxic compounds, alternariols, altenuene, tentoxin and tenuazonic acid (Figure 15). These organisms are common in many foods and grains. *Alternaria* species require high-moisture conditions and tend to be found in foods that are high in moisture such as grains prior to harvest and fruits and vegetables. The *Alternaria* toxins can be found in grains when drying in the field and harvest are delayed by rain, high humidity, or early frost. *Alternaria* species are most common in sorghum grain, but the toxins have only been found in heavily weathered sorghum. Postharvest occurrence of *Alternaria* species in fruits and vegetables is more common because the moisture content remains high after harvest. *Alternaria* infection of fruits and vegetables has been observed in apples, oranges, tomatoes, and bell peppers. *Alternaria* toxins have been detected in oranges, tomatoes, tomato paste, and commercial apple products. *Alternaria* toxins are toxic to *Bacillus mycoides* and HeLa cells. The toxins, however, are only weakly toxic to mice and do not appear to be toxic to rats or chicks when administered as single, purified compounds. There is some evidence that mixtures of the compounds may be more toxic. The *Alternaria* toxins are also phytotoxins which affect various plants. *Alternaria alternata* f. sp. *lycopersici*, which is a pathogen of tomatoes, produces a host specific phytotoxin known as AAL toxin which is nearly identical in structure to fumonisins.

Ergot

Ergot is a disease of plants, particularly small grains such as rye and barley and other grasses, which is caused by species of *Claviceps*, in particular *C. purpurea, C. paspalli*, and *C. fusiformis*. These fungi invade the female sex organs of the host plant and replace the ovary with a mass of fungal tissue known as a sclerotium. The sclerotia, also called ergots, are about the same size and density as the grain kernels and tend to go with the grain when harvested. The sclerotia contain alkaloids that are produced by the fungus. The alkaloids ergotamine (Figure 16), ergosine, and others are derivatives of

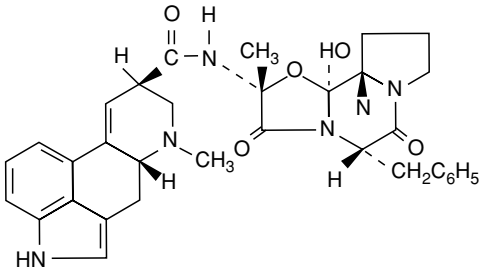

Figure 16 Chemical structure of ergotamine.

lysergic acid, and cause disease in animals and humans. The disease is manifested by a sensation of cold hands and feet followed by an intense burning sensation. As the disease progresses, the extremities may become gangrenous and necrotic, and in animals, sometimes the extremities are sloughed. In severe cases, death may ensue. Ergotism, also known as St. Anthony's fire, reached epidemic proportions during the Middle Ages. At that time, the cause of the disease was not known, but it was most probably associated with bread made from flours of rye and other grains that were infested with ergot sclerotia. In recent times, outbreaks involving humans have occurred in Africa and India. Outbreaks of animal poisonings still occur in areas where rye, barley, and other susceptible small grains and grasses are grown.

Stability of Mycotoxins in Foods

Most of the information on mycotoxin contamination of commodities concerns agricultural products such as grain (Table 1). Therefore, much of what is known about the stability of mycotoxins pertains to the effects of storage, food processing, and cooking. Aflatoxins tend to be stable to moderately stable during storage under most conditions and in most food processes. Various food processes can reduce the amount of aflatoxin by destruction or removal, but usually, some percentage of the toxin will persist and carry into the finished food. Aflatoxins are stable in peanut materials at room temperature, but are partially destroyed by roasting; however, destruction is not complete. In the wet milling of corn, aflatoxin, if present, will be found primarily (over 97%) in the steep water and fiber fractions, but little (1% or less) in the starch. Aflatoxins may be reduced in the baking process, but are not completely destroyed. The manufacture of corn flakes has been shown to reduce aflatoxin levels in flaking grits by 75–80%. Similarly, some sterigmatocystin will be lost during roasting of coffee beans, but some will also remain. Ochratoxin is not eliminated from grain by cleaning or milling, after which it appears equally divided between flour and bran fractions. Ochratoxin will persist through

the baking process, manufacture of corn flakes and through the cooking of mash for beer. However, roasting of green coffee beans has been shown to completely destroy ochratoxin. Patulin and penicillic acid appear to be moderately stable in processed apple products but are unstable in grains, grain-based foods, meats, and cheese. Patulin and penicillic acid react with sulfydryl and amino compounds to form nontoxic adducts. Patulin also appears to be destroyed by the alcoholic fermentation of apple juice and by wine-making. Deoxynivalenol (DON) in wheat milled into flour will be found primarily in the bran fraction but is not destroyed. Also, baking does not destroy DON, though there may be some reduction of DON levels. Likewise, extrusion processing of cereal grains may give some reduction of DON under conditions of high temperatures and pressures. In the wet milling of zearalenone-contaminated corn, like aflatoxins, zearalenone concentrates in the fractions used for animal feed and not in the starch. Likewise, in wet milling of T-2 toxin-contaminated corn, most of the T-2 toxin is found in the steep water, germ, gluten, and fiber, and only 6–8% is found in the starch. Extrusion processing of corn (maize) contaminated with zearalenone has been shown to reduce zearalenone concentrations by 65–83%. Ethanol fermentation of fumonisin-contaminated corn results in little degradation of fumonisin during fermentation, with most of the toxin being found in the distillers' grains, thin stillage and distillers' solubles fractions. None of the fumonisin is found in the distilled alcohol. Fumonisins are stable in baked or canned corn (maize) products, with little or no loss. Roasting at temperatures above 200 °C result in apparent loss of fumonisins, whereas the corn flake process and extrusion processing result in low to moderate reductions of fumonisins. However, if glucose is added, the reduction of fumonisins increases dramatically to more than 80% in both the corn flake process and extrusion processes. Thus, in most cases, mycotoxins are not completely destroyed by processing and cooking. Some destruction occurs, the extent of which depends on the process and the toxin present, though destruction usually is not complete. Also, mycotoxins may tend to concentrate in certain fractions during milling and fermentation, depending upon the type of mycotoxin and process used.

Occurrence and Determination

A Chrevatidis, Eclipse Scientific Group, Chatteris, Cambs, UK

Occurrence

The name mycotoxin is a compound word derived from the Greek *mykes*, which means fungus (mold), and the Latin *toxicum*, which means poison. From early on, fungi were used in food preservation and processing, producing particular flavors and taste in products like cheese and soy sauce. They are also

producers of antibiotics and other useful chemicals. On the other hand, such species have been linked with a number of toxic outbreaks around the world, causing serious illnesses and even death. They have been discovered after the outbreak of 'St Anthony's fire,' when a large number of people died in Russia in the early 1900s after the consumption of rye contaminated with ergot alkaloids produced by the mold *Claviceps purpurea*. In their despair, due to a tremendous burning sensation and epileptic fits, many pilgrims travelled to St Anthony's shrine in France hoping for a cure.

During the last 40 years of research on mycotoxins, hundreds have been discovered but it is fortunate that a relatively small number has been proven to be harmful. Although the number is limited, it is important to bear in mind that a number of agricultural products are susceptible and the fungi infesting them are capable of producing amounts of toxins able to cause devastating effects.

Mycotoxins are toxic secondary metabolites (byproducts) occurring naturally by several fungal species under various climatic conditions on a large number of agricultural commodities. The reason for their existence is not quite clear; however, it has been suggested that they are produced under adverse conditions or that they may play a role in the survival of the fungus itself. Spores of these fungi exist in the air and soil throughout the world and can germinate when appropriate conditions arise. Mycotoxins can be formed in the field prior to and after harvest during inappropriate storage. More specifically, mycotoxin occurrence is due to several factors:

1. Biological: crop susceptibility and fungus compatibility;
2. Environmental: temperature, moisture, mechanical injury, insect damage, fungus;
3. Harvesting: crop maturity, temperature, moisture, detection/diversion;
4. Storage: temperature, moisture, detection/diversion;
5. Distribution/processing: detection/diversion.

Mycotoxins are a reason for concern because they affect the economy and health status of the world population. It has been estimated that approximately 25% of the world's grain is lost annually as a result of contamination by mycotoxins leading to produce being destroyed, dumped, or degraded, therefore, causing heavy financial burden on the exports of many developing and developed countries. Some Asian, African, and Latin American countries whose economy strictly relies on agricultural commodities can suffer dramatically when their consignments are denied export. These losses can vary from year to year depending on the environmental conditions, which entirely depend on nature. They are also a significant burden to the farming industry by reducing the growth rate and reproductive efficiency of animals as well as condemning meat and dairy products. The health implications associated with mycotoxins are numerous, and include acute toxicity outbreaks and chronic cases of disease. Acute effects such as death are caused by the ingestion of high amounts of the toxin in a given short time period; such cases have been recorded in Asia, India, and Africa, where quality control of food may be compromised. Chronic effects are a more serious matter, as is a type of exposure that can take place more frequently. It is caused by the long-term ingestion of low levels of the toxin; such exposure has been associated with increased risk of primary liver carcinoma in Asia. Further health effects caused by exposure to mycotoxins are allergies and infections.

Mycotoxins are very stable at high temperatures with little or no destruction occurring under the conditions of ordinary cooking or conventional processing. As a result they have repeatedly been detected in many final products. Consumption of contaminated foods is considered the main route of exposure to mycotoxins, and this must be avoided. Table 1 provides an overview of the most frequently occurring mycotoxins, their fungal source, and the foods susceptible to infestation.

Aflatoxins

A single event in the UK in 1960 established the significance of mycotoxins. During this outbreak thousands of turkeys, ducklings, and chicks died as a result of Turkey X disease. Chemical analysis by thin-layer chromatography (TLC) identified several ultraviolet (UV) fluorescent compounds in the feed (Brazil peanut meal) which were thought to be responsible for this outbreak. These compounds were named aflatoxins. Aflatoxins are produced primarily by the *Aspergillus* genera, and more specifically by *A. flavus, A. parasiticus*, and *A. nonius*, which are ubiquitous in the environment and infest a large variety of commodities. Within the aflatoxin family, aflatoxin B_1 (AFB_1) is the most acutely and chronically toxic, carcinogenic, and mutagenic of all. There is sufficient epidemiological evidence to support the carcinogenic properties of AFB_1 to humans and animals and therefore to lead to its classification as a class 1 carcinogen by the International Agency for Research on Cancer (IARC).

To date, a total of 20 compounds have been designated as aflatoxins with AFB_1, AFB_2, AFG_1, and AFG_2 the most significant and common food contaminants. Aflatoxin M_1 and M_2 are metabolites of AFB_1

and AFB_2 excreted in milk and urine of ruminants that have consumed contaminated feeding stuffs. Aflatoxins are produced when food is stored for long periods of time under high temperature and humidity. Seasonal variation has been found to affect mycotoxin levels, while regional variations due to the cultural habits of storing the food are usually considered as secondary factors. The occurrence of aflatoxins in foods and feeds has been reported in several countries and, although it is greatest in the warmest and humid parts of the world like Asia, Africa, and South America, it is also an annual problem to some degree in areas of the USA and Europe. Agricultural commodities rich in lipids and carbohydrates are susceptible to aflatoxin contamination and such raw ingredients include cereals, rice, pulses, oilseeds, dry fruits, spices, nuts (peanuts, Brazil, and pistachios) and animal-derived products (i.e., milk, eggs). Aflatoxins were also detected in Indian chilli powder, capsicum pepper, nutmeg, and dried chilli peppers. Recent evidence has revealed that aflatoxins have been detected in heroin and marijuana samples, compromising even further the health status of drug-dependent individuals. Since aflatoxins are very stable, food-processing techniques like pasteurization or sterilization may not be effective in removing the toxin from its natural substrate and as a consequence may be detected in the final product. Epidemiological evidence in Asian and African countries has revealed a positive correlation between exposure to aflatoxins and primary liver carcinoma in humans. In order to protect the consumer from such a potent food contaminant, the Food and Drug Administration (FDA) in the USA has set action levels for the presence of aflatoxins in foods ranging from 0.5 p.p.b. (for AFM_1 in milk) to 20 p.p.b. for total aflatoxins in other food. In Europe, the European Commission (EC) has set lower levels of 0.05 p.p.b. and 15 p.p.b. for milk and other foods respectively, while new legislation has set limits of 10 p.p.b. for total aflatoxins in spices.

Ochratoxin A

Ochratoxin A (OTA) is the most commonly encountered and important of the group. It is produced mainly by *Penicillium verrucosum* under temperate climatic conditions of Eastern and South Europe,

Canada, and South America. It is also of great concern to the Baltic states and Scandinavia as the local cereals grown (barley and oats) are particularly susceptible to high levels of ochratoxin contamination. *Aspergillus ochraceus* has been associated with the production of OTA in tropical areas of the world. The most frequently contaminated commodities are wheat, nuts, and corn, while a number of raw and processed commodities have been found to be contaminated by OTA; some of these are coffee, beer, wine, dried fruit, cocoa, and green coffee. Water activity of foods is important for the growth of fungi, therefore storage under dry conditions is critical. Similarly to aflatoxins, ochratoxin A is a moderately stable molecule and will survive most food processes, thus it is important that it is absent in the raw materials used. It is also important to highlight that ochratoxin is a regular contaminant of a large number of feeding stuffs, therefore contamination is transferred to animals such as swine and poultry. As a result humans are exposed directly by consumption of contaminated foods, as well as indirectly by consuming various animal tissues of an affected animal.

OTA is a potent toxin targeting the kidney and causing acute and chronic lesions, while associations have been made with Balkan endemic nephropathy on various parts of the world. As a result of its potency, it has been classified as a class 2B (potential) carcinogen by the IARC. To date, the EC has set legal limits for the presence of OTA in various food groups ranging from 3 to 10 p.p.b. for cereal products and dried vine fruit respectively.

Patulin

Patulin is a secondary metabolite of certain *Penicillium, Aspergillus*, and *Byssochlamys* species but, more specifically, *P. expansum* appears to be the fungus responsible for patulin production. It is a common contaminant of apples and apple products but commodities such as grains and other fruits and vegetables are also susceptible although to a lower extent. Even though the contamination incidence is high, it is fortunate that the levels are usually low. Refrigeration temperatures are shown to be ideal for the production of patulin by several fungi, thus long storage periods must be avoided. The presence of patulin in apple juice is evidence that rotten fruit were being used; however, it is fairly easy to avoid contamination as most of the toxin is located in the rotten part of the fruit and once it has been removed, the problem is minimized. Juice fermentation also results in a 99% destruction of the toxin. Patulin has been a reason for concern due to its carcinogenic properties; however, the IARC was unable to establish the severity of its effects on humans and as a consequence no classification exists at present. Regulation levels set in several countries vary from 30 to 50 $\mu g\,l^{-1}$. The EC proposed limits of 50 p.p.b. in apple juice and 25 p.p.b. in solid apple products.

Trichothecenes

Trichothecenes are a family of closely related chemical compounds. They are metabolites of the fungi of *Fusarium, Trichoderma*, and *Stachybotrys*. They have been reported in colder climates of Scandinavia, Canada, Japan, and a number of European countries, but they also occur worldwide and in high diverse geographic regions. The group was discovered in 1932 in the Soviet Union after an acute episode of alimentary toxic aleukia, which caused 60% mortality to the exposed population. Among the 50 known trichothecenes, a limited number appear to be of importance. According to their chemical characteristics, they have been divided into type A, including diacetoxyscirpenol, HT-2, neosolaniol and T-2 and type B trichothecenes including 3-acetyldeoxynivalenol, 15-acetyldeoxynivalenol, deoxynivalenol, fusarenone-X, and nivalenol. Commodities affected by *Fusarium* toxins are oats, rye, cassava, sorghum, bananas, groundnut, soybeans, mangoes, and many more. Some of the most commonly produced toxins are deoxynivalenol (DON), nivalenol (NIV), and diacetoxyscirpenol (DAS) produced by *F. graminearum, F. nivale*, and *F. sambucinum*, while HT-2 and T-2 are produced by *F. tricinctum* and *F. roseum* and are more rare and the most harmful of the group. DON has repeatedly been found in corn and wheat as well as other cereals and is considered the most ambudant trichothecene produced.

Trichothecenes are fairly stable compounds and can persist for long periods. Evidence has shown that 50–60% of the toxins are transmitted to the finished product as processing removes only a small amount, therefore, there are concerns in regard to dietary exposure through foods like breakfast cereals, breads, noodles, beer, and infant foods. Epidemiological data have associated DON ingestion with human mycotoxicoses in China, India, and Japan while trichothecenes have been associated with feed refusal, depression of immune response, nausea, occasional vomiting, and anemia in humans and animals. In addition to crops destined for human consumption, a large number of feeding stuffs have also been found to be contaminated by the same toxin; however, transfer to the human food chain appeared to be minimal. Infestation of crops by the mold appears red-pink colored, usually located at the head or tip of the crop. Formation of DON in the field can vary due to climate and geographical

region as well as variations from year to year. In view of consumer protection, the FDA has set advisory levels for DON of 1 p.p.m. in foods intended for human consumption. In Europe, the EC proposed action levels of 500 and 750 p.p.b. at the retail and raw material stage respectively.

Zearalenone

Zearalenone (ZEN) is a mycotoxin with estrogenic properties produced by the field fungi Fusaria. Similarly to the trichothecenes, ZEN is produced under the same conditions; however, a drop in the temperature during growth stimulates production of toxins. In addition to trichothecene production, *Fusarium graminearum* and *F. culmorum* are the primary fungi responsible for the production of ZEN; however, eight others can also produce the toxin at varying amounts. It is the second most commonly encountered *Fusarium* metabolite and is known to contaminate crops such as maize, wheat, barley, oats, and rye in Canada, the USA, and Japan. Although there is no epidemiological evidence to support esophageal cancer development from exposure to ZEN, an association in certain parts of Africa has been made. ZEN metabolites have been shown to transfer into milk; however, the evidence that they may pose potential risks to humans is limited. It is a compound that survives processing and fermentation and, as a result, it has been found not only in animal feed but products intended for human consumption. Examples are corn meal, breakfast cereals, beer, and fermented products.

The ZEN producing fungi usually grow in the field, causing pink discoloration of the kernel; however it is not always evidence of the presence of the metabolite. ZEN is only partly decomposed by heat treatment but cleaning a crop by removing its outer hull may result in 40–100% reduction of the toxin. The FDA has not issued an advisory level for ZEN but observations should continue. The EC has also urged member states to monitor ZEN levels in inflant foods and cereals.

Fumonisins

Similarly to aflatoxins and ochratoxins, fumonisins are a group of approximately 15 closely related mycotoxins. They were isolated in 1988 from cultures of *F. moniliforme*; however, several other *Fusarium* species, including *F. proliferatum* and *F. nygamoni*, are also producers. Among the six members of fumonisins, fumonisin B_1 (FB_1) is the most important as it is the most frequently occurring and potent of the group. They mostly occur in maize, with 90% of its amount produced in the field. Initially it was thought that their presence was limited to corn products, but they have also been found in lower concentrations in rice, sorghum, and navy beans. Fumonisins often occur together with other mycotoxins such as aflatoxins, ZEN, and deoxynivalenol and studies on their toxic interactions are currently under way. Crop infestation results in a disease called *Fusarium* ear rot and is the most common in the Midwest USA and around the world in both the northern and southern hemispheres. In terms of health implications, it has been associated with esophageal cancer in parts of South Africa, China, and Northeast Italy. Recently, the IARC has classified the toxins produced by *F. moniliforme* as class 2B (potential) carcinogens. No advisory level has been set in the USA nor Europe since there is insufficient evidence on its effects. However, the EC proposed a maximum daily intake of $2\,\mu g\,kg^{-1}$ body weight (based on rat studies).

Cyclopiazonic acid

Aspergillus flavus and various *Penicillium* species such as *P. cyclopium* are responsible for the production of cyclopiazonic acid, which has been detected in crops such as corn and peanuts and in several cheeses. Feeding stuffs are also commonly contaminated by cyclopiazonic acid and have been reported to coexist with aflatoxins in a range of substrates. It has been implicated in Kodua poisoning in India: this is a disease causing tremors, sleepiness, and giddiness. As a mycotoxin it is not well documented because the existing methods of analysis are not fully developed and therefore, this precludes a full assessment.

Moniliformin

Moniliformin is a mycotoxin which is produced by a number of *Fusarium* species, including *F. moniliforme, F. chlamydosporus, F. anthophilum*, and *F. proliferatum*. Only a limited number of surveys have shown that it is a frequent contaminant of maize and at low levels. It has also been reported to occur in wheat and rice and limited information exists about its stability during processing. In humans, a possible link between moniliformin ingestion and Keshan disease (a chronic heart condition) in certain areas of China has been suggested. Therefore, it has been recommended that food monitoring will continue to collect data on its frequency and levels of occurrence.

Sterigmatocystin

Sterigmatocystin was first isolated in 1957 from a mycelial mass of *A. versicolor* but *A. nidulans* is also known to produce it. AFB_1 has a very similar structure to sterigmatocystin and it is thought that it may be derived from it. With the same thought in mind, it is not accidental that sterigmatocystin has

been found in samples of pistachio nuts, pecans, wheat, and green coffee beans as well as reported in processed foods. Reports claim that its occurrence is not as frequent as aflatoxins, but this may be due to the lack of sensitive methods for its detection.

Citrinin

Citrinin was first recognized as a promising antibiotic but it was later found to cause kidney damage, retard growth, and eventually cause death in animals. Citrinin was isolated in the 1930s and produced by *Penicillium citrinum*; however, *P. verrucosum* is also known to produce the toxin. It is known as the yellow-rice toxin discovered in Japan in 1950–60, when hundreds of tonnes of rice imported from various parts of Asia were declared unfit for consumption. It was found in cereal products in parts of Europe, north America, and Canada and in maize samples from South-east Asia. A survey in Denmark detected both citrinin and OTA in barley samples and it is usually a cocontaminant with OTA, causing damage to the kidneys.

Penicillic acid

Penicillic acid was first isolated in 1913 from a moldy corn culture and has never been found in processed foods as it is an unstable compound. Penicillic acid is produced by *Penicillium* genera and is usually found in apples, corn, and beans at moderate incidence. Additional fungal species that occur during storage are able to produce substantial amounts.

Miscellaneous

There are many other mycotoxins that have been known to occur in foods and feeds; however, more work is required to establish their occurrence pattern and implications involved. Names of some mycotoxins are: alternaria toxins, aspergillic acid, kojic acid, ergotoxins, rubratoxins, the group of tremorgenic mycotoxins, and many more.

Determination

Once mycotoxins are formed, they are difficult to eliminate and being able to detect them is very important to ensure consumer protection. Their levels can vary from mg to pg levels, therefore, identification and quantitation at such low levels are challenges for the chemist. Since their discovery, a large number of methods have been developed by scientists and some have been used more extensively than others as their diversity varies depending on their physical and chemical properties. The methods used for the identification and quantitation of mycotoxins must be sensitive, specific, and as simple as possible. The presence of mycotoxins in their natural substrate is extremely unhomogeneous, therefore, it is critical that a representative sample is selected to avoid obtaining false results. Since sampling comprises the highest source of variation in the analytical procedures, a large number of random samples must be taken from a lot of commodity using the appropriate device. Although it is not always feasible and

Table 2 The most common methods used for the analysis of various mycotoxins

Mycotoxin	*Extraction solvents*	*Clean-up*	*Detection method*		*Approval status*
			Immunoassays	*Chemical*	
Aflatoxins	Me, AN, W, DiClMt, Ac	IAC	ELISA	HPLC	AOAC

economical to obtain a large number of samples, a balance between sampling variation and costs should be maintained.

Once appropriate sampling has taken place, the mycotoxins are isolated from their substrate by extraction. Several aqueous, organic solvents or mixtures of them with water and/or acid are used to assist the partition of the toxin in the solvent. Such solvents include methanol, acetonitrile, chloroform, dichloromethane, ethyl acetate and many others, shown in Table 2. The extract obtained is then cleaned up by various types of columns, which remove potential interfering compounds. This is a crucial step as the level of sensitivity depends on how clean the sample is. Immunoaffinity columns (IACs) are the most common clean-up and concentration systems used because they are simple and easy to use and the fact that the analysis is fully automated makes them amenable to a large number of samples. They are coupled with specific antibodies developed for the target mycotoxin and, when the extract is passed through the IAC, the toxin is bound and is then eluted with the appropriate solvents. The eluate is then ready for analysis either by a chemical or immuno-based method. Other clean up columns include MycoSep, fluorosil, C_{18}, and celite.

After clean-up, the sample will be subjected to analysis to identify and quantitate the mycotoxins present. The method used for this purpose depends on the chemical properties of the mycotoxin, as separation of the contaminants must take place prior to their quantitation. Thin-layer chromatography (TLC) was one of the first and most widely used chemical methods for mycotoxin analysis and relied on the fluorescent properties of the mycotoxin because the color produced and its intensity reflect the concentration of the toxin. Although TLC is a powerful tool in mycotoxin analysis, the data obtained are considered to be presumptive as they roughly estimate the quantity of the toxin and as a consequence further confirmation is required. High-performance liquid chromatography (HPLC), on the other hand, is considered a more sophisticated and sensitive technique which can provide information regarding the identity and quantity of a compound simultaneously. It is also possible to increase the fluorescence of a compound by derivatization, increasing the sensitivity of the method. Identification of the toxin is made by comparison of the retention time with a standard and its quantity determined by the absorbance value as well as the area of the elution peak. Therefore, HPLC has replaced TLC and is now the officially approved method of testing by the Association of Official and Analytical Chemists (AOAC). Even though HPLC is more extensively used, it suffers the disadvantages that it can only run one sample at a time and the samples to be tested have to be clean to achieve the required sensitivity. In addition to other methods, gas chromatography (GC) is commonly used for mycotoxins that do not have chromophores and fluorescent groups. It is considered one of the most effective methods for the analysis of trichothecenes and ZEN but the extract must be derivatized prior to analysis. Derivatization may differ depending on the detection method used, for example, acylation agents are used when flame ionization detection (FID) is used and trifluoroacetyl (TFA) esters are made when an electron capture detector (ECD) is used. Confirmation of the mycotoxin identified by GC is usually done by mass spectrometry (MS).

In order to overcome the problems encountered with the chemical methods, efforts to develop immunoassays have been made over the past 25 years. Antibody-based bioassays such as enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA) are constantly under development and are being used for a number of mycotoxins. When compared with chemical methods, ELISA is more sensitive, requires smaller volumes of sample, and is more rapid, as a large number of samples can be processed on the same ELISA plate. A larger number of antibodies (monoclonal and polyclonal) exist and the efforts to develop new ones are ongoing. The only problem with ELISA assays is that the results obtained are usually semiquantitative and they can roughly estimate the quantity of the contaminant. Therefore, it must be used in conjunction with a quantitative method (such as HPLC) for confirmation. Table 2 gives a summary of the most commonly used reagents and methods for the analysis of mycotoxins.

Toxicology

F S Chu, University of Wisconsin, Madison, WI, USA

Introduction

Developments in the last three decades have revealed many new mycotoxins that are potentially hazardous to human and animals. In considering their toxic effects, it is important to distinguish between 'mycotoxicosis' and 'mycosis.' Mycotoxicosis is used to describe the toxic action of mycotoxin(s) and is frequently mediated through a number of organs, notably the liver, kidney, and lungs, and the nervous, endocrine, and immune systems. Part of the name of the toxin or commodity involved is generally used to describe mycotoxicosis. For example, 'aflatoxicosis' generally refers to the toxicosis having typical clinical and pathological symptoms associated with the ingestion of aflatoxins. 'Mycosis,' however, refers to a generalized invasion of living tissue(s) by growing fungi.

Owing to their diverse chemical structures, mycotoxins may exhibit a number of biological effects, including both acute and chronic toxic effects as well as carcinogenic, mutagenic/genotoxic, teratogenic, and immunotoxic effects. Their toxic effects are often organ-specific. Once mycotoxins are ingested in the body, the toxins may either directly react with the target organs to exert toxic effects or be metabolized to an active intermediate (activated) and then exert their toxic effects. The toxins and their metabolites may also be detoxified and excreted. Thus, factors such as species, age, nutrition, and hormone status, etc. that affect the metabolism of mycotoxins, can also manifest mycotoxin toxicity. As will be shown below, the interaction of mycotoxins, either activated through metabolism or as intact molecules, with cellular macromolecules plays a dominant role in their toxic actions. Modulation of the immunosystem also plays an important role for the overall toxic effects, and mycotoxins can be either immunosuppressive (most often) or immunostimulatory. Recent studies on the effect of mycotoxin on apoptosis further revealed their mode of action at the cellular level. Owing to the large body of literature on mycotoxins that has accumulated over the years, this chapter will focus only on the toxic effects of selected mycotoxins (see **Table 1**) that are the most frequent contaminants in foods and feed. The mode of their toxic action will also be highlighted.

Historical Considerations

The mycotoxin problem is actually an old problem. Two classical examples, i.e., ergotism and mushroom poisons, have been known for centuries. Outbreaks of other types of mycotoxicoses have also been recorded. Because intoxications by ergots and poisonous mushrooms are a result of ingestion of a fungal body containing toxic metabolites, these two types of poisons are excluded from the most modern discussion on mycotoxins. Nevertheless, ergots and poisonous mushrooms still can be unintentionally introduced into food chains in the modern days. For a historical point of view, the toxicology of ergotism and one of the mycotoxicoses that occurred in World War II are briefly reviewed here.

Ergotism

Ergotism is a human disease that results from consumption of the ergot body in rye or other grains infected by a parasitic fungus of the genus *Claviceps*. Two types of ergotisms have been documented. In the 'convulsive' type, the affected persons have general convulsions and a tingling sensation in the muscles (such as the feeling of one's foot going to sleep), and sometimes, the entire body is racked by spasms. Epidemics occurred between 1581 and 1928 in European and other countries. Although it has been suggested that the consumption of ergots that cause convulsive ergotism may play a role in 'Salem Witchcraft' incidence, this is still a controversial issue. In the 'gangrenous' type, the affected parts became swollen and inflamed with violent, burning pains, hence, the term 'Fire of St. Anthony.' The affected area became numb first, turned black, then shrank, and finally became mummified and dry. Outbreaks occurred from the Middle Ages up to the nineteenth century. In some areas of France, grain contained as much as 25% ergots. Patients died as a result of consumption of

Table 1 Toxicological effects of selected commonly occurring mycotoxins[a]

Major mycotoxins	*Toxicological effect*[a]	*Mode of action*
Alternaria (AAL) mycotoxins	A, Hr, M	Inhibition of ceramide synthase
Aflatoxin B1 (AF) and other aflatoxins	A, C, H, I, M, T	Form DNA adducts and mutate p53 tumor suppressor gene
Citrinin (CT)	C(?) Nh, M	Inhibition of protein synthesis
Cyclopiazonic acid (CPA)	Cv, I, M, Nr,	Alteration of Ca^{2+} hemostasis and inhibition of Ca^{2+}-dependent ATPase
Deoxynivalenol (DON)	I, Nr	Inhibition of protein synthesis
Cyclochlorotine (CC)	A, C, H,	Binding with DNA
Fumonisins (FM)	A, C, Cv, H, Nr, R	Disruption of sphingolipid metabolism by inhibiting ceramide synthase
Luteoskyrin (LT)	A, C, H, M	Binding with DNA
Moniliformin (MN)	Cv, Nr	Binding with pyruvate dehydrogenase and affecting TCA cycle enzymes
Ochratoxin A (OTA)	A, I, Nh, T	Inhibition of protein synthesis and several enzymes; enhancement of lipid peroxidation; impaired cellular Ca^{2+} and cAMP homeostasis
Patulin (PT)	C(?), Nr, D, T	Inhibition of -SH enzymes
Penicillic acid (PA)	C(?), Nr, M	Inhibition of -SH enzymes
Rubratoxin B (RB)	A, H, T	Inhibition of protein synthesis
Sterigmatocystin (ST)	H, C, M	Same as aflatoxin
T-2	A, ATA, Cv, D, I, T	Inhibition of protein synthesis, binding with peptidyl transferase, membrane proteins and other enzymes
12–13, Epoxy-trichothecenes (TCTC) other than T-2 and DON	A, D, I, Nr	Same as T-2 toxin
Tenuazonic acid	Hr	Inhibition of protein synthesis
Tremorgenic toxins	Nr	Binding and inhibition of acetylcholinesterase
Zearalenone (ZE)	G, M	Binding with estrogen receptor

[a]Letters in parentheses are the abbreviations for the mycotoxin's name used throughout the text. A, apoptosis, ATA, alimentary toxic leukemia; C, carcinogenic; C(?), carcinogenic effect is still questionable; Cv, cardiovascular lesion; D, dermatoxin; G, genitotoxin and estrogenic effects; H, hepatotoxic; Hr, hemorrhagic; I, immunomodulation effects, M, mutagenic, Nh, nephrotoxin; Nr, neurotoxins; R, respiratory; T, teratogenic. From CAST (1989) *Mycotoxins, Economic and Health Risks*. Task Force Report No. 116. Ames, IA: Council of Agricultural Sciences and Technology and Chu (1998) Mycotoxins – Occurrence and toxic effects. In: Encyclopedia of Food and Nutrition – Food Contaminants, 2nd edn., pp. 858–869. New York: Academic Press.

100 g of ergot over a few days. In general, 2% ergots in the grain is sufficient to cause an epidemic. Between 1770 and 1771, about 8000 people died in one district alone in France. European and other countries have a regulatory limit of 0.1–0.2% ergots in flour. Ergotisms result from the intoxication of ergoline alkaloids that are produced by the fungus present in the sclerotia of *Claviceps purpurea*. The most active components are amides of D-lysergic acid, including both the cyclic-type peptide and nonpeptide amide of ergot alkaloids. These alkaloids cause smooth-muscle contraction, block neurohormones, have both vasoconstriction and vasodilation effects, and also affect the central nervous system. Thus, they have some therapeutic uses.

Alimentary Toxic Aleukia (ATA)

A well-documented example of mycotoxicosis in humans is the outbreak of ATA, a disease that resulted in more than 5000 deaths in humans in the Orenberg district of the former USSR during World War II. The cause of this outbreak was later determined to be trichothecene mycotoxins produced by fungi growing on grain allowed to stand in the field during winter. The toxicology of ATA will be discussed later.

Discovery of Aflatoxin

Although a number of antibiotics produced by fungi were found, in the middle of the 1940s, to be toxic to animals, renewed interest on toxic fungal metabolites only begun after the discovery of aflatoxin B1 in the early 1960s because of its highly potent carcinogenic effects to test animals, and the name of 'mycotoxin' was adopted thereafter.

Toxic Effects of Selected Mycotoxins

Aflatoxins

Since various aspects on aflatoxins have been dealt with elsewhere, the toxicology and mode of action on this groups of mycotoxins are reviewed only briefly herein.

Toxic effects Aflatoxin B1 (AFB1) is one of the most potent naturally occurring carcinogens and is the most toxic member of this group of mycotoxins. Other AFs are less toxic (B1 > G1 > B2 > G2). Although the main target organ is liver, AFB1 also affects other organs and tissues, including kidney and lungs, to a lesser degree. Typical symptoms for aflatoxicosis in animals include proliferation of the bile

duct, centrilobular necrosis and fatty infiltration of the liver, and hepatomas, in addition to generalized hepatic lesions. The susceptibility of animals to AFB1 varies considerably with species with a decrease in sensitivity (LD50: $mg\,kg^{-1}$) in the following order: rabbits (0.3), ducklings (0.34), mink (0.5–0.6), cats (0.55), pigs (6–7 kg size, 0.6), trout (0.8), dogs (1.0), guinea-pigs (1.4–2.0), sheep (2.0), monkeys (2.2), chickens (6.3), rats (5.5 for male, 17.9 female), mice (9.0), and hamsters (10.2). In addition to these acute (hepatotoxic) effects, carcinogenic effects of AFB1 is of most concern. A 10% incidence of hepatocarcinoma was observed in male Fisher rats fed a diet containing only 1 μg AFB1 per kilogram over a period of 2 years. Rats, rainbow trout, monkey, and ducks are most susceptible, but mice are relatively resistant to AFB1. Because of their presence in foods and strong evidence of their association with human carcinogenesis, aflatoxins are still a serious threat to human health, even after more than 40 years of research. Consumption of AFB1-contaminated feed by dairy cows results in the excretion of AFM1 in milk. AFM1, a hydroxylated metabolite of AFB1, is about 10 times less toxic than AFB1, but its presence in milk is of concern for human health.

Immunotoxic effects Animals fed with AFB1 are more susceptible to infection. While AFB1 primarily affects cell-mediated immunity (CMI) and phagocytic cells, it also reduces/suppresses delayed hypersensitivity (DH). For example, suppression of DH to keyhole limpet hemocyanin and a decrease in splenic CD4 cell (T-helper cells) and IL-2 were found in CD-1 and C57B/16 mice fed with AFB1.

Mode of action AFB1 must first be activated by mixed-function oxidases, more specifically cytochrome P450 1A2 and 3A4, to a putative short-lived AFB-8, 9-*exo*-epoxide before exerting its carcinogenic effects. The activated intermediate either can be converted to hydroxylated metabolites, conjugated to glutathione or glucuronic acid, etc. and then be excreted, or it can bind to DNA, RNA, and protein to exert its toxic, carcinogenic, and mutagenic effects. Adduct formation of this intermediate with DNA occurs thorough nucleophilic attack primarily at the N-7 guanine position, which then involves G–C to T–A or to A–T nucleotide substitutions and causes mutations.

Aflatoxin-induced G:C mutations, both G to T and G to A, have been implicated in the inactivation of the human *p53* tumor suppressor gene, and a high frequency of mutations has been found at the third position of codon 249 of *p53*. The prevalence of codon 249 mutation, i.e., AGG to AGT (Arg to Ser) was found to be around 50% in human primary hepatocellular carcinoma (PHC). In contrast, the prevalence of such mutations is low in nonPHC patients. The identification of mutations/inactivation of p53 at this site has been used as a biomarker for AFB-induced liver cancers in humans.

The role of the covalent interaction between AFB and specific enzymes/proteins is less clear. Several aflatoxin metabolites do interact with enzymes and proteins. Both aflatoxins B2a and G2a, which are very reactive with proteins through formation of Schiff's bases between the dialdehyde groups in AFB2a and the $-NH_2$ groups of proteins, have been shown to be very effective inhibitors of DNase *in vitro*. The activated AFB1 and AFG1 also react with albumin to form albumin adducts through the same Schiff-base mechanism, followed by Amadori rearrangement and subsequent condensation with another aldehyde group. The presence of this adduct in human serum has been used as an index of human exposure to AFs.

Aflatoxins B1 and G1 also bind with serum albumin, nucleic acid, and proteins such as lysine-rich histone and chromatin noncovalently. Aflatoxicol, a major AFB metabolite, interacts with estrogenic receptors. Although the role of such interaction was not clearly defined, NMR analysis of the binding of AFB1 and AFG1 with double-stranded $d(ATGCAT)_2$ or $d(GCATGC)_2$ and B-DNA and gel-shift analysis of the binding of both mycotoxins with plasmid pBR322 revealed that intercalation of aflatoxins between the base pair was involved. Intercalation of stable epoxide-AFB1 with these nucleotides has also been demonstrated. These data suggest that intercalation may be significant for subsequent covalent attachment of the carcinogen at the N7 position of guanine in DNA. The activity of several enzymes, such as deoxyribonuclease and RNA polymerase, is inhibited by AFB1, but these inhibitory effects are secondary. Recent data also showed that oxidative DNA damage is involved in the genotoxicity of AFB.

Apoptosis (APT) Induction of apoptosis by AFB has been observed in several cell systems. In the HL-60 human promyelocytic leukemia cells, the dose of AFB1 needed for induction of APT by AFB1 was considerably higher ($1–20\,\mu g\,ml^{-1}$) than those needed by trichothecene mycotoxins ($0.001–0.2\,\mu g\,ml^{-1}$). Such an effect was attributed to their inhibitory effect on RNA synthesis as a result of its binding with DNA and the inhibitory effect of DNA-dependent RNA polymerase.

Aflatoxin and human carcinogenesis Whereas AFB1 has been found to be a potent carcinogen in many

animal species, the role of AF in carcinogenesis in humans is complicated by hepatitis B virus (HBV) infections in humans. Epidemiological studies have shown a strong positive correlation between AF levels in the diet and PHC incidence in some parts of the world (China, Kenya, Mozambique, Philippines, Swaziland, Thailand and Transkei of South Africa). Aflatoxin–DNA and AF–albumin adducts, two of the major biomarkers for human exposure to AFB, as well as several AF metabolites, mainly AFM1, have been detected in serum, milk, and urine of humans in these regions. However, the prevalence of HBV infection is also correlated to liver cancer incidence in these regions and HBV in humans. Data on the enhancement of mutation of the *p53* gene suggest a synergistic effect of these two risk factors for PHC in humans. (*See* **Aflatoxins**; **Cancer**: Carcinogens in the Food Chain.)

Ochratoxins

Toxic effects Ochratoxin A (OA), the most toxic member (LD50 about 20–25 mg kg^{-1}) and also most commonly found toxin in this group, is a potent nephrotoxin causing kidney damage, including degeneration of the proximal tubule, in many animal species. Liver necrosis and enteritis were also observed. Other than acute toxic effects, OA also acts as an immunosuppressor and teratogen. Although OA has never been shown to be mutagenic, a weak genotoxic effect has been demonstrated in several systems. Ochratoxin A is only a weak nephrocarcinogen because a high level of toxin and an extended period of exposure are necessary to induce the tumors. A dose-related induction of renal tubular cell tumors was found in Fisher rats (F344/N) with a significant increase in renal tubular cell tumors at levels of 70 and 210 μg of OA per kg of body weight per day; but cancer incidence was not significantly different from the control at lower levels (21 μg of OA per kg of body weight per day). Recent studies showed that OA also causes liver cancer in rats.

Modulation of immune system Animals receiving OA show general immunotoxic signs, including lymphocytopenia and depletion of lymphoid cells, especially in the thymus, bursa of Fabricius and Peyer's patches. Increased counts of total leukocytes and neutrophils in the blood with reduced lymphocyte levels were observed in the weaner pigs receiving OA. A striking increase in the counts of eosinophils and of apoptotic phagocytes was also found. Depressed humoral immune responses, including lower serum IgM and IgG levels and suppressed antibody response to SRBC and other antigens in mice, have been observed in animals fed or injected with OA. DH was also suppressed. The immunosuppressive effects of OA were prevented by phenylalanine both *in vitro* and *in vivo*. OA also stimulates cytokine production with increase in IL-2 nd IL-5 in the EL4.IL-2 cell system.

Mode of action The mode of the toxic effect of OA is not as clearly defined as those of AFB. OA inhibits several enzymes, including phenylalanine hydroxylase, phenylalanine-tRNA synthetase and renal phosphoenolpyruvate carboxykinase, which may play a role in its toxic effects. The synthesis of the latter two enzymes was found to be inhibited by OA. In addition, it is also a strong inhibitor for carboxypeptidase A. Enhancement of lipid peroxidation is considered as one of the manifestations of cellular damage in OA toxicity. The induction of free radicals in a bacterial model system by OA was found to be regulated by Ca^{2+} ions. Superoxide dismutase and catalase have been shown to have some protective effect for OA-induced nephrotoxicity in rats. OA-induced lipid peroxidation in the Vero cell was also found to be decreased in the presence of these two enzymes, but the effects of aspartame and piroxcam were less pronounced. In the renal epithelial cells, OA interferes with hormonal Ca^{2+} signaling, leading to altered cell proliferation. Thus, OA may impair cellular Ca^{2+} cyclic AMP (cAMP) homeostasis.

Ochratoxin A binds strongly with serum albumin; thus, the toxin has a long half-life in animal (35 days with a single dose of OA) and human bodies. Such an interaction has not only played a significant role in the toxic effect of this mycotoxin because of its heterogenous body distribution, but also been used as a biomarker for human exposure of OA. Although OA has been found to bind to several proteins and enzymes noncovalently, administration of labeled OA to rats showed no covalent binding of OA to DNA of kidney and liver. Using the P-32 postlabeling technique, however, OA–DNA adducts were found in kidney, liver, and several other organs of mice and rats with OA. Such adducts may be due to the products derived from OA-mediated cytotoxicity. OA induces unscheduled DNA synthesis in cell cultures *in vitro*.

Apoptosis OA induces APT in lymphocytes and several other cell systems. The apoptotic effect was attributed to its inhibition of protein synthesis. Specific cell types with distinct members of the mitogen-activated protein kinase family were involved in the APT at OA concentrations at which no acute toxic effect can be observed. Induction of apoptosis via the c-jun amino-terminal-kinase pathway can explain some of the OA-induced changes in renal function

as well as part of its teratogenic action. Exposure of human proximal tubule-derived cells and renal epithelial cell lines to low OA concentrations can lead to direct or indirect caspase 3 activation and, subsequently, apoptosis. (*See* **Immunology of Food**.)

Ochratoxin A and human health Ochratoxin A has long been considered to be associated with the nephropathy of people residing in certain areas of Tunisia, Scandinavia, and the Balkan regions, where exposure may be 'endemic.' The pathological lesions of nephropathy in humans are similar to those observed in endemic porcine nephropathy, which is due to the consumption of feeds contaminated with OA. Since a high proportion of the patients suffering from endemic nephropathy in the Balkan region develop tumors of the renal pelvis and ureter, the possible involvement of nephropathy in tumor development was suggested. Ochratoxin A has been found in human serum in Tunisia and several European countries, including Bulgaria, Poland, Yugoslavia, and Germany. In certain areas of the Balkans and Tunisia, OA levels in the foods and in human serum in endemic regions are higher than in the nonendemic areas. OA also has been found in human milk and kidneys in some endemic regions.

Human exposure to OA could occur through consumption of OA-containing cereals or animal foods. The mean daily intake of OA by humans in European Union member countries, as calculated from data on OA levels in foods and in human bloods, was estimated to be 1.8 ng of OA kg^{-1} (range: 0.7–4.7) and 0.9 ng kg^{-1} (range: 0.2–2.4), respectively. The main dietary sources (55%) were from cereals and cereal products (0.2–1.6 μg kg^{-1}). Thus, the EU Committee for Food has recommended that the OA daily intake in humans should be below 5 ng kg^{-1}. Coffee (mean level 0.8 μg kg^{-1}), beer, pig meat, blood products, and pulses also contribute to the OA intake in humans. These findings reemphasize the possible involvement of OA in human carcinogenesis and the health hazard of exposure to OA in humans. Among 77 countries that have regulations for different mycotoxins, eight have specific regulations for OA, with limits ranging from 1 to 20 μg kg^{-1} in different foods.

Fumonisin (Fm)

Toxicologic effects Although FmB1 was originally found to be a potent cancer promoter, it is now recognized as a carcinogen. It is primarily a hepatotoxin and carcinogen. Feeding the toxin to rats has resulted in cirrhosis and hepatic nodules, adenofibrosis, hepatocellular carcinoma-ductular carcinoma, and cholangiocarcioma. In addition to liver, lesions were also observed in kidney, including renal carcinoma. Tubular nephrosis was found both in rats and in horses of field cases associated with equine leukoencephalomalacia (ELEM). The effective dose of FmB1 for cancer initiation in rat liver depended on both the level and duration of exposure. All of the three major Fms, i.e., FmB1, FmB2, and FmB3, show cancer initiation and promoting activities in rats. In cell-culture systems, FmB1 has been found to be a mitogen, cytotoxic to the cells, and can alter the expression of genes associated with the cell cycle. It induces *in vivo* genotoxicity, but has no mutagenic effect in the *Salmonella* system.

FmB1 was identified as an etiological agent responsible for ELEM in horses and other Equidae (donkeys and ponies), and for porcine pulmonary edema (PPE) in pigs. ELEM was originally found to be a seasonal disease occurring in late fall and early spring. The disease primarily causes neurotoxic effects in animals, including uncoordinated movements and apparent blindness. Liver damage has also been reported. Death sometimes occurs with no nervous symptoms. Clinically, the disease is characterized by edema in the cerebrum of the brain. The levels of FmB1 and FmB2 in feeds associated with confirmed cases of ELEM range from 1.3 to 27 p.p.m. In pigs, PPE occurs only at high FmB levels (175 p.p.m.), whereas liver damage occurs at much lower concentrations with a no observable adverse effect level (NOAEL) of < 12 p.p.m. Cardiovascular function is altered by FmB1. The FmB1-induced PPE is caused by left-sided heart failure, and not by altered endothelial permeability. In the cattle, renal injury, hepatic lesions, and alteration of sphingolipid in various organs were observed. The level causing disease in poultry is also high. Fms are also toxic to some plants: jimsonweed, black nightshade, duckweeds and tomatoes with the *asc/asc* genotype being most susceptible.

Mode of action The primary effect of FmB1 is due to its disruption of sphingolipid metabolism by inhibiting the enzyme sphinganine (sphingosine) *N*-acyltransferase (ceramide synthase). Because complex sphingolipids and ceramides are heavily involved in cellular regulation, including cell differentiation, mitogenesis, and apoptosis, such effects play an important role in the early phase of most of the diseases discussed above. The target organs may be very sensitive to the sphingolipid dysregulation. Because sphingolipids are natural inhibitors of Ca^{2+}-activated-protein kinase C (PKC), it has been suggested that FmB may affect PKC-regulated functions. A direct interaction of diacylglycerol binding site of PKC to phorbol esters, which are well-known tumor promotors, by FmB1 has been observed. The

alteration of sphingolipid metabolism results in a dramatic increase in the free sphingolipid bases, i.e., sphinganine (Sa) and sphingosine (So), in tissues and a decrease in complex sphingolipid levels. Significant increases in the So/Sa ratio were found in serum of pigs fed a diet containing as little as 5 p.p.m. of total FmB. Thus, Sa/So ratios in serum and urine are now being used in testing as an early biomarker of FmB exposure in animals and humans. FmB1 disrupts ω-6 fatty acid metabolic pathway and/or prostaglandin synthesis; such an effect is likely to be an important event in the mitoinhibitory effect of FmB1 on growth-factor responses. FmB1 was also found to inhibit the cytochrome P-450 enzyme selectively with most significant effect on CYP2C11. Such inhibition was considered to be due to a suppressed activity of protein kinase activity resulting from the inhibition of sphingolipid biosynthesis.

Apoptosis Whereas the role of FmB1 on immunosystem is not entirely clear, the effect of FmB1 on apoptosis in many cell lines has been extensively studied. Immune cells are one type of target cell. For example, an increase in nitric oxide and prostaglandin E-2 production was found when a murine macrophage cell line was grown in the presence of FmB1. The kidney, liver, and tomato cells, and other animal or plant cells treated with FmB or TA (one of the major AAL toxins), showed typical apoptotic characters with the degree of injury being related to the dose and time of exposure. The fundamental elements of apoptosis, as characterized in animals, are conserved in plants. Inhibition of the ceramide synthase by FmB and related mycotoxins are considered to play a key role in the apoptosis of the cells of the target organs/tissues. FmB1 diminished the cytotoxic effects of the lipids on esophageal tumor cells. The marked apoptosis induced by PGA2 and the PG2- and AA-induced p53 levels were lowered. It repressed specific isoforms of protein kinase C and cyclin-dependent kinase activity and induced expression of CDK inhibitors in monkey kidney cells (CV-1). Such effects lead to cell-cycle arrest and apoptosis. Eight genes induced by FmB1 have been identified. The ability of FmB1 to alter gene expression and signal transduction pathways are considered to be necessary for its carcinogenic and toxic effects. Since FmB1 is not genotoxic in bacterial mutagenesis screens and does not affect unscheduled DNA synthesis, the apoptotic necrosis, atrophy, and consequent regeneration may play an essential role in its carcinogenic effects. FmB1 may be the first example of an apparently nongenotoxic (nonDNA-reactive) agent producing tumors through such a mechanism.

Impact on human and animal health While Fms are commonly detected in corn-based foods and feeds, the impact of low levels of Fms in human foods is not known. Current data suggest that they may have more impact on the health of farm animals than on humans. Thus, the Mycotoxin Committee of the American Association of Veterinary Laboratory Diagnostics recommends that the FmB1 levels be limited to 5, 10, 50, and 50 p.p.m. for feeds to be used for horses, swine, beef cattle, and poultry, respectively. Several reports indicated that significantly higher levels of Fms, sometimes together with AFs, trichothecene mycotoxins, and carcinogenic nitrosamines, were present in corn samples collected from areas with high rates of human esophageal cancer. Thus, FmB1 in combination with several other etiological agents may play an important role in carcinogenesis in humans. Currently, only Switzerland regulates the Fm level (1.0 p.p.m.) in foods.

Selected Important Trichothecene (TCTC) Mycotoxins

General consideration of toxic effects The structural diversity of TCTC mycotoxins results in different toxic effects in animals and humans. Unlike AFB1, OA, and Fm, where the primary effects and clinical manifestations are well defined, TCTC mycotoxicoses are difficult to distinguish because they affect many organs, including the gastrointestinal tract, hematopoietic, nervous, immune, hepatobiliary, and cardiovascular systems. Ingestion of foods and feeds that contain TCTC mycotoxins cause many types of mycotoxicoses in humans and animals, including moldy corn toxicosis, scabby wheat toxicosis (red-mold, akakbi-byo disease, or scabby barley poisoning), feed refusal and emetic syndrome (swine), fusaritoxicoses, hemorrhagic syndrome, and alimentary toxic aleukia (ATA). More than 100 TCTC have been identified in the laboratory; only a few selected toxins that have been found in foods are described herein.

T-2 toxin and other type A TCTCs Although T-2 toxin occurs naturally in cereal grains, contamination with T-2 toxin is less frequent than with deoxynivalenol (DON). However, T-2 toxin (LD50 in mice: 2–4 mg kg^{-1}) is much more toxic to animals, perhaps also to humans, than DON (LD50 in mice: 50–70 mg kg^{-1}). Almost all the major TCTCs, including T-2 toxin, are cytotoxic and cause hemorrhage, edema, and necrosis of skin tissues. Inflammatory reactions near the nose and mouth of animals are similar to some lesions found in humans suffering from ATA disease. The severity of lesions is also related to chemical structure. Macrocyclic toxins such as verrucarin

A are most active, followed by group A toxins (T-2 toxin), and least with type B toxins, such as nivalenol. Neurologic dysfunctions, including emesis, tachycardia, diarrhea, refusal of feed/anorexia, and depression, were also observed. T-2 toxin and some TCTCs also induce major GI lesions, including perioral dermatitis, stomatitis, esophagitis, gastritis, radiomimetic lesions, and sometimes hemorrhage in the intestines. However, the major lesion of T-2 toxin is its devastating effect on the hematopoietic system in many mammals, including humans. Typically, there is a marked initial increase in the number of circulating white blood cells, especially lymphocytes, followed by a rapid decrease to 10–75% of normal values. Platelet counts are also reduced. There is also extensive cellular damage in the bone marrow, intestines, spleen, and lymph nodes, and in severe cases, complete atrophy of bone marrow and marked alteration of plasma coagulation factors. T-2 toxin and related TCTCs are the most potent immunosuppressants of the known mycotoxins and cause significant lesions in lymph nodes, spleens, thymus, and the bursa of Fabricus. The heart and pancreas are other target organs for T-2 toxin intoxication. Although urinary and hepatobiliary lesions have been observed for T-2 toxin and diacetoxyscirpenol (DAS), these effects are considered to be secondary.

Deoxynivalenol (DON) Deoxynivalenol, a major type B TCTC, causes feed refusal and emesis in swine; the name 'vomitoxin' is also used. Although DON is considerably less toxic than most other TCTC mycotoxins, the level of contamination of DON in corn and wheat is generally high (usually above 1 p.p.m., sometimes greater than 20 p.p.m.). Contamination of DON in the cereal grains is also world-wide. Toxicologically, DON induces anorexia and emesis in both humans and animals. Swine are most sensitive to feed contaminated with DON. Because of the frequent occurrence of high levels of DON in wheat and corn, its stability, and reported food poisoning outbreaks in humans, contamination of cereals with DON is a major concern of both the government and food and feed industries. Contamination of DON in wheat and corn may be associated with other toxic effects because other *Fusarium* toxins, including zearalenone and other TCTCs may be present also. Other type B TCTCs such as nivalenol and acetylated-DON are more toxic than DON to test animals.

Modulation of immune systems Because TCTC mycotoxins such as T-2 toxin exert a major toxic effect on the bone marrow, lymph nodes, thymus, and spleen in mammals, modulation of the immune system by this group of mycotoxins has been studied most extensively.

Effects on humoral immune response Trichothecenes have been shown to have a marked effect on humoral immunity. Administration of T-2 toxin and DAS to animals results in a reduction of their resistance to infection and a decrease in antibody formation. T-2 toxin may selectively affect subpopulations of T-suppressor cells or their precursors, and this suppression of antibody synthesis may be due to impairment of either antibody-forming or T-helper cell activities. Immunosuppressive effects have also been observed for other TCTCs, including the macrocyclic types. Mice fed a diet containing more than 10 p.p.m. of DON experienced atrophy of the thymus and other structural changes, decreased antibody formation, as well as suppressed B- and T-cell proliferation. However, DON is one TCTC that has both immune stimulation and suppression effects in experimental animals. Serum and saliva immunoglobulin (Ig) A was significantly increased in mice fed with high levels (25 p.p.m.) of DON, whereas serum IgM and IgG decreased. The increased IgA production is related to IgA-mediated nephropathy in mice; thus, it was postulated that DON might be one of the etiologic agents in IgA nephropathy, which is the most common glomerulonephritis in humans world-wide.

Cell-mediated immunity Lymphocyte proliferation is inhibited *in vitro* by T-2 toxin and DAS. Although the response of both T- and B-cells to mitogens was inhibited, the T-cell response was more sensitive. There is a stimulating effect due to a low concentration of T-2 toxin. Structure–activity studies showed that T-2, HT-2, and 3′-OH T-2 toxins were most effective in inhibiting proliferation of mitogen-stimulated human lymphocytes, whereas 3′-OH HT-2, T-2 triol, and T-2 tetraol toxins were 50–100 times less effective. The macrocyclic TCTCs, roridin, and verrucarin A, were 75–100 times more potent than the T-2 toxin. The differences in the immunotoxic effects of various TCTCs were attributed to the differences in both the uptake and metabolism of toxins by the cells. Interleukin-1 and 2 (IL-1, 2) production in spleen cell cultures was stimulated by trace amounts of TCTC. Hyperinduction of cytokines in T-helper cells by DON (most) as well as several other mycotoxins (cyclopiazonic acid, OA, and alpha-zearalenol) has been found, but patulin and T-2 toxin were inhibitory. Induction of expression of mRNA of ILs-2, 4, 5, 6 in a T-cell model EL4.IL-2 by DON was found at levels required for partial or maximal protein synthesis inhibition.

A single oral gavage with DON is sufficient to induce IL-1 beta, IL-2, IL-6, TNF α mRNA levels in Peyer's patches and spleen. The effect in IL-6-deficient mice was refractory to DON-induced dysregulation of IgA production and development of IgA nephropathy. TCTC-induced cytokine superinduction could lead to the terminal differentiation of immunoglobulin-secreting cells via T-cell-mediated polyclonal differentiation of B-cells or its precursors. The Peyer's patch might be particularly sensitive to such dysregulation.

Rather than suppression, an apparent increase in DH by T-2 toxin was found when the toxin was administered within a few days after the mice were sensitized with sheep red blood cells. The toxin treatment caused a marked decline in the cell population of the thymus. Thus, T-2 toxin may interfere with the generation of suppressor cells. Pretreatment of animals with either T-2 toxin or DAS was also found to prolong skin-graft survival time.

Mode of action

TCTCs are potent protein synthesis inhibitors Although a number of mycotoxins, including AFB1, OA, citrinin, PR-toxin, and tenuazonic acid (TzA), inhibit protein synthesis, most of these effects are secondary. For example, AFB1 inhibits protein synthesis at the transcriptional level. Inhibition of protein synthesis, however, is one of the early events in the manifestation of toxic effects of TCTC mycotoxins, which act at different steps in the translation process. The potency of inhibition varies considerably with the chemical structure of the side-chain. In general, T-2, HT-2, NIV, FS-x, DAS, verrucarin A, and roridin A affect at the initiation step, whereas verrucarol, trichotecin, and crotocin affect elongation. Binding of TCTC with ribosomes, specifically peptidyl transferase, is a key step leading to the inhibition of protein synthesis. Inhibition of the elongation step by DAS and fusarenon X has also been demonstrated. Some of the less well-known TCTCs such as trichodermol and trichodermone affect the termination step.

Binding with membrane proteins/enzymes TCTC may have a direct effect on cells through interaction with other cellular components such as cell membranes in addition to their effects on protein synthesis. Both T-2 toxin and fusarenon X interact with a number of '–SH enzymes,' thus inhibiting their activity.

Apoptosis Several TCTCs, including roridin A, T-2 toxin, nivalenol, and DON, induce APT in HL-60 human promyeloytic leukemia cells at significantly low levels with a minimum effective dose ranging from 0.001 to 0.2 $\mu g\,ml^{-1}$. Depending on the lymphocyte set, tissue source, and glucocorticoid induction, DON can either inhibit or enhance apoptosis in murine T, B, and IgA cells. Whereas suppression of protein synthesis was considered the mechanism for induction of APT by TCTC, a later study showed that the T-2-induced apoptosis was mediated by the elevation of Ca^{2+} ion levels. Epidermal cells developed apoptosis after T-2 toxin was applied to the dorsal skin of hypotrichotic WBN/ILA-Ht rats. Such an effect was found to be associated with the induction of c-fos and perhaps also c-jun mRNAs.

Impact of TCTC on human and animal health Because of their diverse toxic effects and also because of frequent contamination by toxins or toxigenic fungi in foods and feeds, TCTCs are also potentially hazardous to human and animal health. However, among the many types of TCTC mycotoxicoses mentioned earlier, only ATA and scabby wheat toxicosis have been demonstrated in human populations. The former, ATA, was attributed to the human consumption of overwintered cereal grains colonized by *Fusarium sporotrichioides* and *F. poae*; this caused the deaths of hundreds of people in the former USSR between 1942 and 1947. Later studies indicated that T-2 toxin and related TCTCs were the primary cause. The signs and symptoms of ATA disease, which include skin inflammation, vomiting, damage to hematopoietic tissues, leukocytosis, and leukopenia, are common in humans and animals, including cats, cattle, guinea-pigs, poultry, monkeys, and swine.

Deoxynivalenol has been found to be primarily responsible for outbreaks of scabby wheat toxicosis in humans that are quite common in several countries, but these toxicoses rarely cause death. For example, between 1961 and 1985, 35 outbreaks involving 7818 cases were found to be caused by consumption of foods made from either scabby wheat or moldy corn in China. The symptoms, which occurred within 15 min to 1 h after consumption of foods made from moldy corn meal, included: nausea (90%), emesis (61%), headache and drowsiness (78%), and 5–6% had abdominal pain, diarrhea, and a mild fever. People generally recovered 2–4 days after consumption of the foods. Analysis of the leftover moldy corn revealed that the samples had 0.34–93.8 p.p.m. of DON; no T-2 toxin or nivalenol (NIV) were found. Similar cases have been reported in people consuming scabby wheat flour.

The widespread natural occurrence of DON in wheat in Canada and the USA in the late 1970s and

early 1980s has alerted the general public to the potential hazard of this mycotoxin. The tolerable daily intakes of DON for adults and infants were estimated to be 3 and 1.5 $\mu g\,kg^{-1}$, respectively. A tolerance level of 1 p.p.m. for DON in grains for human consumption has been set by a number of countries, including the USA. In Canada, the guideline for DON in the uncleaned soft wheat used for nonstaple foods is 2 p.p.m., but 1 p.p.m. for the infant foods. Although inadequate storage may lead to the production of some TCTC mycotoxins, infestation of *Fusarium* spp. in wheat and corn in the field is of most concern for the DON problem.

TCTCs may also be involved in the so-called 'sick building syndrome' (SBS) in humans. *Stachybotrys atra* was isolated from a badly water-damaged Chicago suburban home, in which the occupants complained about headaches, sore throats, hair loss, flu symptoms, diarrhea, fatigue, dermatitis, and general malaise. Several TCTCs (verrucarins B and J, satratoxin H, trichoverrins A and B) were found in the *S. atra*-contaminated materials of this home. T-2 toxin, DAS, roridine A, and T-2 tetraol were isolated from the dust samples from the air ventilation system of another suspected sick building syndrome in three urban Montreal office buildings. *S. chartarum*, an indoor mold, has been associated with pulmonary hemorrhage cases in the Cleveland, Ohio, area. Although *Stachybotrys* spp. are consistently found in these buildings, other molds and mycotoxins might also be present. In a survey of buildings with moisture problems in Finland, scientists have identified sterigmatocystin (24%), TCTC (19%), and citrinin (4%) in 79 samples analyzed. The trichothecenes found included satratoxin G or H (five samples), DAS (five samples), and 3-acetyl-DON, DON, verrucarol, or T-2-tetraol in an additional five samples. *Aspergillus versicolor* was present in most sterigmatocystin-containing samples, and *Stachybotrys* spp. were present in the samples where satratoxins were found. Thus, it is important to identify both the mold and mycotoxins for the cause of SBS. A remediation program involving removal of all contaminated wallboard, paneling, and carpeting in the water-damaged areas of the home, as well as spraying a sodium hypochlorite to all surfaces during remediation, appeared to be effective. Air samples taken from post-remediation buildings showed no detectable levels of *S. chartarum* or related toxicity.

Other Selected Mycotoxins

Other than those mycotoxins discussed above, several naturally occurring mycotoxins with typical toxicoses may also be potentially hazardous to human and animal health.

Mycotoxins produced by *Aspergillus* other than AF and OA Sterigmatocystin (ST), structurally related to AFB1 and a precursor for biosynthesis of AFB1, is another naturally occurring hepatotoxic and carcinogenic mycotoxin. Although the carcinogenicity of ST is less than that of AFB1 in test animals (10–100 times less), this mycotoxin has been found to be mutagenic and genotoxic, and has been found in foods in certain high esophageal cancer incidence regions of China and Mozambique. Toxigenic fungi have been isolated from patients with esophageal cancer, and these strains are capable of producing ST in many commodities. Although the role of ST in human carcinogenesis appears to be indirect and inclusive, it acts mechanistically similar to AFB in carcinogenesis through the formation of DNA adducts and mutation of p53 suppressor gene. The carcinogenic effects of ST seem to be mediated by failure of p53-mediated G1 checkpoint because exposure of cells to ST resulted in failure of G1 arrest.

Aspergillus terreus and several other fungi (*A. flavus* and *A. fumigatus*) produce the tremorgenic toxins territrem A, B, and C, aflatrem, and fumitremorgin. Some of these, bound to acetylcholinesterase, cause irreversible inhibition of the enzyme. Gliotoxin, an epipolythiopiperazine-3,6-dione antibiotic containing sulfur produced by piperazines antibiotic produced by *A. terrus*, *A. fumigatus*, and *Trichoderma viride*, exerts immunosuppressive effects in animals. The toxic effect is due to its covalent binding with -SH enzymes. It induces apoptosis in spleen cells with a dose-related simultaneous increase in cAMP levels and markedly inhibits both perforin-dependent and Fas ligand-dependent cytotoxic T-lymphocyte (CTL)-mediated cytotoxicity. In addition, *A. flavus*, *A. wentii*, *A. oryzae*, and *Penicillium atraovenetum* are capable of producing nitropropionic acid (NPA), a mycotoxin causing apnea, convulsions, congestion in lungs and subcutaneous vessels, and liver damage in test animals. This toxin was also identified as an etiological agent for the 'deteriorated sugarcane poisoning (SP),' a fatal food poisoning that occurred in China. However, the fungi involved in the contamination in the sugarcane and NPA production were *Arthrinium sacchari*, *A. saccharicola* and *A. phaeospermum*.

Other mycotoxins produced by *Penicillium* Other than OA, *Penicillium* spp. produce many mycotoxins with diversified toxic effects. Cyclocholortine, luteoskyrin (LS), and rugulosin (RS) have long been considered to be possibly involved in the yellow rice disease during World War II. They are hepatotoxins and also produce hepatomas in test animals. However, incidences of food contamination with these

toxins have not been well documented. LS inhibits RNA polymerase through binding with the enzyme and also forms a three-component complex, i.e., DNA–Mg^{2+}–luteoskyrin, with DNA. LS and several related anthraquinone-type mycotoxins are capable of inducing free radicals leading to the formation of 8-hydroxydeoxyguanosine. Several other mycotoxins, including patulin (PT), penicillic acid (PA), citrinin (CT), cyclopiazonic acid (CPA), citreoviridin, and xanthomegnin, which are produced primarily by several species of *Penicillium*, have attracted some attention because of their frequent occurrence in foods. PT and PA are hepatotoxins and teratogens, but PT is not an immunotoxin. They inhibit dehydrogenases reversibly through interaction of the toxin with the -SH group in the enzyme active center. The α,β-unsaturated double bonds conjugated in lactone ring of the toxin were considered to be sites for the interaction with the –SH and $–NH_2$ groups of proteins through addition or substitution reactions. In the model systems, PT forms the same type of adducts with glutathione and *N*-acetyl-L-cysteine (NAC). However, free cysteine formed markedly different adducts, including mixed thiol/amino-type adducts involving the α $–NH_2$ group. PT–cysteine adduct(s) still have a teratogenic effect. Due to its highly reactive double bonds that readily react with –SH groups in foods, patulin is not very stable in foods containing these groups. Nevertheless, PT is considered a health hazard to humans. Many countries have regulatory limits, most commonly at a level of 50 μg kg^{-1}, for PT in various foods and juices.

Frequently associated with the natural occurrence of OA is CT, which is also a nephrotoxin. In addition to *Penicillium* and *Aspergillus* spp., a recent discovery of the ability of *Monocuus ruber* and *M. purpureus* (two molds frequently used in the preparation of certain oriental foods) to produce CT reiterated the potential health hazard of CT to human health. One of the mycotoxins closely associated with the natural occurrence of AF in peanuts is CPA, which causes hyperesthesia and convulsions as well as liver, spleen, pancreas, kidney, salivary gland, and myocardial damage. CPA alters Ca^{2+} hemostasis and induces charge alterations in plasma membranes and mitochondria. The reversible inhibition of reticulum Ca^{2+}-dependent ATPase is the primary cause of this effect. *Penicillium rubrum* and *P. purpurogenum* produce two highly toxic hepatotoxins (LD50, 3.0 mg kg^{-1} in mice, I.P.) called rubratoxins A (minor) and B (major), which are complex nonadrides fused with anhydrides and lactone rings. Rubratoxin B has been shown to have synergistic effects with AFB1. It induced apoptosis in several cell systems. A lack of extracellular Ca^{2+} ion accelerates RB-induced DNA fragmentation of HL-60 cells. Neither protein synthesis nor nucleic acid interaction was related to the RB-induced APT, but proteases are likely to be involved. p53 has also been found not to be involved in the RB-induced APT signal transduction. Secalonic acid D, a cleft palate-inducing mycotoxin produced by *P. oxalicum* and other fungi, reduces palatal cAMP levels. It inhibits the binding of the cAMP response elements to the binding protein, alters phosphorylation, and leads to altered expression of genes involved in cell proliferation, an event critical for normal palate development.

In addition to the above hepatotoxins and nephrotoxins, *Penicillium* spp. produce many mycotoxins with strong pharmacological effects on neurosystems. For example, the indoloditerpenes, penitrem A–F are a series of temorgenic mycotoxins. Penitrem A, the major toxin in this group, causes tremorgenic effects in mice at a level of 250 μg kg^{-1}. Roquefortines A–C (C is most toxic), produced by *P. roqueforti* and several other *Penicillium* spp., have neurotoxic effects in animals. Tremorgens in the paspalitrem group (paspalicine, paspalinine, paspalitrem A and B, paspaline and paxilline) are produced by *Claviceps paspali* and some *Penicillium* spp. Paxilline, a reversible, noncompetitive inhibitor of the cerebellar inositol 1,4,5-triphosphate (InsP-3) receptor, inhibits the InP-3-induced Ca^{2+} release.

Other mycotoxins produced by *Fusarium* Other than TCTCs and Fm, some *Fusarium* spp. also produce other mycotoxins. Zearalenone (ZE), also called F-2, is a phytoestrogen that has hyperestrogenic effects and causes reproductive problems in animals, especially swine. It interacts with estrogenic receptors and stimulates protein synthesis by mimicking the action of the hormone. Contamination with this mycotoxin, sometimes together with DON, in feed may result in a large economic loss in the swine industry. It has been postulated that ZE may contribute to the overall estrogen load of women because of its frequent natural occurrence. ZE stimulates cytokine production. It also stimulates the growth of estrogen receptor-positive human breast carcinoma cell line MCF-7 and functions as an antiapoptotic agent by increasing the survival of MCF-7 cell cultures undergoing apoptosis caused by serum withdrawal. The mitogen-activated protein kinase signaling cascade is required for ZE's effects on cell-cycle progression in MCF-7 cells. *Fusarium moniliforme* also produces several other mycotoxins, including fusarins A–F, moniliformin, fusarioic C, fusaric acid, and beauvericin, in addition to Fms. Although the impact of these mycotoxins on human health is still not known, fusarin C (FC) has been identified

as a potent mutagen. Moniliformin, which causes cardiomyopathy in test animals, may be involved in Keshan disease in humans in regions where dietary selenium deficiency is also a problem. It binds strongly with pyruvate dehydrogenase, thus affecting the enzymes in the TCA cycle. *Fusarium moniliforme* was also found to be most effective among a group of several fungi tested in reducing nitrates to form potent carcinogenic nitrosamines. Thus, the contamination of foods with this fungus could be one of the etiological factors involved in human carcinogenesis in certain regions of the world. Fusarochromanones, a group of mycotoxins produced by some *Fusarium equiseti* isolates, cause tibial dyschondroplasia in broiler chicks, turkeys, and ducks and were considered as the possible cause of Kashin-Beck disease in China.

Mycotoxins produced by other species *Alternaria alternata* and other *Alternaria* spp. species are capable of producing dibenzo-α-pyrone types of mycotoxins (alternariol, alternariol monomethyl ether (AME), altenuene, isoaltenuene and altenuisol), tetramic acid metabolites, tenuazonic acid (TzA) and related compounds, and perylene derivatives altertoxins (ATX) I, II (also called stemphyltoxin II), III and stemphyltoxin. Although most of those compounds are relatively nontoxic, AME has been shown to be positive in Ames tests at relatively high concentrations. TzA, a protein synthesis inhibitor that interacts with peptidyltransferase in ribosomes, is more toxic than others. It can chelate metal ions and is capable of formation of nitrosamines. It is also produced by *Phoma sorghina* and *Pyricularia oryzae*, and may be related to 'Onyalai,' a hematological disorder in humans in the south of Sahara in Africa. Although no extensive survey has been conducted to determine the occurrence of these mycotoxins in human foods, limited studies indicate that the incidence of some of these mycotoxins, such as AME and TzA, could be high in apple and tomato products. A recent discovery of the structural and functional similarity between fumonisins and AAL toxins, a series of phytotoxins produced by *Alternaria*, further shows the importance of mycotoxins produced by fungi in the *Alternaria* family.

Sporidesmine, a group of hepatotoxins produced by *Pithomyces chartarum* and *Sporidesmium chartarum*, causes facial eczema and liver damage in animals. Contamination of these mycotoxins in feeds can result in great economic loss to the sheep industry. Slaframine, an interesting mycotoxin produced by *Rhizoctonia leguminicola* (in infested legume forage crops), causes excessive salivation in ruminants as result of the blockage of acetylcholine receptor sites.

Role of Metabolism and Dietary Modification

Role of Metabolism

Because metabolism plays a key role in the activation and detoxification of mycotoxins, the biological effects of mycotoxins are greatly affected by the metabolism of the toxins in different animals. AFB1 is metabolically activated before the formation of the AFB–DNA adducts, which exerts carcinogenic effects. However, activated AFB1 can also be conjugated to proteins and interact with glutathione and then be excreted from the body. Thus, glutathione *S*-transferase serves as a key enzyme in the detoxification process for AFB1. Mice are resistant to the carcinogenic effects because they constitutively express an α-class glutathione *S*-transferase (mGSTA3-3). Rats do not constitutively express a GST with a high AFB1-epoxide conjugating activity and thus are sensitive to AFB1-induced hepatocarcinogenesis. Constitutively expressed human hepatic α-class GSTs have little or no AFB1-epoxide-detoxifying activity. In contrast to rodents, the v-class GSTs are responsible for most of the AFB–epoxide-conjugating activity in the liver. Other types of cytochrome P450 are also capable of metabolizing AFB1 to various hydroxylated metabolites, including AFM1 and AFQ1. Demethylase is capable of converting AFB1 to AFP1. The cytosolic steroid reductase can convert AFB1 reversibly to aflatoxicol, which serves as a reservoir for AFB1.

The importance of metabolism for other mycotoxins is generally related to the detoxification processes. For example, metabolic deacetylation and deepoxidation of trichothecence mycotoxins lead to the formation of hydroxylated derivatives and deepoxide-TCTCs that are less toxic. Hydrolysis of OA by proteolytic enzymes leads to the production of nontoxic metabolites. Hydroxylated OA, formed by the action of cytochrome p450, is also less toxic; no evidence of OA metabolism to form glutathione conjugate or other adducts was found. Hydroxylation of T-2 at the C-3′ and OA at the C-4 position by microsomal enzymes has also been demonstrated. Most of the hydroxylated mycotoxins and metabolites may be excreted directly or form conjugates of glucuronide or sulfate, which are then excreted. Thus, various factors affecting the kinetics of formation of adducts and detoxified metabolites greatly affect the toxicity of mycotoxins. A number of factors, including the sex

and species of the animal (genetics), environmental factors, nutritional status, and mycotoxin synergism, etc., can either directly or indirectly modulate the toxic effects.

Dietary Modifications

As discussed elsewhere in this encyclopedia, dietary modification greatly affects carcinogenesis in experimental animals and in humans. Without exception, the carcinogenic and other toxic effects of mycotoxins, especially aflatoxins, are also affected by nutritional factors, dietary additives, and anticarcinogenic substances. Since the manifestation of carcinogenic/toxic effects of AFB1 depends on its ability to be absorbed and metabolized to an active form and on its subsequent interaction with DNA to form AFB1–DNA adducts, dietary modifications on any or all of these steps would lead to an increase or decrease in the carcinogenic effects of aflatoxin. Mycotoxins have a high affinity for the hydrated sodium calcium aluminasilicate (or NovaSil) and other related products. Diets containing NovaSil and related absorbers are effective in preventing absorption of AFB1 and several other mycotoxins in animals. Chemoprotective agents and antioxidants such as ascorbic acid, BHA, BHT, ethoxyquin, oltipraz, pentaacetyl geniposide, Kolaviron biflavonoids, and even green tea have also been found to inhibit carcinogenesis caused by AFB1 in test animals. Dietary administration of the naturally occurring chemopreventive agents, ellagic acid, coumarin or α-angelicalactone has been shown to cause an increase in the activity of glutamate–cysteine ligase, a key enzyme for the synthesis of glutathione. The mechanism of such protective effects was found to be the shifting of metabolism to a detoxification route by formation of a AFB1–glutathione conjugate rather than the formation of AFB1–DNA adducts. Ebselen exerts a potent protective effect against aflatoxin B-1-induced cytotoxicity; such a protective effect may be due to its strong capability in inhibiting intracellular reactive oxygen species formation and preventing oxidative damage.

Other absorbents such as zeolite, bentonite, and superactive charcoal are also effective in decreasing the toxicity of mycotoxins such as T-2 toxin. The toxicity of OA in test animals is minimized when antioxidants such as vitamins C and E are added to the diet. Aspartame, which has been found to be partially effective in decreasing the nephrotoxic and genotoxic effects of OA, may compete with OA for binding to serum albumin. L-Phenylalanine was found to protect the toxic effects of OA; administration of this amino acid prevented the OA's inhibitory effect on some of the enzymes discussed earlier. Vitamin E was found to efficiently prevent cytotoxicity induced by FB1. (*See* **Aspartame**.)

Concluding Remarks

Mycotoxins can cause both acute and chronic effects in prokaryotic and eukaryotic organisms, including humans. Most of their effects are organ-specific, but some mycotoxins may affect on many organs. Induction of cancer by some mycotoxins through initiation and promotion processing, in animals and possibly in humans, is one of the major concerns for their chronic effects. Modulation of immune systems by some mycotoxins is another concern. Interaction with marcomolecules through noncovalent or covalent binding, or both, is the basis of their mode of action. With some mycotoxins, such as aflatoxins, metabolic activation is necessary for their binding with specific macromolecules, but with others, metabolic activation is not necessary. Nevertheless, metabolism plays a key role in modulating their toxic effects because metabolism can produce either activated or nontoxic metabolites for subsequent conjugation and excretions. Thus, factors affecting the metabolism of mycotoxins greatly affect the toxicity of mycotoxins. Recent studies have shown that many mycotoxins modulate apoptosis, and investigation of the mechanisms involved has become an effective tool for understanding the mode of action of mycotoxins.

Almost all of the mycotoxins are very stable; only a limited number of detoxification methods are currently available, and some of these are not economically feasible. From a toxicological point of view, dietary modifications can reduce the risk to some degree. Because most of these control measures are not very effective, rigorous programs for preventing human and animal exposure to the contaminated foods and feed are important, and the availability of effective methods for monitoring the toxin levels in the foods is essential. Although a risk assessment has been carried out for some mycotoxins, more epidemiological data for human exposure are needed for establishing toxicological parameters and safe doses in humans. The mycotoxin problem may be with us for a long time, and many mycotoxicoses are not well characterized. It is unrealistic to eliminate the problem. Only through multiple approaches can we minimize the problem and enhance human and animal health.

NATAMYCIN

L V Thomas and J Delves-Broughton, Danisco Innovation, Beaminster, Dorset, UK

Introduction

Natamycin (also known as pimaricin) is a polyene macrolide antimycotic produced by *Streptomyces natalensis*. It is marketed commercially as the Natamax™ family of products by Danisco, and as the Delvocid® family of products by DSM. Natamycin is used worldwide as a food preservative; its primary application is surface treatment of cheese and processed meat (e.g., dry sausages) by dipping, spraying, or in emulsion coatings. It has several advantages as a preservative, including broad activity spectrum, efficacy at low concentrations, lack of resistance, and activity over a wide pH range. Due to its low solubility, natamycin does not migrate from the surface into the food, and thus does not affect the organoleptic properties. It has no effect on bacteria, including those used as starter cultures or to promote ripening. It is chemically stable and has prolonged effectiveness. Moreover, it is easy to apply and has a proven safety record. Its general characteristics are summarized in Table 1.

History

Natamycin was first discovered in 1955, when it was isolated from culture filtrates of an *Actinomycetes* bacterium isolated from soil near the town of Pietermaritzburg, in the Natal province of South Africa. The antimycotic was first called pimaricin, a name derived from this place of origin. Its current name natamycin, as well as the name of its producer organism *Streptomyces natalensis*, was similarly derived from Natal. Natamycin has also been produced from closely related *Streptomyces* strains isolated from other locations and has been given various names (e.g., tennecetin, antifungal A-5283) and trade names. Its potential as a food preservative was recognized shortly after its discovery, when its efficacy against molds and yeasts was investigated in foods including fruit juice, carbonated drinks, fresh strawberries and raspberries, dressed poultry, sausages, cottage cheese, and hard cheese.

Structure

Natamycin has the empirical formula $C_{33}H_{47}NO_{13}$ and a molecular weight of 665.7. The structure was first determined in 1958, and later revised. It belongs to the group of polyene macrolide antifungals, compounds characterized by possession of a macrocyclic ring of carbon atoms closed by lactonization, and four conjugated double bonds. This classes it as a tetraene antimycotic (Figure 1). The structure is closely related to other antimycotics such as nystatin, rimodicin, and amphotericin. The molecule is amphoteric due to one basic and one acid group and has an isoelectric point of 6.5.

Stability and Solubility

Natamycin is a white/cream-colored crystalline powder with no taste and little odor. It is usually found as the stable trihydrate formulation. No significant loss of activity occurs for several months if the powder is stored in the dark at room temperature. Aqueous suspensions are less stable, particularly if exposed to light, certain oxidants, and heavy metals, but remain sufficiently stable during practical use. Although solutions are more unstable in acid or alkaline conditions, the pH of food products is not normally at levels that would cause problems. For instance, natamycin stored at 30 °C for 21 days reportedly retained 100% activity at pH 5–7, retained *c.* 85% at pH 3.6, and 75% at pH 9.0. In acid solutions, the molecule undergoes hydrolysis at the glycosidic linkage, forming mycosamine and aponatamycin and subsequently other compounds. Aqueous suspensions at neutral pH are stable for 24 h at 50 °C and show little reduction in activity at this temperature for several days and for shorter periods at 100 °C.

Natamycin is poorly soluble in water (30–100 p.p.m. at room temperature) and almost insoluble

in nonpolar solvents, but shows good solubility in strongly polar organic solvents (Table 1). To be active, natamycin must be in solution. However, solubility is not normally a limiting factor as natamycin is usually effective at relatively low concentrations. In solution, natamycin has an ultraviolet absorption spectrum with minima at 250, 295.5, and 311 nm, and maxima at 220, 290, 303, and 318 nm.

Table 1 General characteristics of natamycin

Characteristic	*Description*
Names	Natamycin, pimaricin (pimafucin), tennecetin, antifungal A-5283 (trade names: Natacyn, Myprozine)
Commercial products	Natamax™, Delvocid®
Producer organism	*Streptomyces natalensis*
EU number	E235
Formula	$C_{33}H_{47}NO_{13}$
Molecular weight	665.7 Da
Structure	Polyene macrolide antimycotic compound with a macrocyclic ring of carbon atoms closed by lactonization, and four conjugated double bonds
Properties	Amphoteric. Isoelectric point: 6.5
Solubility in different solvents	Water: 30–100 p.p.m. *n*-Butanol: 50–120 p.p.m. Glycerol: 15 000 p.p.m. Methylpyrrolidone: 120 000 p.p.m. Glacial acetic acid: 185 000 p.p.m.
Absorption spectrum	Maxima: 290, 303, 318 nm Minima: 250, 295.5, 311 nm
Antimicrobial spectrum	Most molds and yeasts (MIC: < 5–20 p.p.m.)
JECFA ADI	0.3 mg kg^{-1} body weight

MIC, minimum inhibitory concentration; JECFA, Joint Food and Agriculture Organization/World Health Organization Expert Committee on Food Additives; ADI, acceptable daily intake.

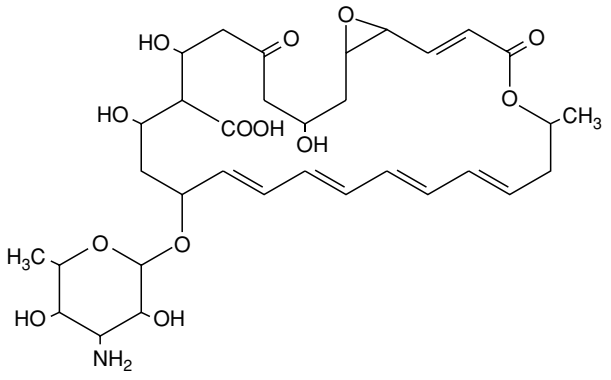

Figure 1 The structure of natamycin.

Mode of Action and Antimicrobial Effect

Mechanism of Action

Natamycin acts against yeasts and molds but is ineffective against bacteria. It combines with ergosterol and other sterols such as 24, 28-dehydroergosterol and cholesterol, compounds present in the cell membranes of yeast and molds but (with rare exceptions) not present in bacteria. The irreversible binding of natamycin to sterols, in particularl ergosterol, disrupts the cell membrane integrity and increases membrane permeability. This results in leakage of essential cellular constituents including cations, causing a rapid drop in intracellular pH and ultimately cell lysis. A study of laboratory-forced natamycin-resistant mutants of *Aspergillus flavus* has confirmed this theory. These either had reduced levels of ergosterol or none at all (and consequently much slower growth rates – critical to survival *in vivo*). A secondary mode of action is the inhibition of glycolysis and respiration.

Antimicrobial Spectrum

Natamycin is active against an extensive range of yeasts and molds (Table 2). The preservative is usually effective at concentrations between < 1 and 10 p.p.m. In general, yeasts are more sensitive than molds: the minimum inhibitory concentration (MIC) of yeasts is usually < 5 p.p.m., whereas that of molds can be at least 10 p.p.m. Examples of MICs are shown

Table 3 Examples of sensitivity of yeasts and molds to natamycin

Strain	*Minimal inhibitory concentration (p.p.m.)*
Aspergillus chevalieri 4298	0.1–2.5
Saccharomyces cerevisiae H	0.15
Penicillium chrysogenum	0.6–1.0
Aspergillus niger	1.0–1.8
Saccharomyces bailii	1.0
Candida albicans	1–2.5
Mucor mucedo	1.2–5.0
Penicillium notatum 4640	5.0
Saccharomyces rouxii 0562	5.0
Rhizopus oryzae 4758	10.0

in Table 3. Less susceptible species include *Verticillium cinnabarinum, Botrytis cinerea*, and *Penicillium discolour*, and also occur among the genera *Aspergillus, Fusarium, Penicillium*, and *Trichophyton*. The outcome of antifungal activity is usually cidal, in contrast to sorbate, which is fungistatic. Natamycin can inhibit aflatoxin synthesis, furthermore overall control of fungi leads to control of aflatoxins.

Resistance to polyene antimycotics such as natamycin does not seem to occur naturally and it has also proved difficult to generate resistant mutants in the laboratory. For example, in a survey of factories of natamycin-producers, no detectable difference in natamycin sensitivity was found for isolates compared to other factories. Similarly, in both a cheese warehouse and sausage factory where natamycin had been used for some time, no resistant strains were isolated. This lack of resistance may be partly explained by the fact that natamycin occurs as micelles in solution. Thus if a cell comes into contact with natamycin in solution, the antimycotic concentration is high and consequently lethal. Furthermore, the site of activity is an essential component of the cell membrane.

Factors Affecting Efficacy

The antimycotic activity of natamycin is affected by several factors, which may also affect its stability, such as pH, temperature, light, oxidants, and heavy metals. Natamycin is active over a wide pH range (pH 3–9); pH does not appear to affect its antimycotic activity but does affect stability. Compounds such as peroxides or chlorides, often used as cleaning/disinfecting agents, should be used with care in the proximity of natamycin.

Methods of Assay

The natamycin content of food products can be determined by microbiological, immunochemical, spectrophotometric, and liquid chromatographic (LC) procedures. The agar diffusion bioassay using *Saccharomyces cerevisiae* can also be used for quantitative assessment. Spectrophotometric and LC methods are commonly used for routine analysis. High-performance liquid chromatography (HPLC) with ultraviolet detection is considered one of the most sensitive and accurate methods, with a detection limit of 0.5 mg kg^{-1}. (*See* **Chromatography**: High-performance Liquid Chromatography.)

International Dairy Federation standard 140A: 1992 specifies the method for determining the natamycin contents of cheese rind and cheese adjacent to the rind. In this method a known quantity of sample is extracted with methanol, which is then diluted with water and cooled to between −15 and −20 °C to congeal and precipitate the majority of fat, followed by filtration. The natamycin content can then be determined in the filtrate by either a spectrometric or HPLC method. For the spectrometric measurement the spectrum of both a natamycin standard solution and the test sample is recorded in the range 300–340 nm. Absorbance is measured at the maximum of approximately 318 nm, at the minimum of approximately 311 nm, and then at 329 nm. For measurement by HPLC, ultraviolet detection should be at 308 nm and it is recommended that the mobile phase of the column should comprise methanol/water/acetic acid, 60 + 40 + 5 (v/v/v). Before analysis of test samples, a standard natamycin solution is first injected to determine retention time and for calibration.

More recently, a rapid method using derivative spectrophotometry has been described. In this method cheese is extracted with acidified aqueous acetonitrile, and natamycin content is directly quantified in filtered extracts on the basis of the depth of the trough at 322.6 nm after third-derivative processing of the normal ultraviolet spectrum. An enzyme immunoassay involving the use of a natamycin–protein conjugate has also been reported, in which natamycin coupled to horseradish peroxidase was used as the labeled ligand. Detection limits were 200–2000 pg ml^{-1}, which enabled the determination of concentrations as low as 0.005 mg dm^{-2} (0.1 mg kg^{-1}) in cheese rinds.

Toxicology and Legislation

Toxicology studies have been undertaken using mice, rats, rabbits, and guinea pigs. Natamycin was least toxic if administered orally (LD50 = 1500 mg kg^{-1} in rats and mice) or subcutaneously (LD50 = 5000 mg kg^{-1} in rats), and most toxic if administered intravenously (LD50 = 5–10 mg kg^{-1}). No natamycin was

absorbed from the human intestinal tract after 7 days' feeding of up to a maximum of 500 mg day^{-1}. Feeding studies have been conducted in rats, rabbits, and dogs. The acceptable daily intake was set at 0.3 mg kg^{-1} body weight per day in 1976.

Specification of natamycin in the USA (21 CFR 172.155) requires purity of the anhydrous compound to be 97% $\pm$ 2%, containing < 1 p.p.m. arsenic and not more than 20 p.p.m. heavy metals.

Natamycin is approved for use as an antimycotic in various cheeses and processed meats in 32 countries worldwide. A more general use as a food additive is allowed in a few countries such as South Africa (Table 4). In the European Union (EU) natamycin (designated E235) is permitted for surface treatment of hard, semihard, and semisoft cheese as well as dry sausages. The maximum surface coverage permitted in the EU is 1 mg dm^{-2}, and penetration is restricted to 5 mm from the surface. In the USA, natamycin is permitted only if the cheese standard allows the use of 'safe and suitable' antimycotics. Table 4 is a guide to food legislation. This list is not comprehensive – one should be aware that legislation for food additives is under constant review. The reader is advised to check the current legal situation with the appropriate authorities.

Table 4 Food legislation on the use of natamycin

Country	*Food in which natamycin is permitted*	*Maximum permitted level*
Algeria	Cheese rinds	Used in suspension at 2.5 g l^{-1}
Argentina	Surface treatment of hard and semihard paste cheeses	Limit of 1 mg dm^{-2}. Penetration limit of 2 mm
Australia	Surface treatment of cheese rind	Limit of 15 mg/kg
	Uncooked fermented manufactured meat products	Penetration limit of 3–5 mm
Bahrain	Permitted food preservative	
Brazil	Surface treatment of cheese	Limit of 2 mg dm^{-2}
Bulgaria	Cheese rind	500 mg kg^{-1}
Canada	Surface treatment of 47 listed cheeses	20 mg kg^{-1} based on total weight
	Grated/shredded cheese (0.5% sodium lauryl sulfate prohibited as dispersant)	10 mg kg^{-1}
Chile	Surface treatment of hard cheese (prohibited in wine)	
China	Surface treatment of cheese, processed meat products, moon cakes, baked goods, fruit juices, and processing utensils for easily moldy foods	Application by spraying or dipping in 200–300 mg kg^{-1}, to leave a residue of < 10 mg kg^{-1}
Colombia	Cheese	12.5 mg kg^{-1}
Czech Republic	Dairy and meat products – as EU regulations (contact authorities for further information)	Limit of 1 mg dm^{-2}. Penetration limit of 5 mm
Cyprus	Surface treatment of specified cheeses	
Egypt	Surface treatment of cooked cheese (dehydrated, semidehydrated, and semisoft cheese)	Limit of 2 mg 100 cm^{-2} (1 mg dm^{-2})
European Union (EU)	Surface treatment of specified cheese and sausage	Limit of 1 mg dm^{-2}. Penetration limit of 5 mm
Hungary	Surface treatment of hard and semihard cheese, dried, cured sausage	Limit of 1 mg dm^{-2}
Iceland	Surface treatment of ripened and whey cheese	Limit of 2 mg dm^{-2}
India	Surface treatment of hard cheese	Maximum application level: 2 mg dm^{-2}. Maximum residual level in finished cheese: 1 mg dm^{-2}. Penetration limit of 2 mm
Israel	Surface treatment of specified cheese	
Kuwait	Permitted food additive	
Lithuania	Surface treatment of hard, semihard, and semisoft cheese	Limit of 1 mg dm^{-2}. Penetration limit of 5 mm
Mauritius	Surface treatment of hard, semihard, and semisoft cheese and dried cured sausage	Limit of 1 mg dm^{-2}. Penetration limit of 5 mm

Continued

Table 4 Continued

Country	*Food in which natamycin is permitted*	*Maximum permitted level*
Mercosur	Surface treatment of cheese	Limit of 1 mg dm^{-2}. Maximum application of 5 mg kg^{-1}. Penetration limit of 2 mm
Mexico	Cheese surfaces	Limit of 0.002 %
Norway		Maximum level of suspension: 2 g kg^{-1}
	Surface treatment of hard, firm, and semifirm cheese, dried, cured sausage	Limit of 1 mg dm^{-2}. Penetration limit of 5 mm
Oman	Surface treatment of specified cheese	
Philippines	Surface treatment of specified cheese	
Poland	Permitted in colored and uncolored soft wax and polyvinyl acetate for application to skin of hard cheese	No limits
	Surface treatment of smoked, dried sausage	Limit of 1 mg dm^{-2}
Saudi Arabia	Permitted as a mold inhibitor in foodstuffs but controlled by standards of composition	
Slovakia	Surface treatment of cheeses and dried, cured sausage	Limit of 1 mg dm^{-2}
South Africa	Wine, alcoholic fruit beverages, and grape-based liquors	30 mg l^{-1}
	Fresh fruit pulp	5 mg kg^{-1}
	Fruit juice (blackcurrant, pineapple, etc.)	5 mg kg^{-1}
	Fish sausages	6 mg kg^{-1} to be applied to the outer inedible casing only
	Manufactured fish products, fish pastes, fish roe and spawn, with the exception of frozen fish, salted snoek, and canned fish products	6 mg kg^{-1}
	Lobsters (quick frozen)	6 mg kg^{-1}
	Edam, Gouda, Tilsiter, Limburger, Cheddar, Cheshire	2 mg kg^{-1} in rind without plastic coating; 500 mg kg^{-1} in a plastic coating; 10 mg kg^{-1} for application to the surface of the cheese only
	Cottage cheese, cream cheese	Limit of 10 mg kg^{-1}
	Process or blended cheese, including cheese spread, process cheese preparations, and soft cheese	10 mg kg^{-1} for application to the surface of the cheese only
	Yogurt	10 mg kg^{-1}
	Canned foods	6 mg kg^{-1}
	Manufactured meat products	Limit of 500 mg kg^{-1} on casing or 6 mg kg^{-1} in contents
	Canned chopped meat, canned corned beef, cooked cured luncheon meat, cooked cured pork shoulder, Biltong, frozen cooked-meat pie fillings	Limit of 6 mg kg^{-1}
Tunisia	Surface treatment of hard, semihard and semisoft cheese; dried, cured sausage	Limit of 1 mg dm^{-2}
Turkey	Surface treatment of hard and semihard cheese, dried cured sausages, salami, and hot dogs	Limit of 1 mg dm^{-2}. Penetration limit of 5 mm
Ukraine	Surface treatment of cheese	Limit of 1 mg dm^{-2}. Penetration limit of 5 mm
United Arab Emirates	Permitted food additive	
USA	Surface treatment of cuts and slices of cheese	Limit of 20 mg kg^{-1}
	Nonstandard of identity yogurt	Limit of 7 mg kg^{-1}
	Nonstandard of identity cream cheese	Limit of 7 mg kg^{-1}
	Cottage cheese	Limit of 7 mg kg^{-1}
	Sour cream	Limit of 7 mg kg^{-1}
	Soft tortillas	Limit of 20 mg kg^{-1}
	Nonstandard of identity salad dressing	Limit of 20 mg kg^{-1}
Venezuela	Surface treatment of specified cheeses and sausages	Maximum 0.5% suspension

Preservation of Foods with Natamycin

Types of Food Suitable for Natamycin Use

The principal use of natamycin is on the surface of cheese and dry sausages. Due to its low solubility, natamycin remains effective on the surface for extended periods. When first applied, only 30–50 p.p.m. will be present in solution on the surface – the remainder is present in the more stable crystal formation. The preservative then gradually dissolves, insuring a slow release and prolonged effectiveness. An additional advantage of surface treatment is that natamycin does not penetrate far into the food; a limit of penetration of 1–4 mm has been reported in cheese rind. This is particularly useful for the preservation of blue cheese, especially in comparison to sorbate. Sorbate migrates into the cheese matrix where it inhibits the desired blue mold development inside the cheese. Natamycin remains on the surface, acting only where it is needed to prevent the growth of surface spoilage molds.

Much of the early work on natamycin investigated its ability to inhibit fungal growth on fruit. Strawberries, raspberries, and cranberries sprayed with 50 p.p.m. natamycin in the field prior to harvesting showed reduced spoiling during storage. Treatment by immersion in 10–100 p.p.m. proved more effective. A lecithin coating containing natamycin can be used to treat harder fruit, such as apples and pears. An addition level of 1–10 p.p.m. natamycin may be effective for a variety of beverages, including juices, beer, wine, and beverages containing tea or milk solids. Natamycin (at 20 p.p.m.) has proved effective against *S. cerevisiae* spoilage of orange juice. Further potential applications include ready-to-eat frostings, salad dressings, and mayonnaise susceptible to yeast spoilage. Natamycin control of *Aspergillus niger* and *S. cerevisiae* in cottage cheese has been investigated. Levels of 20–100 p.p.m. added to wash water or 1–5 p.p.m. added to the cheese dressing inhibited fungal growth. A level of 5–10 p.p.m. can be effective in controlling yeast and mold growth in yogurt. Natamycin has also been shown to be effective against molds isolated from bakery products. A level of 100 p.p.m. has been shown to inhibit the growth of yeasts and molds in fillings and icings. (*See* **Yeasts**.)

Natamycin can also be used to treat the surface of cured-meat products such as raw hams and investigations have been conducted into its ability to inhibit the spoilage microflora on raw cut chicken. Dipping in a solution of 10 p.p.m. inhibited yeast counts for 12–15 days at refrigeration temperature.

Mode of Application

To treat the surface of cheese and sausages, the food can be immersed, sprayed, or coated in an aqueous suspension or the suspension can be used in a plastic coating. Penetration into the food then depends on the food type, being greater in soft cheese compared to hard cheese.

Aqueous dipping solutions for cheese usually contain 1250 p.p.m. natamycin, but concentrations vary depending on cheese type. For example, dips for blue cheese may require dip concentrations as high as 2500 p.p.m. The cheese should be dipped into the natamycin slurry for a few seconds, whilst the slurry is kept constantly agitated to maintain the natamycin in suspension. The concentration of natamycin in the dipping solution becomes reduced after each dipping, at a rate dependent on the ratio of surface area to weight of each piece of cheese.

A suspension of 1250 p.p.m. is recommended for spraying cheese, applied at a rate of 6 l t^{-1} to achieve 7–15 p.p.m. natamycin on the surface. It is important that the natamycin is evently applied as it binds rapidly and tightly on contact with the cheese surface, so that subsequent mixing after initial application will not achieve better distribution of the preservative. A tumbler of at least 1 m in length is recommended with a space of at least 0.3 m between the natamycin and flow agent application.

Lower levels of natamycin (100–750 p.p.m.) can also be added to an emulsion of a polymer in water, mostly polyvinyl acetate, which can be applied as a cheese coating. Alternatively, 100–20 000 p.p.m. of natamycin can be mixed with 0.5–50 g l^{-1} of a suitable thickener and approximately 20–250 g l^{-1} salt and used on the surface of cheese or sausages. This method of application overcomes the problem of uneven distribution of the fungicide caused by the heterogeneity of the fat content of the product. Coatings can be applied by 'painting' multiple layers on to the surface with a sponge or soft cloth, or by a commercially available coating machine.

Natamycin can also be used in natural and fibrous casings of dry fermented sausage products, preventing mold growth during the ripening and storage process. Commonly, casings can be prepared by immersion for 2 h in a 1000-p.p.m. suspension. Alternatively the sausages can be dipped or sprayed in a 1000–5000-p.p.m. natamycin suspension.

Fermentation and Production

Natamycin is produced by fermentation of *Streptococous natalensis* in an aqueous nutrient medium containing a carbon source (e.g., starch, molasses,

glycerol, glucose, lactose, maltose, sucrose, alcohols, organic acids), a fermentable organic and/or inorganic nitrogen source (e.g., corn steep liquor, casein, zein, lactalbumin, soya bean meal). The carbon source usually comprises 0.5–5% of the medium. Inorganic cations (potassium, sodium, or calcium) and anions (sulfate, phosphate, or chloride) may be needed as well as trace elements such as boron, molybdenum, or copper. Fermentation is aerobic and mechanical agitation and use of antifoaming agents can aid the process. The temperature is usually 26–30 °C and the pH range pH 6–8. The period of fermentation, varying with the medium, can be between 48 and 120 h.

Due to its low solubility in water, natamycin will accumulate mainly as crystals in the broth. Recovery commonly involves dissolving the natamycin using polar solvents with limited water miscibility such as butanol, methanol, and acetone and adjusting the medium to approximately pH 10. The fermentation broth is filtered to remove the mycelial biomass and impurities, and adjusted to a lower pH (*c*. pH 7) in order to crystallize the natamycin, which is then recovered and finally dried. An alternative process that does not use organic solvents involves the disintegration of the fermentation biomass by homogenization, high shear mixing, or ultrasonic techniques or treatment with heat, alkali, or enzymes.

Introduction

Niacin (nicotinic acid and nicotinamide) occurs widely in nature. Chemically, nicotinic acid is 3-pyridine carboxylic acid, and nicotinamide is 3-pyridine carboxylic acid amide (Figure 1). It should also be noted that in the USA niacin is used as a specific name for nicotinic acid, and niacinamide for nicotinamide.

Nicotinic acid (mol wt 123.11) occurs as colorless (white) nonhygroscopic needles or crystalline powder. It has a melting point of 235.5–236.5 °C and sublimes. It is soluble in water (1.67 g per 100 ml at 25 °C). It is also soluble in ethanol, acids, alkalis, and propylene glycol, but insoluble in ether. It has an absorption maximum at 261 nm, but the intensity is pH-dependent.

Nicotinamide (mol wt 122.11) also occurs as colorless (white) needles or crystalline powder but is slightly hygroscopic. It has a melting point of 128–131 °C and a distilling point of 150–160 °C at 5×10^{-4} mmHg. It is very soluble in water (100 g per 100 ml at *c.* 25 °C), ethanol (67 g per 100 ml) and glycerol (10 g per 100 ml) but is almost insoluble in ether. Like nicotinic acid, it has an absorption maximum at 261 nm. Both nicotinic acid and the amide are stable in the dry form and in neutral aqueous solutions. Nicotinamide can be converted to nicotinic acid by treatment with acids or alkalis. Nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) are coenzyme forms. They combine with a wide variety of proteins and catalyze a large number of oxidation and reduction reactions and substrates in living organisms. (*See* **Coenzymes**.)

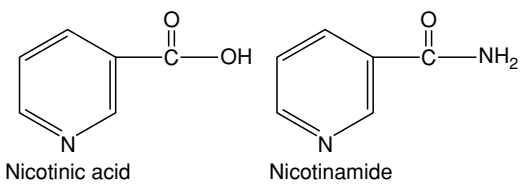

Figure 1 Structural formulae for nicotinic acid and nicotinamide. Reproduced from Niacin: Properties and Determination, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Salder MJ (eds), 1993, Academic Press.

The human requirement of nicotinic acid or nicotinamide is dependent on the tryptophan intake (60 mg of tryptophan is equivalent to 1 mg of nicotinic acid). Tryptophan is converted via a complex pathway. This pathway from tryptophan to NAD^+ does not directly produce nicotinic acid or nicotinamide; NAD^+ is transformed to nicotinamide, which is further *N*-methylated, and reenters the pyridine nucleotide cycle or may be deaminated to nicotinic acid, which is further converted to nicotinic acid mononucleotide.

Occurrence

Nicotinic acid and nicotinamide are found in a wide variety of foods: yeast, liver, heart, and muscle meats are good sources (Table 1). Because of the tryptophan contribution, milk, milk products, and eggs are also considered to be sources of niacin activity, although their actual content of niacin itself is relatively low. In natural products, niacin is usually in the bound form. Thus, in order to measure the total content it is necessary to include a hydrolytic stage. It is important to realize that this measure of total niacin must not necessarily be equated with what is biologically available. Most nicotinic acid in maize is in the form of nicotinyl esters, which are thought not to be hydrolyzed in the gut. In wheat bran it is bound to polysaccharides, peptides, and glycopeptides. Around 50% of niacin in unenriched wheat and wheat products has been reported to be in a bound form. The treatment of maize with lime water has been reported to liberate bound niacin, making it biologically available to pigs. It has also been claimed that, in areas where corn is routinely steeped in lime water, there is an absence of pellagra compared to areas with an equal consumption of unsteeped corn where pellagra was endemic. However, the various claims for bound forms of

niacin require thorough reinvestigation. (*See* **Bioavailability of Nutrients.**)

Biological Fluids (Blood) and Tissues

Nicotinamide is the primary circulating form of the vitamin. All tissues can incorporate nicotinamide into NAD. In the liver, nicotinic acid is incorporated into NAD, which is broken down into nicotinamide. The primary regulatory substance of the homeostasis in whole animals is nicotinamide itself. The levels in blood are buffered by the liver by being converted into a storage form of NAD.

Determination

Biological Assays

Historically, biological assays with animals such as the chick or the rat have been used as a baseline for other methods and to provide an evaluation of vitamin potency and availability of vitamins. However, biological assays are expensive to carry out and have an inherent lack of precision but, most importantly, are directly relevant only to the species used and conditions of the assay procedure. Thus, 'animal' assays for the determination of niacin are generally no larger used.

Other Assays

Unlike a biological system, which responds to the bioavailable vitamin in a food material, nonbiological assays are usually geared to measuring the total vitamin content. However, it is possible, using differential hydrolysis in conjunction with the microbiological assay, to make some assessment of the distinction between the 'free' and 'bound' vitamins, although this information must be treated with caution. Hydrolysis to release bound forms is normally carried out with sulfuric acid, although in some methods the use of alkali has been recommended, particularly for cereals.

Chemical assays This assay is based on the formation of colored complexes formed as a result of the reaction between niacin and cyanogen bromide. The reaction is as follows: an α-unsubstituted pyridine forms a pyridinium salt with cyanogen bromide, which reacts with an amine under ring opening to form a derivative of glutaconaldehyde. The color

produced can be measured spectrophotometrically. It has been reported that the colored products from the amide are not as stable or intense as from the acid. The amide is usually hydrolyzed to the acid. The Association of Official Analytical Chemists (AOAC) method employs sulfanilic acid as the chromogenic base in the manual and automated methods for nicotinic acid and nicotinamide in drugs, foods, feed, and cereal products, and barbituric acid in the analysis of the amide in multivitamin preparations. Foods and feeds are extracted with acid, and cereal products with calcium hydroxide. Factors which must be controlled for the method to produce reliable results include reaction temperature, pH, and preparation of blank corrections. However, this method lacks specificity, since all 3-pyridoxine derivatives react, and it requires the use of the highly toxic reagent cyanogen bromide. Thus, this method has been largely replaced by microbiological and high-performance liquid chromatography (HPLC) methods. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Microbiological methods Although probably not suited for occasional use because of the specialist facilities and expertise required, the microbiological assay has been widely used for the determination of nicotinic acid in a variety of materials. It is more sensitive and specific than the chemical assay. The microbiological assay is based on the specific nutritional requirements in a defined medium for a particular vitamin(s) by a microorganism. The most widely used organism is *Lactobacillus plantarum* (ATCC 8014). In order to present the vitamin in a biologically active form to the organism the material to be assayed is normally subjected to acid hydrolysis. This procedure also converts any amide into nicotinic acid. This organism responds to nicotinic acid, nicotinamide, and nicotinuric acid (an inactive metabolite), and NAD, but not tryptophan, and it is also able to utilize bound nicotinic acid, present in cereals, to a considerable extent. It is specified in official methods for the determination of total niacin activity in food. The AOAC and AACC extraction procedures involve autoclaving the sample at 121–123 °C for 30 min with 1 mol l^{-1} sulfuric acid.

High-performance liquid chromatography HPLC offers an alternative to the chemical or microbiological assay, although the initial equipment cost and subsequent recurrent costs are relatively high. Analysis is commonly carried out after alkali, acid, or acid/enzyme hydrolysis, by separation on a reversed-phase column and ion pair reagents in the mobile phase and ultraviolet detection. A particular problem in the HPLC analysis of niacin in food materials is that because of its relatively low ultraviolet absorption, interference from other compounds can make peak identification and quantification difficult. The application of this technique to food products often requires clean-up procedures, like cartridge extractions and column switching. The use of fluorescence detection increases specificity and sensitivity, but requires postcolumn derivatization, because niacin is not natively fluorescent. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Dietary Requirements

As stated earlier, the evaluation of data obtained from the analysis of foods is complicated by the uncertainties surrounding the bioavailability of bound forms of the vitamin and the contribution of tryptophan. These factors must be considered when considering the nutritional implications of niacin intake. (*See* **Dietary Requirements of Adults**.)

The presently accepted conversion rate of tryptophan to niacin is 60:1. Using this conversion rate and the tryptophan requirement to maintain nitrogen balance, it is possible to establish the niacin requirement.

Recommended daily amounts or reference nutrient intake values are based on niacin equivalents. The UK figures are calculated in terms of resting metabolism, that is, 2.7 mg of niacin equivalents per MJ or 11.3 mg per 1000 kcal. The daily level for men is about 17 mg, and about 13 mg for women, and is independent of activity. The recommended level does not fall with increasing age. An additional 2 mg is recommended during lactation. Recommended levels for infants and children are dependent on age, ranging from 3 to 5 mg for infants under 1 year, about 11 mg at 5 years and about 12 mg at 10 years of age. US recommendations are very similar.

Physiology

D A Bender, University College London, London, UK

Introduction

The vitamin niacin (nicotinic acid and nicotinamide) forms the functional moiety of the nicotinamide nucleotide coenzymes, nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). These act as electron carriers in a wide variety of oxidation and reduction reactions. NAD is also the source of adenosine diphosphate (ADP)-ribose for the ADP-ribosylation of proteins, a mechanism of enzyme regulation, and the poly(ADP-ribosylation) of nucleoproteins controlling the deoxyribonucleic acid (DNA) repair mechanism. Nicotinic acid adenine dinucleotide and cyclic ADP-ribose both have a role in regulation of intracellular calcium concentration in response to hormone action.

Although niacin is generally regarded as a vitamin, it is not strictly a dietary essential, since the nicotinamide moiety of the coenzymes can be synthesized *in vivo* from the essential amino acid tryptophan. Under normal circumstances, the intake of tryptophan is probably adequate to meet niacin requirements without the need for any preformed niacin in the diet.

Metabolism of Niacin

Dietary Forms and Sources

Niacin is present in tissues, and therefore in foods, largely as NAD and NADP. The postmortem hydrolysis of NAD(P) is extremely rapid in animal tissues, so it is likely that much of the niacin of meat (a major dietary source of the vitamin) is free nicotinamide.

Coffee may provide significant amounts of nicotinic acid, formed as a result of the pyrolysis of trigonelline (*N*-methyl nicotinic acid) during roasting.

In the calculation of niacin intakes, the niacin content of cereals is normally ignored. Although chemical analysis reveals niacin in cereals (largely in the bran), this is mostly biologically unavailable, since it is bound as niacytin – nicotinoyl esters to a variety of polysaccharides and glycopeptides with molecular weights ranging between 1500 and 17 000. Although niacytin is not hydrolyzed by digestive enzymes, a small amount is hydrolyzed nonenzymically by gastric acid, and up to 10% of the niacytin in cereals may be biologically available.

Treatment of cereals with alkali (e.g., soaking overnight in calcium hydroxide solution, the traditional method for the preparation of tortillas in Mexico) or baking with alkaline baking powders releases much of the bound nicotinic acid. Roasting of whole-grain maize has a similar effect, since there is enough ammonia released from glutamine to form free nicotinamide by ammonolysis.

Digestion and Absorption

Nicotinamide nucleotides in the intestinal lumen are not absorbed as such, but undergo hydrolysis to free nicotinamide. A number of intestinal bacteria have nicotinamide deamidase activity, and a proportion of dietary nicotinamide may be deamidated in the intestinal lumen.

Both nicotinic acid and nicotinamide are absorbed from the small intestine by a sodium-dependent saturable process of active transport, although at unphysiologically high concentrations there is also passive diffusion across the intestinal mucosa.

Synthesis of the Nicotinamide Nucleotide Coenzymes

As shown in **Figure 1** NAD(P) can be synthesized from either of the niacin vitamers, or from quinolinic acid, which is a metabolite of the amino acid tryptophan.

In liver there is little utilization of preformed niacin for nucleotide synthesis. The enzymes for nicotinic acid and nicotinamide utilization are more or less saturated with their substrates at normal concentrations in the liver, and hence are unlikely to

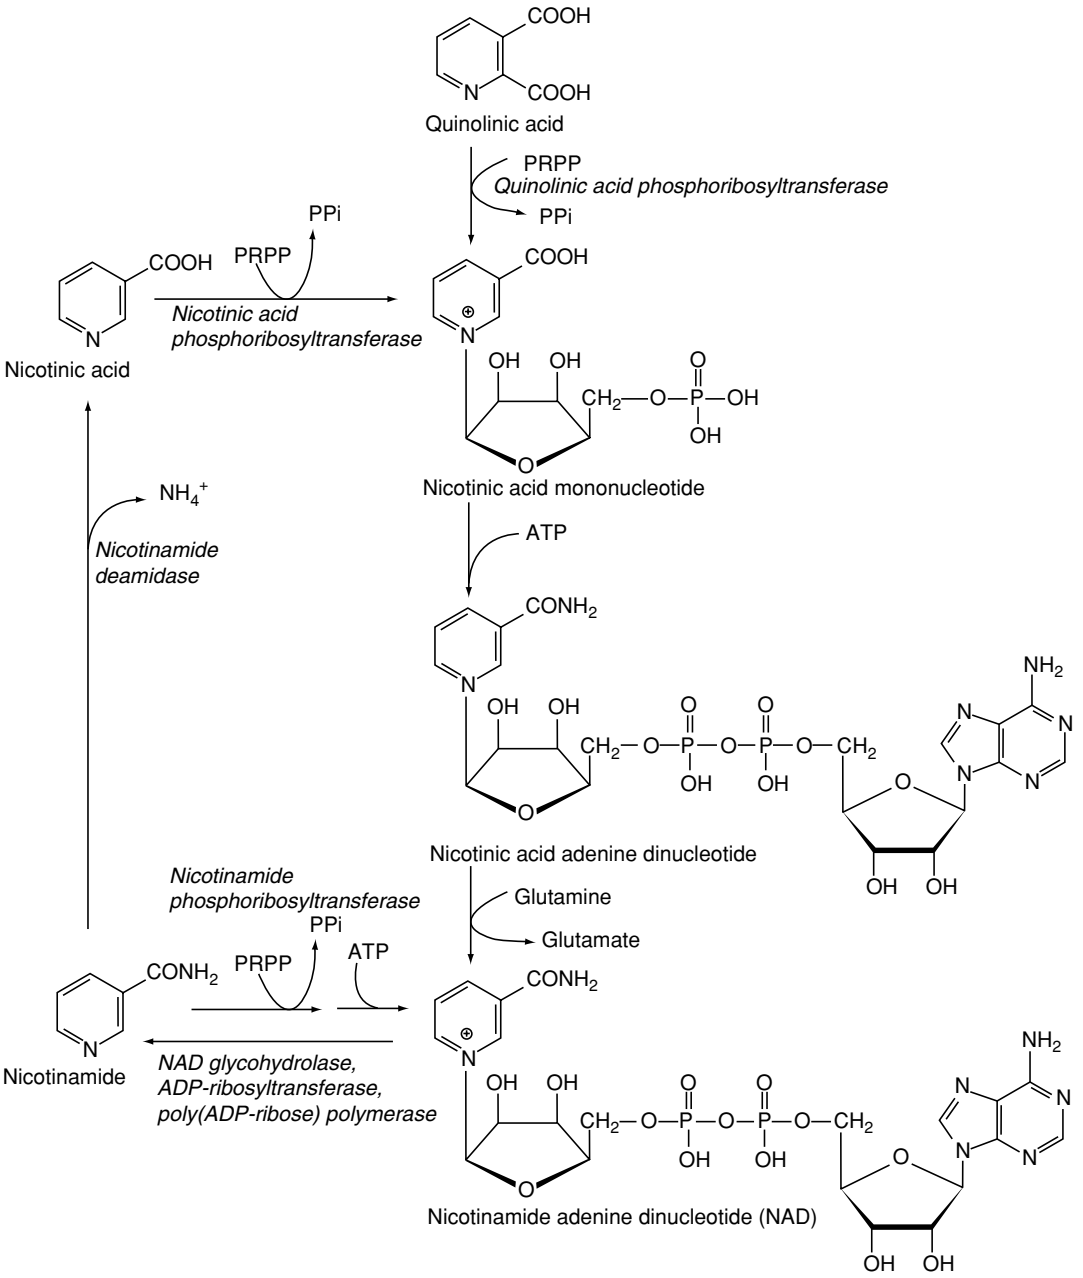

Figure 1 Synthesis of nicotinamide adenine dinucleotide (NAD) from nicotinamide, nicotinic acid, and quinolinic acid. be able to use additional niacin for nucleotide synthesis. The liver synthesizes relatively large amounts of NAD(P) from tryptophan, followed by hydrolysis to release nicotinic acid and nicotinamide into the circulation for use by other tissues.

In most extrahepatic tissues, nicotinic acid is a better precursor of nucleotides than is nicotinamide. However, muscle and brain are able to take up nicotinamide from the blood stream effectively, and apparently utilize it without prior deamidation.

Synthesis of Nicotinamide Nucleotides from Tryptophan

The oxidative pathway of tryptophan metabolism is shown in Figure 2. Under normal conditions, almost all of the dietary intake of tryptophan, apart from the

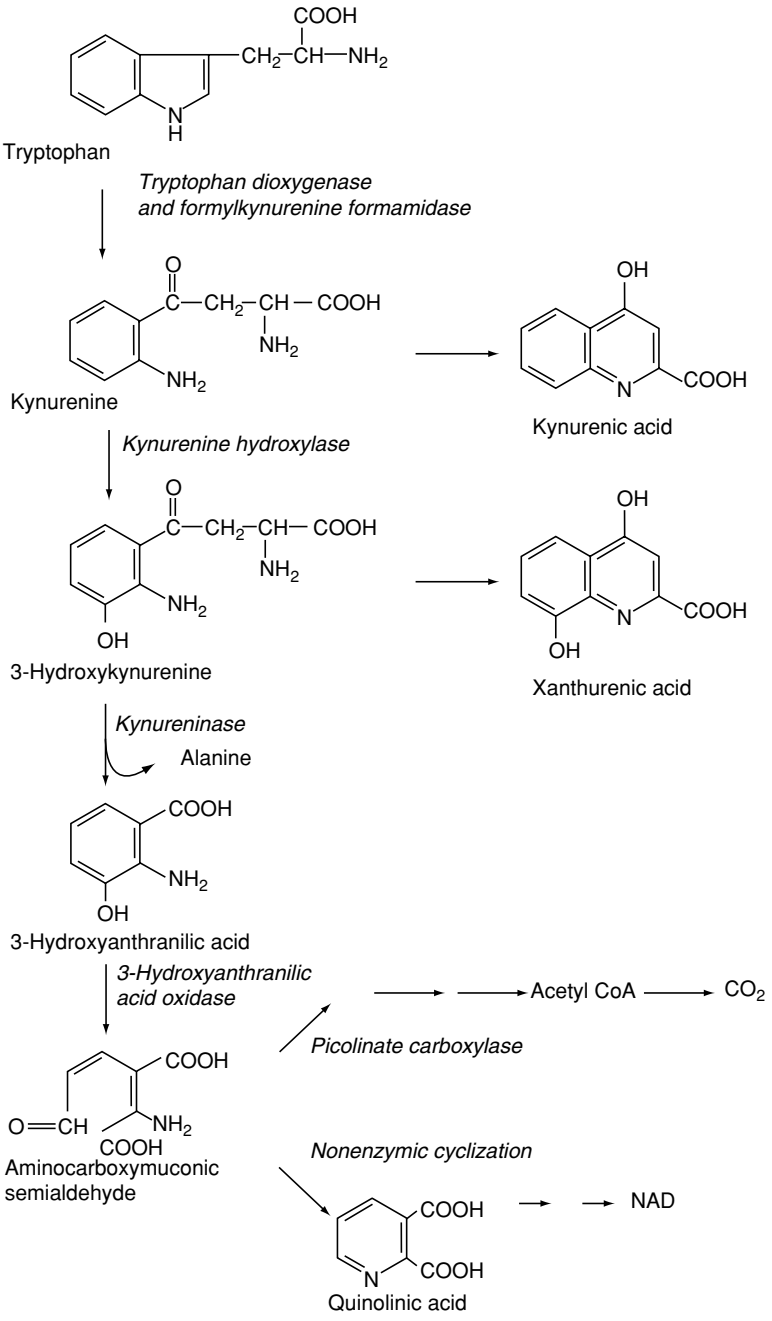

Figure 2 Tryptophan metabolism and the formation of quinolinic acid: tryptophan dioxygenase EC 1.13.11.11, formylkynurenine formamidase EC 3.5.1.9, kynurenine hydroxylase EC 1.14.13.9, kynureninase EC 3.7.1.3, 3-hydroxyanthranilate oxidase EC 1.10.3.5, picolinate carboxylase EC 4.1.1.45.

small amount that is used for net new protein synthesis, is metabolized by this pathway, and hence is potentially available for NAD synthesis. About 1% of tryptophan metabolism is by way of 5-hydroxylation and decarboxylation to form the neurotransmitter 5-hydroxytryptamine (serotonin).

The equivalence of dietary tryptophan and preformed niacin as precursors of the nicotinamide nucleotides has been assessed by determining the excretion of N^1-methylnicotinamide and methylpyridone carboxamide in response to test doses of the precursors, in subjects maintained on controlled diets. There is a considerable variation between subjects. It is generally accepted that in order to allow for individual variation it should be assumed that 60 mg of tryptophan is equivalent to 1 mg of preformed

niacin – an overestimate of the average requirement of tryptophan for NAD synthesis. This is the basis for expressing niacin requirements and intake in terms of niacin equivalents – the sum of preformed niacin and 1/60 of the tryptophan.

The synthesis of NAD from tryptophan involves the nonenzymic cyclization of aminocarboxymuconic semialdehyde to quinolinic acid. The alternative metabolic fate of aminocarboxymuconic semialdehyde is decarboxylation, catalyzed by picolinate carboxylase, leading to the formation of acetyl coenzyme A. There is thus competition between an enzyme-catalyzed reaction, which has hyperbolic, saturable kinetics, and a nonenzymic reaction which has linear, first-order kinetics.

At low rates of tryptophan metabolism, most will be by way of the enzyme-catalyzed pathway, leading to oxidation, and there will be little accumulation of aminocarboxymuconic semialdehyde to undergo nonenzymic cyclization. As the rate of formation of aminocarboxymuconic semialdehyde increases, and picolinate carboxylase becomes saturated, there will be an increasing amount available to undergo cyclization to quinolinic acid, and hence onward metabolism to NAD. There is thus not a simple stoichiometric relationship between tryptophan and niacin, and the equivalence of the two coenzyme precursors will vary as the amount of tryptophan to be metabolized and the rate of metabolism vary.

The activities of three enzymes, tryptophan dioxygenase, kynurenine hydroxylase, and kynureninase, may all affect the rate of formation of aminocarboxymuconic semialdehyde, as may the rate of uptake of tryptophan into the liver.

Tryptophan dioxygenase Tryptophan dioxygenase (also known as tryptophan oxygenase or tryptophan pyrrolase) has a short half-life *in vivo* (of the order of 2 h) and is subject to regulation by three mechanisms: stabilization by its heme cofactor, hormonal induction, and feedback inhibition and repression by high concentrations of NADP.

The holoenzyme is more stable than the apoenzyme, and in the presence of relatively large amounts of heme both the activity and the total amount of enzyme protein in the liver are increased. Induction of heme synthesis thus results in increased oxidative metabolism of tryptophan. This is not induction of tryptophan dioxygenase apoenzyme, but the result of reduced catabolism of the enzyme protein.

Tryptophan and a number of tryptophan analogs have a similar effect by promoting conjugation of the apoenzyme with hematin, and thus stabilizing the holoenzyme.

Tryptophan dioxygenase is induced by glucocorticoid hormones and glucagon; the mechanisms involved are different, and the effects are at least partially additive.

Glucocorticoid hormones cause induction of the new messenger ribonucleic acid (mRNA) and protein synthesis, unlike the increase in activity observed in the presence of higher than normal amounts of tryptophan or heme. In response to the administration of the synthetic glucocorticoid, dexamethasone, there is increased transcription of the rat liver tryptophan dioxygenase gene, resulting in a 10-fold increase in tryptophan dioxygenase mRNA in the liver.

Glucagon, mediated by cyclic adenosine monophosphate (cAMP), increases the synthesis of tryptophan dioxygenase following the administration of glucocorticoids, although it has little effect in unstimulated animals. The effect of glucagon appears to be the result of an increase in the rate of translation of mRNA rather than an increase in transcription, and is antagonized by insulin.

Kynurenine hydroxylase and kynureninase The activities of kynurenine hydroxylase and kynureninase are only slightly higher than that of tryptophan dioxygenase under basal conditions. Impairment of the activity of either enzyme may reduce the rate of tryptophan metabolism, and so reduce the accumulation of aminocarboxymuconic semialdehyde, and the synthesis of NAD.

Kynurenine hydroxylase is a flavoprotein, and in riboflavin-deficient rats its activity is only 30–50% of that in control animals. Riboflavin deficiency may thus be a contributory factor in the etiology of pellagra when intakes of tryptophan and niacin are marginal.

In a number of studies, sexually mature women show a higher ratio of urinary kynurenine to hydroxykynurenine than do children, postmenopausal women, or men, suggesting impairment of kynurenine hydroxylase by endogenous estrogens or their metabolites. In experimental animals the administration of estrogens results in a very considerable reduction in kynurenine hydroxylase activity. The mechanism of this effect is unclear, but it is physiologically important; in most areas where pellagra was common, about twice as many women as men were affected.

Kynureninase is a pyridoxal phosphate-dependent enzyme; impairment of its activity in vitamin B_6 deficiency leads to accumulation of kynurenine and hydroxykynurenine, and their transamination products, kynurenic and xanthurenic acids. This is the basis of the tryptophan load test for assessing vitamin B_6

nutritional status. It is also inhibited by estrogen metabolites, and both vitamin B_6 deficiency and inhibition reduce the rate of metabolic flux through the oxidative pathway, hence reducing the formation of quinolinic acid and NAD from tryptophan.

Catabolism of the Nicotinamide Nucleotide Coenzymes

There is no evidence of any specific storage of niacin or the nicotinamide nucleotide coenzymes in the body. Free NAD(P), which is not associated with enzymes, is rapidly hydrolyzed, and the resultant nicotinamide is either used for resynthesis of nucleotides or is methylated and excreted. The catabolism of NAD is catalyzed by four enzymes:

1. NAD glycohydrolase, which catalyzes the hydrolysis of $NAD(P)^+$ at the *N*-glycoside linkage to yield nicotinamide and either ADP-ribose or ADP-ribose phosphate. This enzyme catalyzes hydrolysis of both NAD^+ and $NADP^+$. It is also important in the formation of nicotinic acid adenine dinucleotide and cyclic ADP-ribose
2. NAD pyrophosphatase, which releases nicotinamide mononucleotide. This can either be hydrolyzed by NAD glycohydrolase to release nicotinamide, or be a substrate for nicotinamide mononucleotide pyrophosphorylase, to form NAD
3. ADP-ribosyltransferase(s)
4. Poly(ADP-ribose) polymerase

ADP-ribosyltransferases and poly(ADP-ribose) polymerase normally transfer ADP-ribose on to acceptor proteins (see below), although both are also able to catalyze simple hydrolysis of NAD^+ in the absence of an acceptor protein.

Urinary Excretion of Niacin and Metabolites

There is normally little or no urinary excretion of either nicotinamide or nicotinic acid, because both vitamers are actively resorbed from the glomerular filtrate. It is only when the plasma concentration is so high that the resorption mechanism is saturated that significant excretion occurs.

The metabolites of niacin are shown in Figure 3, and the use of their urinary excretion as an index of niacin nutritional status in Table 1. The principal metabolite of nicotinamide is N^1-methylnicotinamide, which is actively secreted into the urine by the proximal renal tubule. N^1-Methylnicotinamide can also be metabolized further, to yield methylpyridone carboxamide. The extent to which this oxidation occurs, and the relative proportions of the 2-pyridone and 4-pyridone, varies from one species to another and also shows considerable variation between different strains of the same species. Aldehyde oxidase catalyzes the formation of both pyridones, and some additional 2-pyridone arises from the activity of xanthine oxidase.

Nicotinamide can also undergo oxidation to nicotinamide *N*-oxide. This is normally a minor metabolite in humans, unless large amounts of nicotinamide are ingested. At high levels of nicotinamide intake, some 6-hydroxynicotinamide may also be excreted.

Nicotinic acid can be conjugated with glycine to form nicotinuric acid (nicotinoyl glycine), or may be methylated to trigonelline (N^1-methylnicotinic acid). Small amounts of 6-hydroxynicotinic acid may also be formed.

It is not clear to what extent urinary excretion of trigonelline reflects endogenous methylation of nicotinic acid. There are significant amounts of trigonelline in foods, and some is formed by the intestinal bacterial metabolism of niacytin. Trigonelline is absorbed, but cannot be utilized as a source of niacin, and is excreted unchanged.

Nicotinic acid can give rise to N^1-methylnicotinamide and methyl pyridone carboxamide as a result of its incorporation into NAD(P) and subsequent hydrolysis to release nicotinamide. Similarly, nicotinamide can give rise to nicotinic acid, and hence nicotinuric acid and trigonelline, as a result of deamidation. However, test doses of nicotinamide are excreted mainly as N^1-methylnicotinamide, pyridones, and nicotinamide *N*-oxide, while doses of nicotinic acid are excreted mainly as nicotinuric acid.

Metabolic Functions of Niacin

Redox Function of NAD(P)

The nicotinamide nucleotide coenzymes are involved as proton and electron carriers in a wide variety of oxidation and reduction reactions. Before their chemical structures were known, NAD and NADP were known as coenzymes I and II respectively. Later, when the chemical nature of the pyridine ring of nicotinamide was discovered, they were called diphosphopyridine nucleotide, or DPN (NAD), and triphosphopyridine nucleotide, or TPN (NADP). These names will still be found in the literature, and the nicotinamide nucleotide coenzymes are sometimes referred to as the pyridine nucleotide coenzymes.

As shown in Figure 4, the oxidized coenzymes have a formal positive charge, and are represented as NAD^+ and $NADP^+$, while the reduced forms, carrying two electrons and one proton (and associated with an additional proton) are represented as NADH and NADPH. The two-electron reduction of $NAD(P)^+$ proceeds by way of a hydride (H^-) ion transfer to carbon-4 of the nicotinamide ring.

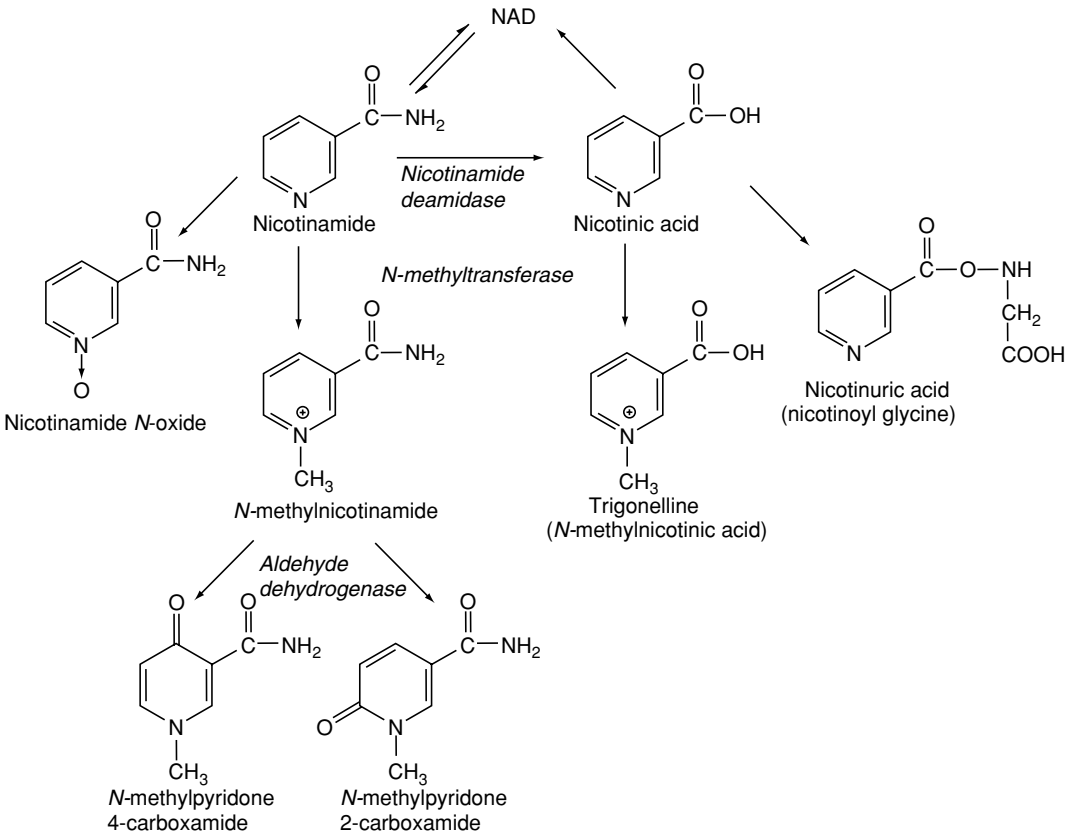

Figure 3 Metabolites of nicotinamide and nicotinic acid.

Table 1 Urinary excretion of niacin metabolites as an index of niacin nutritional status

	Elevated	*Adequate*	*Marginal*	*Deficient*
N^1-methylnicotinamide				
μmol $24\,h^{-1}$	> 48	17–47	5.8–17	< 5.8
mg g^{-1} creatinine	> 4.4	1.6–4.3	0.5–1.6	< 0.5
mmol mol^{-1} creatinine	> 4.0	1.3–3.9	0.4–1.3	< 0.4
Methylpyridone carboxamide				
μmol $24\,h^{-1}$		> 18.9	6.4–18.9	< 6.4
mg g^{-1} creatinine		> 4.0	2.0–3.9	< 2.0
mmol mol^{-1} creatinine		> 4.4	0.44–4.3	< 0.44
Ratio of methyl pyridone carboxamide to N^1-methylnicotinamide		1.3–4.0	1.0–1.3	< 1.0

In general, NAD^+ is involved as an electron acceptor in energy-yielding metabolism, being oxidized by the mitochondrial electron transport chain, while the major coenzyme for reductive synthetic reactions is NADPH. An exception here is the pentose phosphate pathway (hexose monophosphate shunt), which reduces $NADP^+$ to NADPH, and is the principal metabolic source of reductant for fatty acid synthesis.

Role of NAD in ADP-ribosylation of Proteins

ADP-ribosyltransferases catalyze the transfer of ADP-ribose from NAD^+ on to arginine, lysine, or asparagine residues in acceptor proteins, to form *N*-glycosides. In addition to endogenous ADP-ribosyltransferases, a number of bacterial toxins, including diphtheria and cholera toxins, *Escherichia coli* enterotoxin LT and *Pseudomonas aeruginosa* exotoxin A, also have ADP-ribosyltransferase activity, which is not subject to the same regulation as the enzymes in tissues.

ADP-ribosylation (Figure 5) is a reversible modification of proteins, and there are specific hydrolases which cleave the *N*-glycoside linkage. A variety of guanine nucleotide-binding protein (G protein)

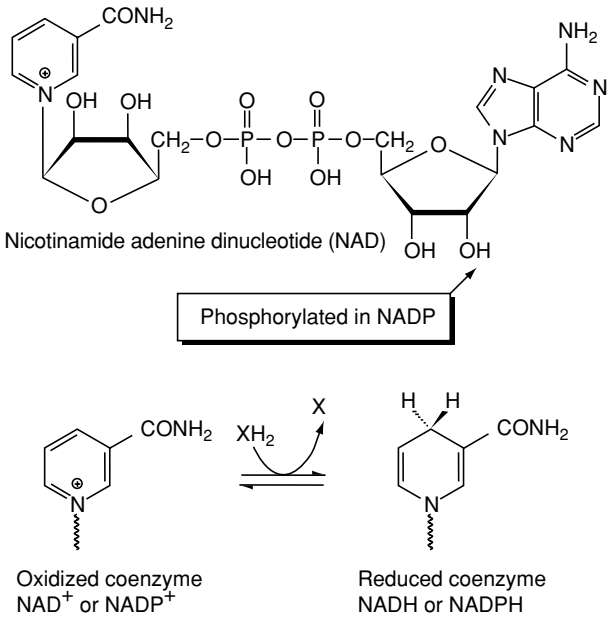

Figure 4 Oxidation and reduction of the nicotinamide coenzymes.

α-subunits involved with the regulation of adenylate cyclase activity are substrates for ADP-ribosylation, either activating the stimulatory G protein or inactivating the inhibitory G protein. The result of ADP-ribosylation by either mechanism is increased adenylate cyclase activity, and hence an increase in intracellular cAMP and the opening of membrane calcium channels. Other proteins that are regulated by ADP-ribosylation include the elongation factor(s) in protein synthesis and integrin and other cytoskeletal proteins.

Poly(ADP-ribose) polymerase (Figure 5) is primarily a nuclear enzyme, which is present in relatively large amounts – up to 1 mol per 1000 base pairs in DNA. It is a zinc finger protein that binds to a nick in DNA caused by strand breakage or excision of an incorrect base. When bound to DNA the enzyme undergoes an autocatalytic poly(ADP-ribosylation), adding branched chains of up to 200 ADP-ribose monomers at each of multiple sites on the enzyme. This poly(ADP-ribosylated) protein then interacts with the α-helical tail of histones, and displacing histones from DNA binding, so leaving the site clear for the DNA repair enzymes to act. There is then slow hydrolysis of the poly(ADP-ribose), permitting the histones to return to bind the repaired DNA.

There is some evidence that poly(ADP-ribose) polymerase may also be involved in DNA replication, since it copurifies with the replication fork and enzymes of DNA replication.

NAD Glycohydrolase and Intracellular Calcium Regulation

A cell membrane-bound NAD glycohydrolase catalyzes a base exchange between NAD^+ and nicotinic acid, yielding nicotinic acid adenine dinucleotide, as shown in Figure 6. The same enzyme also catalyzes exchange of the nicotinamide of NAD^+ with a variety of other compounds, including histamine; there is some evidence that this may provide a mechanism for rapid sequestration, and hence inactivation, of histamine.

The enzyme-bound ADP-ribose that is the intermediate in this base exchange reaction may also undergo either hydrolysis to yield ADP-ribose (so that the enzyme catalyzes overall hydrolysis of NAD^+ to nicotinamide and ADP-ribose), or internal cyclization to release cyclic ADP-ribose.

Both nicotinic acid adenine dinucleotide and cyclic ADP-ribose act to release intracellular stores of calcium. They appear to act as second messengers in transmembrane signal transduction, although the extracellular ligand has not been identified. There is evidence that all-*trans*-retinoic acid stimulates the cyclase activity of the enzyme, although it is not clear whether this is by a cell surface action or as a result of nuclear actions. In β-islet cells of the pancreas, glucose acts to stimulate the cyclase activity, and the resultant cyclic ADP-ribose causes a calmodulin-dependent mobilization of calcium and increased secretion of insulin.

Requirements and Recommendations

In view of the central role of the nicotinamide nucleotides in energy-yielding metabolism, and the fact that, at least under normal conditions, the nicotinamide released by ADP-ribosyltransferase and poly(ADP-ribose) polymerase is available to be reutilized for nucleotide synthesis, niacin requirements are usually expressed per unit of energy expenditure.

Depletion and repletion studies suggest that, on the basis of urinary excretion of N^1-methylnicotinamide, the average niacin requirement is 5.5 mg per 1000 kcal (1.3 mg per MJ). Allowing for individual variation, recommended dietary allowances (RDAs) in most countries are set at 6.6 mg niacin equivalents (preformed niacin plus 1/60 of the dietary tryptophan) per 1000 kcal (1.6 mg per MJ). When energy intakes are very low, it is assumed that expenditure will not fall below about 2000 kcal, and this is the basis for the calculation of RDAs for adults with low energy intakes.

There is little requirement for preformed niacin in the diet, since average intakes of protein (at least in developed countries) will provide enough tryptophan

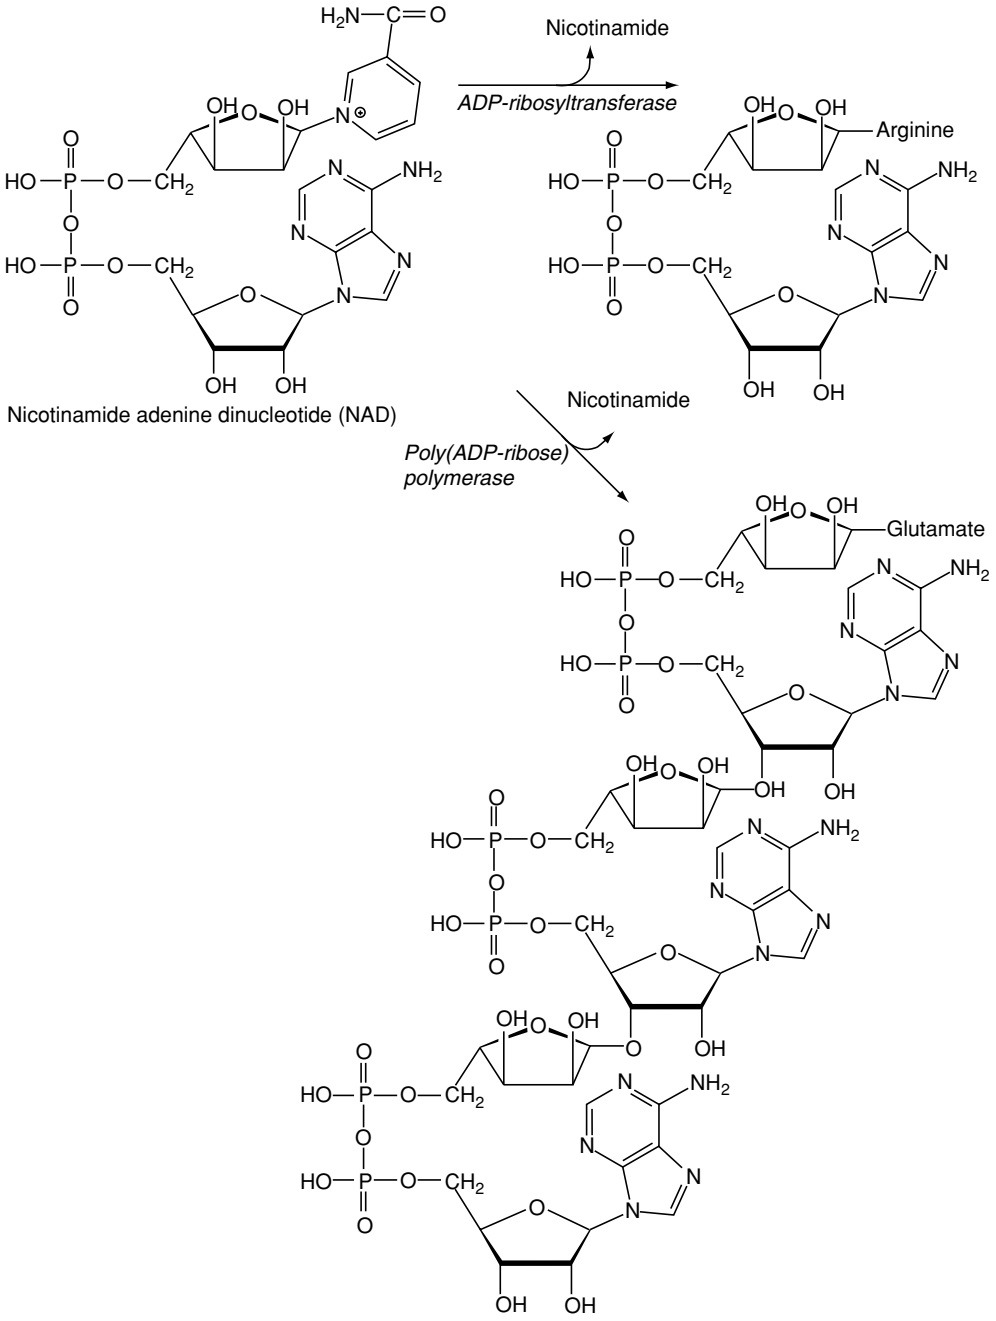

Figure 5 The reactions of adenosine diphosphate (ADP)-ribosyltransferase and poly(ADP-ribose) polymerase.

to meet requirements. Assuming that the diet provides some 15% of energy from protein, and this protein provides 14 g of tryptophan per kg, this implies an intake of 37.5 g of protein (525 mg of tryptophan) per 1000 kcal. Since 60 mg of tryptophan is equivalent to 1 mg of dietary niacin, this suggests that an average diet provides 8.75 mg niacin equivalents per 1000 kcal (2 mg per MJ) from tryptophan alone.

Groups at Risk of Niacin Deficiency (Pellagra)

The tryptophan–niacin deficiency disease pellagra has been a problem in areas of the world where maize or sorghum is the dietary staple, and intakes of both tryptophan and niacin are inadequate. The problem may be compounded by deficiency of riboflavin or vitamin B_6, both of which are required for the synthesis of NAD from tryptophan.

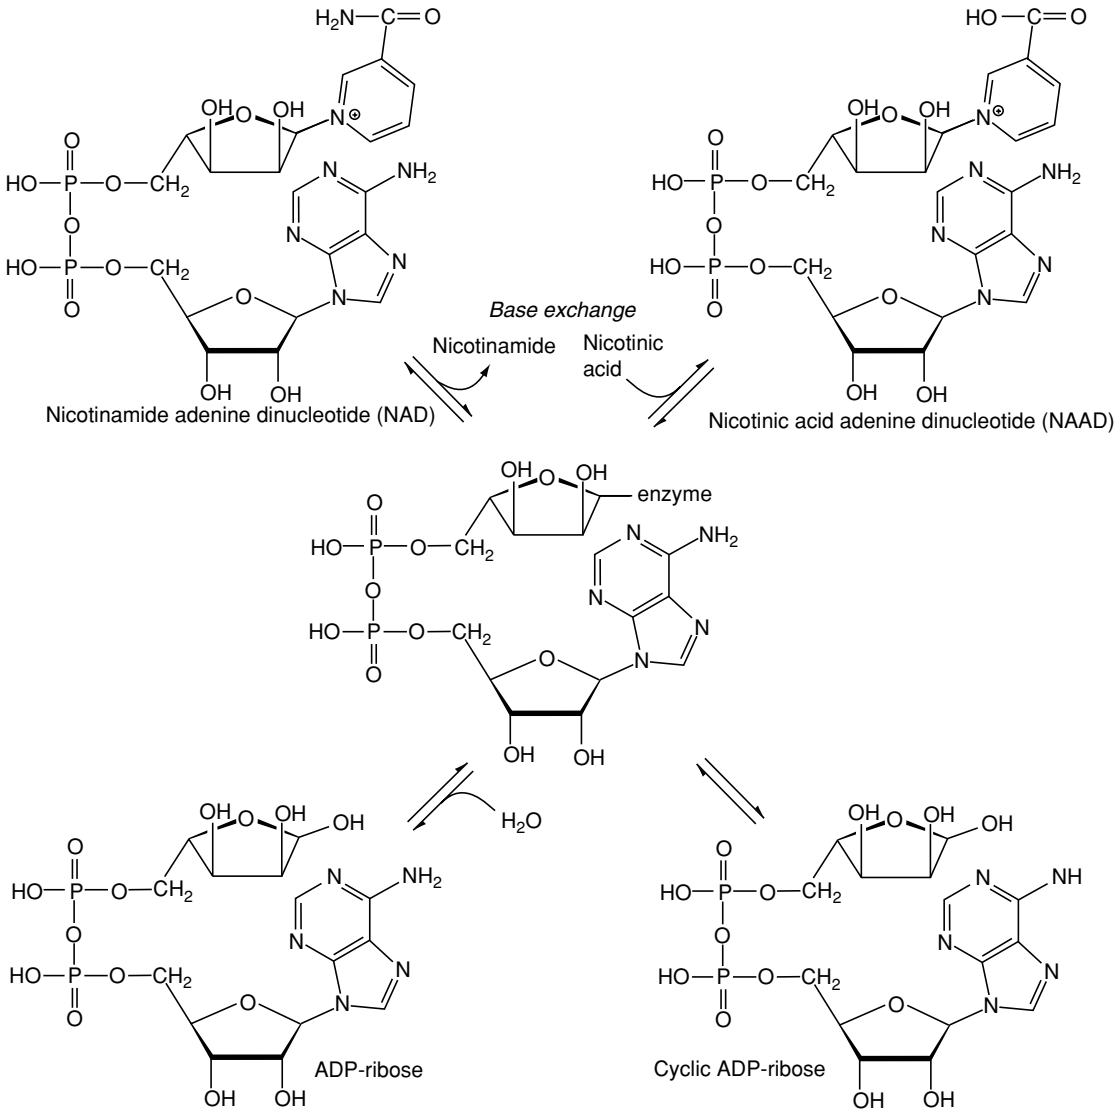

Figure 6 The reactions of nicotinanide adenine dinucleotide (NAD) glycohydrolase and formation of nicotinic acid adenine dinucleotide and cyclic adenosine diphosphate (ADP)-ribose.

A number of mycotoxins and chemotherapy agents used in the treatment of cancer activate poly(ADP-ribose) polymerase; exposure may result in significant depletion of NAD, and hence contribute to the development of pellagra.

Pellagra may arise as a result of drug-induced inhibition of tryptophan metabolism, e.g., by the anti-tuberculosis drug isoniazid (iso-nicotinic acid hydrazide) and the anti-parkinsonian drugs benserazide and carbidopa. Massively increased synthesis of 5-hydroxytryptamine, as occurs in the carcinoid syndrome, results in the development of pellagra, as a result of diversion of tryptophan away from NAD synthesis.

Pellagra also arises as a result of rare inborn errors of tryptophan metabolism or the impairment of tryptophan absorption (Hartnup disease).

Toxicity

Nicotinic acid has been used clinically in large doses (of the order of 1–3 g per day) as a hypolipidemic agent. It reduces both triglycerides and total cholesterol by about 20%, acting as an inhibitor of cholesterol synthesis. It has a more marked effect on cholesterol in low-density and very-low-density lipoproteins, and increases high-density lipoprotein cholesterol.

Nicotinic acid in such doses caused a marked vasodilatation, with flushing, burning, and itching of the skin; after a large dose there may be sufficient vasodilatation to cause hypotension. After the administration of 1–3 g of nicotinic acid daily for several days, the effect wears off to a considerable extent.

At intakes in excess of 1 g of niacin per day there are ultrastructural changes in the liver, and changes in liver

function tests, carbohydrate tolerance, and uric acid metabolism, which are reversible on withdrawal of niacin. Sustained-release preparations are associated with more severe liver damage than simple preparations, and may cause clinical liver failure, presumably because they permit more prolonged maintenance of high blood and tissue concentrations of the vitamin.

Supplements of several grams of tryptophan per day have been used with some success in the treatment of depressive diseases, apparently without ill effect. However, a potentially fatal eosinophilia–myalgia syndrome associated with the use of tryptophan supplements has been reported, with more than 1200 cases reported to the US Center for Disease Control in 1989. It seems most likely that the problem was due to a trace contaminant (ethylidene *bis*-tryptophan) in a single batch of tryptophan, rather than toxicity of tryptophan *per se*.

NISIN

G C Williams and J Delves-Broughton, Danisco Innovation, Beaminster, Dorset, UK

Introduction

Nisin is a polypeptide bacteriocin that exhibits antibacterial activity against a wide range of Gram-positive bacteria and is particularly effective against bacterial spores. It shows little or no activity against Gram-negative bacteria, yeasts, and molds. Nisin is produced by certain strains of *Lactococcus lactis* subsp. *lactis*. Commercial preparations of nisin are widely used as food preservatives throughout the world. It is recognized as both a toxicologically safe and natural substance.

History

Nisin was discovered in England in 1928 when problems arose in cheese-making. Batches of milk became contaminated with a nisin-producing strain of *L. lactis*, and as a result of nisin's inhibitory properties, the growth of the cheese starter cultures was inhibited. Nisin was subsequently isolated and characterized. Its name was derived from Group *N* (*Streptococcus*) inhibitory substance. The discovery of nisin predated that of penicillin, so therefore it is not surprising that initial research focused on its potential use for

therapeutic purposes in medical and veterinary applications. It was found to be unsuitable for such purposes, mainly because of its limited antimicrobial spectrum in addition to its poor solubility and stability in body fluids. The first interest in its potential as a food preservative came in the 1950s when it was evaluated for the control of gas-producing *Clostridium* spp. in Swiss cheese. However, problems occurred due to the fact that the cheese starter cultures were inhibited, which adversely affected the cheese-ripening process. This problem has now been largely overcome by the development of nisin-resistant cheese starter cultures. The next milestone was its development as a preservative in processed cheese in the mid-1950s. During this period Aplin & Barrett Ltd were experiencing unacceptable spoilage problems due to clostridial growth in processed cheese spreads. This problem was eliminated by the inclusion of nisin-rich curd into the processed cheese mix. With this success the company went on to develop the commercial concentrated preparation of nisin termed Nisaplin. Nisaplin has a nisin content of 25 mg g^{-1} and is currently used worldwide as a food preservative. Recently Chr. Hansen from Denmark has introduced a similar product of the same potency, termed Chrisin.

Units of Activity

The first definition was that of a reading unit (later known as an international unit), which was defined as the amount of nisin necessary to inhibit one cell of *Streptococcus agalactiae* in 1 ml of broth. It was so termed in recognition that much of the early work on nisin was carried out at the National Institute for Research in Dairying, Shinfield (Reading), England. Since then an international reference preparation of nisin has been established by the World Health Organization Expert Committee in Biological Standardization. This reference preparation contains, like the commercial preparations Nisaplin and Chrisin, 25 mg (1 million international units) of pure nisin per gram. Throughout this article all levels of nisin are expressed as mg pure nisin per kilogram or liter.

Structure and Biosynthesis

Two natural nisin molecules exist, termed nisin A and nisin Z. The structure of the nisin A molecule was elucidated in 1971 and is presented in Figure 1. It is a 34-amino-acid polypeptide with amino and carboxyl endgroups, and five internal ring structures involving disulfide bridges. It possesses three unusual amino acids: dehydroalanine, lanthionine, and β-methyllanthionine. Lanthionine appears to be a common feature in a number of more recently characterized bacteriocins that are collectively known as lantibiotics. Nisin Z differs from nisin A by the substitution of asparagine for histidine at position 27. Nisin Z has a similar antimicrobial activity to nisin A, although nisin Z shows greater diffusion in agar gels. Japanese workers have successfully synthesized the nisin A molecule and confirmed its basic structure. Nisin A has a molecular weight of 3354 Da. There is evidence that nisin can exist as both dimers and tetramers.

A precursor molecule to nisin has been identified and its structural gene isolated and characterized. The

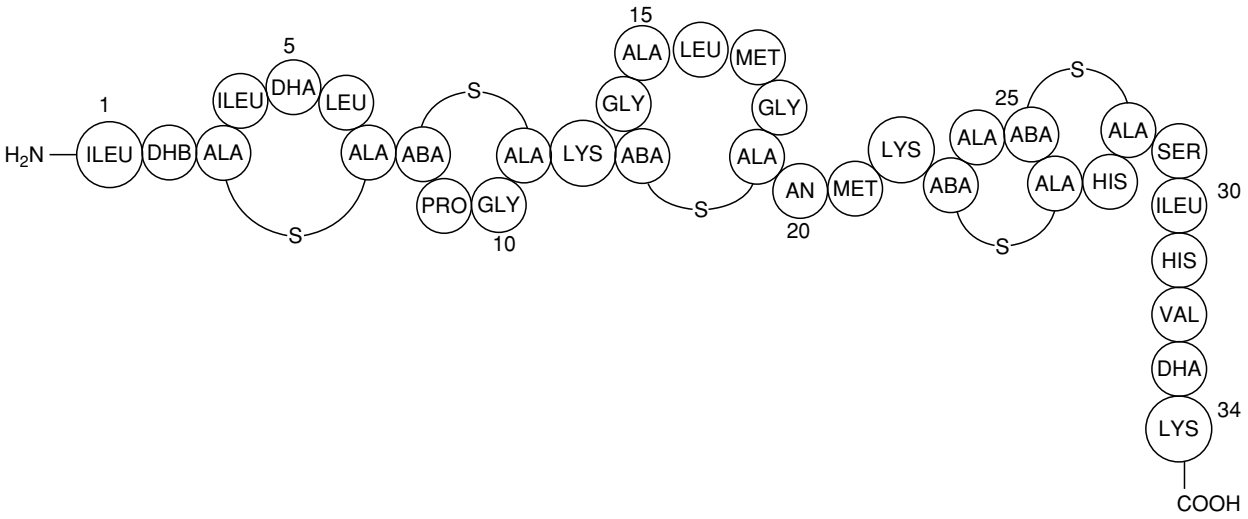

Figure 1 The structure of nisin A. ABA, aminobutyric acid; DHA, dehydroalanine; DHB, dehydrobutyrine (β-methyldehydroalanine); ALA-S-ALA, lanthionine; ABA-S-ALA, β-methyllanthionine.

nisin determinant of *L. lactis* is a component of a large transmissible gene block that also encodes for sucrose metabolism and nisin immunity. The gene block is located in the chromosome as opposed to being in a plasmid. The ability of *L. lactis* to synthesize nisin is a conjugally transmissible property that has been transferred to negative phenotype recipients.

Mode of Action and Antimicrobial Effect

Nisin works in a concentration-dependent manner both in terms of the amount of nisin applied and the number of vegetative cells or spores that need to be inhibited or killed. The primary site of action in sensitive Gram-positive cells is the cytoplasmic membrane where insertion of nisin into the membrane causes disruption of membrane function. An initial step is the docking of nisin on to lipid II, which is followed by the insertion of the nisin II lipid into the membrane where it forms pores. Through these pores, essential cell constituents leak from the inside to the outside of the cell and cause depletion of the proton motive force. Gram-negative bacteria are normally protected from nisin by their outer cell wall acting as an impermeable barrier to the nisin molecule. However, if the outer wall of Gram-negative cells is made permeable to nisin by partial or complete disruption, the cells can then become sensitive to nisin. This indicates that their cytoplasmic membranes are sensitive to nisin. Recent work has demonstrated that yeast protoplasts and spheroblasts are also sensitive to nisin. Gram-negative bacteria can be sensitized to nisin by sublethal heat treatment, freeze–thaw cycling, and exposure to chelating agents that remove divalent ions from their cell walls, thus making them more permeable to nisin. Good effects can be demonstrated against Gram-negative bacteria by the combined use of nisin and a chelating agent such as ethylenediaminetetraacetic acid (EDTA) in a simple buffer system. In food systems, however, such good results are not usually observed as the chelating agent will preferentially bind with the divalent ions that are more readily available in the food matrix.

The action of nisin against spores is predominantly sporostatic as opposed to sporicidal. Nisin affects the postgermination stages of spore development. It inhibits preemergent spore swelling, and thus the outgrowth and formation of vegetative cells. The active sites in spores are thought to be membrane-bound sulfhydryl groups. An important factor in relation to heat-processed foods is that progressive heat damaging of spores results in them becoming increasingly sensitive to nisin.

The nisin sensitivity of both cells and spores can vary between genera and even between strains of the same species. Nisin action against vegetative cells can either be bactericidal or bacteriostatic depending on a number of factors, such as nisin concentration, bacterial population size, physiological state of the bacteria, and the conditions of growth. Bactericidal effects against vegetative cells are enhanced under optimal growth conditions when the bacteria are in an energized state. In contrast, bacteriostatic effects are enhanced when nisin forms part of a multipreservation system in which growth conditions are nonoptimal and other inhibitory factors are exerted (hurdle technology). The fact that different conditions are required to insure either bacterial destruction or inhibition needs to be taken into consideration when applying nisin in a food preservation system. Nisin efficacy in foods is dependent on an effective level of nisin being maintained throughout the whole shelf-life of the food.

Solubility and Stability

Nisin is most soluble in acid substrates and becomes progressively less soluble as the pH increases. Thus at pH 2.2 the solubility is 56 000 mg l^{-1}, at pH 5 it is 3000 mg l^{-1} and at pH 7 it is 1000 mg l^{-1}. In practical food preservation situations the level of nisin treatment is unlikely to exceed 50 mg l^{-1} and thus solubility is never a problem. Commercial powder preparations of nisin contain residual solids from the fermentation process that are insoluble. This can produce cloudy suspensions in water but has no detrimental effect on the efficacy of nisin.

Commercial preparations of nisin are remarkably stable. They show no loss of activity over a 2-year period providing they are stored under dry conditions, in the dark, and at temperatures below 25 °C. Nisin solutions are most stable to autoclaving (121 °C for 15 min) in the pH range 3.0–3.5 (< 10% activity loss). Values below and above this pH range result in a marked loss of activity, especially those furthest removed from the range (> 90% activity loss at pH 1 or pH 7 in a buffer system). Losses at typical pasteurization temperatures used in foods are significantly less and food components can protect nisin during heat processing.

The stability of nisin in a food system is dependent on three factors: incubation temperature, length of storage, and pH. In a nonheat-processed food a fourth factor will be the possible presence of protease enzymes. Nisin retention at warm ambient temperatures above 25 °C will be far less than at cooler temperatures. On a practical level this means that higher nisin addition levels are required for the preservation of foods in warmer climates. Retention of nisin activity in an acidic food product will be better than in a

more neutral food stored under similar conditions. Nisin can be inactivated by many nonspecific proteases and by any proteolytic enzyme that can cleave the histidine-valine bond (residues 31–32) or the dehydroalanine bond (residues 33–34), e.g., thermolysin, chymotrypsin, subtilisin, ficin, papain, and bromelain. Elastase, pepsin, and leucine aminopeptidase have no action on nisin, and trypsin has a reversible action. A variety of bacteria can produce the enzyme 'nisinase' which specifically inactivates nisin. Some of the bacterial species reported as being able to produce nisinase include *Lactobacillus plantarum, Streptococcus thermophilus*, and *Bacillus cereus*.

The food additives, and related sulfiting agents sodium metabisulfite (an antioxidant, bleaching, and broad-spectrum antimicrobial agent) and titanium dioxide (a whitening agent) can also cause nisin degradation.

Methods of Assay

A number of bioassay methods have been devised. These include dye reduction methods using resazurin or methylene blue with a sensitive lactic acid bacterium in a milk-based medium, turbidometric growth measurement assay, horizontal agar plate diffusion assay, the bioluminescent measurement of released adenosine triphosphate (ATP) from *Lactobacillus casei*, and an enzyme-linked immunoabsorbent assay (ELISA). The method in most common use is the horizontal agar plate diffusion assay employing the test organism *Micrococcus luteus*. The lower limit of detection in this assay is about $0.025\,mg\,l^{-1}$. A recently described novel technique has been the development of a strain of *L. lactis* that can sense nisin and transduce the signal into bioluminescence with as little as $0.0125\,ng\,ml^{-1}$ nisin being detectable by this method.

Quantitative analysis of nisin can also be achieved by high-performance liquid chromatography (HPLC) analysis. A nisin-containing liquid is assayed chromatographically on a hydrophobic (C18) narrow-base HPLC column by gradient elution. Calculations are based on the peak height and quantification done by comparison with a standard nisin preparation. The lower limit of detection by HPLC is around $10\,mg\,l^{-1}$.

Toxicology and Legislation

Toxicity studies carried out in laboratory animals with levels of nisin far in excess of those used in foods have shown that nisin is nontoxic and is not carcinogenic. Nisin is rapidly inactivated in the intestine by digestive enzymes and cannot be detected in the saliva of human beings 10 min after consumption of liquid containing $5\,mg\,l^{-1}$ nisin. There is no evidence of sensitization (allergy problems) and microbiological studies have not shown any cross-resistance problems that may affect the efficacy of therapeutic antibiotics. It is important that nisin and other bacteriocins are not classified as antibiotics as this could hamper their future acceptance as food preservatives.

In 1969, the Joint Food and Agriculture Organization/World Health Organization (FAO/WHO) Expert Committee on Food Additives reviewed the toxicological data for nisin and recommended its use as a food preservative, with an acceptable daily intake (ADI) of $0.825\,mg\,kg^{-1}$ of body weight per day. At present its use is permitted in approximately 60 countries, including the US, the former USSR countries, and China. In the EU it has the food additive number E234.

Preservation of Foods using Nisin

Although nisin use as a food preservative originated with processed cheese products, other application areas have since been identified. Many of these are in products that, by their nature, are pasteurized during production but are not fully sterilized. In such foods Gram-negative bacteria, yeasts, and molds are destroyed by the heat treatment, and the surviving microflora consists of Gram-positive spore-forming bacteria that can be controlled by the use of nisin. The effectiveness of nisin in such products is only complete if postprocessing contamination is eliminated or minimized. Nisin is also used in canned vegetables to control thermophilic spoilage, in non-heated acidic products to control lactic acid bacteria, and in products that are at risk from the psychroduric food-poisoning bacterium, *Listeria monocytogenes*.

Table 1 summarizes the major categories of food in which nisin is used, and the typical spoilage or pathogenic bacteria in these products that are controlled by nisin.

Processed Cheese Products

Processed cheese products cover a wide range, including block cheese (approximately 44–46% moisture), slices (46–50% moisture), spreads (52–60% moisture), and sauces and dips (56–65% moisture). All are heat-processed and contain emulsifying salts. Product innovation in the industry is considerable and formulations can be of low fat or reduced sodium chloride content and may contain various flavor additives such as herbs, fish, shellfish, and meat. All these factors, along with bacterial quality of the raw ingredients, severity of the melt process, filling

Table 1 Typical addition levels of nisin (and Nisaplin) in examples of food applications

Type of food/application	*Addition level of nisin (mg kg^{-1} or mg l^{-1})*	*Addition level of Nisaplin (mg kg^{-1} or mg l^{-1})*	*Typical target organisms*
Processed cheese	5–15	200–600	*Bacillus* spp. *Clostridium* spp.
Pasteurized chilled dairy desserts	1.25–3.75	50–150	*Bacillus* spp.
Pasteurized milk and milk products	0.25–10.0	10–400	*Bacillus* spp. *Clostridium* spp.
Pasteurized liquid egg products	1.25–5.0	50–200	*Bacillus* spp., e.g., *B. cereus*
Pasteurized chilled soups	2.5–5.0	100–200	*Bacillus* spp.
Crumpets	3.75–6.25	150–250	*Bacillus cereus*
Canned foods (low acid)	2.5–5.0	100–200	*Bacillus stearothermophilus* *C. thermosaccharolyticum*
Canned foods (high acid)	1.25–2.5		*C. pasteurianum* *B. macerans* *B. coagulans*
Canned lobster	25.0	1000	*Listeria monocytogenes*
Ricotta cheese	5.0	200	*Listeria monocytogenes*
Continental-type cooked sausage:			
Added to mix	1.25–6.25	50–250	Lactic acid bacteria
Dipping	5.0–25.0	200–1000	
Salad dressings	1.25–5	50–200	Lactic acid bacteria
Beer:			
Pitching yeast wash	25–37.5	1000–1500	Lactic acid bacteria, e.g., *Lactobacillus* spp.
During fermentation	0.63–2.5	25–100	*Pediococcus* spp.
Postfermentation	0.25–1.25	10–50	

temperature, and shelf-life requirement can affect the microbial stability of processed cheese products and hence the requirement for nisin and the level at which it needs to be applied.

The ingredients used in the manufacture of these products are raw cheese, butter, skimmed milk powder, whey powder, phosphate, or citrate emulsifying salts and water. Spores of anaerobic clostridial species are often present in some of these ingredients, particularly the cheese, and are able to survive the heat process of 85–105 °C for 6–10 min commonly used in the heat process. The composition of processed cheese in terms of the relatively high pH (5.6–6.0) and moisture content combined with low redox potential (anaerobic conditions) can result in spore germination and growth, which may result in subsequent spoilage due to production of gas, off-odors, and digestion of the cheese. *Clostridium* spp. often associated with the spoilage of processed cheese are *C. sporogenes, C. butyricum*, and *C. tyrobutyricum*. Trials with processed cheese products have been carried out in the UK using a cocktail of spores of the aforementioned *Clostridium* spp. at inoculation levels of approximately 200 spores per gram. Spoilage was prevented during storage at 37 °C by 6.25 mg kg^{-1} nisin. Partial control was achieved with 2.5 mg kg^{-1} whilst control samples that did not contain nisin readily became spoiled.

The potential for growth and toxin production by *C. botulinum* in processed cheese products, particularly spreads, is of considerable significance. Trials in the US have indicated that, in processed cheese spreads, nisin is effective in delaying or preventing the growth and subsequent toxin production by inoculated spores of *C. botulinum* types A and B. These studies indicated that the use of nisin as an effective preservative in processed cheese spreads should form part of a multicomponent food preservation system. Levels of moisture, sodium chloride, phosphate emulsifier salt, and pH are all factors important in determining the necessary level of nisin to provide the required shelf-life. Facultative aerobic *Bacillus* spp. can also cause spoilage problems in processed cheese products and these organisms are also controllable using nisin. Levels used to prevent spoilage are 5–20 mg kg^{-1}, whereas levels used to provide protection against *C. botulinum* are 12.5 mg kg^{-1} and above.

Other Pasteurized Dairy Products

Other pasteurized dairy products, such as dairy desserts, cream, clotted cream, and mascarpone cheese, often cannot be subjected to full sterilization without damaging their organoleptic properties, texture, and/or appearance, and are thus sometimes preserved with nisin to extend their shelf-life. For example, tests on a chocolate dairy dessert resulted in a

20-day increase in shelf-life with 3.75 mg kg^{-1} nisin at 7 °C. The same nisin level gave a 30-day increase in shelf-life for a crème caramel dessert stored at 12 °C.

The addition of nisin to pasteurized milk is permitted in countries that may experience shelf-life problems due to high ambient temperatures, long-distance transport, and inadequate refrigeration. Trials at Reading University, UK, with nisin added at 1 mg l^{-1} before pasteurization at 72 °C for 15 s, 90 °C for 15 s, or 115 °C for 2 s all resulted in significant shelf-life extension of the milk when stored at 10 °C. Similar benefits to shelf-life have also been demonstrated with pasteurized flavored milk.

Pasteurized Liquid Egg Products

Pasteurized liquid egg products (whole, yellow, and white) and value-added egg products (e.g., omelets, scrambled eggs, pancake mixes) receive heat treatments designed to insure the destruction of *Salmonella*. In the UK, for instance, liquid whole egg must be pasteurized for at least 2.5 min at a temperature of 64.4 °C. However, such heat treatment is insufficient to kill bacterial spores and the more heat-resistant nonspore-forming Gram-positive bacteria such as *Enterococcus faecalis*. Many of these surviving bacteria are capable of growth at refrigerated temperatures and pasteurized egg products often have a short shelf-life. Application of nisin at levels of 2.5–5 mg l^{-1} has been shown to act as an effective preservative, giving significant increases in shelf-life and providing protection against the growth of the psychroduric food-poisoning bacteria *B. cereus* and *L. monocytogenes*.

Pasteurized Soups

A recent trend in soup manufacture has been a move towards the production of fresh pasteurized products with a relatively limited chilled shelf-life. Heat-resistant spores of *Bacillus* spp. are able to survive the pasteurization treatment and may be capable of growing and causing spoilage under conditions of chill abuse storage. Trials with nisin at levels of 2.5–5.0 mg l^{-1} have been found to be very effective at preventing or delaying the outgrowth of psychroduric spoilage *Bacillus* spp. during prolonged shelf-life storage of these pasteurized soup products.

High-moisture Hot Plate Products

Crumpets are high-moisture flour-based products that are popular in the UK, Australia, and New Zealand. Crumpets are produced on a hot plate from a flour batter and contain yeast, an aerating agent or both to give them a raised profile and open texture. They are toasted before eating. Crumpets have a non-acid pH (pH 6), high moisture (48–54%) and high water activity (0.95–0.97). The product is sold at ambient temperature and has a shelf-life of 5 days. There have been a number of food-poisoning outbreaks due to the growth of *B. cereus* in crumpets, particularly in Australasia. Flour used in the manufacture of crumpets invariably contains low numbers of *B. cereus* spores that are not killed during the hot plate cooking process. During the 3–5-day ambient shelf-life of the product, levels of *B. cereus* can increase from undetectable levels to $> 10^5$ cfu g^{-1} – sufficient bacteria to cause food poisoning. Addition of nisin to the batter mix at 3.75 mg kg^{-1} prevents the growth of *B. cereus* to these potentially dangerous levels. Such use of nisin has received regulatory approval in Australia and New Zealand.

Canned Foods

Nisin is used in canned foods mainly for the control of thermophilic spoilage. It is mandatory in most countries that low-acid canned foods (pH > 4.5) receive a minimum heat process of $F_0 = 3$ to insure the destruction of *C. botulinum* spores, i.e., the minimum botulinum cook. Low-acid foods processed at F_0 of 3 are susceptible to spoilage from surviving heat-resistant spores of thermophilic bacterial species of *B. stearothermophilus* (cause of flat sour spoilage) and *C. thermosaccharolyticum* (cause of can swells). Thus nisin addition can facilitate prolonged storage of canned vegetables at warm ambient temperatures by inhibiting spore outgrowth of these thermophilic spoilage organisms. The use of nisin can also allow a reduction in the F_0 process down to the minimum of 3 without increasing the potential risk of thermophilic spoilage. Other advantages are reduced heat damage to the foods as well as potential saving in energy consumption. Nisin usage levels in low-acid canned vegetables are 2.5–5.0 mg kg^{-1}. Residual nisin levels in canned foods after high temperature processing can be as low as 2% of the addition level. However, the fact that heat-resistant thermophilic spores are highly sensitive to nisin combined with the heat damage enhancing their sensitivity means that extremely low levels of residual nisin can still be effective in this application. Preacidification of the brine with citric acid improves nisin retention with minimal effect on the pH of the vegetables after processing.

Examples of use are canned peas, carrots, peppers, potatoes, mushrooms, okra, baby sweetcorn, and asparagus. Nisin is also used in canned dairy puddings containing semolina and tapioca.

Bacterial spoilage of canned high-acid foods (pH below 4.5) is restricted to nonpathogenic spoilage

species such as *C. pasteurianum*, *B. macerans*, and *B. coagulans*. Nisin addition levels of 1.25–2.50 mg kg^{-1} are used in high-acid tomato-based products.

Meat Products

Concern regarding the high levels of nitrite in cured meat has resulted in research investigating the use of nisin as a partial replacement for nitrite. Results indicated that only high (and uneconomic) levels of nisin achieved good control of *C. botulinum*. Further work is necessary before a case for such an application is demonstrated. More encouraging results have been obtained in vacuum-packed cooked continental-type sausages where lactic acid bacteria can cause spoilage by production of gas, off-odors, and slime. Addition of nisin into the sausage mix at levels of 1.25–6.25 mg kg^{-1} or dipping the cooked sausage into nisin solutions of 5.0–25.0 mg l^{-1} has proved effective in increasing shelf-life at storage temperatures of 6–12 °C. Investigations have shown that nisin is more inhibitory against lactic acid bacteria in sausages with lower fat levels. It was also shown that nisin had a greater effect in sausages containing diphosphate compared to those with orthophosphate.

Fish and Shellfish

Relatively few studies have been carried out using nisin in fresh fish mainly because the predominant flora tends to be Gram-negative bacteria. The potential hazard of botulism in both vacuum-packed and modified-atmosphere-packed fish has led to work at the Torry Research Station in the UK on the use of nisin as an antibotulinal agent. Application of nisin by spray to fillets of cod, herring, and smoked mackerel inoculated with *C. botulinum* type E spores resulted in a significant delay in toxin production at 10 and 26 °C. Another problem in smoked fish is the presence and growth of the psychroduric pathogen *L. monocytogenes*, especially in fresh and lightly preserved products. Nisin has been shown to be an effective antilisterial agent in smoked salmon, especially when packed in a carbon dioxide atmosphere.

L. monocytogenes can also be a problem in shellfish, particularly crabs and lobsters, as their meat can only be lightly heat-processed without significant product damage occurring. Nisin, in combination with a reduced heat process, that does not cause product damage of lobster meat, has been shown to achieve a *Listeria* kill that is significantly better than either heat or nisin used alone. An effective nisin level for this application is 25 mg kg^{-1}. Washing crabmeat with nisin has been shown to reduce levels of *L. monocytogenes*.

Salad Dressings

The development of cold blended salad dressings with reduced acidity can improve the flavor of many varieties that are considered to have an over-acid taste. Using reduced levels of acetic acid and raising the pH from 3.8 to 4.2 can make salad dressings prone to lactic acid bacterial spoilage during ambient storage. Such growth has been successfully controlled by the addition of nisin at 2.5–5.0 mg l^{-1}.

Natural Cheese

The first application of nisin was to prevent blowing problems in semihard ripe cheese such as Emmenthal and Gouda due to growth of *C. butyricum* and *C. tyrobutyricum*. Although promising results were obtained, a problem with inhibition of the starter cultures and consequent delay of the ripening process led to the work being discontinued. However, the increase in knowledge of lactic acid bacterial genetics and the need to devise methods for the control of *L. monocytogenes* has resulted in fresh interest into the use of nisin in natural cheese. To achieve success, nisin-resistant starters must be used in conjunction with nisin to insure successful development of the cheese. Natural nisin-producing, nisin-resistant strains tend to lack important properties associated with cheese starter cultures such as good flavor production, eye formation, acidifying characteristics, and bacteriophage resistance. Using the food-grade genetic transfer technique of conjugation it has been possible to develop nisin-producing, nisin-resistant starter cultures with the above-desired properties. Cheeses have been made with sufficient nisin content to provide protection against growth of *Clostridium* spp., *Staphylococcus aureus*, and *Listeria monocytogenes*.

Yogurt

The addition of nisin to stirred yogurt postproduction has an inhibitory effect on the starter culture (a mixture of *Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus thermophilus* strains), thereby preventing subsequent overacidification of the yogurt. Thus an increase in shelf-life is obtained by maintaining the flavor of the yogurt (less sour) and preventing syneresis. Typical addition levels for this application are 0.5–1.25 mg kg^{-1}.

Alcoholic Beverages

Acid-tolerant lactic acid bacteria of the genera *Lactobacillus, Pediococcus*, and *Leuconostoc* can spoil beer and wine due to growth along with production of off-flavors, off-odors, slime, or haze. At levels of 0.25–2.5 mg l^{-1}, nisin is effective in preventing such

spoilage. Yeasts are unaffected by nisin, thus the preservative can be added during the fermentation. Nisin can be added to fermenters to prevent or control contamination and can also be used to increase the shelf-life of unpasteurized and bottle-conditioned beers. Furthermore, nisin can be used in the pitching yeast wash as an alternative to acid washing for the control of lactic acid bacteria. Unlike nisin treatment, acid washing can have an adverse effect on yeast viability and performance. Typical levels for this application are 25.0–37.5 $mg\,l^{-1}$. Similar applications occur in the wine industry with the limitation that nisin cannot be used in wines that depend upon a desirable malolactic fermentation as the bacteria responsible are usually nisin-sensitive. This latter problem has been overcome by developing nisin-resistant strains of *Leuconostoc oenos* that can grow and maintain malolactic acid fermentation in the presence of nisin. In the production of distilled spirits, nisin can inhibit the lactic acid bacteria that compete with the yeast for substrate in the fermentation mash, thus resulting in increased alcohol yield in the final distillate. Alcohol yield has been increased by over 10% using this method.

Potential Future Applications

Research on nisin as a food additive continues as the demand increases for convenient long shelf-life and safe food preserved by safe preservatives with a natural connotation. Current research includes the use of nisin in combination with novel food preservation systems such as ultra high pressure, electroporation, pulsed electric fields, and nanothermosonication. It is evident that, like the classical use of heat preservation processes, bacterial spores are more resistant to these novel processes than bacterial vegetative cells and nisin in combination with these processes is synergistic against bacterial cells and surviving bacterial spores. Nisin in combination with other safe food additives that provide synergistic effects against Gram-positive bacteria or widen the antimicrobial spectrum to include Gram-negative bacteria, yeasts, and molds are also objectives of many research teams. Incorporation of nisin into packaging and edible films may also provide new areas of application. Finally, emerging food spoilage bacteria such as *Alicyclobacillus acidoterrestris* (an acid-tolerant, spore-forming bacteria that can grow at pH 2.5 and is a potential problem in pasteurized fruit juice) and *B. sporothermodurans* (a mesophilic, spore-forming bacteria whose spores can survive ultra heat-treated (UHT) processing) have been shown to be nisin-sensitive. New applications to control such bacteria are currently being realized.

NITRATES AND NITRITES

M J Dennis and L A Wilson, Central Science Laboratory, Sand Hutton, York, UK

Background

Nitrate is a normal component of plant tissues, whereas nitrite is not normally found in significant quantities unless microbiological spoilage occurs. Both nitrate and nitrite are permitted food additives for use in curing meat. Their original function was to confer microbiological safety, but they were also found to contribute useful color and flavor characteristics, which, with the advent of refrigeration, are now of greater technological significance. There have been considerable concerns over the safety of nitrate and nitrite in foods. Nitrate is largely unreactive but can be reduced to nitrite, which can then react with secondary amines to form nitrosamines (many of which are carcinogens). Equally, it is becoming apparent that oxides of nitrogen play an important role in human physiology. Hence, in this review, we will cover the occurrence of nitrate and nitrite in food, the legislation governing their use as food additives, and legislation governing their occurrence in vegetables, their human dietary intake, their potential health benefits, and concerns.

Occurrence in Foods

Nitrate is found as a naturally occurring compound in foods such as vegetables, fruit, cereals, fish, milk, and dairy products, and is also found in water as a consequence of agricultural practices such as the use of nitrogen-containing fertilizers and from animal waste. Low levels are generally found from these sources, except in the case of some vegetables. Nitrate and nitrite are also permitted as food additives in some foods, primarily as protection against botulism.

Vegetables and Fruit

Nitrate in the soil is taken up by plants for use as a nitrogen source in the formation of proteins. Protein production occurs as a result of photosynthesis, but when light levels fall, the rate of photosynthesis decreases, and nitrate accumulates in cell fluids and sap. The levels of nitrate in vegetables grown under low light conditions are thus correspondingly higher than those grown under bright light, as shown in Figure 1. Overall, nitrate accumulation in plants is determined by genotype, growing conditions, especially light levels and soil temperature, and nitrogen fertilization.

Nitrate content varies considerably according to species, with vegetables such as spinach and lettuce often containing up to 2500 mg kg^{-1}, whereas those such as asparagus have levels as low as 13 mg kg^{-1}. Table 1 lists the concentrations of nitrate found in some vegetables and fruits, and compares the levels found in different countries. The natural levels of nitrate in vegetables generally are high when compared with other food groups. It is estimated that 75–80% of the total daily intake comes from vegetables, compared with only about 5–10% from drinking water. Cooking has been shown to decrease the concentration of nitrate in foods, dependent on the cooking technique used (see Table 2).

Nitrite levels in vegetables and fruit are low, usually below 2 mg kg^{-1}, except where there has been damage or improper storage leading to the microbiological reduction of nitrate to nitrite.

Meat and Meat Products

Fresh meat normally contains low levels of nitrate and nitrite, estimated at < 4–7 mg kg^{-1} and < 0.4–0.5 mg kg^{-1}, respectively, in the UK in 1997, although higher concentrations of about 10–30 mg kg^{-1} of nitrate are found in cured meats such as ham and salami, where nitrite and nitrate have been incorporated as a permitted additive. Nitrite salts have

Data from: Ysart G, Miller P, Barrett G, Farrington D, Lawrance P and Harrison N (1999) Dietary exposures to nitrate in the UK. *Food Additives and Contaminants* 16(12): 521–532. All data used with the author's permission.

customarily been added to a range of meats for preservation purposes, especially as an antimicrobial agent with regard to *Clostridium botulinum*, to produce the pink color of cured meats via the formation of a nitric oxide–myoglobin complex and to give the traditional flavor expected from these products. Nitrite is preferred as a curing agent, as it reacts more quickly than nitrate, and less is required for color stabilization, but nitrate may be added to act as a reservoir in case the nitrite level is depleted during curing. Measures have been taken to reduce the amounts of nitrite used during meat curing processes owing to concern over the formation of nitrosamines. These restrictions have led to significant reductions in the nitrate and nitrite contents of cured meats. Nitrite is now frequently added to meat products at much lower levels, commonly 80–160 mg kg^{-1}, in conjunction with sodium ascorbate or sodium erythorbate. It is considered that the benefits of adding nitrite to products of this type far outweigh the potential risks. (*See* ***Clostridium***: Botulism.)

Cheese

Potassium nitrate is permitted as an additive in cheese manufacture in order to control microbiological contamination, which may produce early gassing, and thus to improve the quality of the finished product. Natural concentrations in cheese were found at 1–8 mg kg^{-1} of nitrate, with concentrations rising to 4–27 mg kg^{-1} of nitrate and < 0.6–1 mg kg^{-1} of nitrite when nitrate was used as an additive.

Fish and Fish Products

Nitrite is permitted in some countries as an additive to some smoked and cured fish and fish products, when it is used as a preservative and color fixative. Levels of both nitrate and nitrite are low in the fresh product, but a recent Japanese survey (1998) analyzed nitrite levels in different salted and processed

fish products and found that, although the mean concentrations were about 30–40% of the permitted limit, some products contained nitrite at levels of up to 32 mg kg^{-1}.

Beverages

Beverages make a significant contribution to nitrite intake due to high consumption. Although the concentrations found are low (< 0.4–0.8 mg l^{-1}), the mean nitrite intake in the UK from this source is 0.34 mg per person per day.

Water

Nitrate is ubiquitous in potable water. Its presence is due to a number of factors: significant sources are agricultural activity, for example, the use of nitrogenous fertilizers; sewage effluents and urban run-off and the geology of the area. It is formed when nitrogenous organic sources, such as urea and proteins, or fertilizers containing inorganic nitrogen are decomposed by microorganisms in water or soil to form ammonia, which is then oxidized to nitrate and nitrite. Up to 5 mg l^{-1} of nitrate have been found in rainwater in European urban areas, although levels are somewhat lower in rural areas. However, levels rise as a result of human activities, and groundwater with concentrations of up to 1500 mg l^{-1} have been found in an agricultural area in India. Nitrate is very soluble in water and easily moves through the soil into aquifers and into the drinking water supply. Nitrite is readily oxidized to nitrate and is consequently found in water at much lower levels, especially after water treatment involving chlorination. Water obtained from public water companies tends to contain lower levels of nitrate, usually less than 10 mg l^{-1} in most countries, but private wells throughout the world, especially in agricultural areas, may have concentrations often exceeding 50 mg l^{-1}. However, the exposure to water from the latter source is less common; for example, it is estimated that only about 2% of the European population draw their water from private wells.

Legislation

Maximum permitted levels of nitrate in potable water have been set at levels intended to prevent the occurrence of methaemoglobinemia in infants and other susceptible sections of the population. The second edition of the WHO Guidelines for drinking-water quality recommended a guideline value of 50 mg l^{-1} for nitrate and 3 mg l^{-1} for nitrite levels for water. The US Federal Government has set a similar maximum contaminant level of 45 mg l^{-1}.

Concern over the *in vivo* formation of nitrosamines from nitrites has led to a reduction in the levels permitted when they are used as food additives. In the UK, the current residual concentration of nitrite (as sodium nitrite) in cured bacon is limited to 175 mg kg^{-1} and 100 mg kg^{-1} for other cured meats. The maximum residual concentration of nitrate (as sodium nitrate) in all cured meats is 250 mg kg^{-1}. The use of potassium nitrate in cheese is limited to that giving a residual concentration of 50 mg kg^{-1}. Regulations in other countries are similar: Australia and New Zealand set a maximum of 125 mg kg^{-1} of sodium nitrite for cured meats and 50 mg kg^{-1} of total nitrate/nitrite in cheeses such as Gouda, Edam, and Havarti.

In Europe, Commission Regulation No. 194/97 sets the maximum levels for certain contaminants in foodstuffs, including nitrate in lettuce and spinach. By the use of specific measures intended to provide better control of the sources of nitrate and good agricultural practices, the levels in spinach should not exceed 2500 mg kg^{-1} (summer crop) and 3000 mg kg^{-1} (winter crop) and in lettuce, levels should not exceed 3500 mg kg^{-1} (summer crop except open-grown lettuce where the limit is 2500 mg kg^{-1} from May to September) and 4500 mg kg^{-1} (winter crop).

Dietary Intake of Nitrate and Nitrite

The acceptable daily intake (ADI) is defined as the maximum amount of a chemical that can be ingested daily over a lifetime with no appreciable health risk, and is based on the highest intake that does not give rise to observable adverse effects. The European Commission's Scientific Committee for Food set the ADI for nitrate at 0–3.65 mg per kilogram of bodyweight (equivalent to an intake of 219 mg day^{-1} for a 60-kg person) and 0–0.06 mg per kilogram of bodyweight (equivalent to an intake of 3.6 mg day^{-1} for a 60-kg person) for nitrite. These ADIs are similar to those set by the joint FAO/WHO experts committee. The ADIs apply to all sources of intake, although the use of nitrite as an additive in baby food intended for infants below the age of 3 months is not permitted. The nitrite ADI does not apply to infants under 3 months.

Dietary exposure to food components may be assessed by the use of several approaches, including the use of market basket studies, food diary records, *per capita* estimations using consumption data with the concentrations of nitrate and nitrite in foods, and urinary biomarkers. Intake studies have shown that the ADIs are not exceeded by the general population across the world, as shown in Table 3. The question of whether some subgroups of the population are consuming high levels of nitrate was addressed by the UK's Food Standards Agency, who carried out a study into the nitrate intake of vegetarians. This

Table 3 Comparison of daily dietary exposures to nitrate in different countries

Country	*Dietary exposure (mg day^{-1})*
UK	52
Finland	77
The Netherlands	52
The Netherlands	78–91
Basque Country, Spain	60
Belgium	154 (vegetables)
Egypt	296 (nitrate and nitrite)
USA	300
Poland	85 (duplicate hospital diets)
Poland	65 (estimate from hospital diets)
India	78
EU	18–131 (vegetables)

From Ysart G, Miller P, Barrett G *et al*. (1999) Dietary exposures to nitrate in the UK. *Food Additives and Contaminants* 16(12): 521–532.

showed that, although there was a slightly higher intake, dietary exposure was similar to other consumers and was well below the ADI.

In summary, food is the main source of nitrate, especially potatoes, green vegetables, and other vegetables. Water also makes a significant contribution. Estimates of nitrite intake suggest that 1–3 mg day^{-1} is typical and occurs mainly from beverages, due to high consumption.

Microbiological Nitrate Reduction

A detailed investigation of the reduction of nitrate to nitrite by microbiological contaminants of the brewing process has been undertaken. Concerns over the presence of nitrosamines in beer have led to detailed studies of the mechanism of formation of these compounds in order to prevent their formation as far as technologically feasible. Nitrosodimethylamine was formed in malt from nitrogen oxides present in kiln gases. Concentrations of this contaminant were greatly reduced by modifications to kilning conditions. Apparent total *N*-nitroso compounds (ATNC) provide an estimate of the total *N*-nitroso compounds present in a sample. The brewing industry sought to minimize ATNC and set a target of 20 μg (N-NO) kg^{-1}. It was established that the major source of nitrosating agent was from microbial reduction of nitrate. Hence, care in ensuring that microbiological contamination was minimized played an important role in meeting this target.

Microorganisms can be differentiated into assimilatory and dissimilatory nitrate reducers. The former reduce nitrate to nitrite and ammonia for use as their source of cell nitrogen. The latter use nitrate as a terminal electron acceptor for energy production (oxygen is the usual terminal electron acceptor under aerobic growth conditions). Nitrite, nitric oxide, nitrous oxide, and sometimes nitrogen may all be produced by dissimilatory nitrate reduction. A number of different bacteria and yeasts are capable of nitrate reduction. The effect is not merely to produce nitrite that subsequently undergoes the well-known acid-catalyzed chemical nitrosation reactions. Rather, the nitrosation reactions appear to be catalyzed by the nitrate and nitrite reductase enzymes. This mechanism enables nitrosation to occur at pH 6–9 which cannot happen in the chemical reaction at alkaline pH.

However, the significance of microbiological reduction of nitrate is wider than that caused by the microbiological contamination of food. Nitrate-reducing bacteria can be found in the mouth and the colon. Nitrate from the diet (or that produced metabolically) is transferred from the blood to the saliva in the salivary glands. It has been suggested that 25% of orally ingested nitrate may be secreted in saliva. Twenty per cent of this nitrate can then be reduced by oral bacteria to nitrite, which is swallowed. Hence, it is apparent that saliva makes the major contribution to dietary nitrite intake. Saliva nitrite levels rise at night and are higher in older people, especially men. Salivary nitrate and nitrite vary little from day to day, but vary more over a 5-year period.

Bacterial nitrosation may occur at any site in the body where there is infection, and these may be linked to cancers at these sites. However, the colon provides a site rich in microorganisms at all times. It is apparent from measurements of fecal ATNC that bacterial nitrosation reactions occur at this site. ATNC formation is influenced by the nature of the organisms present, the transit time of the fecal mass through the colon and to consumption of nitrate and (surprisingly) red meat. Since dietary nitrate is absorbed by the small intestine, it is difficult to appreciate how the nitrosation reaction may occur. It is possible that there may be diffusion of nitrate from the colonic epithelium. Alternatively, red meat might influence fecal ATNC by carrying nitric oxide into the colon as nitrosyl myoglobin, by favoring the growth of nitrate-reducing bacteria in the colon, or possibly by nitrosyl myoglobin acting as a nitrosating agent itself. These possibilities require further study.

Concerns over Nitrate and Health

A considerable body of evidence has been collected concerning the direct effects on health of the nitrate and nitrite ion. There is no evidence of carcinogenicity from nitrate consumption in experimental animals or through human epidemiological studies. Long-term animal studies on nitrite do not indicate carcinogenicity unless combined with amine intake

leading to the formation of carcinogenic nitrosamines. The latter studies usually involved nitrite concentrations far higher than those commonly encountered in the diet. Nitrite has demonstrated mutagenic activity in *in vitro* assays. There is considerable evidence of the safety of substantially higher exposures to nitrite during clinical use than those normally encountered from the diet.

The most important direct toxic effect of nitrite (or nitrate after its reduction) is the condition known as methemoglobinemia. Absorbed nitrite ion is rapidly oxidized to nitrate by reaction with oxyhemoglobin to produce methemoglobin. The latter can not carry oxygen around the body, and although the reaction can be reversed enzymatically, if large quantities of methemoglobin are produced, fatality can result. Infants are deficient in this repair enzyme and hence are especially at risk if they receive unusually high intakes of nitrate, for example from contaminated well water. This may be exacerbated by concurrent infections resulting in endogenous nitrate synthesis.

Another concern is that consumption of nitrite (or nitrate reduced by oral bacteria to nitrite) may result in the nitrosation of amines to produce carcinogenic nitrosamines in the acid conditions of the stomach. Such an effect has been found in a human study after consuming a meal consisting of vegetables high in nitrate and fish (to provide a source of amines). Similar studies in animals have been shown to induce cancer. Such nitrosation reactions may be enhanced by bacterial nitrosation in the achlorhydric stomach.

Volatile nitrosamines are not normally found in urine (unless a urinary infection is present) or in feces. However, feces do contain ATNC, although the toxicological significance of this measurement is not understood. The formation of ATNC appears to require an active microbiological flora in the colon capable of nitrate reduction. Hence, ATNC would appear to be, at least, a biomarker of nitrosation reactions occurring in the colon. It is possible for the colonic bacteria to make a more subtle contribution to colon cancer than just the production of potential carcinogens. For example, nitrate-reducing enteric fermentative bacteria lead to the production of more acetate and less butyrate from substrate. Butyrate is considered to have a protective effect against cancer, since it promotes apoptosis (programmed cell death), so any selection for bacteria producing acetate may favor colonic epithelial cell proliferation.

There are a number of medical conditions other than cancer that have been associated with nitrate/nitrite intake. In Finland, a significant correlation has been found between the occurrence of type 1 diabetes and the nitrite intake of both the children and their mothers. No association was found for nitrate intake. Since most nitrite intake arises from saliva, it seems likely that the association with nitrite is in fact a proxy for preformed dietary nitroso compounds, some of which (e.g., *N*-nitrosomethylurea) have well established toxic effects on pancreatic beta cells. Studies in Iceland and Sweden have also found similar correlations.

An association has been observed between maternal periconceptional exposure to nitrate and an increased risk of anencephalopathy (but not spina bifida). The lack of a quantitative association between nitrate intake and risk may indicate that something other than nitrate is the causative factor. It should be noted that not all studies have been able to demonstrate such a link, but nitrosocompounds have been shown to cause defects in the central nervous system of experimental animals.

Nitrate acts as a competitive inhibitor of iodine uptake by the thyroid and thyroid hypertrophy has been demonstrated experimentally in rats given drinking water containing large amounts of nitrate. There is some epidemiological evidence that populations exposed to high nitrate concentrations in drinking water show an average increase in thyroid volume, although it cannot be excluded that the effects are due to other compounds.

Potential Health Benefits of Nitrate

Nitric oxide plays a crucial role in human metabolism. It is synthesized from arginine by two related enzyme systems – one constitutive and one inducible. The constitutive form provides continuous vasodilation and inhibits platelet adhesion and aggregation; hence, it can help to prevent hypertension. The inducible isozyme is generated in response to bacterial lipopolysaccharide and hence is considered to play an important role in prevention of bacterial disease. However, NO production is also greatly increased in inflammatory bowel disease (e.g., Crohn's disease). NO synthesis also occurs in the central nervous system, but its physiological role in this tissue remains unexplained. These mechanisms for nitric oxide generation mean that man excretes more nitrate than is ingested.

Dietary nitrate is readily absorbed, transported in plasma, and concentrated 10-fold in the saliva by the salivary gland. Although nitrate is excreted in the urine, the kidney recovers some 80% of the nitrate. Hence, this renal salvage and salivary concentration suggest that nitrate is physiologically important. Nitric oxide has widespread antimicrobial activity, and hence, it is hypothesized that the salivary concentration of nitrate and its microbial conversion to nitrite are a symbiotic activity to generate quantities

of nitric oxide in the stomach for protection against pathogens. Inhibition of gastric NO synthesis does not have clinical relevance, but this could be due to the high microbiological standards of contemporary diets. Nitrate is also expressed in sweat where significant amounts of nitrite and bacterially generated nitric oxide can also be found and where a protective effect against pathogens has also been postulated.

Gastric juices provide a rich source of nitrosatable substrates, which, some consider, far exceeds those provided by food. Hence, since nitrate can be endogenously formed, carried in the blood, and excreted in saliva, it would appear unavoidable that some gastric nitrosation takes place. However, much more gastric nitric oxide is produced than might be expected from acid-catalyzed dissociation of nitrite to nitric oxide and nitrogen dioxide. Thus, it would appear that another reductant (e.g., ascorbic acid) is produced in gastric juice in order to facilitate the generation of NO. Therefore, it may be that man is metabolically adapted to the possibility of gastric nitrosation. This view is supported by the failure of a number of epidemiological studies to demonstrate a link between nitrate intake and cancer in man.

NITROSAMINES

R A Scanlan, Oregon State University, Corvallis, OR, USA

Introduction

Investigations during the past 30 years on the occurrence of *N*-nitrosamines and the etiology of these compounds in human cancer began with two important discoveries. In 1956, the UK scientists David Barnes and Peter Magee reported *N*-nitrosodimethylamine (NDMA) as a carcinogen in experimental animals. In Norway in the early 1960s, NDMA proved to be the causative agent in the death of agricultural animals which had been fed nitrite-preserved fish meal. The nitrite had reacted with amines in the fish meal to produce lethal amounts of NDMA. Since nitrite is added to human foods, particularly cured meats, and amines occur commonly in most foods, this raised the question as to whether carcinogenic nitrosamines might also form in human foods. This article summarizes the results of the many investigations which have addressed this important issue.

Chemistry of *N*-Nitrosamine Formation

Basic Reactions

N-Nitrosamines are formed by a chemical reaction between a nitrosating agent and a secondary or a tertiary amine. Primary amines react with nitrosating agents to form unstable *N*-nitroso derivatives which degrade to olefins and alcohols. The structures of several nitrosamines which occur in foods are shown in Figure 1.

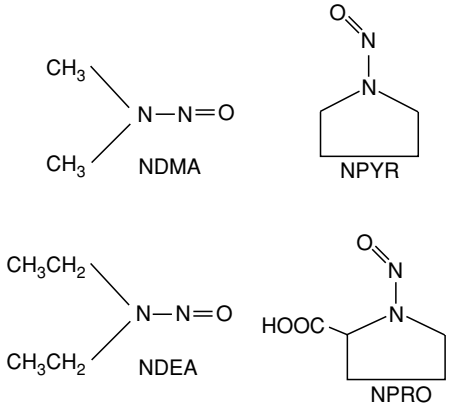

Figure 1 Structure of some nitrosamines which occur in foods. NDMA, *N*-nitrosodimethylamine; NPYR, *N*-nitrosopyrrolidine; NDEA, *N*-nitrosodiethylamine; NPRO, *N*-nitrosoproline.

Oxides of nitrogen (NO_x) in which the nitrogen is in a $+3$ or $+4$ oxidation state can serve as nitrosating agents. A much studied nitrosating agent which participates in nitrosamine formation in foods is nitrous anhydride (N_2O_3). Nitrous anhydride forms readily from nitrite in aqueous acidic solution, as shown in eqn (1).

$$2NO_2^- + 2H^+ \rightleftharpoons N_2O_3 + H_2O \qquad (1)$$

Nitrous anhydride combines with the unshared pair of electrons on unpronated secondary amines through a nucleophilic substitution reaction to form *N*-nitrosamines, as depicted in eqn (2).

$$R_2NH + N_2O_3 \rightarrow R_2N - N = O + HNO_2 \qquad (2)$$

The rate of nitrosation is pH-dependent and is governed by the concentrations of amine and nitrite, as shown in eqn (3):

$$\text{Rate} = k[\text{amine}] \times [\text{nitrite}]^2 \qquad (3)$$

Since the nitrous anhydride reacts with unprotonated amine, the rate of nitrosation for secondary amines is inversely proportional to amine basicity. The pH optimum for nitrosation of most secondary amines is between 2.5 and 3.5. This is due to the counteracting effects of acidity on nitrous anhydride concentration, which increases at low pH, and the concentration of unprotonated amine, which increases at high pH.

The pH optimum has a number of implications. Although most foods are less acidic than pH 2.5–3.5, many foods are sufficiently acidic to allow nitrosation, albeit at rates slower than maximal. Furthermore, the 2.5–3.5 pH range is sufficiently close to the acidity of the human stomach to allow nitrosamine formation, providing that amines and nitrosating agents are present.

Tertiary amines react with nitrosating agents in acidic aqueous solution through a mechanism called nitrosative dealkylation to form nitrosamines. Nitrosative dealkylation involves conversion of a tertiary amine to a secondary amine, which subsequently reacts with nitrosating agent to form a nitrosamine.

Nitrosation Inhibitors

Nitrosation can be influenced by a wide range of catalysts and inhibitors. Ascorbic acid, α-tocopheral, and sulfur dioxide are used to inhibit nitrosamine formation in foods. Ascorbic acid reduces nitrous anhydride to nitric oxide, as shown in eqn (4).

$$\text{Ascorbic acid} + N_2O_3 \rightarrow \text{Dehydroascorbic acid} + 2NO + H_2O \quad (4)$$

Ascorbic acid is not completely effective in blocking nitrosation, since under oxidative conditions the nitric oxide can be reconverted to nitrous anhydride. Presumably α-tocopheral reacts with nitrous anhydride through a similar redox process to inhibit nitrosation. Both ascorbic acid and α-tocopheral are added to cured meats, and sulfur dioxide is used in processing barley malt to inhibit nitrosation.

Carcinogenicity

Although *N*-nitroso compounds have been shown to be acutely toxic, mutagenic, and teratogenic, their carcinogenic properties are of grave concern and have been studied extensively. Over 300 *N*-nitroso compounds, including many nitrosamines, have been demonstrated to be carcinogens in experimental animals. More than 50 animal species, including higher primates, are susceptible to *N*-nitroso compound-induced carcinogenesis. It has been observed that tumors induced by nitrosamines in experimental animals show similar morphological properties to tumors in corresponding human organs. Few scientists doubt that nitrosamines are capable of inducing cancer in humans. However, the amount of a given nitrosamine which is required to induce cancer in a human population is unknown. (*See* **Cancer**: Carcinogens in the Food Chain.)

Analytical Methodology

For purposes of analysis, nitrosamines are classified as either volatile or nonvolatile. Volatile nitrosamines are relatively nonpolar, low-molecular-weight compounds, such as NDMA and *N*-nitrosopyrrolidine (NPYR). They possess sufficient vapor pressure to allow removal from a food matrix by distillation and subsequent separation by gas chromatography. Chemiluminescent detectors designed to be relatively specific for nitrosamines allow quantitative analysis of volatile nitrosamines in foods and other biological materials at submicrogram per kilogram levels. Confirmation of nitrosamine identity is accomplished by mass spectrometry. (*See* **Chromatography**: Gas Chromatography; **Mass Spectrometry**: Principles and Instrumentation.)

Nonvolatile nitrosamines such as *N*-nitrosoproline (NPRO) tend to be of higher molecular weight, or more polar than volatile nitrosamines, and hence possess relatively low vapor pressures. These properties have impeded development of analytical methodology. Although procedures are available for determination of some nonvolatile nitrosamines, mainly *N*-nitrosated amino acids and amino acid derivatives, analytical methodology generally is less well developed for this class of compounds.

A procedure usually referred to as apparent total *N*-nitroso compound determination has been developed and used for analyses of foods and body fluids. Presumably when using this procedure all *N*-nitroso compounds in the sample are measured as a single entity. A limitation is that information regarding the identity of individual *N*-nitroso compounds is not provided by this methology. It is therefore impossible to access the carcinogenicity of compounds detected by this procedure.

Formation and Occurrence

Exogenous Formation

Foods During the past 25 years many foods have been analyzed for volatile nitrosamines. In general, foods in most western diets have been examined more extensively than foods from Asia, Africa, and South America. Although approximately 20 volatile nitrosamines have been identified in a variety of foods and beverages, NDMA and NPYR have been found most commonly. Most of the other volatile nitrosamines which occur in foods do so infrequently. Table 1 presents a condensation of many reports of the occurrence of volatile nitrosamines in foods from around the world. The summary is not comprehensive; rather, it is intended to show the foods in which nitrosamines occur most commonly.

Nitrosamines form in foods because under certain circumstances the precursors, amines and nitrosating agents, occur in foods. Amines occur commonly in food, and are formed biosynthetically and by

Table 1 Volatile nitrosamines which occur most commonly in foods

Food	*Nitrosamine*	*Range*[a] *($\mu g\,kg^{-1}$)*	*Occurrence*
Fried bacon	NDMA, NPYR	1–100	Consistent
Cured meats	NDMA, NPYR, NPIP	ND–50	Sporadic
Beer	NDMA	ND–5	Sporadic
Cheese	NDMA	ND–5	Sporadic
Cooked fish	NDMA, NDEA	ND–50	Sporadic
Salt-dried fish	NDMA, NDEA	ND–1000	
Nonfat dry milk	NDMA	ND–1	Consistent in direct-fire dried product

[a]The range is intended to encompass data in most reports since 1980. In general, most positive samples contained nitrosamines at the lower end of the range. ND, not detectable.
NDMA, *N*-nitrosodimethylamine; NPYR, *N*-nitrosopyrrolidine; NDEA, *N*-nitrosodiethylamine; NPIP, *N*-nitrosopiperidine.

microbial activity. Nitrosating agents can be formed from certain compounds added to foods and as a result of specific processing conditions. In most instances, nitrosamines are found in foods in one of the three following categories.

Cured meats Nitrosamines are formed in cured meats because nitrite, and sometimes nitrate, are added to these products during processing. Nitrate is reduced to nitrite by the enzyme nitrate reductase, which occurs in a number of bacteria. As discussed earlier, nitrite is converted to nitrosating agents which subsequently react with amines in the meat during processing, storage, and cooking to form nitrosamines. (*See* **Curing**.)

Nitrite and nitrate have been added to cured meats for many years to prevent outgrowth and toxin formation by *Clostridium botulinum*. Nitrite, in combination with other curing ingredients such as sodium chloride, is particularly effective in inhibiting formation of the deadly botulism toxin. In addition, nitrite reacts with pigments in meat to impart the desirable pink color of cured meats and it prevents the development of off-flavors. (*See* **Nitrates and Nitrites**.)

Although not all cured meats have detectable amounts of nitrosamines, fried bacon has been shown consistently to contain these compounds. Typically, fried bacon contains 1–20 $\mu g\,kg^{-1}$ of NPYR and 1–3 $\mu g\,kg^{-1}$ of NDMA. The formation is related to the relatively high internal temperature of bacon during frying and the relatively low moisture content of bacon as compared to other cured meat products. When bacon is cooked by other methods, particularly in a microwave oven, considerably lower amounts of nitrosamines are found. The majority of evidence suggests that the free amino acid proline is first nitrosated and then decarboxylated to form NPYR during frying. Neither the precise chemical nature of the nitrosating agent nor the amine precursor for NDMA in bacon is known with certainty. However, the evidence suggests that the nitrosating agent is a reaction product of nitrite and lipids in the bacon.

Dried foods and ingredients A variety of processes and equipment are used to dry foods and food ingredients. During the direct-fire process, air used to dry the food is first heated by passing the air through the flames of burners. As a result, products of combustion, including oxides of nitrogen, are directly incorporated into the hot air used to dry the food. The oxides of nitrogen which include nitrosating agents such as nitrous anhydride can then react with amines in the food being dried to produce nitrosamines.

In 1979, scientists in Europe reported the occurrence of NDMA in beer. Soon after, reports from a number of countries confirmed that most beers contained 1–5 $\mu g\,kg^{-1}$ of NDMA. Although beer was found to contain NDMA, the NDMA was not formed during the brewing process. Investigation led to the discovery that direct-fire-dried malted barley, an ingredient used in the manufacture of beer, was the source of the NDMA.

A number of investigators have attempted to identify the amine precursors of NDMA in malted barley. The evidence suggests that dimethylamine and perhaps the tertiary amine alkaloids gramine and hordenine serve as precursors for NDMA in malted barley.

The discovery of nitrosamine formation in direct-fire-dried malted barley has led to the investigation of other dried foods. In the USA, certain dried dairy products, notably nonfat dry milk, are manufactured by the direct-fire drying process. Nonfat dry milk manufactured by this process consistently contains low amounts (less than 1 $\mu g\,kg^{-1}$) of NDMA. Since the direct-fire drying process is not used commonly in Europe for manufacture of nonfat dry milk, the product does not contain NDMA.

Seafood can contain nitrosamines as a result of either cooking or salt-drying. When fish is broiled with a gas flame, the oxides of nitrogen produced in the flame can cause nitrosamine formation in a manner analogous to nitrosamine formation in direct-fire drying. In certain areas of the world, particularly the Orient, fish is preserved by salt. Often sea salt is used which contains appreciable amounts of nitrate. The nitrate is reduced to nitrite with subsequent formation of nitrosating agents. In some cases, reaction with amines in the fish produces relatively large amounts of nitrosamines, principally NDMA. The potential for NDMA formation in fish is considerable since high levels of NDMA precursors, such as dimethylamine and trimethylamine, can occur in fish.

Migration from surfaces which contact foods Vulcanized rubber products, such as baby nursing nipples, have been shown to contain nitrosamines. It has been demonstrated that when baby bottle nipples are stored inverted in milk, the nitrosamines partially migrate from the nipples to the milk. Furthermore, studies have shown that nitrosamines migrate from rubber netting used to hold cured meats during the smoking process. In addition to rubber, nitrosamines in such substances as wax-treated wrapping paper and paperboard-based materials have been shown to migrate to foods.

Nonvolatile nitrosamines in foods The notion that nonvolatile nitrosamines might form in foods follows logically from the fact that the precursors,

nonvolatile amine and nitrosating agents, occur in foods. Due to limitations in analytical methodology for nonvolatile nitrosamines, less is known about the occurrence of nonvolatile than volatile nitrosamines in foods. Recently developed methods for nonvolatile nitrosamines have been limited to the detection of *N*-nitrosated amino acids and amino acid derivatives. Most analyses have been on cured meats and include reports of compounds such as NPRO, *N*-nitrososarcosine (NSAR), *N*-nitroso-4-hydroxyproline, *N*-nitrosothiazolidine-4-carboxylic acid, *N*-nitroso-2-methylthiazolidine-4-carboxylic acid, and *N*-nitroso-2-hydroxylmethylthiazolidine-4-carboxylic acid. Other than NSAR, which is a weak carcinogen, all the other *N*-nitrosated amino acids and amino acid derivatives which have been tested have not shown a carcinogenic response in animals.

Scientists conjecture that other nonvolatile nitrosamines such as nitrosated peptides and nitrosated amides occur in foods. Definitive information in this regard awaits further application of analytical methodology for nonvolatile nitrosamines to foods.

Reduction of nitrosamine formation Considerable efforts have been expended during the past 25 years to reduce nitrosamine formation in foods. Scientists have looked critically at the use of nitrite and nitrate in the manufacture of cured meats. Since nitrite is considered essential to guard against outgrowth and toxin production by *C. botulinum*, its use in the manufacture of cured meats has been retained. However, in many countries, permissible levels of nitrite have been reduced to the minimum necessary for control of botulism. Generally, nitrate is only permitted in a few fermented cured meat products where long-term inhibition of *C. botulinum* is required.

The nitrosation inhibitors ascorbic acid and α-tocopheral are either required or extensively used in processing cured meats. Alternatives and/or partial substitutes for nitrite in cured meats include use of lactic acid-producing organisms, potassium sorbate, sodium hypophosphite, fumarate esters, and ionizing radiation. To date, no adequate alternative for nitrite has been found. Consequently, nitrosamines continue to be found in cured meats, especially fried bacon, but generally at lower levels than occurred a number of years ago.

Efforts to reduce nitrosamine levels in barley malt, and hence in beer, have been very successful. This is largely due to conversion of direct-fired kilns to indirect-fired kilns for the manufacture of barley malt. With indirect-fired kilns, the products of combustion are not incorporated into the drying air and, therefore, nitrosamine formation in the barley malt is greatly reduced. Interestingly, use of an indirect-fired kiln does not completely inhibit nitrosation, probably because ambient air which is drawn into the kiln usually contains trace levels of oxides of nitrogen and, therefore, some nitrosation occurs. In addition to the use of indirect-fired kilns, sulfur dioxide, which has been shown to be a nitrosation inhibitor, is sometimes used with both direct-fired kilns and indirect-fired kilns to reduce nitrosamine formation.

Due to these changes in processing, the NDMA levels in beer have been markedly reduced. In a recent survey, Canadian and US beers were found to contain on average $0.07\,\mu g\,kg^{-1}$ of NDMA whereas, prior to 1980, beer commonly contained $1–5\,\mu g\,kg^{-1}$ of NDMA.

Similarly, nitrosamine formation in rubber products, including baby nursing nipples, has been reduced. This has been accomplished by substituting nitrosatable with nonnitrosatable vulcanization accelerator compounds in the manufacture of rubber products.

Products other than food A variety of industrial, agricultural, and consumer items have been shown to contain nitrosamines. These include cosmetics, tobacco products, industrial cutting fluids, vehicle tires, and pesticides. In each case, the formation can be traced to use of amines and contact with nitrosating agents during product formulation, manufacture, or use.

Tobacco products are especially important in terms of nitrosamine occurrence and subsequent human exposure. During growth, tobacco plants biosynthesize a variety of alkaloids such as nicotine and nornicotine. These compounds are either secondary or tertiary amines. During curing, fermentation, and aging the alkaloids react with nitrosating agents formed from nitrate to produce a group of compounds commonly referred to as tobacco-specific nitrosamines. Tobacco-specific nitrosamines have been shown to occur in a wide range of tobacco products such as cigarettes, cigars, pipe tobacco, chewing tobacco, snuff, masheri, zarda, and nass. It is noteworthy that the tobacco-specific nitrosamines frequently occur in tobacco products at several orders of magnitude higher than volatile nitrosamine occurrence in foods and beverages.

Endogenous Formation

Convincing evidence exists for endogenous formation of nitrosamines in humans. Based on our knowledge of nitrosation in acidic, aqueous media, it is not surprising that nitrosamine formation has been demonstrated to occur in the stomach. Estimation of endogenous nitrosation in humans and experimental animals has been accomplished by measuring urinary

NPRO following oral administration of proline and nitrate. Inhibition of nitrosamine formation has been accomplished by the administration of nitrosation inhibitors such as ascorbic acid. Gastric nitrosation proceeds through reaction between amines and nitrosating agents derived from the diet. Nitrate, which occurs in substantial amounts in certain vegetables, is partially reduced to nitrite by nitrate reductase-containing bacteria in the oral cavity.

Recently, the existence of endogenous nitrosation pathways other than gastric nitrosation has been recognized. Evidence exists for mammalian cellular enzymatic conversion of arginine to nitric oxide, which in turn affects nitrosation. Scientists believe that this process occurs in several cell types, including macrophages. The extent and relevance of cellular nitrosation are yet to be determined.

Estimates of Exposure to Nitrosamines from Foods

Several groups have made estimates of human exposure to volatile nitrosamines from food and beverage consumption. Most of the estimates relate to exposure from consumption of foods and beverages in western Europe. Volatile nitrosamine exposure was predominately from NDMA and NPYR.

The estimation of daily exposure to volatile nitrosamines in most reports ranged from 0.1 to 1.0 μg per person. In comparison, a US National Academy of Sciences report in 1981 estimated exposure to nitrosamines from cigarette smoking to be 17 μg per person per day.

Several recent reviews reported an estimated daily exposure to nitrosamines of 10–120 μg per person from diet. Estimates in this range include, in addition to volatile nitrosamines, *N*-nitrosated amino acids and amino acid derivatives and some include apparent total *N*-nitroso compounds as well. It should be recognized that most *N*-nitrosated amino acids and amino acid derivates have failed to elicit a carcinogenic response in animals and the identity and carcinogenicity of the apparent total *N*-nitroso compounds are unknown.

Some cautionary comments are needed regarding estimates of exposure to nitrosamines. First, estimates should be based on nitrosamines with known identity and known carcinogenicity in animals. Second, a number of the estimates were conducted a decade ago or are based on reports of the volatile nitrosamine content of foods from over a decade ago. As discussed previously, the volatile nitrosamine content of foods, e.g., NDMA in beer, has been dramatically reduced in recent years. Therefore, some of the estimates in the literature may be higher than reflected by current levels of volatile nitrosamines. Third, information currently available does not allow reliable estimation of exposure from currently undetected carcinogenic nonvolatile nitrosamines, of nitrosamines formed endogenously, and of other *N*-nitroso compounds formed exogenously and endogenously. A fourth limitation of estimates is that they are based on average food consumption for relatively large populations. Food consumption patterns for subgroups and individuals within populations vary widely and, therefore, so does exposure to nitrosamines in the diet.

Role of Nitrosamines and Other *N*-Nitroso Compounds in Human Cancer

Based on current information on carcinogenicity in experimental animals, and on other pertinent information, most scientists believe that nitrosamines and other *N*-nitroso compounds are capable of inducing cancer in humans. However, at the present time we do not know what exposure to the various nitrosamines is required to induce cancer in a human population.

Convincing evidence exists for the role of tobacco-specific nitrosamines in cancer induction in people who use tobacco products. Particularly compelling evidence exists for the causative role of tobacco-specific nitrosamines in cancer of the oral cavity for people who engage in snuff dipping and chewing betel quid.

In order to assess more fully the part nitrosamines and other *N*-nitroso compounds play in human cancer, progress will be needed in the following areas: improvement and application of analytical methodology will be required for estimation of exposure to nonvolatile nitrosamines and other *N*-nitroso compounds in foods and in other materials; second, a better understanding of formation and exposure to endogenously formed nitrosamines and other *N*-nitroso compounds is needed; and, finally, methodology will need to be improved in order to allow reliable estimation of human cancer incidence from exposure to relatively low levels of carcinogens, including nitrosamines.

Presence of Nucleic Acids in Food

Nucleic acids are natural constituents of all foods derived from animal or plant sources, for they are intrinsic components of the cells making up food tissue. They occur usually in close association with basic proteins (histones, protamines), forming nucleoproteins. In general, their effect on texture, nutritive value, or sensory properties of foods is small in view of their low tissue concentrations (typically < 200 mg of nucleic acid phosphorus per 100 g of fresh tissue). These low tissue concentrations normally also preclude the occurrence of detrimental health effects. However, health consequences may arise with persons suffering from metabolic disorders such as impairment of purine excretion. In these instances, the dietary breakdown of the nucleic acids can generate

unacceptably high levels of uric acid in blood as well as tissues, producing ultimately hyperuricemia, acute and chronic arthritis, or other symptoms of gout.

Properties of Nucleic Acids

Chemical Properties

Nucleic acids are macromolecules of high molecular weight, made up of heterocyclic pyrimidine (Py) and purine (Pu) bases, a five-membered (furanose-type) sugar ring, and orthophosphate. Bases, sugar and phosphate occur in equimolar ratios, i.e., Pu(Py): sugar: phosphate of 1:1:1. Thus, schematically, their chemical composition may be denoted as

$$[\mathrm{Pu(Py)} - \mathrm{pentose} - \mathrm{PO_4^-}]n, \qquad (1)$$

with n being a large number. Among naturally occurring nucleic acids, n may range from 4.5×10^3 (polyoma virus) to 7.0×10^7 (*Drosophila melanogaster* chromosome). Two broad categories exist, deoxyribonucleic acids (DNAs) and ribonucleic acids (RNAs), depending on whether the sugar moiety is β-D-2′-deoxyribose or β-D-ribose (note: primed entities refer to sugar-binding sites). Their elemental composition is roughly 15% nitrogen, 10% phosphorus, 36% carbon, 4% hydrogen, and 35% oxygen. Cellular DNA is localized almost exclusively in the nucleus, while RNA is found predominantly in the cytoplasm.

The principal bases found associated with DNAs are the purine derivatives adenine (6-aminopurine, Ade) and guanine (2-amino-6-hydroxypurine, Gua), and the pyrimidine derivatives cytosine (2-hydroxy-4-amino-pyrimidine, Cyt) and thymine (5-methyluracil, Thy). Occasional base variations (e.g., 5-methylcytosine or 5-hydroxymethylcytosine) are encountered. In RNAs, the base Thy is replaced by uracil (2,4-dihydroxypyrimidine, Ura). Certain RNAs, e.g., (transfer) tRNAs, show considerable base variations: they may contain a wide variety of methylated bases, including Thy, bases with thio groups, inosine, etc.

The Pu bases are bound to the sugar in an N9 → C1′-glycosidic linkage; with Py bases, bonding occurs via Nl → Cl′. The resulting compounds are N-glycosides; they are called nucleosides. Some nucleosides are: adenosine (Ado or A), guanosine (Guo or G), cytidine (Cyd or C), uridine (Urd or U), and thymidine (dThd or dT). Attachment of orthophosphate in positions O3′ (or O5′) produces the corresponding 3′ (or 5′) (mono)nucleotides. 5′-Mononucleotides are the actual building blocks of DNAs and RNAs. Schematically, their polymerization takes place by 5′ → 3′ phosphodiester bond formation, e.g., the 5′-phosphate group of one nucleotide links up with the free 3′-hydroxyl group of another, thereby forming a dinucleotide. It is customary to use short-hand notations such as 5′-pApCpGpT-3′ or 5′-ApCpGpTp-3′ to indicate 5′-terminal and 3′-terminal phosphate, respectively.

In both DNA and RNA, *in-vivo* diester bond formation proceeds solely in the 5′ → 3′ direction, producing long-chain, unbranched structures (strands). Branching in RNA molecules can occur transiently during RNA splicing. Both DNA and RNA strands display polarity, meaning that their primary structure is to be read in the direction → O3′ → [PO_2 → O5′ → C5′ → C4′ → C3′ → O3′] → [PO_2 → O5′ → C5′ → C4′ → C3′ → O3′], etc. (the brackets define a DNA/RNA monomer subunit). The strand polarity is a consequence of furanose pucker as well as associated base stacking.

The chemical, i.e., base composition of nucleic acids is variable and differs from one species to another. Variation in base composition forms the basis of the genetic information content of DNAs. However, in DNAs, certain regularities apply (Chargaff's rules): (1) $\sum \mathrm{Pu} = \sum \mathrm{Py}$, (2) $\sum \mathrm{A} = \sum \mathrm{T}$ and $\sum \mathrm{G} = \sum \mathrm{C}$, (3) $\sum(\mathrm{A} + \mathrm{C}) = \sum(\mathrm{G} + \mathrm{T})$. On occasion, 5-methylcytosine needs to be taken into consideration, too, in order to satisfy points (2) and (3). These rules hold because of the double-stranded (complementary) structure of DNAs brought about, in part, by Watson–Crick hydrogen bonding between opposite bases (A $=$ T and G $\equiv$ C base pair formation; the symbols $=$ and $\equiv$ denote that base pairing between A and T involves two hydrogen bonds, while three hydrogen bonds are formed in the base pairing between G and C). Chargaff's rules do not apply to single-stranded nucleic acids, whether they are RNAs (usually) or DNAs (occasionally).

Physiochemical Properties

At physiological pH values, the orthophosphate groups of the nucleic acids are negatively charged. Outward charge neutralization occurs through positively charged counterions aligning themselves with the negative charges on the polymers. Counterions can be Na^+, Mg^{2+}, basic proteins, polyamines, etc. Nucleic acids are therefore polyelectrolytes, a property that determines their solution behavior: they are extensively hydrated and form gel-like structures if present in higher concentrations. Even in dilute solutions they display non-Newtonian behavior, as noted, for instance, by their shear-rate-dependent viscosity. Once hydrated, they are readily soluble in water. Isolation of nucleic acids from tissues usually yields their sodium salt. How they really exist *in vivo* is unknown, although it is assumed that Na^+ also serves there as the principal counterion.

DNAs, with very few exceptions, are double-stranded helices of opposite polarity. By contrast, RNAs are usually single-stranded, although double- (as well as triple-) stranded RNAs are known to exist. There are also duplex helices made up of DNA and RNA single strands; they form, for example, *in vivo* during transcription. DNA double-strandedness, brought about by interstrand hydrogen bonding and intrastrand base stacking, is termed DNA secondary structure; this structure is salient to the preservation of genetic information by DNA. Hydrophobic bonding and London dispersion forces are the major factors contributing to base stacking. DNA secondary structure is quite stable over a wide range of pH (3–12), ionic strength, I (0.001–5), and temperature (up to 100 °C). The ranges given are approximate: not only are the effects of I and temperature interdependent (rule-of-thumb: the higher I is, the higher the thermal stability), but base composition (GC-rich DNAs are more heat-stable than AT-rich DNAs) contributes heavily to the stability of DNA secondary structure as well. Lastly, at elevated levels of I, individual cation/anion effects, often destabilizing in nature, also become noticeable. Transforming the DNA double helix into two single strands of DNA, a process occurring cooperatively, is called 'denaturation.' Synonymous terms are 'helix-to-random coil transition' or 'order–disorder transition.' 'Denaturation' represents a change in DNA conformation (conformational changes are those that rupture hydrogen bonds and/or hydrophobic bonds but leave covalent bonds intact). It is evident from the above that variations in pH, I, and temperature can be used to bring about changes in DNA conformation experimentally. While much is known regarding the subtleties of DNA secondary structure, very little information is available with respect to the structural properties of the single-stranded states of DNA (or RNA).

Nucleic acids are optically active molecules, i.e., they rotate the plane of (linearly) polarized light and, hence, display chirality. The major contribution to optical activity comes from base stacking, for it imparts molecular asymmetry. The optical activity of the asymmetric carbon atoms of deoxyribose or ribose does not contribute much to the overall effect. Double-stranded DNAs are usually of right-handed screwness or helicity. This information has been obtained from X-ray diffraction analysis of DNA fibers. Depending on the sign and magnitude of the parameters defining the orientation of a base pair in DNA relative to the helix axis (e.g., rotational twist, t, tilt, θ_T, roll θ_R, propeller twist, θ_p, axial rise, h, pitch, width, and depth of major and minor grooves), one can distinguish between conformational families such as A-, B-, C-, and Z-type DNA. They exist among naturally occurring DNAs, i.e., DNAs with random base sequences. Synthetic DNAs (polynucleotides with nonrandom sequences) are characterized by additional families such as B′, C″, D, E, S, Z′. Z-type DNA is a left-handed double helix.

Until quite recently, the consensus was that double-stranded DNA is rather inflexible ('rod' or 'worm-like chain') and that, apart from its exciting base-pairing capabilities, the structure of the sugar–phosphate backbone, in view of its seeming monotony, is of little consequence to its biological function. This perception was due to the fact that X-ray diffraction studies executed on DNA fibers gave structural information only at low levels of resolution. However, experimental evidence has shown that double-stranded DNA is surprisingly flexible locally, giving rise to what has been termed DNA 'polymorphism.' DNA polymorphism refers to seemingly minor, quite localized alterations in secondary structure that may very well be of crucial importance in biological processes such as replication and transcription. That there is such a thing as DNA polymorphism has been demonstrated by X-ray diffraction analysis of oligonucleotide crystals. Oligonucleotide crystals (formerly not available) yield high-resolution X-ray data down to atomic dimensions. It was found that DNA polymorphism resides in the nonplanar ring structure of β-D-2′-deoxyribose (or β-D-ribose in RNA) and that this structure is conformationally quite flexible. Its two main conformations (called sugar pucker) are envelope E (four atoms in a plane, the fifth out of plane) and twist T (three atoms in a plane, the two others out of plane on opposite sides). Out-of-plane atoms on the same side of C5′ are denoted *endo*, while those on the opposite side are denoted *exo*. Transitions between E and T are facile, giving rise to a pseudorotation cycle of the furanose ring in nucleosides. The cycle contains 10 different (*endo*/*exo*) T and E forms. In addition, O5′ can assume a number of orientations about the C4′–C5′ bond axis; they are known as *gauche, gauche* (+ *synclinal*); *gauche, trans* (*antiperiplanar*); and *trans, gauche* (− *synclinal*). Lastly, relative to the sugar moiety, a Pu can adopt two major orientations along the N—Cl′ bond; *anti* (the bulk of the base turns away from the sugar) and *syn* (it is over or toward the sugar). All orientations influence each other, giving rise to a multitude of sugar conformations – and, hence, structural DNA families – with important implications for biological function. Thus, the binding of enzymes (e.g., DNase I, restriction endonucleases) or regulatory proteins such as TFIIIA (zinc fingers) to DNA is now known to be greatly influenced by the geometry of the backbone. In fact,

it has been said that while base pairing may be viewed as the 'brain' of DNA, the conformational flexibility of the sugar–phosphate backbone constitutes its 'heart.'

Determination and Characterization of Nucleic Acids

There exist literally hundreds of techniques that permit the detection, quantitative evaluation, structural, and biological characterization of nucleic acids. They are chemical, biochemical, physicochemical, or physical in nature; however, their description is beyond the scope of this article. 'Determination of nucleic acids' is therefore understood here to mean their detection (qualitatively as well as quantitatively) in cells and tissues in particular, and the determination of their chemical composition (average base composition) when in solution. Hence, techniques that serve their physical characterization in terms of structure, mass, or shape, or techniques used in DNA sequencing, in the enzymatic manipulation of DNA and RNA, in recombinant DNA research, in cloning, etc., are not presented. Techniques relating to their isolation from animal and plant tissues or from microbial sources are also not discussed here.

Detection of Nucleic Acids in Cells and Tissues

Histochemical approaches (*in-situ* staining) Most advantageous are histochemical staining techniques. Each constituent of DNA/RNA (cf. eqn (1)) can be identified histochemically: acidic phosphate groups are demonstrated with the aid of basic dyes, β-D-2′-deoxyribose with the help of a triphenylmethane dye, and Pu(Py) can be made visible via intercalation with fluorescent dyes. The specificity of the techniques can be improved further through judicious use of DNA (deoxyribonuclease) and RNA (ribonuclease) degrading enzymes prior to staining. This eliminates possible interference by the other polymer. Although staining techniques are usually used to obtain qualitative information, they can be adapted to furnish also quantitative data.

Techniques detecting DNA

Feulgen nucleal reaction DNA in tissue is depurinated by strong acid treatment. The resulting apurinic acid releases β-D-2′ deoxyribose, which in turn is converted to its open-chain aldehyde form. The sugar aldehyde reacts with the colorless triphenylmethane derivative leucofuchsin (Schiff's reagent) to give a magenta color (fuchsin). The chemistry of the reaction is known. Since the ribose of RNA cannot be changed to an open-chain aldehyde form, RNA will not be stained; hence, this technique is very specific.

Kurnick's methyl green method Methyl green, a triphenylmethane dye possessing two positively charged amine groups, adds on to double-stranded DNA. Details of the process remain obscure but appear to be related to the secondary structure of DNA: the two positively charged amine groups of the dye are said to have just the correct distance to add on to phosphate groups separated from one another by one turn of the DNA double helix. DNA stains green or green-blue.

Fluorescence flow cytometry A number of macrocyclic dyes (acridine orange (derivative of acridines), Hoechst 33342, Hoechst 33258 (derivatives of piperazine), ethidium, propidium (derivatives of phenanthridine), etc.) bind to DNA bases. Some of them (e.g., acridine orange) will also react with RNA. Their commonality resides in the fact that they are planar, highly aromatic molecules that fluoresce when irradiated. Because of their flatness, they can bind to DNA through intercalation, i.e., they can sandwich themselves between bases. Intercalation increases their basic fluorescence, which makes the nucleic acids visible. Excitation sources are mercury arc lamp, argon ion laser, or krypton ion laser. Since DNA–dye emission spectra differ usually from those of the RNA–dye complexes, distinction between the two types of nucleic acids is possible. Determination of DNA (or RNA) is quantitative. The technique is used most frequently in cell-culture work or in studies in which free-flowing cellular or subcellular particles are available (e.g., red blood cells).

Techniques detecting DNA and RNA

Methyl green–pyronin method If proper experimental conditions are maintained, nuclei (DNA) will be stained green or blue (methyl green), and nucleoli and cytoplasm (RNA) red (pyronin). Since pyronin, a xanthene derivative, is also a fluorescent dye, the technique can be adopted for flow-cytometric determination of RNA.

Acridine orange method The dye acridine orange binds to DNA and RNA. The two dye–polymer complexes exhibit different fluorescence emission spectra: when illuminated with purple light, DNA fluoresces green–yellow to bright yellow and RNA reddish brown to orange; when illuminated with ultraviolet light, DNA fluoresces greenish yellow and RNA crimson red. (*See* **Spectroscopy**: Fluorescence.)

Nonhistochemical Approaches

Radioactive labeling method Nucleic acids can be further identified qualitatively or quantitatively in cells or tissues by labeling them radioactively. Frequently used radionuclides are ^{31}P, ^{14}C, and ^{3}H.

They are administered experimentally in the form of labeled precursors of DNA or RNA (e.g., [^{3}H]dT for DNA, [^{3}H]U for RNA, [α-^{32}P]dATP for DNA, [α-^{32}P]ATP for RNA, etc.) and are incorporated into the polymers enzymatically during macromolecular synthesis. Labeling can be performed *in vitro* or *in vivo*. The presence of the radionuclides and, hence, of the nucleic acids is noted by the radioactive decay of the nuclides in the form of α or β particles or γ rays.

Burton assay for DNA This assay is a colorimetric procedure for measuring the deoxyribose moiety of diphenylamine DNA. Color is produced by a secondary amine (phenylamine) reacting with the sugar. The assay is relatively specific, although RNA in high concentrations, or sucrose, should be absent. DNA does not have to be present in purified form; thus, determinations can be undertaken in crude cellular extracts. DNA is usually extracted from tissue or cells through treatment with strong acids (perchloric acid, trichloroacetic acid), although alkaline extractions have also been used. Extraction is undertaken to remove interfering substances, particularly proteins. Color readings are taken at 595 and 650 nm. A standard curve is prepared by using samples of pure DNA (commercially available). A number of modifications of the basic procedure exist. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

3,5-Diaminobenzoic acid fluorescence assay DNA is extracted from cellular material with acid treatment (usually perchloric acid) and the sample exposed to hydrochloric acid (1 N) for about 45 min at 55–57 °C. This produces apurinic acid and free β-D-2′-deoxyribose (see section *Feulgen nucleal reaction*). The C1′ and C2′ carbons of the sugar then react with 3,5-diaminobenzoic acid to produce a strongly fluorescent compound. Excitation occurs at 410 nm; fluorescence is measured at 510 nm. Calibration with pure DNA is required. Submicrogram quantities of DNA can be determined.

Detection of Nucleic Acids in Solution

These techniques assume DNA as well as RNA to exist in solution in essentially pure form, i.e., extraction from tissues or cells and purification occurring prior to analysis.

Spectrophotometric methods

Spectrophotometry in the ultraviolet (concentration determinations) The presence of stacked Pu(Py) bases in DNA/RNA makes the polymers absorb radiation in the ultraviolet region. With duplex DNA, absorption starts at wavelengths below 300 nm and reaches a maximum near 260 nm and a minimum around 230 nm. The presence of a second peak around 200 nm has been suggested; however, its demonstration is not simple because most spectrophotometers cease functioning around 200 nm. Concentration determinations are usually performed at 260 nm by applying the Bouguer–Lambert–Beer law:

$$A^{260} = \varepsilon^{260} cd, \qquad (2)$$

where A^{260} is the absorbance of DNA at 260 nm, ε^{260} the DNA molar absorptivity (1 (mol phosphate)$^{-1}$ cm^{-1}), c its molar concentration in solution (mol phosphate l^{-1}), and d the optical pathlength (cm). By measuring A^{260}, one can readily compute c, the desired quantity, ε^{260}, and these are available from the literature for almost all DNAs. They are usually around 6.6×10^3 l (mol phosphate)$^{-1}$ cm^{-1}. Because of the 1:1:1 molar relationship between phosphate, sugar, and base, c can also be expressed in terms of moles of base per liter or moles of monomer per liter, etc. Since the average molecular weight of a nucleic acid monomer unit is 330, it is easily derived from eqn (2) that for duplex DNA:

$$1\, A^{260}\,\text{unit} = 50\,\mu\text{g DNA ml}^{-1}, \qquad (3)$$

while for single-stranded DNA or for RNA

$$1\, A^{260}\,\text{unit} = 40\,\mu\text{g RNA ml}^{-1}. \qquad (4)$$

Spectrophotometric methods in the ultraviolet (base composition determinations) The secondary structure of DNA can be used for analytical purposes. Heating duplex DNA at a given pH and ionic strength ultimately yields single-stranded DNA ('denaturation'). The process can be followed spectrophotometrically since single-stranded DNA has a higher absorbance (by about 25% at room temperature) at, say, 260 nm than double-stranded DNA. The increase in absorbance is called 'hyperchromicity' (H) and is defined as follows:

$$H^{260} = \left(A_t^{260} - A_0^{260}\right)/A_0^{260}, \qquad (5)$$

where A_t^{260} is the absorbance of DNA at 260 nm at a given temperature, t, while A_0 is its absorbance prior to heating (usually room temperature). H is thus the normalized absorbance increase of DNA due to heat-induced denaturation. Plotting H_{260} against temperature produces the so-called DNA 'melting curve.' The expression 'melting' refers to the fact that DNA 'helix-to-random coil transitions' resemble the infinitely sharp temperature-dependent phase transitions occurring in ice during melting. DNA 'melting curves' are of sigmoidal shape. The limiting value of A_t^{260} at

T_{max} is about 40% higher than A_0^{260}. The temperature at which H^{260} amounts to 50% of its limiting value H_{max}^{260} is called the 'melting temperature' (T_m in °C). T_m is linearly related to the (average) base composition of DNA. For the 'standard saline citrate' medium (0.15 M sodium chloride and 0.0015 M sodium citrate, pH 7.0):

$$\% \text{ GC} = 2.44(T_m - 69.3). \quad (6)$$

Since % GC = $100X_{GC}$, with X_{GC}, representing the 'mole fraction' of GC base pairs in DNA, and since $X_{AT} = 1 - X_{GC}$, eqn (6) furnishes equally well information on %AT. Equations similar to eqn (6) have been established for other solvents. In conclusion, heating native DNA under controlled conditions (constant pH and ionic strength, application of a linear temperature gradient, automatic recording of hyperchromicity) enables the rapid determination of its chemical (base) composition. It is best to work at $A_0^{260} \approx 1$ ($\approx 50\,\mu$g DNA ml^{-1}).

Physiology

Nucleic acids are essential components of all cells and consequently are found in many foods. The term 'nucleic acid' commemorates the first isolation of this vital cell constituent, 'nuclein,' from the spermatic fluid of Rhine salmon and the nuclei of pus cells, by Miescher in 1868. Some 20 years later, it was demonstrated that uric acid, which had been recognized by the Swedish chemist Scheele in 1776 as a constituent of human urine and kidney stones, arose from nucleic acid degradation. Fischer and his school in Germany at the end of the nineteenth century (1895–1899), established the first chemical structure for uric acid, as well as that of other purine and pyrimidine bases. It was demonstrated subsequently that nucleic acids consisted of chains of these purine and pyrimidine bases linked to a pentose sugar, esterified with phosphoric acid (**Figure 1b**). Two types of nucleic acid have been identified – deoxyribonucleic acid (DNA) and ribonucleic acid (RNA).

Physiological Roles

The purine and pyrimidine bases of DNA carry the genetic information of all prokaryotic and eukaryotic organisms, with the sugar and phosphate groups performing a structural role. The human genome is considered to contain between 50 000 and 100 000 genes, each of which is composed of a linear polymer of DNA of varying length. In viruses, genes are made of either DNA or RNA. The infinite variation in genetic information is achieved by the sequence of the four bases that constitute DNA (**Figure 1b**) – the purines, *adenine* and *guanine*, and the pyrimidines, *thymine* and *cytosine*. DNA is double-stranded, and each nucleotide of the chain in one strand is linked by hydrogen bonding to a complementary nucleotide in the other. Complementary pairs of nucleotides are adenine and thymine, and guanine and cytosine. DNA is principally found in the nucleus and is considered to be relatively stable in most cell types. (*See* **Viruses**.)

Ribonucleic acid is essential for the transmission of the genetic message in the form of protein synthesis and must first be synthesized from DNA. In the case of RNA, one of the four bases differs from that in DNA – *uracil* replaces the pyrimidine base thymine – and the molecule is single-stranded, except in some viruses. In contrast to DNA, most of the RNA is in the cytoplasm. Cells contain three types of RNA: *messenger* RNA (mRNA; 5% of total RNA) provides the template for protein synthesis and is relatively labile; *transfer* RNA (tRNA; 15%) carries the message in the form of activated amino acids to the ribosome for the synthesis of specific polypeptides, as determined by the particular mRNA template; and *ribosomal* RNA (rRNA), the major RNA component (80%), is metabolically stable. (*See* **Protein**: Synthesis and Turnover.)

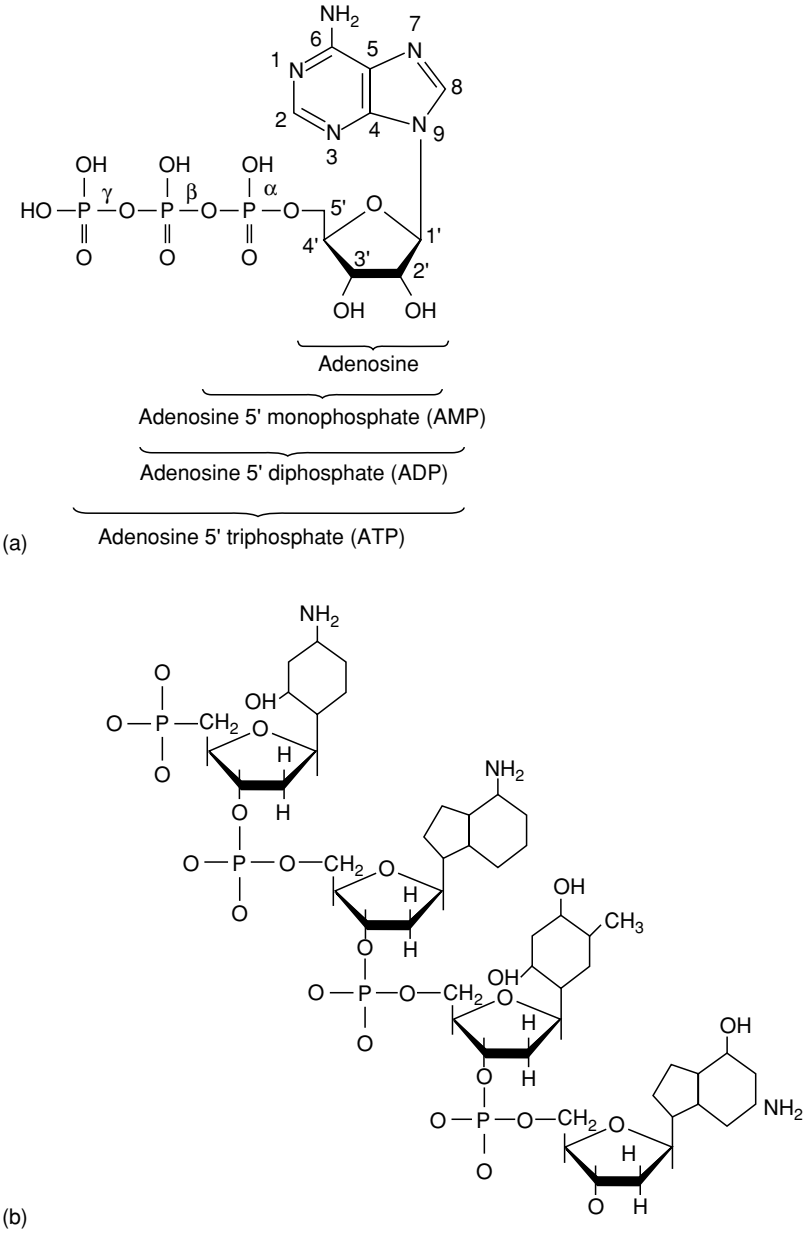

Figure 1 (a) Structural formula of adenosine 5′-triphosphate (ATP) indicating the numbering of the atoms on the ribose, as well as the purine ring, which consists of a six-membered pyrimidine ring fused to a five-membered imidazole ring. The position of attachment of the phosphate groupings for AMP, ADP, and ATP is also indicated. (b) Schematic representation of the structure of part of a single DNA strand made up of a sequence of the four bases, the pyrimidine cytosine, the purine adenine, the pyrimidine thymine, and purine guanine respectively, showing that the deoxyribose has an H group at the 2′ position on the pentose ring, instead of the OH group of ribose. These bases are linked via the 3′-OH group of the deoxyribose-phosphate moiety to the 5′-OH group of the next deoxyribose. Reproduced from Nucleic Acids: Physiology, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The important physiological roles played by the metabolic pathways responsible for sustaining these different nucleic acid pools in humans is demonstrated by the clinical manifestations when different steps in the synthesis, degradation, and repair of the constituent mononucleotides are defective or absent.

Nucleic Acid Metabolism in Humans

The building blocks of the nucleic acids, the purine and pyrimidine ribonucleotides, are of central importance to virtually all biological processes. Whereas cellular purines are derived exclusively from endogenous sources, cellular pyrimidines are

not. As discussed in detail later, dietary purines are degraded by a battery of enzymes in the intestinal mucosa and enter the circulation as uric acid. By contrast, dietary pyrimidines can be absorbed in the nucleoside form and incorporated by salvage into the nucleotide pool, as evidenced by the lifelong treatment of patients with the pyrimidine *de-novo* salvage defect, hereditary oroticaciduria, with oral uridine.

Nucleotides in infants

Over the past two decades, there has been considerable interest in the role of dietary ribonucleotides in infant feeds, in which significant effects have been claimed. This debate stemmed from reports that ribonucleotides were present in human milk, but not in cows' milk or infant formulas. However, claims that nucleotide concentrations were much lower in cows' than in human milk were apparently related to the state of lactation, with concentrations higher during lactation. Infant formulas were confirmed as being devoid of nucleic acid.

These findings stimulated investigations to determine: (1) whether the nucleotides found in human milk result from degradation of nucleic acids, or are actively secreted as a response to a nutritional demand of the infant, and (2) the newborn infant's endogenous capacity to digest nucleic acids to absorbable products. Nucleotides were found in the greatest quantity in human milk followed by nucleic acids, nucleosides being a minor component. Importantly, the nucleotide/nucleosides were predominantly pyrimidines, purines being present only as uric acid. This specific profile must result from catalysis in the breast. Enzymes capable of degrading nucleotides, including xanthine dehydrogenase (XDH), are known to be present in human milk. Evaluation of the endogenous capability of infants to metabolize RNA and nucleotides confirmed that the intestine of infants, as in adults, digested RNA to cytidine, uridine, and uric acid *in vitro*. This study confirmed the extensive data derived from dietary purine loading in adults that dietary purine nucleotides (if not already degraded by gut bacteria) would be degraded to uric acid in the intestinal mucosa. However, uridine and cytidine would be absorbed (although the latter would be degraded rapidly to uridine by cells *in vivo*).
