GLA is the first intermediate in the metabolic conversion of linoleic acid to arachidonic acid. The change involves introduction of a (third) double bond at the Δ6 position under the catalytic influence of the 6 desaturase enzyme. This step is believed to be the rate-limiting stage in the metabolic pathway. For humans in good health, this presents no problem, but there are some conditions such as aging, smoking, diabetes, high alcohol intake, stress-related hormones, and viral infections that inhibit the rate-determining step and where it is considered wise to supplement the intake of GLA. Nutritional factors can also influence this metabolic pathway.

Table 1 shows the series of changes by which linoleic and linolenic acids are converted to the long-chain polyunsaturated fatty acids.

Occurrence of GLA in Seed Oils and Microorganisms

As an intermediate in the conversion of linoleic acid to arachidonic acid, it is not surprising that GLA is found at low levels in many animal fats. It is present in cow milk fat (~0.1%) and human milk fat (0.35–1.0%), and its presence in the latter has often been cited as an indication of its importance. However, richer sources of this acid are found in the seed oils of some less common plants and are also produced by some microorganisms.

There are three commercial sources of GLA from seed oils: evening primrose (*Oenothera biennis* and *O. lamarckiana*), borage (*Borago officinalis*), and blackcurrant (*Ribes nigrum*). Typical fatty acid profiles for these three oils are given in Table 2. Ucciani found GLA in 164 higher plant families belonging to 10 botanical families.

Evening primrose oil was the first to be developed and used as a source of GLA. It contains 6–14% (generally 9–10%) of this acid and is accompanied by high levels of linoleic acid. Borage (starflower) is a richer source of GLA in terms of oil content of the seed and level of GLA in the oil, but it has less linoleic acid than evening primrose oil and also contains a

series of *n*-9 higher monoene acids viz. 20:1, 22:1, and 24:1 at a combined level of about 8%. Blackcurrant oil is intermediate between the other two sources in its level of GLA, but it also contains the 18:3 and 18:4 *n*-3 acids.

Molds belonging to the Mucorales family produce GLA as the only 18:3 acid, and commercial processes have been developed in Japan based on *Mortierella isabelina* and in the UK based on *Mucor javanicus*. UK production has been discontinued following a change in ownership of the producer company. These products differ from the seed oils in their higher levels of saturated and monoene acids and their lower level of linoleic acid. This makes the oil more suitable as a source of pure GLA or of upgraded triacylglycerols, since the necessary separations are easier to effect.

The blue–green algae *Spirulina platensis* (18–21% GLA) and *S. maxima* (12% GLA) are also potential sources of GLA. However, this is present in various galactosyldiacylglycerols or phosphatidic acids rather than in triacylglycerols.

The distribution of these fatty acid chains between the *sn*-1, 2, and 3 positions has been examined in a number of ways. Results for GLA are summarized in Table 3.

Because of the high level of linoleic acid in evening primrose oil the major triacylglycerols contain two (or three) linoleic acyl chains: LLL 54.3 mol%, LLG 17.6%, LLO 13.7%, LLP 7.9%, and other 6.5% (L = linoleic, G = γ-linolenic, O = oleic, and P = palmitic acyl group). The triacylglycerol composition of borage oil is more complex, with 10 molecular species each exceeding 4 mol%: LLG 15.4, OLG 12.3, LLL 10.1, LGG 9.8, PLG 9.5, PLL/OOG 8.9, OLL 8.2, SLG/POG 5.0, LLE 4.1, OOL 4.1, and other 12.6 (symbols as above and E = 20:1, S = stearic and). No sterochemistry is implied in these symbols, and PLG, for example, represents the sum of six isomers.

Evening primrose oil grows in many countries in Europe and also in New Zealand, but for commercial reasons, the crop is now grown mainly in China (75–80%) and Eastern Europe. Seed is produced at a level of 1000–1200 kg ha^{-1}. Annual production is estimated to be about 10 000–12 000 tonnes of seed yielding 1300–1500 tonnes of oil. Over 10 years to 1999, the price of the oil fell from $45 to $17.5.

Britain is the main source of borage (starflower), but it is also grown in Holland, Canada, New Zealand, and Poland. Annual production of seed is estimated at 3000–4000 tonnes, which provides about 800 tonnes of oil. Borage seed is $3000–4000 per tonne. The price of the oil fell from $60 to $35 per kilogram over the 10 years to 1999.

Blackcurrant seed oil is a byproduct of the production of blackcurrant juice and jelly, and production is estimated to be perhaps 50–100 tonnes per annum.

These oils are most often supplied in capsules with added tocopherol and ascorbyl palmitate to serve as antioxidants. The products have a shelf-life of about 3 years.

Sources with Higher Levels of GLA

It is possible to raise the level of GLA in these oils by selective enzymic reaction, and enhanced evening primrose and borage oils, with twice the normal level of GLA, have been produced and offered for sale. These materials are mainly triacylglycerols but may contain up to 20% of diacylglycerols. Procedures are based on the fact that some enzymes discriminate against acids having a double bond close to the acyl function and GLA with Δ6 unsaturation can be distinguished from the more common unsaturated acids with Δ9 unsaturation (oleic and linoleic). This differentiation is apparent in hydrolysis, esterification, acidolysis, and alcoholysis reactions promoted by appropriate lipases. The following examples are typical.

- Borage oil (22% GLA) is hydrolyzed completely (*Pseudomonas* species, 35 °C, 24 h), and the acids are selectively esterified with lauric alcohol in the presence of *Rhizopus delemar* lipase at 30 ° for 20 h. The latter enzyme discriminates against GLA, and this acid is concentrated in the unesterified acids, which finally contain 70% GLA (74% recovery). If the esterification is repeated, 94% GLA is obtained with 68% recovery (*C. rugosa*, 35 °C, 15 h).
- Selective hydrolysis of borage oil (22% GLA) with *C. rugosa* lipase at 35 °C for 15 h gives glycerol esters with 46% of this acid that can hardly be raised above this value. After removal of free acids, a second hydrolysis raises the concentration to 54% with 76% recovery. On a pilot-plant scale, 7 kg of borage oil gives 1.5 kg of upgraded oil (56%

GLA) after removal of free acid by molecular distillation. Starting with an already upgraded borage oil (10 kg, 45% GLA), high-quality GLA (2.1 kg, 98% pure, 49% recovery) is obtained by hydrolysis and two separate partial esterifications.

There are several reports of plants such as rapeseed/canola genetically modified to produce GLA, but commercial products are not yet available. One example that has been cited has the following fatty acid composition: 16:0 4.2%, 18:0 3.7%, 9–18:1 21.6%, 11–18:1 3.4%, 18:2 26.0%, 6,9,12–18:3 37.0%, 9,12,15–18:3 1.3%, and other 2.8%.

Nutritional and Medical Uses

The major applications for the oils are in the area of healthfood supplements, but markets have also been developed in infant nutrition, pet food, and cosmetics, and the total market for these oils is around $50 million per year.

Available evidence indicates that only around 5–10% of the daily intake of linoleic acid can be converted to GLA and beyond. For a 60-kg adult with a dietary intake of 5–20 g day^{-1} of linoleic acid, the endogenous rate of formation of GLA will be 250–1000 mg day^{-1} or around 4–17 mg kg^{-1} day^{-1}.

Human breast milk contains 100–400 mg l^{-1} of GLA + DGLA (20:3 *n*-6). A 5 kg baby consuming 1 l of milk per day receives 20–80 mg kg^{-1} day^{-1} of these two acids combined. DGLA is converted to two main eicosanoids: PGE_1 and 15-hydroxy DGLA. PGE_1 (prostaglandin E_1) is antiinflammatory, antithrombotic, a vasodilator, and stimulates the formation of cyclic adenosine monophosphate, which inhibits phospholipase A_2, whereas 5-hydroxy DGLA is a potent natural antiinflammatory agent inhibiting the conversion of AA (arachidonic acid) to its 5- and 12-lipoxygenase metabolites. GLA and DGLA are considered to be useful in the treatment of diabetes, atopic eczema, inflammation, stress, cardiovascular disease, and cancer.

Soft gelatin capsules containing evening primrose oil have been sold as nutritional supplements for more than 20 years and of borage oil (also marketed as starflower oil) for more than 10 years. Samples may be blended with other oils (fish, linseed) or have added vitamins, minerals, or herbal extracts. Nutritional supplements probably account for 80% of the total usage of GLA oils.

GLA has been used to treat a wide range of conditions including: atopic eczema, dermatitis and other inflammatory skin conditions, diabetic neuropathy, breast pain, premenstrual syndrome, high blood pressure, and cancer, but not all of these claims have been confirmed.

Doses have not been fully defined, but the following levels have been recommended (levels refer to GLA and not to GLA-containing oils): nutritional purposes (25–50 mg day^{-1}), therapeutic use (100–500 mg day^{-1}), and pharmacological effect (500–2000 mg day^{-1}).

Two products have been licensed as pharmaceuticals Efamast™ for relief of cyclical mastalgia and Epogam™ for treatment of atopic eczema. There are also a range of preterm and term infant formulations on the market (particularly in Europe) containing GLA from various sources. Levels of GLA in infant formula range from 0 to 0.9%. Many skin-care products (creams, lotions, soaps) contain GLA oils at levels between 0.1 and 2.0%.

Analysis

E W Hammond, Greenisle-Consulting, Warkton, Kettering, UK

Background

Fatty acids occur in food lipids mainly as esters of glycerol. Fatty acids are represented in food lipids (typical ranges shown in brackets) by

triacylglycerides (> 90%), diacylglycerides and monoacyglycerides (in the range 0.5–4%), other polar lipids such as lecithin (0.5–5%), phytosterol esters (up to 1%), and free fatty acids (up to 1%).

Extraction of Lipids from Foods

The extraction of lipids from foods in order to analyze their fatty acids is often difficult and specialized. For example, foods may be essentially anhydrous (e.g., biscuits, wheat flour) or wet (e.g., fresh meats, fish). Each food type may require very different handling to obtain the total lipids present. The fat in biscuits can be obtained just by suspending the crushed samples in light petroleum. However, to obtain the total lipids from flour requires rigorous extraction with solvents such as *n*-butanol. Samples containing water in any quantity require dehydrating first, which process might change the lipid materials, or extraction with alcohol based solvent mixtures. The references included in the bibliography cover a range of techniques for specific materials.

Determination of Total Free Fatty Acids

Free fatty acids (FFA) occur in refined edible oils at less than 0.1% (w/w) and in crude oils typically from 1 to 15%. FFA at such levels are present because of lipid hydrolysis and not as a normal natural component of vegetable or animal lipids. The high levels sometimes found in crude oils are as a consequence of tissue damage leading to the release of natural lipases. Tropical fruits such as palm are particularly prone to high FFA levels in crude oils. (*See* **Phospholipids**: Determination; **Triglycerides**: Characterization and Determination; **Vegetable Oils**: Composition and Analysis.)

The normal method of determination is titration (AOAC28:029–28:034) with a solution of potassium hydroxide [approximately 0.1 M in 95% (v/v) ethanol]. This procedure is applicable to all oils and fats that are soluble in the solvent mixture 1/1 (v/v) of ethanol 95% (v/v) and diethyl ether. The titrimetric procedure uses an indicator solution which is phenolphthalein [10 g l^{-1} in ethanol 95% (v/v)], for determining the end point. In the case of fats, which give colored solutions, a potentiometric technique should be used to determine the end point. The result of the titration is the average of two duplicate determinations and is expressed as one of the following:

1. **Acid value (AV)**: the number of milligrams of potassium hydroxide required to neutralize 1 g of the fat. This is given by the formula:

$$\text{A.V.} = (56.1PV)/m,$$

where V = number of milliliters of potassium hydroxide; P = exact molarity of potassium hydroxide; and m = mass (g) of the test portion.

2. **FFA%**: the acidity in per cent given by the formula:

$$\text{Acidity} = (PVM_r)/(10m),$$

where V = number of milliliters of potassium hydroxide; P = exact molarity of potassium hydroxide; M_r = relative molecular mass (see Table 1); and m = mass (g) of the test portion.

When determining FFA%, it is conventional to express the value as 'oleic acid.' However, where the type of fat is known, the relative molecular mass should be used for improved accuracy. This can be calculated from the average molecular weight of fatty acids, determined from the analysis of fatty acids by gas chromatography. Otherwise, the values for M_r, as shown in Table 1, should be used.

To maintain precision, the size of sample to be used in the determination will depend on the expected level of FFA and should follow the data in Table 2. (*See* **Chromatography**: Gas Chromatography.)

Method: Total FFA by Titration

1. A quantity of the solvent mixture (1/1 ethanol/diethyl ether) should be neutralized, just prior to use, by dropwise addition of 0.1 M potassium hydroxide solution after adding the phenolphthalein indicator at the rate of 0.5 ml per liter of solvent.
2. The quantity of sample required is determined by reference to Table 2. Duplicate samples are weighed out accordingly, paying attention to accuracy. The weights are recorded. The samples are dissolved in 50–150 ml of the solvent, each.

Table 1 Total free fatty acids

Type of fat	*Expressed as*	M_r
Coconut, palm kernel	Lauric acid	200
Palm oil	Palmitic acid	256
All other oils	Oleic acid	282

Table 2 Sample mass required for determination of FFA

Expected acid value	*Percentage FFA*	*Mass of test portion (g)*	*Accuracy of weighing (g)*
< 1	(< 1)	20	0.05
1–4	(< 2)	10	0.02
4–70	(2–10)	2.0	0.01
20–70	(10–40)	0.5	0.001
> 70	(> 40)	0.1	0.0002

3. While the solution is stirred continuously, titration with 0.1 M potassium hydroxide should proceed to the end point. The end point is a pink color, which should persist for at least 10 s. The volume of titrant is recorded.

Notes:

1. If the FFA is very low (< 0.2%), atmospheric carbon dioxide may interfere significantly. It is useful to replace the air in the titration flask with nitrogen.
2. If the solution becomes cloudy during titration, the volume of neutralized solvent may be increased. Warming should be avoided.
3. If the quantity of hydroxide required for titration exceeds 10 ml, a solution of 0.5 M may be used.

Determination of Individual Free Fatty Acids

Certain situations arise where it may be advantageous to determine a single fatty acid or the distribution of fatty acids in the FFA fraction of a fat or oil. In this case, titration is of little use, since it does not discriminate between the different fatty acids. The quickest method is to use gas chromatography with an added internal standard. In this method, quantitation of both individual and total FFA is obtained and can be measured down to 0.001% with confidence.

It is possible to analyze free fatty acids directly by capillary gas–liquid chromatography (GLC) using special deactivated acidic phases, such as Restek Stabilwax-DA (Stabilwax-DA crossbond fused silica capillary column; Thames Restek UK Ltd., Berkshire, UK). These reduce the tailing effects and nonproportional losses that are a consequence of hydrogen bonding of FFA on the column. Analysis of derivatives is advised to reduce quantitative errors that can result.

Where FFA is to be analyzed directly, it should first be isolated by thin-layer chromatography (TLC) or clean-up column procedures (see below). Prior to this, an internal standard of heptadecanoic acid (C17:0) should be added to the fat at a level consistent with the expected level of FFA present in the fat. (*See* **Chromatography**: Thin-layer Chromatography.)

The FFA, dissolved in toluene (up to 5 mg ml^{-1}, total FFA), is injected (0.5 µl) using the direct on-column technique. The column can be a 30-m length of 0.53-mm ID fused silica, with a 0.25-µm, cross-bonded film suitable for the analysis of underivatized fatty acids (see Figure 1). A 1.0-m length of fully deactivated, blank fused silica should be fitted as a 'retention gap.' Typical conditions for analysis are shown in Figure 1. A full profile, including unsaturated fatty acids, from butyric acid (C4:0) to arachidic (C20:0) acid can be achieved within 30 min.

Where the chain-length distribution of the FFA is wider than C14 to C20, it may be necessary to apply correction factors to the detector response. The flame ionization detector responds to nonoxidized carbon in a linear relationship. However, the carboxyl carbon is oxidized and does not respond; therefore, formic acid gives no response, while acetic shows the response of one carbon, and so on through the series. Since an internal standard is used in this method, it is a simple job to determine the response factors for the FFA of interest relative to this standard.

Analysis of Derivatized FFA

Methods There are often problems in the measurement of FFA by GLC. It is advisable to derivatize for improved accuracy. Again, it will be necessary to use an internal standard of C17:0 and relative response factors. Two approaches may be used: methyl esters of FFA or silyl ethers of FFA.

In the case of derivatives of FFA, one must consider whether they are to be analyzed free (isolated) or in the presence of other lipid classes such as triacylglyceride (TAG) and partial glycerides. If short-chain, volatile FFA is present (e.g., in butterfat), it is best not to have any concentration step. By far the most specific reagent is diazomethane, but care must be exercised in its use, as the reagent is highly toxic and potentially explosive.

The preparation of methyl esters in this way will provide good quantitative data on the FFA portion of the fat only. If silyl ethers are prepared, and the whole fat mixture is analyzed by GLC, total fat information is obtained.

Methyl Esters via Diazomethane An appropriate amount (up to 50 mg) of the isolated FFA is dissolved in diethyl ether (2 ml) containing a few drops of methanol. The diazomethane in diethyl ether solution is prepared, with all manipulations carried out in a fume cupboard. Sufficient diazomethane solution is added to the sample to leave a slight excess of yellow color remaining. The mixture is left for no longer than 5 min; otherwise, artificially high results may occur. Formic acid in methanol (10%) solution is added dropwise to remove the excess reagent. This solution is now ready for analysis without concentration. The type of GLC column used is typically a 30 m × 0.32 mm i.d. fused silica, with a 1.0-m retention gap of fully deactivated fused silica. A polar phase of bonded FFAP at 1.0-µm film thickness is suitable. The sample is injected using the on-column technique and not split injection. The carrier gas may be hydrogen (linear velocity 40 cm s^{-1}) or helium

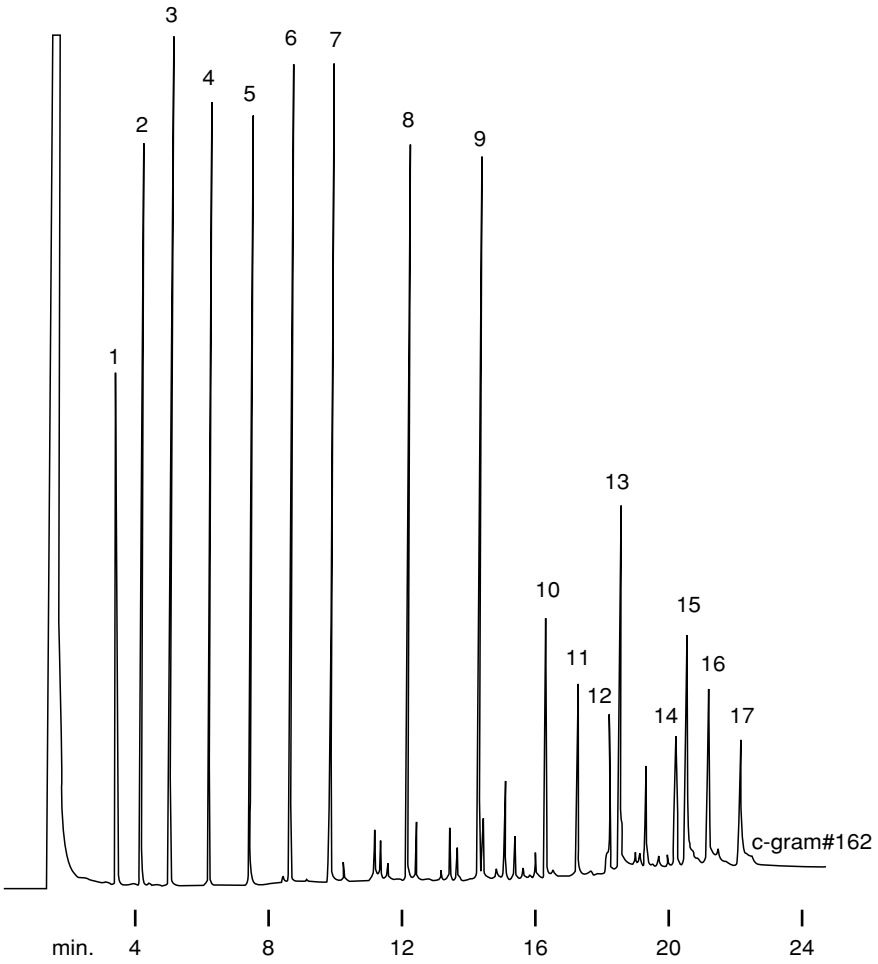

Figure 1 Organic acids and free fatty acids [Stabilwax DA, direct injection; 30 m, 0.53 mm i.d., 0.25 μm Stabilwax-DA (cat. #11025), 0.5 μl direct injection of a 5 mg ml^{-1} standard]. Oven temperature: 100 °C (hold for 2 min) to 250 °C at 8 °C min^{-1}. Injection and detection temperature: 280 °C. Carrier gas: helium. Linear velocity: 40 cm s^{-1} (flow rate: 5.2 cm^3 min^{-1}). FID sensitivity: 8×10^{-11} AFS. 1: C2:0, acetic acid; 2: C3:0, propionic acid; 3: C4:0, butyric acid; 4: C5:0, valeric acid; 5: C6:0, caproic acid; 6: C7:0, enanthic acid; 7: C8:0, caprylic acid; 8: C9:0, capric acid; 9: C10:0, lauric acid; 10: C11:0, myristic acid; 11: C12:0, pentadecanoic acid; 12: C13:0, palmitic acid; 13: C14:0, palmitoleic acid; 14: C15:0, stearic acid; 15: C16:0, oleic acid; 16: C17:0, linoleic acid; 17: C18:1, linolenic acid. Reproduced by permission of Restek Corporation.

(linear velocity 20 cm s^{-1}). The column initial temperature will depend upon the type of sample but typically is 100 °C, held for 5 min. The temperature is then programmed to 200 °C at 5 °C min^{-1}. The elution order and profile will appear very similar to that for FFA above (Figure 1), with the advantage that peak width and retention time will be improved.

***O*-Trimethylsilyl Ethers (*O*TMSi)** The most useful reagents for the derivatization of fats are bis-trimethylsilyl acetamide (BSA) and trimethylsilyl imidazole (TSIM) (Pierce Chemical Co.), with the latter being the stronger reagent, particularly when diacylglycerides (DAG) and monoacylglycerides (MAG) are present. Derivatization is achieved in the neat reagent or in a solution of the lipid in chloroform or tetrahydrofuran (10 mg ml^{-1}). During the procedure, the *anhydrous* solution is warmed at 50 °C for 5 min in a closed vial. In this reaction, all free hydroxyls and carboxyls are derivatized. Normally, 100% volume excess of the reagent over the fat is sufficient, where the level of FFA and partial glycerides is not abnormally high. The minimum level of reagent will be 50–100-fold molar excess over total free hydroxyls and carboxyls. When using chloroform, allowance must be made for the 2% of ethanol stabilizer. The resulting solution is stable for up to 5 h if maintained anhydrous in a closed vial. After this time, it should be discarded. The solution is injected directly 'on column' and *not* via a split technique. For GLC, use a column of fused silica, 0.53 mm i.d. by 10 m in length with a bonded phase of OV1, OV101 (or

equivalent) of film thickness 0.1–0.2 μm. A 1.0-m length of fully deactivated, blank fused silica is fitted as a 'retention gap.' The helium carrier gas is set high at about 30 ml min^{-1} and a start temperature of 50 °C held for 5 min. The temperature is then programed at 5 °C min^{-1} up to 320 °C in a single ramp. The elution order is fatty acids, MAG, DAG, and TAG in order of molecular weight. The method is suitable for neutral fat extracts. In some fats, the level of free sterols is significant, and OTMSi ethers of sterols will appear on the chromatogram.

Fatty Acid Methyl Esters from Triacylglycerides

There are a number of methods used to prepare fatty acid methyl esters (FAME) from TAG to enable their analysis by GC. The boron trifluoride/methanol reagent is widely used (AOAC -28:057). The reagent is toxic and unstable during storage, and has been found to be prone to form artefacts from some oxygenated, cyclic, and some polyunsaturated fatty acids.

Transmethylation techniques are very rapid, but they produce FAME only from glyceride esters and not from any FFA component. It is important, also, that the reagent and fat solutions are anhydrous; otherwise, significant (and even large) amounts of unesterified FFA can result. Of this group, 0.5 M sodium methoxide/methanol is widely used. This reagent is hazardous to prepare and dispose of. Anhydrous potassium hydroxide/methanol (0.2 M) is perhaps a more preferable reagent, being easy to prepare as required, although storage is acceptable provided it is kept dry. It should be noted that if conjugated unsaturated fatty acids are known to be present, they might be unstable in alkaline reagents. These reagents should be stored in bottles with polycarbonate stoppers; glass stoppers will fuse to glass bottles.

For up to 50 mg of sample in 3–5 ml of reagent (with 1.0 ml of toluene added as solubilizer), heated to 50 °C, the reaction time is normally 15 min. At the end of reaction, the sample is allowed to cool, and 5 ml of aqueous acetic acid (5%) is added carefully, followed by up to 10 ml of hexane (dependent upon sample size) such that the ester concentration is about 5 mg ml^{-1} (suitable for direct sampling on to GLC). This mixture needs to be shaken thoroughly and allowed to separate. The lower layer is removed by aspiration and discarded. A 5-ml aliquot of water is added, and the mixture shaken and separated again. Most of the top layer is then transferred to a vial containing about 2 g of anhydrous sodium sulfate, which dehydrates the solution ready for GLC. No concentration step should normally be necessary.

Acid methanolysis reagents methylate most lipid classes including FFA. They require relatively long reaction times but very short processing times, which means that technicians are not tied to one technique for long periods. Since the reagents are acidic, they are not suitable for epoxy fatty acids or other acid-labile fatty acids. Anhydrous hydrochloric acid/methanol (typically 5% or saturated) is suitable and popular. This produces methyl chloride during storage. In addition, while it is easy to use and prepare by bubbling hydrogen chloride gas from a cylinder into anhydrous methanol, this can be hazardous. Alternatively, acetyl chloride (50 ml) can be added to cold (5 °C) anhydrous methanol (450 ml); methyl acetate is formed as a byproduct. However, several workers, when using this latter reagent, have reported yield problems.

Sulfuric acid/methanol with toluene as solubilizer (1:10:20 by volume of sulfuric acid–toluene–methanol) is a convenient reagent. It is easy and safe to prepare, is stable at ambient for long periods, and is easy to use. Sulfuric acid is added to cooled and stirred methanol, followed by the toluene. The solution is stored in a brown stoppered bottle and must be kept dry. Acid-resistant gloves and a face shield should be worn while mixing in the acid. For use, 5 ml of reagent is added to up to 50 mg of sample, which is refluxed for 60 min in a tube. The sample is then diluted with 5 ml of water. A volume of hexane is added (to give an approximate sample concentration of 5 mg ml^{-1}), and the mixture is shaken thoroughly. On separation, the bottom layer is aspirated to waste. A further 5 ml of water is added and the mixture shaken. The top layer is transferred to a vial containing 2 g of anhydrous sodium sulfate. This solution is then ready for analysis by GLC. If short-chain (< C10) fatty acids are present, the toluene may interfere with the GLC analysis. In this case, a reagent made up without the toluene solubilizer should be used, *but note* that an extended reflux (90 min) may be necessary, unless the fat dissolves rapidly.

Chromatographic Methods

Some of the specific points have been covered above and should be considered in combination with this information.

Thin-layer Chromatography (TLC)

FFA is easily separated from other lipid classes on silicic acid TLC plates. This technique is excellent for preparative work. Plates coated with Kieselgel with ('G') or without ('H') calcium sulfate binder can be used. The plates should be activated before use. For speed, individual plates may be placed flat on the

turntable in a microwave oven for 2 min at full power and then cooled. Multiple samples may be spotted in lanes or, for preparative work, the sample may be applied as a continuous streak 1 cm above the base of the plate. The sample area is focused before the main chromatography by developing the plate to just above the sample application line twice in a solvent of diethyl ether. The plate is air-dried between each focus development, and then developed in the main solvent, which, for FFA, is a mixture of diethyl ether/light petroleum 40–60° with added formic acid (proportions 18/82/1 by volume). After development to within 1 cm of the top of the plate, the plate is air-dried and sprayed lightly with a methanolic solution of dichlorofluorescein (0.1%). After drying, the plate is viewed under ultraviolet (UV) light (254–320 nm), which causes most lipid components to fluoresce. Lipids that absorb in the UV (e.g., conjugated unsaturates) appear as violet spots. FFA lies between TAG and DAG with an Rf of approximately 0.6. If there is some confusion over the position of the FFA, a standard can be run in 1-cm lanes at the sides of the plate. Samples that contain FFA with a wide range of chain lengths (C4 to C20, for instance) often give a broad band or even double bands. The longer-chain FFA is less polar than the short-chain FFA and therefore runs slightly higher up the plate. The FFA band should be marked, scraped off into a sinter glass disc filter stick, and eluted off with diethyl ether. Careful concentration yields the dry FFA fraction. If small or volatile fractions are suspected (this is particularly useful for radioactive labeled fractions), they may be stabilized prior to concentration by the addition of a known, small amount of 10% potassium hydroxide in methanol (enough to form the salts). After concentration, the salts are dissolved in a small volume of 1:1 diethyl ether:methanol containing sufficient formic acid to re-form the acids prior to methylation.

High-performance Liquid Chromatography (HPLC)

It is recommended that FFA be analyzed by GLC, but for various reasons, the use of HPLC may be dictated. To overcome the lack of a chromaphore, most workers use UV-absorbing derivatives of FFA. The most popular and successful has been the phenacyl ester. The dansyl piperazide derivative has been applied successfully for fluorescence. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Typical chromatography conditions for phenacyl esters include a 25-cm × 4-mm i.d. column packed with C18 reversed phase material of 5-μm particle size. A solvent of acetonitrile–water (80:20, v/v) is run isocratically at 2.0 ml min^{-1} for the first 30 min. The solvent is then linearly programed to 85:15 (v/v) for another 15 min. There is a considerable overlap of peak compositions, and it is essential that a full set of standard materials is chromatographed to determine retention behavior and times. For instance, myristic acid (C14:0) has an elution time of about 16 min, whereas arachidonic acid (C20:4) elutes around 18 min. Stearic acid (C18:0) has an elution time of about 50 min.

Gas–liquid Chromatography (GLC)

This item has been covered earlier. However, the applications described are designed for capillary GLC. Modern instruments together with capillary or wide bore columns are relatively easy to use and produce high-quality results. However, the methods do not preclude the use of packed columns, although the chromatography of unesterified FFA is less successful. For esterified FFA, packed columns of either 2 or 4 mm i.d. by about 2 m in length should be used, with a carrier gas of nitrogen at 30 ml min^{-1} for a 2-mm column and 60 ml/min for a 4-mm column. For the column packing, a phase of 10% SP2330 on 100/120 mesh Supelcoport should be used, and this should be operated isothermally at 180 °C or programed from 50 to 200 °C at 5 °C min^{-1} after holding for 5 min. The sample solution is then injected directly on-column into a heated injection area set isothermally at 200 °C.

Determination of *Trans* Fatty Acids

Isolated, methylene-interrupted *trans* double bonds show an infrared (IR) band absorbing at about 967 cm^{-1}. This absorption may be used to estimate the *trans* content in edible fats. The AOAC publishes a typical method AOAC 28.052–28.067 for *trans* values (TV). There are some drawbacks with the IR method, which can lead to some inaccuracies. Essentially, when TV is measured on triacylglyceride, the value obtained is some 2 units higher than when the same sample is measured as methyl esters. This problem is worse for samples below 15% *trans*. Also, isomerized or oxidized fats (mainly) exhibit conjugated species that show absorption close to the isolated *trans* bond. This interferes with the correct allocation of baseline and makes low values less easy to define accurately. The following method takes into account these problems and introduces the use of standards and references, although it must be remembered that problems still exist with the determination of absolute TVs.

The method measures the TV on triacylglyceride, but we recommend conversion to methyl esters for values of less than 5% trans. The values are expressed as the percentage of trielaidin compared with a standard curve of trielaidin in tristearin. Confusions in

interpretation exist where there are compounds present that show absorption in the region 970 cm^{-1}. Pure trielaidin and tristearin (99%) are required as a standard and reference, together with a recording double-beam IR spectrometer suitable for quantitation between 1100 and 900 cm^{-1} and a matched pair of cuvettes of path length 1 mm (deviation < 1%) with windows of sodium chloride or potassium bromide. The solvent is carbon disulfide and solutions and measurements are all at 20 °C. The solvent is toxic, and therefore, all manipulations of open solutions should be done in a fume cupboard and appropriate solvent-resistant gloves must be worn. Alternatively, the use of Fourier transform infrared (FTIR) greatly improves the methodology and accuracy.

Method: Determination of *Trans* Value by IR Spectroscopy

1. The spectrometer is set to record in the range 1050–900 cm^{-1}, with a narrow slit and slow recording speed. (*See* **Spectroscopy**: Infrared and Raman.)
2. Solutions are prepared according to Table 3 and made up to exactly 10 ml in volumetric flasks.
3. A cuvette is filled with solution 1 and placed in the reference beam. The absorbances of the other solutions are recorded against this.
4. For each spectral record, a straight baseline is drawn joining the *minima* at 1000 and 925 cm^{-1}. The absorbance of the peak is calculated. If transmission is recorded, the absorbance can be determined by the formula:

$$\text{Absorbance } A = \log_{10}(BD/BC),$$

where B is the zero/∞ chart point, D is the center point of the baseline, and C is the peak apex.
5. The calibration line is constructed (this should be a straight line).
6. If necessary, all samples are liquefied and homogenized. Solutions in carbon disulfide of 200 mg (to the nearest 0.1 mg) in 10-ml volumetric flasks are made up to volume.
7. All sample solutions are read against the same reference solution 1 (tristearin). The baselines are constructed, and the peaks are measured as above.
8. The values (equivalent to trielaidin) for samples are read off the standard line, and the percentage *trans* from the sample weight is calculated.
9. If there is a significant degree of interference to the construction of the baseline, the samples should be converted to methyl esters. This should also be done where the TV is below 5%. In this method, the standard is methyl elaidate, and the reference becomes methyl stearate. All other manipulations are the same.

Table 3 Calibration solutions for IR spectroscopy

Material (mg)[a]	*Solution*				
	1	*2*	*3*	*4*	*5*
Tristearin	200	175	150	100	50
Trielaidin	0	25	50	100	150

[a]Weighed to the nearest 0.1 mg.

Dietary Importance

C J Field, University of Alberta, Edmonton, Alberta, Canada

Background

In Western countries, an adult eats on average 75–150 g of fat each day, representing 30–45% of the energy in the diet. Triacylglycerols constitute more

than 95% of dietary fat. Each triacylglycerol molecule is composed of three fatty acids esterified to a glycerol backbone, making fatty acids a major constituents of dietary fat. In recent years, it has become clear that fatty acids are more than just a source of energy. Fatty acids, especially long-chain polyunsaturated fatty acids (PUFA), are important regulators of many biological processes important in maintaining health and preventing disease.

Types of Fat in the Diet

Because of the wide range of foods consumed, the human diet contains a great variety of fatty acids. The chain length and degree of saturation are used to classify fatty acids, and these characteristics confer physiological properties. Fatty acids in the diet can therefore be saturated fatty acids (SFA) and contain no double bonds with the maximum number of hydrogen molecules attached, monounsaturated (MUFA) and contain a single double bond or PUFA and contain two or more double bonds. All dietary fats and oils contain a mixture of saturated and unsaturated fatty acids. Individual fatty acids are often referred to by their common names, but are more correctly identified by a systematic nomenclature that classifies them according to their chain length, position and number of double bonds (Table 1). This nomenclature indicates the number of carbon atoms in the acyl chain of the molecule, followed by a colon and then the number of unsaturated bonds. This is followed by the letter '*n*' (or ω) and the number of carbon atoms from the methyl end to the first double bond. Mammalian cells are able to synthesize (from nonfat precursors) saturated and unsaturated fatty acids of the *n*-9 and *n*-7 series but lack the Δ-12 and Δ-15 desaturase enzymes (which is found in most plants) for insertion of a double bond at the *n*-6 or

Table 1 Nomenclature of fatty acids and major sources in the diet

Chemical name	*Common name*	*Fatty acid notation*	*Sources*
Butanoic	Butyric	C4:0	Butter fat
Octanoic	Caprylic	C8:0	Palm kernel oil
Decanoic	Capric	C10:0	*De-novo* synthesis; coconut oil
Dodecanoic	Lauric	C12:0	*De-novo* synthesis; coconut oil
Tetradecanoic	Myrsitic	C14:0	*De-novo* synthesis; milk fat, coconut oil
Hexadecanoic	Palmitic	C16:0	*De-novo* synthesis and most plant and animal fats, including milk, eggs, animal fats, meat, coca butter, palm oil (other vegetable oils contain some but lesser amounts), and fish oils
Octadecanoic	Stearic	C18:0	*De-novo* synthesis and most plant and animal fats, including milk, eggs, animal fats, meat, and cocoa butter
9-Hexadecenoic	Palmitoleic	C16:1*n*-7	Desaturation of palmitic acid, fish oils, animal fats
9-Octadecenoic	Oleic	C18:1*n*-9	Desaturation of stearic acid and all plant and animal fats, including milk; eggs; animal fats; meat; cocoa butter; most vegetable oils, especially olive oil
9,12-Octadecadienoic	Linoleic	C18:2*n*-6	Cannot be synthesized in mammals; some milks, eggs, animal fats, meat; most vegetable oils, especially corn, sunflower, safflower, cottonseed and soybean oils; green leaves
9,12,15-Octadecatrienoic	α-Linolenic	C18:3*n*-3	Cannot be synthesized in mammals; green leaves; some vegetable oils, especially canola, soybean, walnut, mustard and linseed oils
6,9,12-Octadecatrienoic	γ-Linolenic	C18:3*n*-6	Synthesized from linoleic acid, borage, blackcurrant and evening primrose oils
11,14,17-Eicosatrienoic	Mead	C20:3*n*-9	Synthesized from oleic acid; indicator of essential fatty acid deficiency
Eicosanoic	Arachidic	C20:0	*De-novo* synthesis; peanut oil
8,11,14-Eicosatrienoic	Dihomo-γ-linolenic	C20:3*n*-6	Synthesized from γ-linolenic
5,8,11,14-Eicosatetraenoic	Arachidonic	C20:4*n*-6	Synthesized from linoleic acid via γ-linolenic and dihomo-γ-linolenic acids; small amount in meat
5,8,11,14,17-Eicosapentaenoic	Eicosapentaenoic (EPA)	C20:5*n*-3	Synthesized from α-linolenic acid; fish oils
7,10,13,16,19-Docosapentaenoic	Docosapentaenoic	C22:5*n*-3	Synthesized from α-linolenic acid via EPA; fish oils and animal tissues (brain)
4,7,10,13,16,19-Docosahexaenoic	Docosahexaenoic (DHA)	C22:6*n*-3	Synthesized from α-linolenic acid via EPA; fish oils and animal tissues (brain)

n-3 position (Figure 1). As the two types of PUFA, *n*-6 and *n*-3 fatty acids, are essential substrates for many of the regulatory lipids in the body, the precursor fatty acids linoleic (18:2*n*-6) and α-linolenic (18:3*n*-3) must be consumed in the diet (Figure 1). For the most part, the longer chain and more unsaturated *n*-6 and *n*-3 fatty acids such as arachidonic acid (20:4*n*-6), eicosapentaenoic acid (EPA, 20:5*n*-3), and docosahexaenoic acid (DHA, 22:6*n*-3) can be synthesized from either linoleic or linolenic acid (Figure 2).

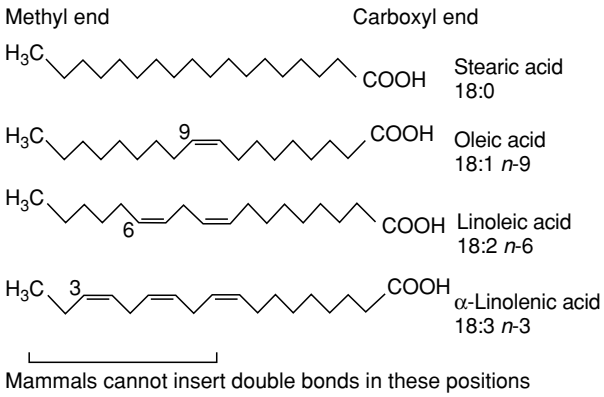

Figure 1 Double-bond location in major dietary fatty acids.

Sources of Fat in the Diet

The quantities and types of fatty acids ingested vary greatly, depending on the dietary source (Table 1). Animal fats contain about 40–60% saturated fatty acids. Some plant oils also contain SFA (i.e., palm oil, palm kernel oil, and coconut oil), which are widely used in processed foods. MUFA are found in animal fats and plant oils, with olive oil being a rich source. Plant oils like corn, soybean, cottonseed, sunflower, and safflower generally have more than 50% of their fatty acids as linoleic acid and are considered excellent sources of PUFA. Poultry and game also contain a small amount of linoleic acid. Linolenic acid, which comprises the majority of most people's *n*-3 fatty acid intake, is found in high amounts in

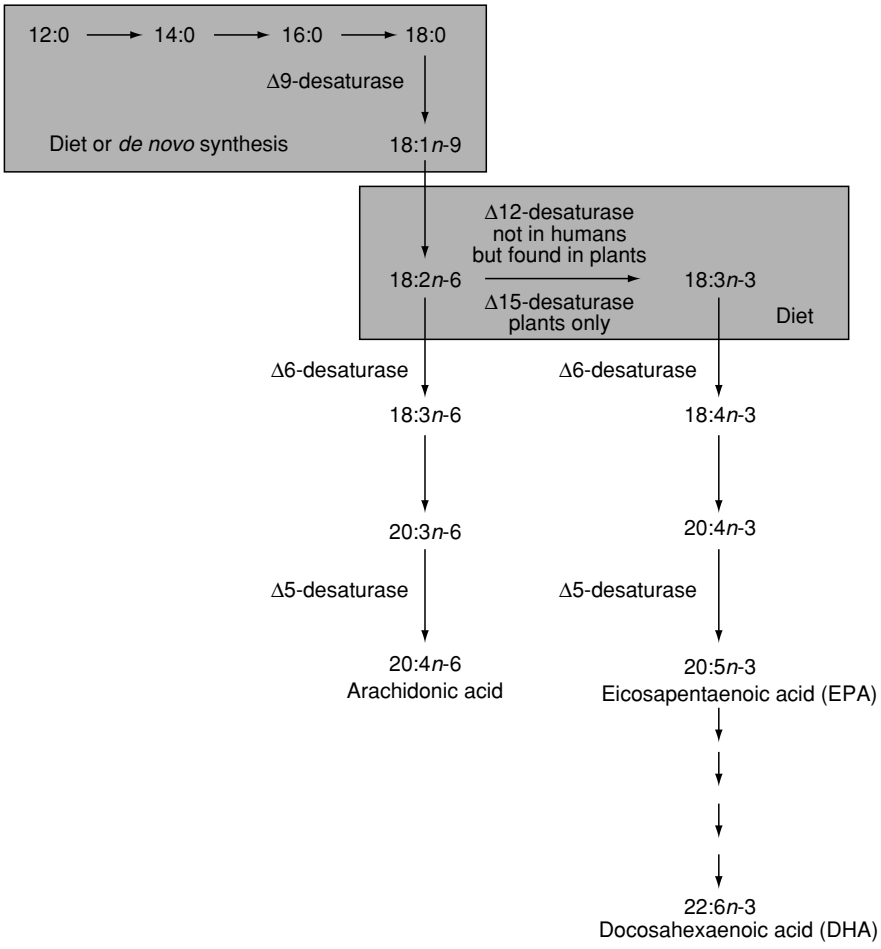

Figure 2 Elongation and desaturation of the major dietary fatty acids.

several plant oils (e.g., canola and flax) and, to a lesser extent, in other plant oils, green leafy vegetables, soybeans, and nuts. The more polyunsaturated long-chain *n*-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), comprise 20–30% of the fatty acids in cold water fish (particularly fatty fish such as herring, mackerel, fresh tuna, sardines, salmon, eel), other marine animals, and in oils extracted from the livers of fish which live in warmer waters (e.g., cod). There are new sources of EPA and DHA, made from single cell organisms, which are available to the food industry to supplement food. Most natural fats contain fatty acids in the *cis* form, but a small number of *trans* fatty acids also occur naturally, principally in meat and dairy products. The majority of the *trans* fatty acids in the diet come from foods made with hydrogenated vegetable oils. Generally, most fruits and vegetables contribute insignificant amounts or no fat to our diets.

Dietary Importance

The dietary importance of fatty acids is listed in Figure 3.

Energy and Essential Fatty Acids

In addition to contributing to the texture, flavor, and aroma of foods, fatty acids are an important concentrated source of energy (9 kcal or 37 $kJ\,g^{-1}$) for most cells in the body. Fat is a particularly important energy source for infants and young children, and restriction is associated with poor growth and delayed development. Although the biological importance is not completely clear, there is evidence suggesting that individual fatty acids are oxidized, metabolized, stored, and released at different rates. Fat slows down the digestion of foods, thus contributing to meal satiety. Dietary fat aids in the absorption of the fat-soluble vitamins. Specific fatty acids have important structural, biochemical, and regulatory functions that are required for optimal tissue function, growth, and repair. Insufficient consumption of the dietary essential fatty acids (linoleic and linolenic acid) results in a deficiency syndrome characterized by immune dysfunction, infections, scaly dermatitis, growth retardation, hair loss, thrombocytopenia, diarrhea, and poor wound healing.

Figure 3 Dietary importance of fatty acids.

Membrane and Cellular Function

Fatty acids, particularly PUFA, when consumed in the diet, integrate into cell membrane lipids. Although membranes can vary in their lipid content, most cell membranes contain approximately 50% lipid and 50% protein. Phospholipids, the major lipid found in cell membranes, are particularly high in long-chain (18–26-carbon) PUFA. The type of fatty acid incorporated into cell membranes is influenced by dietary fatty acids. It can be assumed that all of the *n*-6 and *n*-3 fatty acids found in cell membranes are derived from dietary sources. Changing the relative amount and type of PUFA in cell membranes has been shown to affect many membrane-related functions such as membrane fluidity, ion channel flow, transporter activity, signal transduction, enzyme activity, hormone binding, cell-receptor action, cell-to-cell communication, release of mediators, and susceptibility to microbial invasion and cancer.

Eicosanoid Synthesis

Linoleic acid and α-linolenic acid are substrates for the synthesis of physiological regulators called eicosanoids. Eicosanoids include prostaglandins, prostacyclins, thromboxanes, and leukotrienes. These 'local hormones' are potent mediators of many biochemical processes and play key roles in the regulation of blood clots, blood pressure, blood lipid levels, immune function, inflammation, pain and fever, and reproduction. The two major pathways for eicosanoid synthesis are via the enzymes cyclooxygenase (produce prostaglandins and thromboxanes) and lipooxygenase (produce leukotrienes, hydroxyeicosatrienoic acids, and lipoxins).

Dietary fat composition influences eicosanoid synthesis by changing the supply of substrates for the synthesis of the longer-chain *n*-3 and *n*-6 PUFA. Consuming large amount of linoleic acid increases the quantity of arachidonic acid in cell membranes. Upon activation, in a variety of cells, arachidonic acid is converted to eicosanoids of the 2 series and leukotrienes of the 4 series. However, dietary α-linolenic acid is converted to EPA in the membrane, and when cells are activated, EPA is converted to eicosanoids of the 3 series and leukotrienes of the 5 series. In general, eicosanoids formed from *n*-3 PUFA oppose, or have weaker effects than, eicosanoids formed from *n*-6 PUFA. In addition to competing as substrates for cyclooxygenase, *n*-3 fatty acids can directly suppress the activity of this enzyme. *n*-3 fatty acids also inhibit Δ-6 and Δ-5 desaturase activity, reducing the synthesis of arachidonic acid in the membrane. Indeed, it has been shown that increasing the proportions of *n*-3 in relation to *n*-6 PUFAs in the diet decreases the

quantity of proinflammatory, vasoconstrictive, platelet aggregatory, and immunosuppressive compounds that are regulated by eicosanoids. Recent investigations have shown that γ-linolenic acid (20:3*n*-6) present in some plants (i.e., evening primrose oil, borage, and flaxseed) may also influence the type of eicosanoid synthesized by a cell.

Gene Regulation

PUFA have been shown to alter the expression of numerous genes involved in the metabolic function of the cell. It has been demonstrated that specific dietary fatty acids can modulate the expression of a variety of genes (and transcription regions on genes) coding for key regulatory proteins in metabolic pathways such as those involved in digestion, lipogenesis, glycolysis, glucose transport, inflammation, and cellular communications. For example, dietary *n*-6 and *n*-3 PUFA suppress hepatic lipogenesis by suppressing transcription of fatty acid synthase. Suppression is greater with DHA, EPA, and arachidonic acid than with linoleic acid or α-linolenic acid, whereas SFA and MUFA have little effect. In the future, fatty acid–gene interactions will likely be translated to dietary prescriptions to maintain health and modulate both the response to injury and the progression of diseases in genetically susceptible individuals.

Neurological Development and Function

DHA and arachidonic acid selectively accumulate during fetal and infant brain development and are found concentrated in the brain and retina. Fetal accretion of these lipids occurs during the last trimester of gestation, and a deficiency can result in visual impairment and brain dysfunction. Although DHA and arachidonic acid can be synthesized from dietary precursors, the efficiency of this conversion in young infants (particularly preterm infants) may not be sufficient to meet their high need. Postnatally, human milk provides high amounts of both arachidonic acid and DHA to the infant, but the amount of these lipids in milk can be influenced by the mixture of fatty acids in the maternal diet. The preterm, and perhaps fullterm, infant not fed mother's milk may be at risk of deficiency if these lipids are not provided. Animal studies have clearly illustrated that provision of arachidonic acid and DHA to young animals improves visual and neurological function. Despite considerable evidence of improved visual function in formula infants provided DHA (and in some studies also arachidonic acid), the dietary requirements for these fatty acids in the infant vary greatly between countries. Recently, animal studies have provided evidence that DHA obtained from plasma is involved both in dopamine and serotonin metabolism in the brain and in the retina for the function of rhodopsin. These findings should guide clinical studies to more sensitive measures of the functional roles of dietary *n*-3 fatty acids. At present, there are promising preliminary results regarding the efficacy of treating various visual disorders and forms of depression with dietary DHA.

Immune Function

There is now considerable scientific evidence, from animal and human studies, that the amount and type of fatty acids in the diet can modulate immune function. A deficiency of either *n*-6 or *n*-3 essential fatty acids is associated with a reduced immune function. Amongst the fatty acids, the *n*-3 fatty acids possess the most potent immunomodulatory activities, and amongst the *n*-3 fatty acids, those from fish oil (EPA and DHA) are more potent than α-linolenic acid. In particular, it has been demonstrated that feeding DHA and EPA (often in a mixture of 'immunoactive' nutrients) decreases the rate of infections and improves outcome (i.e., reduced complications, length of stay, hospital cost) in immunosuppressed patients. These effects are likely mediated through mechanisms that involve indirect (i.e., via eicosanoids, hormone action) and direct (regulation of transcription factors) effects on genes in immune cells.

Many of the detrimental and lethal effects of infection and injury (especially detrimental effects) are mediated by the proinflammatory cytokines (e.g., tumor necrosis factor α (TNF-α), interleukin (IL)-1 and IL-6) and eicosanoids. Thus, a reduction in the synthesis of proinflammatory mediators would be beneficial during critical illness and autoimmune states. In both clinical trials and animal studies, feeding DHA and EPA has been demonstrated to decrease the expression of proinflammatory cytokines, genes, eicosanoids, and adhesion molecules, whereas *n*-6 PUFAs increase the expression of proinflammatory genes. These observations have formed the basis for successful interventions with oral EPA and DHA to treat acute and chronic inflammation, and for disorders that involve an inappropriately activated immune response (i.e., inflammatory bowel disease, rheumatoid arthritis, psoriasis, asthma, multiple sclerosis, systemic lupus erythematosus, and atopic dermatitis).

A number of studies have also reported suppressed cell-mediated immunity, but not generally humoral immunity, in humans or animals fed very high levels of DHA and EPA. One might conclude that consumption of long-chain *n*-3 PUFA might be contraindicated in those with poorly functioning immune systems. However, the very low level of DHA and EPA and the high level of linoleic acid currently in the diet of most people questions the physiological relevance of

n-3 immunosuppression in a healthy individual. To support this, there are many studies reporting benefits to the immune system when EPA/DHA are fed to immunosuppressed individuals, such as those with cancer or recovering from surgery. This suggests that the effect of *n*-3 PUFA on immune function may depend on the composition and content of other fatty acids in the diet.

Disease Prevention and Treatment

Epidemiological studies have concluded that consumption of different amounts and types of fatty acids over a lifetime can alter the risk for many chronic diseases (e.g., heart disease, cancer). There is also scientific evidence to support that dietary fatty acid composition can be used in the prevention/treatment of diseases such as coronary heart disease (CHD) and cancer. Both *n*-6 and *n*-3 PUFA have been shown to be of potential benefit in the treatment of acute respiratory distress syndrome and asthma. Beneficial effects of feeding *n*-3 fatty acids have been shown in the secondary prevention of CHD, hypertension, type 2 diabetes, and, in some patients with renal disease, rheumatoid arthritis, inflammatory bowel diseases, and chronic obstructive pulmonary disease.

Coronary heart disease Individual fatty acids differ in their ability to change blood cholesterol and lipoprotein levels, two major risk factors for CHD.

SFA For the past 30 years, epidemiological and experimental studies have found that the consumption of a high SFA diet increases low-density lipoprotein (LDL)-cholesterol levels, a major risk factor for CHD. The precise mechanism for these effects has not been established, but high intakes of SFA decrease the removal of plasma LDL by LDL receptors, and they may promote endogenous cholesterol synthesis. More recently, studies have found that SFA have varying effects on plasma lipid levels, depending on their chain length. Much of this work has been carried out on animals, and there is considerable controversy as to the effect of stearic, palmitic, myristic, and lauric acids on plasma lipid levels and cholesterol synthesis. It is likely that the deleterious effect of SFA on CHD in epidemiological studies is explained by the hypercholesterolemic effects of myristic, palmitic, and perhaps also lauric acid. There are less data to support a hypercholesterolemic effect of consuming stearic acid. Recently, research has suggested that the cholesterol-raising properties of myristic and palmitic acid may be related to the intake of PUFA, such that, when PUFA falls below a threshold intake (around 5% of energy), the cholesterol-raising properties of these SFA are greatly augmented.

MUFA Generally, studies have found that populations that consume high MUFA diets have a lower risk of CHD. Clinical and animal studies have confirmed that consumption of MUFA (i.e., oleic acid) is associated with lower total- and LDL-cholesterol levels and higher high-density lipoprotein (HDL)-cholesterol levels. Consumption of MUFA has also been reported to increase LDL-receptor activity.

n-*6 PUFA* Epidemiological studies report that populations that consume 10% of their fats as linoleic acid have a lower risk of developing CHD. A lower dietary ratio of PUFA/SFA is associated with higher plasma cholesterol concentrations and a higher population risk of CHD. In clinical studies, it has been shown that consumption of linoleic acid decreases the synthesis of cholesterol in the body and increases LDL-receptor activity, resulting in lower total- and LDL-cholesterol levels. Most countries' dietary recommendations have attempted to promote an increase in the intake of *n*-6 PUFA for its beneficial effects on reducing the risk of CHD. However, some studies have also indicated that a high intake of *n*-6 fatty acids (much higher than the current recommendation of 10% of energy) may reduce HDL-cholesterol levels and shift the physiologic state to one that is prothrombotic and proaggregatory, changes that are associated with an increased risk of CHD.

n-*3 PUFA* Epidemiological studies conclude that the incidences of CHD and atherosclerosis are inversely associated with consumption of *n*-3 PUFA, particularly EPA. The antiatherosclerotic actions of *n*-3 PUFA have been supported in animal and human clinical trials. Experimentally, it has been demonstrated that consumption of *n*-3 fatty acids (α-linolenic, DHA, or EPA) reduced plasma triacylglycerol levels (very-low-density lipoprotein-triacylglycerols), a risk factor for heart disease (especially in women). Evidence for the beneficial effects of consuming *n*-3 PUFA on blood triacylglycerols, blood pressure, cardiac and vascular function, eicosanoids, coagulation, and immunological responses has prompted many health agencies to recommend increasing the intake of these fatty acids to reduce the risk of CHD. There is still, however, a high degree of uncertainty in defining both the type and amount of *n*-3 PUFA that is considered preventative. In a recent metaanalysis of studies examining the relationship between fish consumption and CHD, it was concluded that consumption of 40–60 g of fish each day was associated with a markedly reduced CHD mortality in high-risk populations but not in low-risk populations. In cardiac patients, there are reports of beneficial effects of ingesting oily fish on the incidence of bypass graft

occlusions, forearm vasodilation, arrhythmias, nonfatal stroke, nonfatal myocardial infarction, and cardiac death. There is also increasing evidence for an antiarrhythmic action of *n*-3 PUFA in humans. Most of the studies in high-risk populations have been carried out by feeding fish oils (EPA and DHA), and less is known about the effects of their plant-derived precursor, α-linolenic acid.

Trans-*fatty acids* A high consumption of *trans*-fatty acids is associated with an increase in LDL-cholesterol and a decrease in HDL-cholesterol, two changes that would increase the risk of CHD. *Trans*-fats account for about 2–8% of the calories in our diets, compared with 12–14% for saturated fats. Currently, most nutritionists and researchers recommend that hydrogenated fats containing *trans*-fatty acids be limited or reduced in the diet.

Cancer Human epidemiological and experimental studies have established a positive relationship between high (mainly SFA) intake and cancer. However, high intakes of SFA or *n*-6 PUFA increase the growth of tumors in several animal models, while decreasing the *n*-6/*n*-3 ratio (by increasing the intake of *n*-3 fatty acids) has been shown to inhibit the growth and metastasis of rodent tumors. There is convincing evidence that both DHA and EPA can inhibit the growth of cancer cells (breast and colon) both *in vitro* and in explants. It has been suggested that the *n*-6/*n*-3 ratio of the diet, rather than the absolute intakes of these PUFA, may define cancer risk. Possible mechanisms include both direct effects on tumor growth and indirect effects on anticancer immune defenses. Although many studies support a recommendation to decrease the *n*-6/*n*-3 ratio in the diet, most cancer agencies do not yet feel that there are sufficient human data to make recommendations to the population. Current recommendations to prevent cancer have been aimed at promoting a decrease in dietary fat intake, focusing on reducing the intake of SFA. There are currently no specific fatty acid recommendations for those with, or recovering from, cancer. There are data to support beneficial effects of supplementing individuals with DHA/EPA. These benefits include reducing tumor growth, improving anticancer immune defenses, improving the response to surgery, chemotherapy, and radiation treatments, and decreasing cachexia-mediated weight loss.

Estimated Intakes and Recommendations for Fatty Acids in the Diet

Quantitative dietary guidelines for fats were first issued in the late 1970s and have changed relatively little since that time. Current recommendations for total fat in the diet of adults by most Western countries is less than or equal to 30% of energy. The lower limit of fat intake to meet the energy needs of adults is assumed to be between 10 and 15% of dietary energy, provided that enough carbohydrates are available. This minimum level depends on the fat requirement to meet energy needs, the need for essential fatty acids, and the amount of fat in the diet that is necessary to absorb fat-soluble vitamins (particularly vitamins A and E). Most countries recommend that the intake of SFA should not exceed 10% of the energy intake, PUFA should comprise about 10% of energy and the remainder of the intake of fat be comprised of MUFA. A comparison of dietary fat and fatty acid recommendations between several countries is shown in Table 2.

SFA and MUFA

In the past 30 years, the absolute consumption of SFA in Western diets has declined. For example, in the UK, SFA intake has declined by 40%. Based on the lower risk of some chronic diseases in Mediterranean countries, where the population consumes diets high in MUFA, it is generally recommended that the population replace SFA with MUFA. However, since 1970, the intake of MUFA in the UK has declined by 30%.

Table 2 Dietary fat recommendations from selective countries around the world

Country	*Total fat (percentage of energy)*	*SFA (percentage of energy)*	*MUFA (percentage of energy)*	*PUFA (percentage of energy)*
UK	33	10	None stated	6–10
Canada	< 30	10	None stated	> 3.5
USA	30	10	None stated	None stated
Japan	20–25	6–8	8–10	6–8
New Zealand	30–35	12	20	8
Iceland	25–30	15	None stated	None stated
Malaysia	20–30	10	10	10
Singapore	20–30	10	10	10

PUFA

For adults, the recommended intake for essential fatty acids is in the range of 3–5% of dietary energy for linoleic acid, and 0.5–1.0% of dietary energy for linolenic acid (about 1–4 g day^{-1}). During the past 60 years, in the UK, the consumption of PUFA has increased by 25%, despite a decrease in total fat intake. This was likely contributed to by the increased consumption of linoleic acid in margarines and various plant oils (sunflower, safflower, cottonseed, soybean, canola). Estimated intakes of PUFA are similar in North America, with the exception that the intake of *n*-3 fatty acids may be lower than in the diet of those in the UK. This increased intake of linoleic acid (approximately 10–14 g day^{-1}) over the past decades has changed the balance between *n*-6 and *n*-3 fatty acids in the diet. Dietary intake studies, in developed countries, estimate that the dietary *n*-6/*n*-3 fatty acid ratio approaches 14:1–20:1. However, most studies suggest that a ratio between 4:1 and 10:1 is needed to achieve the health benefits associated with consumption of *n*-3 fatty acids.

Despite the health benefits of *n*-3 PUFA, the mean daily intake falls far short of any current recommendation. The intake of DHA and EPA in most developed countries is small and related to the intake of fatty fish, and so promoting fish consumption is the most obvious way to increase *n*-3 PUFA intake. In North America, it is recommended that people should have at least two servings of fish per week. On a cautionary note, PUFA are oxidized more readily than SFA and MUFA and may increase the susceptibility of cellular membranes to lipid peroxidation. Indeed, increased free-radical production has been demonstrated in animals fed diets rich in *n*-3 PUFA. Consuming additional antioxidants such as vitamin E can minimize oxidation risk.

Conclusions and Summary

Fat contributes more than a third of the energy in the diet of most people. Fat comprises a number of different fatty acids varying in carbon chain length and degree of saturation. Specific dietary fatty acids have many essential roles in the body in addition to providing an energy-efficient fuel. Changing the types or fatty acids in the diet changes the composition and function of membranes, eicosanoid synthesis, regulates gene expression, controls neurological and retinal development, and modulates immune function in health and disease. There is considerable research demonstrating the importance of *n*-3 PUFA or the *n*-6/*n*-3 PUFA ratio in the prevention and treatment of CHD and cancer. On the basis of current knowledge, an increase in the consumption of long-chain *n*-3 fatty acids seems a prudent recommendation. In summary, dietary fatty intake represents a major environmental factor affecting optimal growth, development, response to injury, and overall health in the population.

Trans-fatty Acids: Health Effects

A Aro, National Public Health Institute (KTL), Helsinki, Finland

Effects on Serum Lipoproteins

Early studies on the effects of *trans*-fatty acids on serum total cholesterol levels in human subjects gave conflicting results. Studies in experimental animals

like rats, mice, and pigs did not show any appreciable difference between the effects on serum cholesterol of partially hydrogenated vegetable oils and nonhydrogenated oils. Therefore, the common impression was that *trans*-fatty acids were not hypercholesterolemic or that their effect on serum cholesterol concentration was weak and clinically not important. This impression was not changed until studies focusing attention separately on low-density lipoprotein (LDL) and high-density lipoprotein (HDL) became available in the 1990s.

Since 1990, several dietary intervention trials have indicated that, when compared with oleic acid, *trans*-fatty acids from partially hydrogenated vegetable oils or fish oils increase serum LDL-cholesterol and tend to reduce HDL-cholesterol in a dose-dependent manner (Figure 1). The increase in LDL-cholesterol has been apparent in all studies, but without a clear dose-effect. The HDL-cholesterol concentration has showed little change by small doses of *trans*-fatty acids, but higher amounts, in the order of 6–11% of energy, have clearly reduced HDL-cholesterol concentrations in a dose-dependent manner. In most studies, the LDL-cholesterol-raising effect has been somewhat weaker than that of equal amounts of C12–16 saturated fatty acids, but this may partly depend on short study periods. Corresponding effects on serum apoproteins, an increase in apoprotein B and a decrease in apoprotein A-I concentration, have been found in those studies where apoprotein concentrations have been measured. In some studies, an increase in serum triglycerides has been observed but the effect has been weak and generally statistically nonsignificant.

Partially hydrogenated fish oils that are used in some countries like Iceland and Norway and were previously also consumed in other north-western European countries seem to have a more powerful effect on serum lipoproteins than *trans*-fatty acids of vegetable origin (Figure 2). The isomeric composition of C18:1 *trans*-fatty acids is rather similar in partially hydrogenated vegetable and fish oils, but the various long-chain C20–22 *trans*-isomers that are formed when fish oils are chemically hydrogenated may have an exceptionally strong LDL-cholesterol-raising effect. The effect on lipoproteins of the delta-11 isomer *trans*-vaccenic acid, the main *trans*-isomer of animal fats, has not been studied separately from other fatty acids, because pure preparations have not been available for this purpose. The effects of different C18:1 *trans*-isomers may vary, because the isomers are metabolized by different routes. *Trans*-vaccenic acid is desaturated to conjugated linoleic acid (CLA) by the delta-9-desaturase, whereas the main isomers of partially hydrogenated vegetable and fish oils, the delta-9-(elaidic acid) and delta-10-isomers, cannot be metabolized by this pathway. The effects of CLA on the risk of coronary heart disease (CHD) are poorly known, but some CLA-isomers may have antiatherogenic properties according to experimental studies in animals. Information on the metabolism of *trans*-fatty acid isomers is limited. Generally, the *trans*-isomers seem to be metabolized by the same pathways as the corresponding *cis*-isomers.

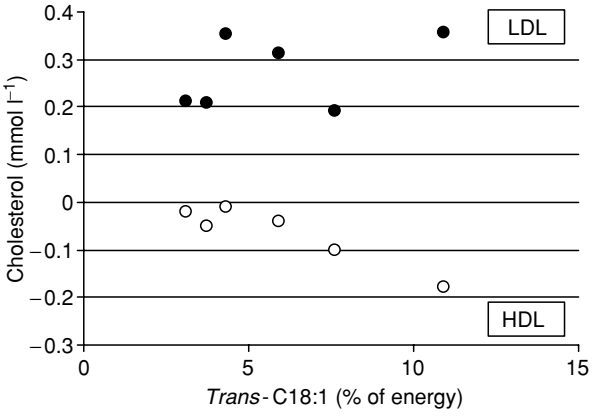

Figure 1 Effects on serum low-density lipoprotein (LDL)-cholesterol (closed symbols) and high-density lipoprotein (HDL)-cholesterol concentrations (open symbols) of *trans*-fatty acids from partially hydrogenated vegetable oils as compared with oleic acid in six controlled dietary trials. Data from Katan MB, Zock PL and Mensink RP (1995) *Trans* fatty acids and their effects on lipoproteins in humans. *Annual Review of Nutrition* 15: 473–493.

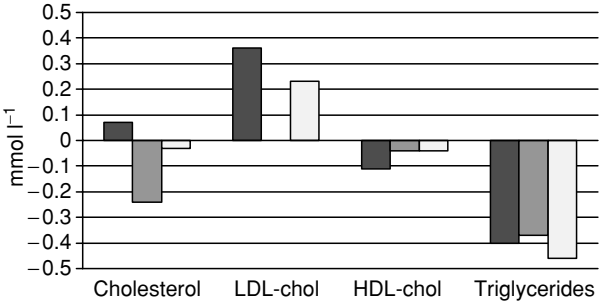

Figure 2 Effects on serum and lipoprotein lipids by 3-week feeding of partially hydrogenated fish oil (dark columns), partially hydrogenated vegetable oil (gray columns), and butter (light columns). The columns indicate changes from a customary Norwegian background diet. LDL-chol, low-density-lipoprotein cholesterol; HDL-chol, high-density lipoprotein cholesterol. Data from Almendingen K, Jordal O, Kierulf P, Sandstad B and Pedersen JI (1995) Effects of partially hydrogenated fish oil, partially hydrogenated soybean oil, and butter on serum lipoproteins and Lp[a] in men. *Journal of Lipid Research* 36: 1370–1384.

In the clinical trials with partially hydrogenated vegetable oils and fish oils, amounts of *trans*-fatty acids (3–10% of energy) have been used that are higher than the habitual consumption in most countries. The *trans*-fatty acids have been derived from specially designed products high in *trans*-fatty acids and not from commonly available foods. Therefore it is difficult to estimate the effects of the amounts that are habitually consumed by people in western countries as part of their diets. Studies on the composition of foods have revealed that processed foods that contain *trans*-fatty acids often contain more *cis*-unsaturated fatty acids than the corresponding foods that are based on saturated animal fats. As an example, icecream that is manufactured from partially hydrogenated vegetable oil contains more *cis*-unsaturated fatty acids than icecream based on milk fat or coconut oil. Thus the effects of moderate amounts of *trans*-fatty acids may be balanced by the neutral or LDL-cholesterol-reducing effects of the concomitant *cis*-unsaturated fatty acids of the same foods.

Trans-Fatty Acids and Risk of Coronary Heart Disease

The observed effects of dietary *trans*-fatty acids on serum lipoproteins, an increase in LDL-cholesterol concentration combined with a reduction in HDL-cholesterol, are expected to increase the risk of CHD. The associations between *trans*-fatty acid intake and risk of CHD have been studied in several case-control studies and cohort studies. Some studies have supported the concept of increased risk of CHD by high consumption of *trans*-fatty acids, but the results have been somewhat controversial.

In most case-control studies the fatty acid composition of adipose tissue or serum has been used as an indicator of *trans*-fatty acid intake. In three studies, C16:1 *trans*-fatty acids that are mainly derived from fats of animal origin were higher in cases than in control subjects, but in other studies the C16:1 *trans*-isomers did not show significant associations with the risk of CHD. In six of the studies, no significant case-control difference was found in C18:1 *trans*-fatty acids. One study showed a direct association between C18:1 *trans*-fatty acids in platelet phospholipids and risk of CHD, and one study showed an inverse association between C18:1 *trans*-fatty acids in adipose tissue and risk of sudden cardiac death. One study from the USA, based on food intake data, showed an increased relative risk of CHD in the highest quintile of *trans*-fatty acid intake but a decreased risk in the third quintile, representing moderate intake. In the largest of the case-control studies, the multicenter EURAMIC study, adipose tissue samples from 671 male survivors of a first acute myocardial infarction and from 717 reference men were studied. No overall case-control difference was found in C18:1 *trans*-fatty acids (Figure 3). The

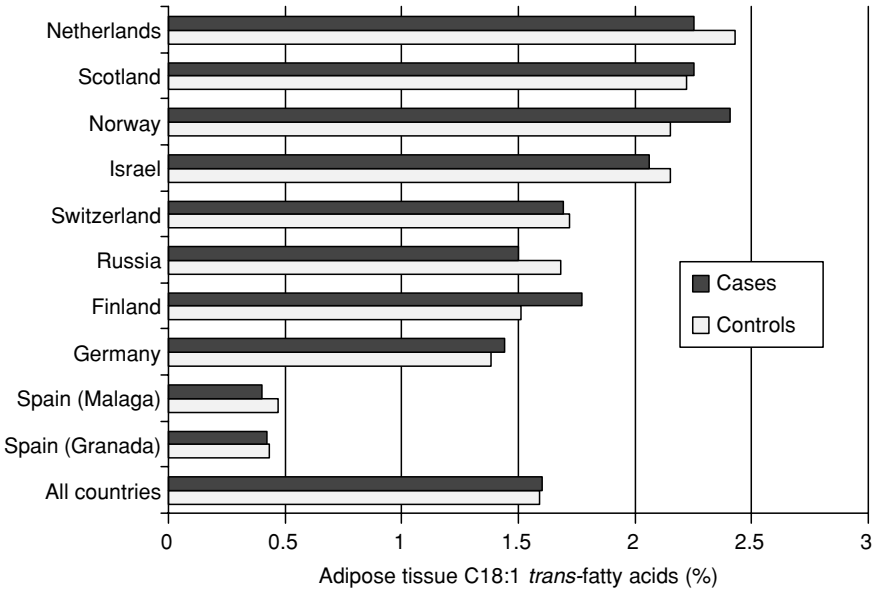

Figure 3 Mean proportions of adipose tissue C18:1 *trans*-fatty acids in male survivors of a first myocardial infarction (cases) and male control subjects without coronary heart disease (controls) in the nine countries of the European multicenter, case-control EURAMIC study conducted in 1991–92. Data from Aro A, Kardinaal AFM, Salminen I *et al*. (1995) Adipose tissue isomeric *trans* fatty acids and risk of myocardial infarction in nine countries: the EURAMIC study. *Lancet* 345: 273–278.

case-control differences differed between the countries. In Norway and Finland, cases with acute myocardial infarction had significantly higher proportions of *trans*-fatty acids in the adipose tissue than control subjects. In Russia and one of the Spanish centers, a significant difference in the other direction was found. The results showed up to sixfold differences between the countries in adipose tissue *trans*-fatty acids, suggesting large differences in the average dietary intakes of *trans*-fatty acids between the nine participating countries.

The differences in dietary intakes were subsequently confirmed by the TRANSFAIR study in 14 European countries. When the two Spanish centers of the EURAMIC study that showed very low proportions of C18:1 *trans*-fatty acids in the adipose tissue were excluded, the results suggested a borderline significant increase in the relative risk of CHD in the two highest quartiles of adipose tissue C18:1 *trans*-fatty acids compared with the lowest quartile. The C18:1 *trans*-fatty acids are the largest and clinically most important cluster of *trans*-fatty acids. The C16:1 *trans*-fatty acids are a minor component mainly derived from ruminant animal fats. Different *cis*/*trans*-isomers of C18:2 are derived in relatively small quantities from both partially hydrogenated vegetable oils and ruminant animal fats. Epidemiological studies do not suggest any major impact on the risk of CHD by these small *trans*-fatty acid clusters.

The discordant results of the case-control studies seem to reflect more analytical problems, problems in interpreting the fatty acid composition of tissues, and difficulties in distinguishing between the causes and effects of the disease in subjects with diagnosed CHD than real effects on the risk of CHD. The differing results may also indicate that *trans*-fatty acids in tissues are markers of some other associated factors that have more impact on CHD risk than the small amounts of *trans*-fatty acids in the diet. Overall, the results seem to agree with the concept that the current average intakes of *trans*-fatty acids are too low to have a significant effect on CHD risk.

Four cohort studies have addressed the association between the intake of *trans*-fatty acids measured either with semiquantitative food-frequency questionnaires or modified dietary history methods. All these studies showed a significantly increased relative risk of CHD in the highest quintile or tertile of *trans*-fatty acid intake compared with the lowest (Table 1). The increased risk was associated with high intakes of C18:1 *trans*-fatty acids only, whereas moderate intakes were not significantly associated with the risk of CHD. In the female and male cohorts from the USA and in the male ATBC study cohort from Finland, the mean intake of *trans*-fatty acids in the highest quintile was between 1.6 and 2.9% of energy intake. In the Dutch Zutphen elderly study, the median intake of the highest tertile was much higher – 6.4% of energy intake. The results of the two US studies suggested that the increased risk of CHD was due to *trans*-fatty acids from partially hydrogenated vegetable oils only, whereas in the Dutch study, no difference between the risk effects

[a]Adjusted for various risk factors of coronary heart disease.

[b]Oomen CM, Ocké MC, Feskens EJM *et al*. (2001) *Trans* fatty acid intake is associated with an increased 10-year risk of coronary heart disease in the Zutphen Elderly Study. *Lancet* 357: 746–751.

of vegetable and animal *trans*-fatty acids was evident. In a fifth analysis based on the cohorts of the Seven Countries Study, initially studied in the late 1950s and early 1960s, the intakes of both saturated fatty acids and C18:1 *trans*-fatty acids showed significant statistical associations with the 25-year CHD mortality. This study was based on analyzed average diets and individual data were not available. In 14 out of the 16 study cohorts, *trans*-fatty acids were mainly derived from animal products. The results thus represent rather the effects on CHD risk of concomitant saturated fatty acids, present in far higher amounts in the main animal sources of *trans*-fatty acids, than the relatively small amounts of *trans*-fatty acids present in these foods.

It has been calculated from the combined results of the cohort studies that a decrease in *trans*-fatty acid intake by 2% of energy decreases the risk of CHD by 25%. This would correspond roughly to the effect of a reduction of 5% of energy in the intake of saturated fatty acids. A reduction of 2% of energy in *trans*-fatty acid intake is seldom possible, because the current average intakes of *trans*-fatty acids are below 2% of energy in most countries, but a reduction of saturated fatty acid intake from 15 to 10% of energy would be feasible in most western countries.

Mechanisms of Action of *Trans*-Fatty Acids

The effects of *trans*-fatty acids on serum lipoproteins clearly have a mechanism that is different from that of saturated C12–16 fatty acids. Both increase the LDL-cholesterol concentration in serum but, in addition, saturated fatty acids increase serum HDL-cholesterol concentration, whereas *trans*-fatty acids decrease the HDL-cholesterol concentration. The effect of *trans*-fatty acids may also appear more slowly, within 3–6 weeks, than that of saturated fatty acids that becomes apparent in 2–3 weeks' time.

An increase of the cholesterol ester transfer protein (CETP) activity by *trans*-fatty acid feeding has been documented in several but not all human intervention studies with *trans*-fatty acids. CETP transfers cholesterol from HDL to very-low-density lipoprotein (VLDL) and LDL. Increased CETP activity could thus explain the decrease in serum HDL-cholesterol concentration combined with an increase in LDL-cholesterol found in intervention studies with *trans*-fatty acids. This could also explain the negative findings in many animal studies, since mice, rats, and pigs do not exhibit CETP activity. The increase in lipoprotein a (Lp(a)) found in most *trans*-fatty acid supplementation studies is another difference between the effects of saturated and *trans*-fatty acids. Lp(a) levels are mainly genetically determined, and the mechanism of the effect of *trans*-fatty acids on LP(a) levels remains unexplained.

In experimental studies on the effects of fatty acids in isolated mouse islets of Langerhans, *trans*-fatty acids increased maximal insulin output compared with the corresponding *cis*-isomers. In human studies, no clear effects on insulin sensitivity by *trans*-fatty acids have been observed.

The effects on hemostatic variables have been measured in two intervention trials. No effects on fibrinogen, factor VII, or tissue plasminogen activator levels, ascribed to *trans*-fatty acids, could be observed. In one of the studies, plasminogen activator inhibitor-I (PAI-I) antigen and activity were increased by the consumption of partially hydrogenated vegetable oil, but this finding was not confirmed by the other study. As far as blood coagulation and fibrinolysis are concerned, there seems to be little difference between the effects of saturated and *trans*-fatty acids.

Trans-fatty acids compete with linoleic acid and alpha-linolenic acid for the metabolizing enzymes. In experimental animals they impair the microsomal desaturation and elongation of the essential fatty acids to their long-chain metabolites arachidonic acid and docosahexaenoic acid. It has been suggested that *trans*-fatty acid intake of the mother during pregnancy and lactation may be harmful for premature and newborn babies, because a high *trans*-fatty acid intake may impair the formation of the essential long-chain polyunsaturated fatty acids in the baby. In adults with ample consumption of polyusaturated fatty acids, this effect of *trans*-fatty acids is probably without practical importance.

Trans-Fatty Acids and Cancer

Experimental Studies

There is much information from animal studies concerning the effects of different fatty acids on experimental cancer, but very few of these yield information on the effects of *trans*-fatty acids. In two studies in mice comparing elaidic acid (*trans*-9 C18:1) as pure fatty acid with esterified oleic acid in triglycerides, a possible tumor-promoting effect of elaidic acid was observed. Subsequent studies comparing *trans*- and *cis*-isomers esterified in triglycerides have shown quite similar effects of *trans*- and *cis*-monoenoic fatty acids on the development of experimental colon cancer and breast cancer.

Epidemiological Studies

It is difficult to assess the effects of dietary *trans*-fatty acids independently of the intakes of the much more

abundant saturated and *cis*-unsaturated fatty acids. Therefore, data on *trans*-fatty acids have not been reported in the majority of the studies. Most studies on the associations between dietary fatty acids and risk of cancer have addressed breast cancer. In the largest of the cohort studies, the Nurses' Health Study, no association between the intake of *trans*-fatty acids and risk of breast cancer was observed. In some case-control studies the fatty acid composition of adipose tissue or serum has been used as a biomarker of intake. In two of these, no association was found between *trans*-fatty acids and the risk of breast cancer. In a third study, *trans*-fatty acids were associated with an increased risk of breast cancer in the lowest tertile of polyunsaturated fatty acids. In one study, a significantly lower proportion of *trans*-11 C18:1 (*trans*-vaccenic acid), mainly derived from cheese, was found in postmenopausal women with breast cancer as compared with matched healthy control subjects, but the *trans*-9 and *trans*-10 isomers in serum showed no association with the risk of breast cancer.

Intake of fatty acids has been associated with the risk of colorectal cancer in some prospective studies, but the contribution of *trans*-fatty acids to the risk has not been assessed in any of the studies. Based on these scanty data, it can be concluded that available evidence does not suggest any appreciable role to the intake of *trans*-fatty acids in relation to the risk of any type of cancer.

Future Aspects

In the past, high intakes of *trans*-fatty acids, exceeding 4% of energy intake, have been recorded in some countries like Norway and the Netherlands, due to the consumption of hydrogenated vegetable and fish oils, and in Canada and the USA, due to common use of partially hydrogenated vegetable oils. As awareness of the undesirable effects on serum lipoproteins of partially hydrogenated vegetable and fish oils has increased, table margarines and other soft spreads containing no or low concentrations of *trans*-fatty acids have become commonly available but industrial shortenings and fats for deep-frying remain high in *trans*-fatty acids. For reasons of texture, e.g., in icecream and leafy pastries, or stability, e.g., in deep-frying and in industrially produced fatty foods with a long shelf-life, *trans*-fatty acids or saturated fatty acids or both will be used in these foods even in the future. In cooking and baking at home, hard fats can be replaced by vegetable oils, but it seems advisable to restrict the consumption of industrially manufactured fatty foods because of their undesirable fatty acid composition. If and when *trans*-fatty acids are removed from foods, as much as possible they should be replaced by *cis*-unsaturated fatty acids. If saturated fatty acids are substituted for *trans*-fatty acids, the benefit in terms of CHD risk is questionable.

The proportion of *trans*-fatty acids derived from ruminant animal products will increase concomitantly with the reduction of *trans*-fatty acids derived from partially hydrogenated vegetable oils in foods. Already in 1995, dairy products and meat contributed more than 50% to total *trans*-fatty acid intake in seven out of the 14 European countries participating in the TRANSFAIR study. It is possible to substitute *trans*-vaccenic acid and CLA for saturated fatty acids in milk and beef fat by modifying the feeding of cows. So far there are no studies indicating whether modifying the composition of milk fat in this way should be considered beneficial or harmful with respect to effects on CHD risk factors.

FERMENTED FOODS

Contents

Origins and Applications

B J B Wood, University of Strathclyde, Glasgow, UK

Introduction

Many entries in this *Encyclopedia* will deal, directly or indirectly, with the actions of microorganisms of foodstuffs. Some will be entirely negative, relating to food poisoning, disease transmission, and toxin production. Others will show that changes effected by microbes can be beneficial and even desirable, bringing about changes that enhance the texture, flavor, color, edibility, and hence the value of the foodstuff concerned. This entry discusses the benefits and probable origins of the fermentations. It further attempts to place them in a historical and economic context.

The Beginnings of Food Fermentation

Although we cannot know how or when the practice of fermentation in relation to food began, all available evidence suggests that it is a very ancient part of human development. In fact, fermentation can be seen as a subset of biodeterioration. All things that can serve as foods for humans (or any other animal) are, by their capacity to act as foods, more or less unstable. If they are food for mammals, then they will also be able to support the life of many types of bacteria and molds. In practice, even such apparently stable materials as wood are open to attack by microbes and insects. There is a powerful drive throughout nature to use the energy and nutrition present in organic materials, eventually mineralizing these materials back to carbon dioxide, water, and simple mineral salts.

We see attack by such microorganisms as, primarily, a deterioration, or loss of desirable characteristics. Some such changes, however, turn out to have desirable characteristics. Such changes may produce improvements in flavor, odor, and texture. In addition, there is substantial evidence of improvements in nutritional status and value arising from controlled fermentations. Various studies have shown that even simple fermentations of basic cereal grains with the indigenous (mainly lactic acid bacteria) microflora generate significant increases in the levels of some B-group vitamins. There are strong suggestions that plant proteins, which are somewhat difficult for the monogastric digestive system to handle, can be made more digestible through the actions of proteolytic enzymes produced by bacteria and fungi. Many adults are intolerant to lactose, the principal sugar of milk, but fermentations such as that to produce yogurt reduce or eliminate this problem. Fermentations can

also reduce or remove toxins and other 'antinutritional factors.' Perhaps the most important example of the former is the detoxification of cassava, while an example of the latter is hydrolysis of phytic acid, with removal of sequestering by it of divalent metals. Perhaps even more significant in the present context may be the prospect that fermentation increases the stability of the affected food, increasing its resistance to attack by other organisms. Before the advent of modern methods for food preservation, such as freezing and canning, even a short extension in storage life would be precious. The prolonged storage possible for the main protein in milk (casein) consequent upon conversion to a hard cheese (such as Cheddar) would thus be of immense value. We must also remember that availability evenly spread through the year is a very modern phenomenon. In any given region (particularly in the temperate parts of the world) food supply is very seasonal. The idea that tomatoes, apples and new potatoes would always be on sale would have seemed unreasonable even a couple of decades ago. Now it is taken for granted throughout the industrialized world.

An Example

The existence of small pits (perhaps a meter cube, or even less) dug into the chalk of southern England has long been known, but their purpose remains a matter for controversy. One suggestion has been that they would have been used to store grain. However, *a priori* this seems unlikely. In the ground grain will be exposed to moisture. All seeds will take up available water as a preparation for germination, and will then become more easily attacked by molds than the dry seeds would be. Chalk, being very porous, will readily conduct water. Thus grain storage in pits dug into the surface of chalk would seem to be an inappropriate method for conserving the material. However, experiments showed an interesting sequence of events. Dry grain was packed into pits prepared for the purpose, and the pits were then sealed with a cap of clay or other impervious material. Initially, the grain closest to the clay took up water and was then colonized by a range of fungi and other microorganisms. Eventually this agglomeration of grains and hyphae formed an impervious layer, preventing further ingress of moisture. In addition, respiration by the stored grain and the microbes feasting in the outer layers of the stored material used up the available oxygen, replacing it with carbon dioxide. Thus, at the sacrifice of the outermost layer of the stored material, the bulk of it was preserved for a long time.

This does not correspond with our normal idea of a food fermentation. However, it has illustrations for a number of key points. The pit makers could have had no understanding of the processes at work in their pits. Despite this, the prevailing conditions favored growth of microbes in a beneficial way. There was some loss of stored material, but this was an acceptable price for the storage of the rest in useable condition. All of the foregoing is speculation; we can have no certain knowledge of how the pits were used by their makers. The grain storage hypothesis is nevertheless a valid one, and experiments show that the pits would operate as conservation devices.

Historical Background

Very often our understanding of how a fermentation began is speculation based on our interpretation of the modern process in the light of our knowledge of conditions in the past. Sometimes this is aided by ancient records, pictures such as those from Egyptian tombs, continuing oral traditions, but in many cases such evidence is scanty or entirely absent. Thus there is a great deal of guesswork in our attempts to reconstruct how particular fermentations originated. In most cases this is unimportant, but it can be irritating when we are faced with a product such as kefir. Here the fermentation relies upon structures called grains. Modern analyses show that these grains are highly structured arrangements of yeasts and bacteria upon polysaccharide membranes. These organisms can be separately cultivated in the laboratory, but they do not reform into the characteristic kefir grains when cultured together. How did the grains arise? Was this a single event, or did it happen several times (kefir is widespread across Russia and Eastern Europe)? Clearly, we are unlikely ever to know the answers to such questions. Even in simpler cases, such a bread making or the conversion of grapes to wine or grain to beer, we have no records showing the beginnings of such activities. Often there are myths showing such knowledge as gifts from gods or other superior intelligences. Also foods such as bread and wine frequently have a place in sacramental activities. The giving and consumption of bread and wine, central to the Christian Eucharist, are also found in older traditions, associated with the Roman gods, for example. This infers the great importance of such activities at the change from hunter/gatherer economies to the beginnings of settled agriculture. I suggest that this knowledge was an essential part of that change. The ability to store foods enhanced survival over winter and other periods of hardship.

Converting dry grains and other seeds into something more appetizing than a gruel must have made agriculture more attractive and valuable. Alcohol, despite its dangers, provided (and still provides), in reasonable moderation, a basis for social interaction.

The apparent changes in the nature of consciousness effected by alcohol must have had spiritual significance, and the economic power possessed by those who control its production and distribution remains important to this day. The vital part played by bread in the agrarian economies of Europe is made starkly plain by the draconian laws controlling the activities of medieval bakers, and that of beer by ordinances such as the German beer laws. The trade in fish sauces throughout the Roman Empire affords another example. We tend to associate fish sauces with the Far East, but it is known that several fish sauces have been produced in the Mediterranean region since ancient times. Archeological evidence indicates that these products were traded in substantial amounts throughout the Empire, even as far as Hadrian's wall. Although we cannot know for certain their nature, it seems clear that these were important condiments in the Roman kitchen.

Options for Food Preservation

Before the advent of bottling, canning, and other methods using a combination of heat and an effective seal against recontamination of the heat-treated food by microbes, there were very few safe technologies available. Cold was recognized as valuable in delaying the onset of putrefaction, but was not generally available for most of the year. The richest people had ice-houses, insulated structures where the winter's snow and the ice from pools could be conserved for at least part of the warmer months, then used to store food, as well as providing the means for preparing cold drinks. Access to such ice-stores was only for the very rich, and zero Celsius is of limited value in food preservation. Despite this, preservation of food in ice attracted the interest of the great Sir Francis Bacon, who died in 1626 from a cold caught as a consequence of experiments in preserving fowl with ice. The discovery that ice mixed with salt gave lower temperatures was of very limited value, and must have been an extremely expensive option.

For most people, the main technologies depended upon reducing the water available for microbial growth. Air-drying is still important in preserving many foods in tropical countries, and even in northern latitudes the drying of fish was important. In practice, such drying is normally accompanied by some microbial growth, frequently demonstrated by the odors emanating from the drying food, particularly fish. Salting is a very ancient practice, its importance demonstrated by salt taxes, the Roman payment of salt to soldiers (hence 'salary'), and so forth. Sugar also has importance, principally, although not entirely, in preserving fruits and some vegetables. Their naturally dry state confers particular value on seeds, even though they can be fairly uninteresting foods without considerable processing. On the other hand some potential foods, such as cassava (*Manioc esculenta*) contain such powerful natural preservatives that they are lethal if consumed in their natural state, while others, such as millet, contain unacceptable levels of tannins or other bitter principles.

Thus, the preservative properties associated with some food fermentations must have been important even at the dawn of agriculture, and became much more so as urban civilization developed. Equally, the abilities of fermentations to detoxify things such as cassava are essential if these materials are to become suitable for human consumption. Another preservative agent derived from fermentation, vinegar, has not been mentioned so far. Its value as both a condiment and a preservative has, however been recognized since the most ancient times. It also had importance in medicine and healing. With the rapid transfer of the British population from a mainly rural existence to an increasingly urban one, consequent upon the Industrial Revolution, the enhanced demand for vinegar resulted in development of the 'quick' vinegar process to replace the slow Orleans method. It must also be recognized that fermentation often went together with other methods of preservation, in order to give the desired results. In particular the capacity of salt, even at fairly low concentrations, selectively to enhance growth of certain lactic acid bacteria (LAB) is vital to the success of important vegetable and meat fermentations. The possible significance of essential oils and other factors derived from herbs and other flavorings will be considered below.

Physical and Chemical Properties of Raw Materials for Fermentations

Appropriate fermentation techniques for given products will be strongly influenced by the physical and chemical properties of the raw materials to be used in its preparation. It is therefore useful to attempt a classification of raw materials. What follows will be entirely pragmatic, and is not intended as a formal classification scheme. Instead it will be a grouping by the characteristics most relevant to fermentation procedures. In order to do this, it is first desirable to review the relevant physical and other characteristics.

Of the physical properties, probably the most important will be the availability of water, as this will strongly influence the types of organisms whose growth can be supported on a particular medium, and, in the extreme case, whether any organisms at all will grow on the material in question. Water availability can be limited by simple physical dryness,

i.e., the actual absence of water, and by osmotic pressure creating a physiological drought. Salt and/or sugar in foodstuffs most commonly induce the latter. It should be noted that quite low concentrations of salt, well below that which might be expected to induce osmotic stress, can strongly influence the course of fermentations. The structures of some fruits and vegetables are remarkably well developed to resist attacks by both plant and microbial invaders. The cassava tuber affords a particularly highly developed example of combined physical and chemical defenses. It has both a tough, fibrous exterior, and a capacity to produce toxic levels of hydrogen cyanide when it is damaged. Such materials require to be mechanically damaged to breach the outer layers. This is generally accomplished by chopping, shredding, or slicing, depending on the material and intended product. The outermost layers may also need to be removed, being tough, fibrous, and lacking in nutritive value. Where toxins are present (as in cassava), measures to neutralize them will also be required. In some cases, however, agents developed by the plant as protection may be desired in culinary practice. Examples include the irritants present in onions and the roots of plants such as radishes. While stress has been placed on roots, tubers, and bulbs in the foregoing discussion, arising from their greater numbers of types, certain other structures also perform in similar manners. Perhaps the most obvious example is the cocoa fruit. This is a robust structure with a tough outer layer, which must be breached before the inner pulp can undergo fermentation both to release and chemically modify the seeds that will yield cocoa powder after roasting and grinding.

The chemical composition of the fermentable material is obviously of overriding importance in determining the types of organisms that can grow on it and the outcomes of fermentations which they effect. In some cases there will be ample supplies of (for example) sugars to give desired levels of organic acids, B-group vitamins to support growth of fastidious LAB, and amino acids. In many cases, however, there will be insufficient readily usable material. Then, organisms which can produce and export appropriate hydrolytic enzymes (amylases or proteases, for example) will be at an advantage. They may also prepare the way for later growth of less competent organisms such as yeasts and LAB.

The part played by chemicals in herbs, onions, and garlic can be particularly interesting. We value these materials principally as flavors in foods, but many of them also have long traditions as healing agents and medicinals. There is increasing evidence that these traditions have a secure basis in scientific fact. claims that onions, garlic, and many culinary herbs are powerfully inhibitory against bacteria associated with food poisoning have been reviewed; it is reported that onions, garlic, allspice, and oregano 'killed every bacterial species tested.' These are clearly valuable properties if shown to apply to actual foodstuffs, but an interesting question arises. Many fermented foods use onions, garlic, and various herbs. Some sausages use particularly high levels of garlic (e.g., salami). Sausages are harsh environments even without these inhibitors. Yet bacteria, such as species of *Carnobacterium* and *Micrococcus*, are present in these products, and are thought to be essential for flavor development. How selective is the toxicity of these plant products? There are clearly interesting biochemical challenges here, even if these claims were shown to be fully justified in the field, i.e., in actual food fermentations. It has been pointed out that, for example, salamis, although particularly heavily spiced with garlic, have been associated with serious illness due to *Escherichia coli*. Thus claims of this type need to be assessed very carefully, with purely laboratory studies and robust trials in actual foods being run in partnership with each other, if the effects on food microflora of herbs and spices are to be fully understood.

The foregoing is not intended as a complete discussion of the issues involved here. Rather it is an indication of some of the factors that require consideration when attempting to understand the factors influencing the initial development and subsequent evolution of food fermentations.

A Classification of Raw Materials

Animal Products

Meats This term is taken to include the flesh from mammals, and also that from fishes, birds, and crustaceans. In all cases, the material as obtained postmortem is usually in the form of chunks of tissue, dissected organs (such as muscles, liver), whole organisms (often, but not always eviscerated; small fish are an obvious example). Occasionally the material may be comminuted in the course of its extraction, but relatively large pieces are more usual. Sometimes, particularly in small fish for conversion to fish sauce or for fermentation with rice, the material can be used without further physical modification. More usually it is necessary to comminute the material by mincing or grinding. This is primarily to insure sufficiently intimate mixing of salt, spices, farinaceous materials, and other additives that both promote the desired fermentation and confer desired texture and flavor on the finished product. It also simplifies packing the prepared mixture into appropriate casings.

In certain cases the raw material may be of relatively low intrinsic value, with fermentation being a way of utilizing residues. Typical of this situation is producing oriental fish sauces from trash fish and the viscera, heads, tails, and other unwanted parts remaining after marketable fish has been prepared for sale. For high-value products, such as quality sausages, producers will specify the meat carefully, with prime cuts being essential for the best products, although sausages can represent a way of using lesser-quality meat economically, while still yielding a merchantable product.

Milk Milk is surely the archetype for a fermentation substrate. Its production, particularly by traditional methods, guarantees that it carries a substantial microbial load ab initio. Even in modern parlors using mechanical milking and strict hygiene, the milk still has a significant number of microbes in it. The high water content, presence of readily fermentable carbohydrate (lactose) and nitrogenous materials, B-vitamin content, and the near-neutral pH combine to provide nearly ideal growing conditions for a wide variety of organisms, including potential pathogens. The temperature of freshly drawn milk is also near the optimum for many bacteria. Thus modern processing, for direct consumption, butter production or fermentation, requires rapid cooling of the milk, swift transport to a processing center, and rapid thermal processing (usually pasteurization or ultrahigh-temperature (UHT) treatment) to provide a safe and relatively stable product. Despite impassioned argument about the greater flavor claimed for cheeses made from unpasteurized milk, some developed countries continue to insist on appropriate heat treatment for all milk to be used for making cheeses. On the other hand it must be acknowledged that the bacteria in unpasteurized milk tend to be predominantly LAB, and that the selected cultures employed in modern production originate from isolates originally found in spontaneous fermentations. The relatively anaerobic conditions, which develop in bulk milk, rapid acidification and various factors elaborated by LAB (bacteriocins, hydrogen peroxide) combine to suppress the growth of many pathogens in cheeses. Thus cheese and yogurt production are still valid technologies for societies where modern milk processing is not available to most of the producers.

Plant Materials

The great diversity of plant materials means that any attempt at grouping into classes will be fraught by difficulties caused by overlaps and ambiguities. For example, tomatoes and cucumbers, although obviously fruit, are often placed among the vegetables, while the edible stems of rhubarb are placed alongside fruits. Thus, what follows is entirely arbitrary, reflecting the practical problems in fermenting plant foods.

Leafy material Grass and other forage materials are converted into silage on an enormous scale as an essential part of modern ruminant farming. Although not normally thought of as a food fermentation, i.e., not part of the human diet, this is probably the most important among leaf fermentations in the wider context. Among materials for direct human consumption, the best-known products are kimchi and sauerkraut. The latter is a highly industrialized process in the major producing nations. Undoubtedly it was developed principally as a storage process for conserving excess cabbage through the winter in areas where the severe winter weather would destroy cabbage heads left in the fields, while cut heads would quickly deteriorate in store if held as the unmodified material. The key factors for fermentation are provided for by adding about 2–3% by weight of salt to shredded cabbage heads, then packing tightly into containers where the sap, withdrawn from the plant tissue by osmotic action of the dissolving salt, quickly displaces remaining air from between the plant material. Bacteria naturally present on the plant surfaces drive the lactic fermentation, although there is a tendency towards using selected cultures now. This simple process gave a product that could be conserved without deterioration for many months, even in the absence of refrigeration. Obviously there is no need to continue this process as a means for conserving cabbage in industrialized societies, where advanced storage systems and transportation which can deliver any food from any part of the world without regard to season provide complete freedom from the old domination by the solar cycle. However, this has not reduced demand for the fermented product. On the contrary, those accustomed to it have taken its production with them when they have migrated to and settled in other parts of the world. Consequently its production is, if anything, increasing. The technology is basically the same as for the materials discussed in the next section, with the key difference that they use salt in prepared brine, whereas here dry salt is added to the raw material.

Fruits Cucumbers are perhaps the classical example here, although olives would be cited first in Mediterranean climates. Other examples include tomatoes. Small onions and certain types of radish roots, although not fruits, are processed in the same way. Again the technology is very simple, easily applicable on a village or domestic level, and originally a way of conserving seasonal surpluses of produce against

winter shortages. Essentially the prepared material is immersed in a salt solution (brine) and a spontaneous lactic fermentation develops. In reasonably cool conditions the products are stable during prolonged storage. The observations about the survival of sauerkraut technology after the conservation need had passed apply with equal force here, as do those on industrialization of the processes. Olives are remarkable in the market penetration that the fermented product has achieved outside its traditional consumers.

Another type of conservation of fruits relies on fermenting the released juices to produce stable liquids. This is a very pedestrian way of describing the delights of wines and the products from apple (cider; USA 'hard cider') and pear (perry) juices, but is deliberately done to place them in a specific context. Undoubtedly the capacity of the products to induce intoxication would have attracted attention as soon as they were discovered. Indeed we have ample evidence that birds and mammals are attracted to fermenting fruits, and will manifest clear evidence of drunkenness, and even of addiction to ethanol. In many cases the intoxication became associated with religious experiences among humans. Despite these complicating sociological factors, we can properly see alcoholic fermentation as a preservation strategy, essentially indistinguishable from those presented in the preceding two sections. Sweet fruits have a very short storage life, although strategies have been developed to permit storing some hard fruits (notably apples and pears) for extended periods. At the other extreme, grapes are so easily bruised that picking them for table use demands great care; the yeasts always present on the grape skins quickly ferment the fruit juice at the slightest opportunity. The only practical alternative to fermentation is drying to raisins, currants, and sultanas.

Roots, bulbs, and tubers In general, root crops are stable enough for their storage in simple systems, and even for them to be left in the ground during winter until required. Thus, with minor exceptions such as the radishes referred to above, root crops are not fermented in temperate climates. Bulbs are also generally stable enough for winter storage, so fermentation in brine is probably done more for culinary than for conservation reasons. The New World gave us, among many other valuable crops, three novel starchy crops that have now become so indispensable that we often forget their origins. Of these, one is a cereal (maize) but the other two are root crops, potatoes (*Solanum tuberosum*), and cassava (*Manioc esculenta*). Of these two, I have no knowledge of potatoes being fermented, except in the very limited sense of them being a source of starch for alcohol production. Potatoes can produce various toxins as defenses against predators, but protecting the tubers from exposure to light easily prevents production of the most important of these, and I am not aware of any evidence that fermentations will reduce toxicity of green tubers. On the other hand, fermentation is absolutely essential for making cassava safe for use. Most varieties are extremely toxic, because of the presence of a cyanogenic glycoside. In the intact tuber this, and the enzyme that can hydrolyze it, are strictly segregated, but mechanical damage brings them into contact, so releasing the highly toxic hydrogen cyanide. It is clear that even very primitive peoples from its native habitats had developed techniques for making the tuber comparatively safe to eat. These are not primarily fermentations, depending as they do on the enzymatic action described above to destroy the cyanogenic glycoside. However, the conditions under which the tubers are harvested and prepared for detoxification insure that there is an abundant microbial flora associated with them. LAB, which do not use iron-containing enzymes, are resistant to cyanide, and their growth on the cassava portions produces acidic conditions that both favor the action of the relevant enzyme and help in removal of the cyanide as the unionized gaseous form. Subsequent processing includes drying, reduction to granular form, and heat treatments such as (in the case of products such as the West Africa gari) roasting. Unfortunately, even garification will not reliably remove the last traces of cyanide. Although the residual material is below the acutely toxic concentration, it can, by competing with iodide, produce the thyroid gland malfunction known as goiter.

Seeds The plant products discussed so far have been characterized by high water content. This it true even of the firmest products, such as the root crops. This water content means both that any injury leaves the foodstuff liable to fermentation or other microbial attack, and that even the undamaged item has a restricted storage life because eventually water loss will reduce it to a flaccid and uninviting state. However, some vegetables can be made suitable for storage by deliberate, controlled dehydration. With seeds, the evolutionary development resulted in a very dry, tough, long-lasting product. Seeds are also packed with nutrients placed there by the parent plant to support initial growth of the new plant whose embryo the seed contains. Thus a seed has many characteristics which make it potentially desirable as a human or animal food. From the human viewpoint, however, seeds have some disadvantages as foods. As harvested, they are difficult to eat. If processed in the obvious way, by soaking and/or boiling in water, the

product is apt to be rather bland and unappetizing. Indeed, of the various grains and seeds harvested by humans, only rice is consumed in this way to any extent. Commination by crushing or grinding can effect limited improvements, but the resulting gruels or porridges are still of limited appeal. Much the same is true if the material is formed into a paste and baked or roasted. On the other hand, even the simplest fermentations can effect considerable improvements. For example, a common breakfast dish in Africa is a maize porridge in which the ground maize is left overnight in water, and then boiled next morning, ready for eating. Overnight there is substantial acidification through the action of LAB. Although this is a fairly minor change, the result is a much more appetizing porridge, especially with the help of a little crude sugar. Most such mixtures of flours and water will develop substantial populations of LAB, alone or associated with yeast cells. Microbial gas production will cause some expansion of the paste or dough, and give a tasty and appealing product upon cooking. The most obvious example of this type is of course sourdough bread. It seems reasonable to believe that this is a very ancient product, and archeological evidence is emerging to support this view. A simple improvement would be to add a part of a good ferment to a fresh mixture of flour and water. This process, sometimes called 'back slopping,' remains the basis for much sourdough bread production to the present.

A more dilute mixture of flour and water would give a crude alcoholic drink. The really important development here was the discovery that germinating the seeds greatly increased the alcoholic content, and the general quality of the resulting drink. Beer production in the west further modifies the properties of the drink by drying and heat treatment of the germinated seeds (barley malt). African sorghum beer does not require this added refinement, and it seems reasonable to think that the earliest barley fermentations would have used 'green' (undried) malt. Again the fermentations would have used a mixture of LAB and yeasts. It is clear that from fairly early times residual yeast from beer and wine fermentations was used for bread making. Equally, *kvass* fermentation from rye bread and water uses a portion of sourdough bread ferment to start a new brew going, although once started, it is maintained by 'feeding' the ferment with additions of bread and water.

Rice flour mixed with legume seed flour and water will ferment with leavening provided by carbon dioxide generated by heterofermentative LAB. In parts of India this simple process yields products such as idli and dosa.

Thus, seeds rich in starch are converted to many foods and drinks by a range of fermentations which depend on yeasts and LAB, alone or in associations. Fermentations of protein-rich seeds, particularly the soybean (*Glycine max*) and the ground nut (peanut, monkey nut, *Arachis hypogea*), of tropical and subtropical origin, together with the seeds of tropical leguminous trees, have provided both staple foods (such as tempeh and oncom (ontjom, onjom, etc.)) and flavoring materials (soy sauce, miso, etc.) throughout the tropics and subtropics for many thousands of years. The driving force for such developments was probably the rather bland nature of the starting materials, but we now know that fermentations can increase the digestibility of constituents of the seeds, particularly the proteins, enrich the products with extra B-vitamins, decrease concentrations of some toxic or antinutritional factors, and increase the availability of essential mineral nutrients. These fermentations are frequently multistage, using mold fungi to manufacture a range of digestive enzymes, then yeasts and LAB to complete the process. The origins of these fermentations are lost in time, but we know that soy sauce and miso have existed for at least 3000 years. Legume seeds tend to be rather well supplied with antinutritional factors, and detoxification during the fermentation is a significant benefit of the process. Perhaps the most remarkable example of seed detoxification, however, concerns the castor bean (*Ricinus* spp.). This seed contains a wealth of toxic materials, including ricinoleic acid (a powerful purgative), strongly allergenic proteins, and ricin. Despite this, in parts of Nigeria the seeds are collected, boiled, dehulled, wrapped in leaves, and allowed to ferment, then used as a food flavoring, apparently without any ill effects on its consumers.

Types of Fermentations

Although space constraints forbid a detailed discussion, it is worth noting the range of fermentation procedures developed for dealing with foods. The simplest are probably the liquid fermentations used in making drinks such as beers, wines, and some of the milk products such as yogurt and buttermilk. These are sometimes called suspension cultures because the microbial cells float suspended in the surrounding liquid. Another name is stirred tank reactor (STR) fermentations. Fermentations involving molds usually require free access to the air, both to meet the organism's need for abundant oxygen, and to remove the products of the fermentation, principally carbon dioxide and heat. In one case however (tempeh) the process requires a very limited exposure to oxygen, traditionally achieved by wrapping the substrate in banana or teak leaves, although plastic bags pierced with a pattern of fine holes now often replace these.

Such fermentations, which do not require free liquid water, are described as solid substrate fermentation (SSF). Some lactic fermentations, for example of starchy or farinaceous materials, might also be placed here, as might sausage fermentations. When a solid substrate is in free water, it appears that this is just a type of suspension culture, but there is evidence to suggest that the active microbes attach themselves to the solid material to a considerable extent, thus producing some characteristics of a SSF. The kefir grain provides an interesting problem. Attachment of the cells to the polysaccharide membrane suggests SSF, but analysis of the fermentation shows that there are large numbers of cells suspended in the liquid, quite free of the grains, and that the proportions of bacterial species in suspension are radically different from the proportions within the grains. In Orleans vinegar production the acetification is effected by a layer of bacterial cells growing as a film or skin at the interface between water and air, so exhibiting some characteristics of a SSF. The 'quick' process features a layer of cells on the surface of the wood shavings, irrigated by the recycling liquid, but also supplied with abundant oxygen, thus showing an even closer relationship to SSF. Citric acid production by *Aspergillus* used to require static growth on the surface of a liquid layer, rather like the Orleans vinegar process. Some processes were described using growth on bamboo supports and a liquid recycle like the 'quick' vinegar process, but it is not clear if these were applied on a production scale.

The Future for Traditional Fermentations

Some very ancient fermentations continue to flourish and develop on a very large scale. Soy sauce production almost seems capable of expansion without limit, as does cheese. Yogurt has been a remarkable success story, with market penetration far beyond its traditional homelands. Vegetable fermentations, such as sauerkraut and olives, also seem to grow, although they perhaps do so more slowly than some of the other cases cited. The sourdough bread story is another remarkable one, with the product now on offer at (it seems) every airport in the USA. There does not seem to be any fear for the future of these and a selection of other products.

On the other hand, I feel substantial concern for some of the more modest traditional fermentations found in the developing countries. These have made a significant contribution to the people's nutrition in the past, and the example of tempeh shows how they can substantially improve the nutritional status of the poorest folk. Tempeh itself seems to be robustly addressing the challenge offered by modernizing Indonesian society, but this is an exception. Sorghum beer in South Africa is another example where (in this case with intelligent support from central government) a traditional food item continues to enjoy a place in an evolving society's markets. In many cases, however, modernization tends to displace traditional foods with imported ones perceived as more 'western' by precisely those consumers who are least able to afford the change to imported food fashions. The drift from rural to semiurban living exacerbates the situation. The traditional food fermentations are essentially rural, low-technology processes conducted at an almost domestic level. Hygiene considerations alarm the western observer, but in general the adapted consumer population seems to suffer no harm from these products. There are exceptions of course. The continuation of poisoning outbreaks caused by consumption of tempeh bonkrek in Indonesia, despite the authorities' efforts to ban its production, demonstrate the kind of danger which exists. On balance, however, I feel that loss of traditional knowledge regarding the conduct and management of traditional fermentations will be a serious matter. This knowledge tends to be the preserve of women. Young people are not interested in learning about these matters, and emerging societies tend to place an even lower value on 'women's knowledge' than developing ones do. Courses on food, and fermentation need to place stress on the value of such information. This is perhaps the only way in which we can hope to conserve this unique knowledge pool.

Fermented Meat Products

F-K Lücke, Fachhochschule, Fulda, Germany

Introduction

Fermented meat products have been subjected to the action of microorganisms or tissue enzymes so that they are modified significantly in a desirable fashion. They are subdivided into fermented sausages (products made from comminuted meat stuffed into casings) and fermented unground meats. This article provides basic information on the manufacture of fermented meat products and on the factors affecting their safety and quality.

Types of Fermented Meats

Fermented Sausages

Fermented sausages are manufactured from comminuted lean and fatty tissue, mixed with salt, spices, sugar, and, in most cases, curing agents (nitrite, nitrate, ascorbate). Particularly in commercial production, starter cultures are also added. The mix is then filled into casings and subjected to a microbial fermentation. Many, but not all varieties of fermented sausages are subsequently aged to dry them and to develop the desired sensory properties. Another criterion for the classification of fermented sausages is the surface treatment (e.g., smoking, mold growth). **Table 1** gives a classification of fermented sausages, along with the definitions of terms used in this article.

An official classification of fermented sausages is important to avoid misleading the consumer and unfair competition between manufacturers. Different parameters are used in different countries; however, they are all more or less related to the degree of drying and the percentage of high-quality raw material (lean muscle tissue) in the formulation. For example, the German Code of Practice (Leitsätze) specifies the minimum content of collagen-free lean meat for different sausage varieties while key parameters in France are the ratio between collagen and protein, the fat content and the percentage of moisture, based on fat-free dry matter.

Fermented Unground Meats

To produce aged hams and related raw cured meats, salt is added by rubbing it on to the meat surface or by immersing the cut into a brine or by injecting brine

Table 1 Classification of fermented sausages

Class	*Final water activity*	*Total ripening time*	*Use of smoke*	*Mold growth on surface*	*Examples*
Dry	< 0.90	> 4 weeks	No	Yes	Traditional Italian salami, French saucisson sec
Dry	< 0.90	> 4 weeks	Yes[a]	Yes	Traditional Hungarian salami
Dry	< 0.90	> 4 weeks	Yes or no	No	German Dauerwurst
Semidry	0.90–0.95	< 4 weeks	No	Yes	Various French and Spanish fermented sausages
Semidry	0.90–0.95	Usually 10–20 days	Yes (with exceptions)	No	Most fermented sausages in Germany, the Netherlands, Scandinavia, USA
Undried	0.94–0.97	< 2 weeks	Yes or no	No	German Teewurst, Spanish sobrasada, Thai nham[b]

[a]During fermentation.
[b]Normally cooked before eating.

into the tissue. Then, cuts are kept at low temperatures (10 °C or below) until the salt is evenly distributed. During subsequent aging at elevated temperatures (15–30 °C), they not only lose some moisture but are also tenderized by tissue proteases. Only such aged products may therefore be termed fermented. They are normally eaten raw, and include raw (pork) ham, but also Italian coppa and some products from beef muscle (e.g., Swiss Bündnerfleisch, Turkish pastirma).

The Manufacture of Fermented Sausages

Choice and Comminution of Raw Material

The microbiological quality of the raw material (lean and fatty tissue) should be controlled by continuously monitoring the temperature during meat handling and transport, by visual inspection of shipments, and by selecting suppliers following good hygienic practice in slaughtering and butchering. For the manufacture of fermented sausages, the pH of the raw material should be 5.8 or lower because higher pH values favor the growth of undesired or hazardous acid-sensitive bacteria. Initial pH values of the sausage mix between 5.8 and 6.0 may still be tolerated if a rapid onset and a sufficient rate and extent of lactic acid formation are ascertained. To obtain products of good sensory quality and shelf-life, the fatty tissue used should be low in polyunsaturated fatty acids and peroxides. To minimize fat deterioration, the material is usually chilled or frozen in order to keep the temperature during comminution below 2 °C, and exposure to oxygen should be minimized during communition and filling.

Formulation and Filling

By removal of oxygen and addition of salt, the normal spoilage flora of aerobically stored fresh meat (mainly pseudomonads) is suppressed. With few exceptions, the target water activity (a_w) of sausage mixes is 0.955–0.965. This is mostly achieved by adding 30–35% fatty tissue (giving a moisture content of about 50% in the mix) and 2.5–3.0% salt. Higher initial a_w values favor growth of Enterobacteriaceae (including *Salmonella*) whereas at a_w below 0.955, acid formation by lactic acid bacteria may be too slow to suppress *Staphylococcus aureus* reliably, a bacterium which still grows well at this a_w.

For most semidry fermented sausages, nitrite is used as curing agent at input levels between 100 and 150 mg $NaNO_2$ kg^{-1}, normally in combination with 300–500 mg sodium ascorbate per kg. Nitrite contributes to the inhibition of Enterobacteriaceae early in fermentation but has little effect on *Staphylococcus aureus* and on lactic acid bacteria. Moreover, by reacting with heme and nonheme iron, nitrite brings about the development of the desired curing color and curing aroma. Dry sausages are often made with nitrate rather than nitrite or with reduced input levels of nitrite. Such products must be fermented at lower temperatures. There is no need whatsoever to add more than 150 mg sodium nitrite kg^{-1}, more than 300 mg potassium nitrate kg^{-1}, or to combine nitrite and nitrate.

Carbohydrates are added to the mix to provide an energy source for lactic acid bacteria. Addition of 0.3% glucose or another rapidly fermentable mono- or disaccharide will enable the lactic acid bacteria to lower the pH from 5.8 to 5.3 or below, which is normally sufficient for microbiological safety. If the initial pH of the mix is higher (5.8–6.0) and/or a lower final pH is desired, the input of rapidly fermentable sugar is increased to 0.5–0.8%. The acidulant glucono-δ-lactone (GdL) is only used for products with a short shelf-life because many strains of lactic acid bacteria ferment this compound to lactic and acetic acid, and acetic acid interferes with reactions leading to and stabilizing desired sensory properties. Also, use of excessive amounts of fermentable sugars, in conjunction with insufficient drying and elevated aging and/or storage temperature, results in high levels of lactic and acetic acids, sometimes even in pore formation and swollen packs due to CO_2 production by heterofermentative lactobacilli. Lactobacilli may also contribute to the spoilage of fermented sausage by forming hydrogen peroxide which attacks heme compounds and polyunsaturated fatty acids. This in turn leads to gray or greenish discolorations and flavor defects, particularly if soft, improperly stored fatty tissue has been used.

In addition to their effects on aroma and flavor, some spices contain antioxidative compounds and may, by means of their manganese content, increase the rate of acid production during sausage fermentation.

During the 1970s and 1980s, it became common practice to use starter cultures in industrial sausage fermentations. Most commercial preparations contain a combination of lactic acid bacteria with nonpathogenic catalase-positive cocci. Such cultures have also been shown to be useful for the manufacture of a wide spectrum of traditional indigenous sausage varieties on a small scale, and also replaced, to a large extent, so-called back-slopping methods where a fermented sausage from the previous batch is used to inoculate the following batch. The disadvantage of the latter method is that desired catalase-positive cocci will tend to become diluted out, and strains with undesirable metabolic properties may be selected.

Suitable starter bacteria must be sufficiently active in the a_w range between 0.93 and 0.96 and at the fermentation temperature chosen (in Europe, 20–25 °C), and must be able to ferment the sugar added. To avoid excessive lag phases, resuscitation times in sausage mix must be short. Obviously, they must not be pathogenic or toxinogenic, and should not form biogenic amines nor metabolites detrimental to the sensory properties of the product.

Use of lactic acid bacteria is important for the safe production of rapidly fermented semidry sausages, whereas at low ripening temperatures their effect is small. Of the species of lactic acid bacteria that are commercially available, *Lactobacillus sakei* strains tend to acidify the sausages most rapidly, and to be most competitive towards acid-sensitive bacteria and other lactobacilli. Acidification rates of *Pediococcus pentosaceus* and *L. curvatus* depend much on the strain used, and may be equal to or higher than those of *L. plantarum* and *L. pentosus*. *P. pentosaceus* is often stated to form a milder aroma. In the temperature range between 20 and 25 °C, acid formation by *P. acidilactici* is too slow to be of much benefit. Suitable starters should thrive in the product while not forming gas, hydrogen peroxide, biogenic amines, or other compounds of sensory or toxicological concern.

Starters containing catalase-positive cocci are of most benefit to products prepared with nitrate, and products to have a long shelf-life. Adding sufficiently high levels (10^6–$10^7\,g^{-1}$) of nonpathogenic *Staphylococcus* or *Kocuria* spp. largely eliminates the need for growing these bacteria in the product by keeping the pH in the permissive range (> 5.3). Strains of *Staphylococcus carnosus, S. xylosus*, and *Kocuria varians* are commercially available. Whether or not a yeast (*Debaryomyces hansenii/Candida famata*) is useful depends very much on the aroma note desired. Surface inoculation with molds is advisable in the manufacture of mold-ripened products. Mold starters must be able to colonize the surface without sporulation and without formation of mycotoxins or antibiotics. Strains of *Penicillium nalgiovense* and *P. chrysogenum* have been selected for sausage fermentation.

Fermentation

Fermentation temperatures between 20 and 25 °C are most common in European-type sausage fermentation. For US-type summer sausage, higher temperatures (up to 41 °C) are used. Rapid onset and rates of acid formation must be ascertained to suppress pathogens such as *Salmonella* and *Staphylococcus aureus* under these conditions. Some traditional products are fermented at lower temperatures for longer times. Sausages expected to have a long shelf-life should be fermented at lower temperatures in order to restrict acid formation and to obtain maximum activity of microorganisms that reduce nitrate and are involved in the formation of aroma and flavor. As pointed out above, fermentation temperature must also be lowered if the initial a_w is outside the range between 0.955 and 0.965, if no nitrite is added, or if the pH is not to drop below 5.3. For genuine Hungarian salami, fermentation temperatures are as low as 12 °C.

Early after stuffing, residual oxygen is consumed by meat enzymes, and oxygenated myoglobin is turned into brownish metmyoglobin. Nitrite accelerates metmyoglobin formation but slows down the former process. Subsequently, acid formation starts, and catalase-positive cocci reduce nitrate to nitrite. Acid favors the reaction of nitrite with metmyoglobin to give rise to pink nitric oxide myoglobin. Residual nitrite is reduced by the sausage microflora. As acid formation continues, the pH drops to about 5.3. At this pH, growth of acid-sensitive bacteria, including catalase-positive cocci, are inhibited, and the water-binding capacity of the mix becomes minimal. Then, fermentation is usually slowed down by adjusting the temperature to about 15 °C and by lowering the relative humidity (RH) in the chamber, thus reducing the a_w of the sausages. The flavor of sausages consumed after little or no aging is dominated by lactic acid and some acetic acid, and by compounds determining the flavor of fresh meat.

Surface Treatment and Aging

After fermentation, most sausages produced in central and northern Europe are smoked. This leads to inhibition of microbial growth on the surface and to a delay of oxidative changes. On unsmoked products common in France and Italy, but also in Spain and Switzerland, a surface bloom develops, mainly consisting of salt-tolerant yeasts (e.g., *Debaryomyces hansenii*) and of molds. This layer also protects the product from oxygen and facilitates drying.

Sausages are usually aged at 12–15 °C. The climate should ensure a slow but steady removal of moisture from the sausages and prevent undesired mold growth on the surface while avoiding uneven drying of the product and concomitant undesired changes in appearance and texture. Hence, the RH in the chamber is gradually lowered to about 75–80%, and air velocity is adjusted to about $0.1\,m\,s^{-1}$. Most sliceable semidry fermented sausages are dried to moisture contents of about 40%, which corresponds to a weight loss of about 18% and an a_w value around 0.93. Dry sausages ($a_w < 0.90$) have 35% moisture or less, corresponding to a weight loss of 25% or more. Obviously, more water must be removed if the formulation includes less fat and more lean meat than common.

During aging, the flavor and aroma characteristics for fermented sausages are formed and stabilized. Lipids are precursors of many unbranched aldehydes, 2-alkanones, and short-chain unbranched fatty acids. The process involves tissue lipases, autoxidation reactions, and the transformation of the reaction products by microorganisms. Use of nitrite results in partial inhibition of oxidative changes of lipids, and in a shift in the reaction products. Tissue proteases split proteins into peptides that are subsequently transformed by microorganisms into amino acids and branched-chain volatile fatty acids. Ethyl esters also contribute to sausage aroma. Sufficient activity of catalase-positive cocci is important for the development and stabilization of the desired sensory properties. To obtain a sausage with full aroma and flavor, it is therefore important to limit rate and extent of acid formation and to age the product for a minimum of several weeks. If undesired mold growth is prevented, oxidative changes in the lipid fraction (rancidity) limit the shelf-life of most semidry or dry sausages.

Safety of Fermented Sausages

Hazards to be controlled during manufacture of fermented sausages are listed in Table 2 and analyzed on the basis of exposure, severity of disease, and epidemiological data, i.e., reports on outbreaks due to the consumption of fermented sausage.

Preventive Measures and Critical Limits to Control Microbiological Hazards

Figure 1 provides a flow diagram of the manufacturing process and includes preventive measures against growth of *Salmonella* and other pathogenic Enterobacteriaceae and *Staphylococcus aureus*.

The critical limits given have been validated by commercial practice. However, they do not cover the whole range of types of fermented sausages. Lowering one hurdle (e.g., addition of less salt or curing agents) must be compensated for by fortifying another hurdle (e.g., by increasing the rate of acid formation). Experience shows that incriminated products have been either fermented at too high temperatures without starters and with nitrate rather than nitrite, or have been eaten after a very short fermentation with little, if any, drying.

In contrast to *Salmonella*, the infective dose of enterohemorrhagic strains of *Escherichia coli* (EHEC) is low. Hence, sausages containing EHEC are a hazard to the consumer, even if growth of EHEC is reliably suppressed during fermentation. The presence of EHEC in meat, especially in beef and lamb, cannot be excluded, and the extent of destruction of EHEC during sausage ripening ranges from less than 1 log (in undried products) to 3–4 log (in smoked dry products of low final pH). Hence, it is crucial to minimize fecal contamination of beef and lamb carcasses during skinning and evisceration. Moreover, beef- or lamb-containing raw sausages with short ripening times should be excluded from the diet of small children (the main risk group for hemorrhagic colitis and its life-threatening sequela disease, hemolytic–uremic syndrome).

Protein degradation by tissue enzymes during prolonged storage of raw meat, in conjunction with growth of psychrotrophic lactic acid bacteria capable of histidine decarboxylation (in particular, certain strains of *Carnobacterium* spp. and of *Lactobacillus curvatus*), appears to be the main risk factor for the formation of biogenic amines. Hence, the formation of these amines can be minimized by proper selection of raw materials and starter cultures.

Table 2 Analysis of microbial hazards during the manufacture of fermented sausages[a]

Agents	*Growth potential during fermentation*	*Prevalence in 25-g samples*	*Minimum cell density for disease*		*Severity of disease*	*Epidemiological evidence*	*Risk priority*
			Normal	*Risk groups*			
Salmonella	Low	0.1–5%	Medium	Low	Low	Yes	High
Enterohemorrhagic *Escherichia coli*	Low	0.001–0.1%	Low	Very low	High	Yes	High
Listeria monocytogenes	Very low	10%	Probably high	Low	High	No	Moderate
Staphylococcus aureus	Low	10%	High (toxin formation in product)		Very low	Yes	Moderate
Yersinia enterocolitica[b]	Low	<1%	Probably high		Low	No	Low
Bacteria forming biogenic amines	Yes[c]	Yes	High (toxin formation in product)		Very low	No	Low
Molds forming mycotoxins	Low	Low	High (toxin formation in product)		Chronic	No	Low[d]

[a]Spore-forming bacteria and *Campylobacter jejuni* are no significant hazard.
[b]Pathogenic serotypes.
[c]Strains of lactic acid bacteria.
[d]Mainly relevant for mold-fermented types.

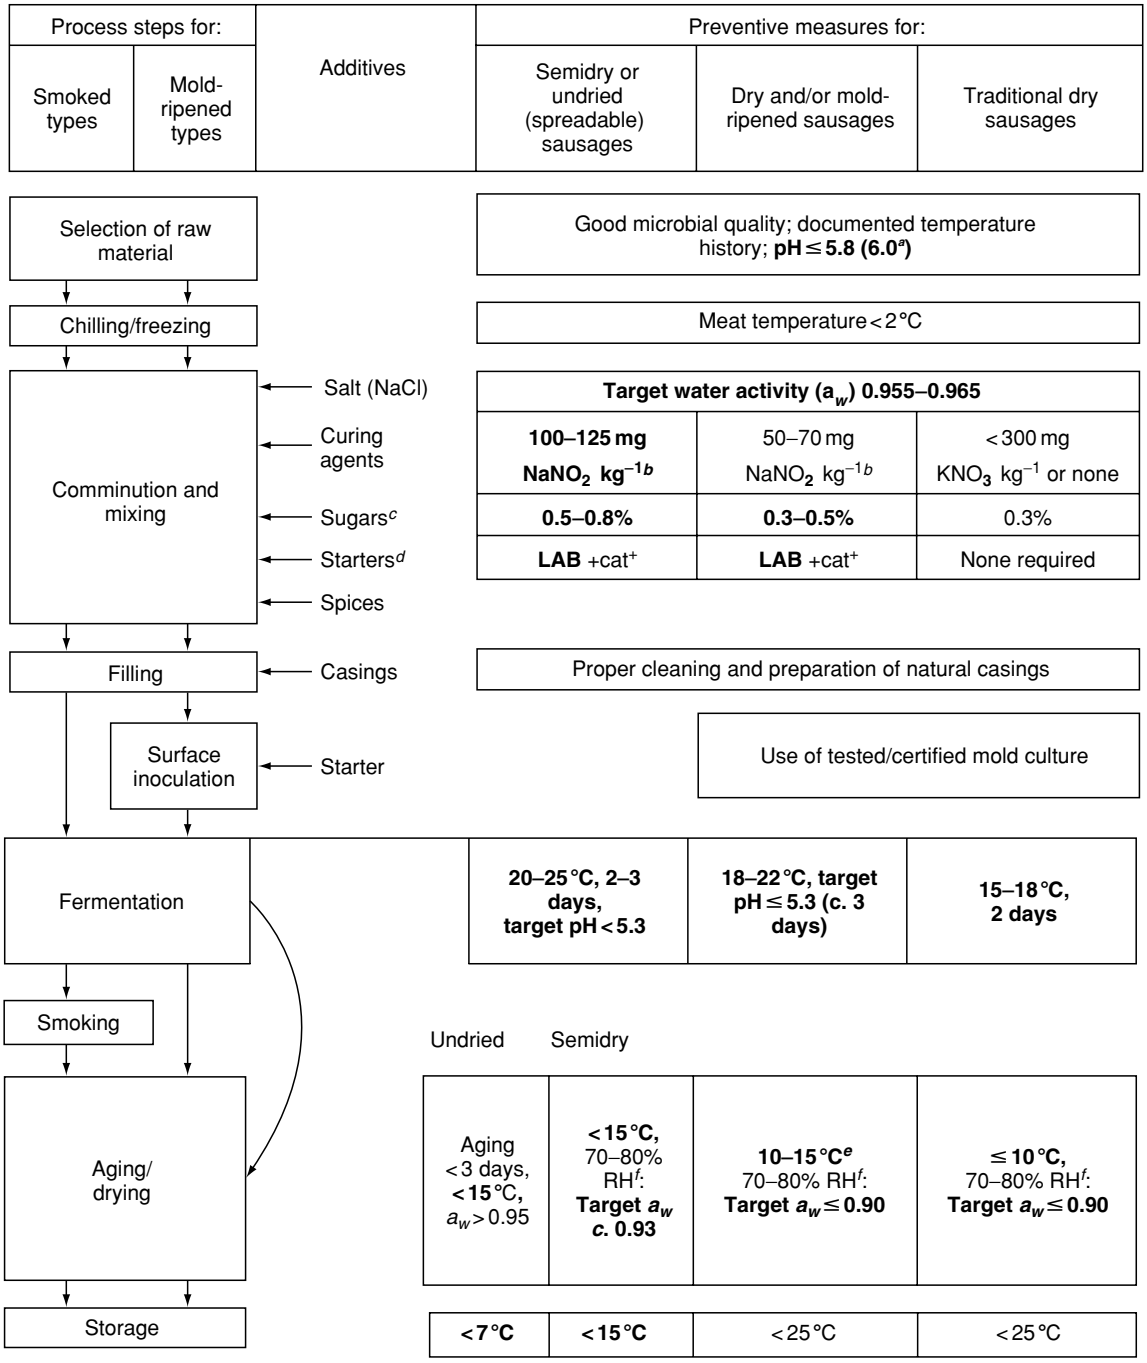

Figure 1 The manufacture of major types of fermented sausages, and measures preventing growth of *Salmonella, Staphylococcus aureus*, and *Listeria monocytogenes*. Critical limits at critical control points are printed in **bold**. [a]Adjustment of sugar addition and fermentation conditions may be necessary. [b]With maximum 500 mg sodium ascorbate kg^{-1}. [c]Rapidly fermentable by the starter used: 0.8% should be used if meat pH is above 5.8. [d]LAB, lactic acid bacteria; cat^+, catalase-positive cocci (*Staphylococcus, Kocuria*). Starters must be active at the fermentation temperature selected. [e]For mold-ripened products, temperature should be lowered to about 10 °C after 2 days of fermentation. [f]RH, relative humidity. Adjustment depends on pH and a_w of sausage. Modified from Lücke FK (2000a) Fermented meats. In: Lund BM, Baird-Parker AC and Gould GW (eds), *The Microbiological Safety and Quality of Food*, pp. 420–444. Gaithersburg: Aspen.

Mold growth on fermented sausages may be inhibited by appropriate control of temperature and RH during aging, storage, and distribution, by excluding oxygen from the packages, and/or by surface treatment with smoke, permitted antifungal agents, or waxes. Products to be mold-ripened should be inoculated with a suitable nontoxic mold strain and dried at temperatures below 15 °C.

Viruses already present in livestock at the time of slaughter normally do not affect humans. However, since these viruses are, as a rule, only slowly inactivated during sausage ripening, fermented meats should, like unprocessed meats, not be exported from areas where viral diseases of meat animals prevail. Viruses pathogenic for humans also retain their infectivity during sausage fermentation, and, as in all cases where food is handled, contamination of the food by human feces must be avoided by proper personal hygiene.

Parasites (protozoa, nematodes, tapeworms) that may occasionally escape detection during inspection of the animals and their meat at the slaughterhouse are inactivated by low a_w values as prevail in dried sausages, and are reliably absent from meats dried to a_w values of 0.90 or below. Parasites are also unlikely to survive the a_w and pH values typical for most semidry sausages. However, in the USA, pork is not generally inspected for the absence of *Trichinella*, and regulations stipulate that semidry and undried fermented sausages must be made from meat which has been stored frozen, or be heated to 58.3 °C (137 °F).

The Safe Manufacture of Fermented Unground Meats

For the manufacture of raw hams and comparable products, it is very important to select cuts of normal pH (≤ 5.8), particularly for large pieces; otherwise, salting proceeds slowly, and the risk of growth of pathogens during the salting process increases unless special precautions are taken.

In contrast to fermented sausages, changes in lipids are of little significance, and the microbiology and sensory characteristics of raw ham are little affected by nitrite. Hence, many aged products with long shelf-life are made with nitrate rather than nitrite, or with no curing agent at all.

The method of salting depends on the type of product and on local tradition. Injection of brine is uncommon in the manufacture of products to be aged and dried. Dry salting proceeds only slowly, but is preferred for most high-quality, expensive products. The meat is salted until sufficient salt has diffused into its core. During this period and the following equilibration time, the temperature must be low (≤ 5 °C in the core of large pieces) in order to prevent growth of any psychrotrophs (including nonproteolytic *Clostridium botulinum*) possibly present in the interior of the meat. Target a_w is 0.96 or below in all parts of the cut. The time required depends on the geometry of the cut, the concentration gradient of salt, and the ratio between meat and brine. There is little microbial activity in the ham under these cool, salty conditions. However, in recycled brines, a population may develop containing halotolerant psychrotrophic Gram-negative bacteria, such as *Halomonas* spp. Using such brines may improve the sensory quality of nitrate-cured hams because *Halomonas*, unlike other bacteria, actively reduces nitrate under the conditions prevailing in concentrated curing brines, and may also form aroma precursors.

After salting and equilibration, excessive salt and moisture are removed from the surface. To prevent growth of *Staphylococcus aureus*, this should be performed at 18 °C or below. Subsequently, the hams may be smoked (e.g., Westphalian ham) or not (e.g., Parma or Serrano ham), and dried to the desired a_w. Once they are microbiologically stable, top-quality hams are further aged at higher temperatures (25–30 °C) to make them very tender and tasty. If the surface is kept moist enough, a surface bloom of catalase-positive cocci, molds, and yeasts may develop and affect the sensory properties of the ham; otherwise, there is little, if any, role of microorganisms in the development of aroma and flavor during aging.

Fermentations of the Far East

W R Stanton, Stanbury, Keighley, UK
J D Owens, The University of Reading, Reading, UK

Background

The origin of oriental food fermentations is lost in antiquity, although there is indirect evidence that the earliest 'cultivated plants' were microorganisms, fermentation being part of the hunter–gatherer practices preceding agriculture. As mentioned later, ideas of what is wild and what is cultivated have changed radically in recent years; most so-called virgin tropical forest is in fact carefully managed by the local people, who have taken advantage of their 'human' skills to extract and detoxify products, whilst leaving them in the wild, biochemically protected against the biota. No precise archeological timing can be assigned, because the techniques adopted by humans were acquired by observation of the behavior of other animals. However, in order to understand these Far Eastern foods, it may be helpful to visualize them as occupying two main groups, a Chinese heartland and migrant-spread group and an indigenous products group.

Chinese Heartland and Migrant-Spread Group: Panoriental Fermented Foods

The Chinese heartland and migrant-spread group consists of those foods that are identifiable as originating in China and, to a lesser extent, the Indian subcontinent. They are encountered in the Far East, following the spread – over the last 2000–3000 years – of migrants from these two founts of culture, mainly south- and eastwards from the temperate and monsoonal regions in which they putatively originated (**Figure 1**).

Because these foods became, through the process of transfer, out of context, as far as both climate and substrate were concerned, they underwent subtle changes:

- in the organisms which took part in the fermentations;
- in the duration of the fermentations;
- in the utensils, materials, and conditions for operating the processes.

For example, the Mucorales such as *Rhizopus*, liking warm humid conditions, replaced *Aspergillus* and *Penicillium*. Bamboo, the banana leaf, and the coconut shell replaced pottery.

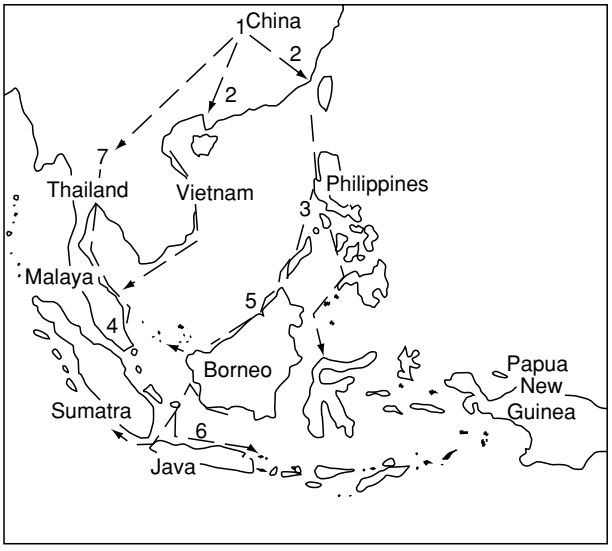

Figure 1 Human migration and the spread of food fermentation techniques in the Far East. 1, Postulated center of origin, 3000–4000 years ago; 2, Land routes within the empire to the 'vassal' kingdoms of Indochina; 3, Sea routes and migratory routes hugging coasts of the South China Sea, or traversing open sea by island hopping; 4, An ancient porterage route across South Malaya; 5, Small victualling and trading ports along the Northwest coast of Borneo; artefacts from this area show strong connections with Chinese trade; 6, Java: a territory rich in traditions of fermented foods; the raw materials, techniques and nomenclature provide evidence for the 'Chinese origin' hypothesis; 7, In addition to the coastal trade, there is a strong tradition of overland migration into Thailand as well as *in-situ* development of richly endowed indigenous cultures, such as the Khmer. After Stanton WR (1985) Food fermentation in the tropics. In: Wood BJB (ed.) *Microbiology of Fermented Foods*, pp. 193–211. London: Elsevier, with permission.

Nevertheless, the links of the tropical foods with their continental cultural roots may be seen in the form of the 'new' foods and the processes used for their manufacture, just as clearly as the links with the cultural and linguistic traits of the Indian subcontinent and China are themselves identifiable.

In-situ (Tropical) Group: Indigenous Products

Much earlier migration initiated the use of the great diversity of plant and animal resources of the equatorial lands of Southeast Asia and their associated freshwater and marine biotopes. This process took place over, putatively, the last 30 000 years, i.e., over the period of the spread of Meso- and Neolithic cultures through the South and Southeast Asian regions. The separation of the two groups of foods is incomplete, but this systematic approach is helpful in understanding the recipes and the current concern over the loss of species diversity, through degradation of habitats with the expansion of the human population, and thus the potential loss of novel raw materials.

Role of Food Fermentation in the Humid Tropics

The function of both groups in the diet has been, and remains, to exploit otherwise toxic or inedible raw materials, to preserve the harvest, to recover wastes and generate attractive, stimulating, and accessory foodstuffs, and to conduct these exercises with economy of expenditure and energy. Figure 2 shows how fermentation fits the scheme of preservation techniques.

Panoriental Fermented Foods

Typical of panoriental fermented products – now used as foods worldwide – are those liquid relishes derived from the soy bean, of which soy sauce is but one of many 'sho', i.e., salt-assisted, processes. The soy bean furnishes the type of substrate for transformation by fermentation, embodying many of the characteristics of a plant raw material requiring processing before it is edible.

Soy sauce is the best known, but there are also solid-state bean fermentations, the *vegetable cheeses*, such as tempe, which have evolved to become 'meat substitutes.' The role of these bean cheeses in diets is more that of balancing, in a cereal diet, vitamin and essential amino acid deficiency. It includes improving digestibility (reducing bean flatulence) and eliminating antinutritional factors, particularly antitryptic factors.

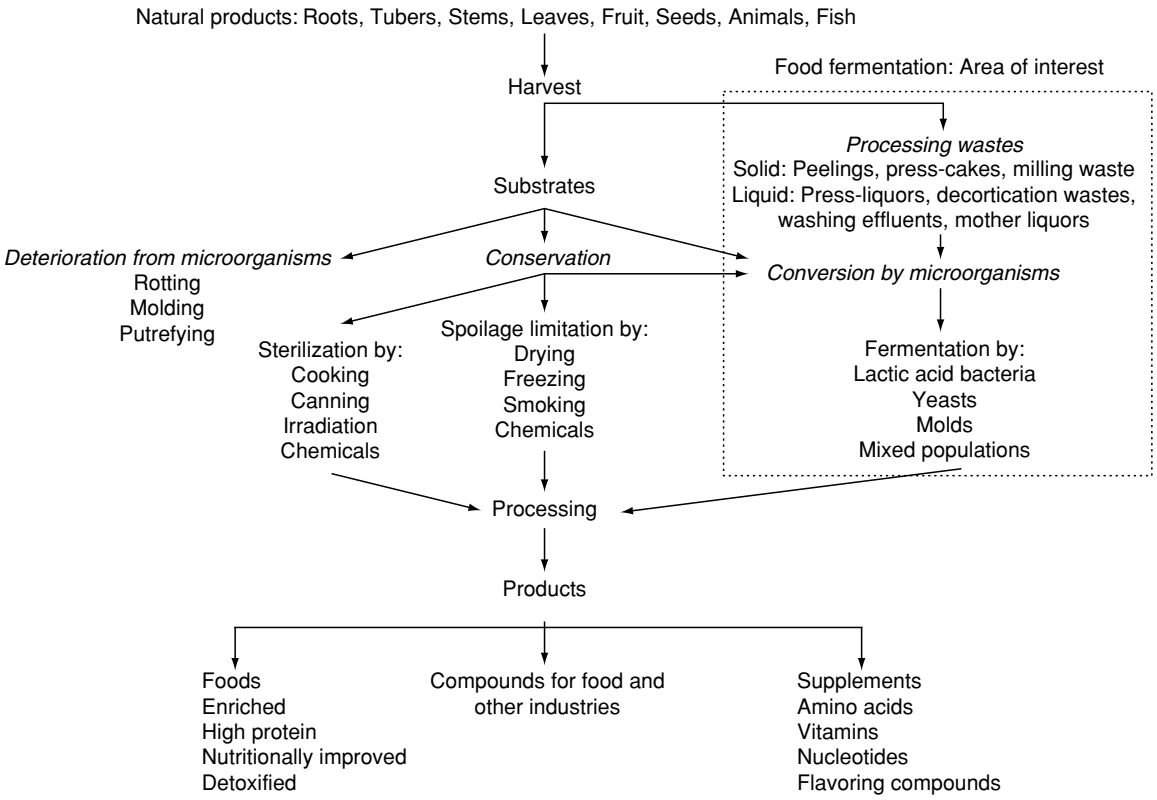

Figure 2 Fermentation in relation to other processes used in the conversion of raw materials to foods. After Stanton WR (1969) Some domesticated lower plants in Southeast Asian food technology. Adapted from Ucko PJ and Dimbleby GW (eds) *The Domestication of Plants and Animals*, pp. 463–469. London: Duckworth.

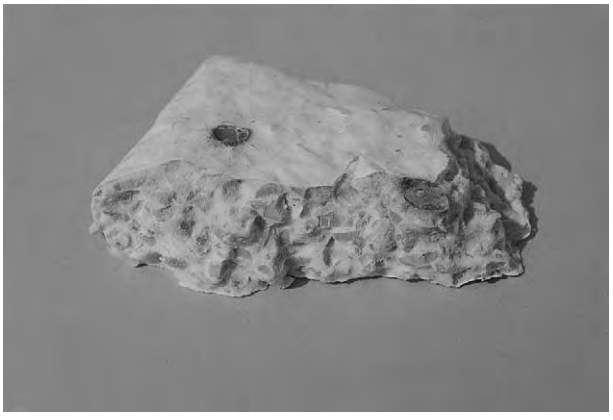
Tempe

Tempe is a traditional Indonesian solid-substrate fermentation in which soybeans are hydrated and acidified, dehulled, cooked, and then fermented with *Rhizopus* spp. The cotyledons become covered and penetrated by a dense, white, nonsporulating mycelium, which binds them into a compact, sliceable mass. Tempe is cooked by frying, steaming, or boiling, and is consumed as a main ingredient of a balanced meal with rice or starchy tubers and vegetables or as a snack food. It is estimated that 50% of the 200 million Indonesians consume tempe daily as a meat substitute. The high protein content and pleasant, relatively bland taste has led to it occupying a small, but expanding part of the vegetarian market in Japan, the USA, and Europe.

Manufacture Unlike soy sauce manufacture, the fermentation of tempe is a short-duration process. The small-scale manufacture of tempe is carried out as follows:

1. Wash soy beans.
2. Soak for 24 h at tropical ambient temperature ($30 \pm 5\,^{\circ}C$), during which time a natural lactic acid fermentation occurs, lowering the pH of the beans to 4.5–5.3.
3. Dehull by treading or by machine.
4. Wash and float off hulls.
5. Cook the cotyledons by boiling or steaming for 0.5–2 h.
6. Drain well and cool to below 35 °C.
7. Inoculate with *Rhizopus* spp.
8. Pack into perforated polythene bags or wrap in banana leaves.
9. Ferment at ambient temperature ($30 \pm 5\,^{\circ}C$) for about 24 h to yield tempe.



Slide 1 (see color plate 52) Tempe. Growth of a fungus, *Rhizopus oligosporus*, binds cooked, dehulled soybeans into a solid cake. Tempe is a traditional Indonesian meat substitute that also has a small part of the vegetarian market in Japan, the USA, and Europe.

Acidification is important to avoid misfermentation and invasion of undesirable bacteria. Perforated plastic, normally polythene, was first used by Hesseltine – a pioneer of the study of the industrialization of oriental fermented foods – in the late 1960s; it is possibly one of the most elegant examples (in its simplicity and small-scale applicability) of advances in solid-state fermentation technology during the twentieth century. Although primarily a mold fermentation, most commercial tempe also includes a substantial bacterial population. There are suggestions that the bacteria fulfill useful functions, such as the production of vitamin B_{12}, but their presence is not necessary for the production of good tempe. The composition of tempe is given in Table 1. The wide range of values shown in Table 1 is attributable to a diversity of factors, including variation in the quality of the beans and the extent of the use of additives and adulteration. However, under laboratory conditions, the protein content should be near the upper limit of the range of values shown, i.e., 50%, as loss of protein in preparation is generally below 2%. Apart from binding the cotyledons into a firm cake, the main changes in the beans effected by the fermentation are:

1. A net loss of 7–10% in dry matter. Approximately 15–20% of the initial substrate is used by the mold, yielding 50–100 g of dry biomass per kilogram of dry tempe.
2. Hydrolysis of a substantial proportion of the triacylglycerides to free fatty acids and mono- and diacylglycerides. In mature tempe, free fatty acids comprise 15–30% of total crude lipid. Fatty acids serve as a major source of carbon and energy for the mold, and around 25% of the initial lipids present in the cotyledons are utilized during the fermentation.
3. Hydrolysis of about 25% of the initial protein, most of which remains in the tempe as free amino acids. A small part is oxidized, with the release of ammonia and increase in the pH of the cooked cotyledons from the initial 4.5–5.3 to 6.5–7.0 in mature tempe.

Table 1 Composition of tempe

Nutrient	*Content (%, dry-weight basis)*
Protein	40–50
Crude fat	15–30
Carbohydrate	15–30
Crude fiber	5–12
Ash	1.5–3.0

4. The mold does not use the soy bean oligosaccharides, stachyose, raffinose, and sucrose, and the concentrations of these change little during the fermentation. However, a large proportion (70–80%) of the oligosaccharides in the original beans is lost by leaching during the hydration, washing, and cooking of the cotyledons.
5. Isoflavone glycosides are largely hydrolyzed to the aglycones, dadzein and genistein, which, it is suggested, are more available than the isoflavones in cooked soybeans. There is currently considerable interest in possible health-promoting properties of isoflavones.

Other Tempe-type Fermentations

Many of the fermentations make use of waste materials, such as oil extraction residues or other food processing by-products.

Common in western Indonesia is a product called oncom (ontjom). It is made by a tempe-like fermentation, but the process differs in some respects:

1. Peanut (*Arachis hypogaea*) press cake is used in place of the soy bean.
2. The preferred fungus is the orange–red-spored *Neurospora sitophila*.
3. Sporulation of the fungus is encouraged, in contrast to tempe manufacture, where it is avoided.

Oncom also may incorporate cassava press cake or the residue from soy milk preparation, or it can be prepared solely from soy milk residue. Coconut oil extraction residue is another processing material that can be fermented with *Rhizopus* spp., giving a product called tempe bongkrek. However, this may be lethal, if incorrectly prepared, because of the growth and toxin production by *Pseudomonas cocovenenans*.

Slide 2 (see color plate 53) Oncom (ontjom) in Bandung market, Indonesia. Oncom is similar to tempe but uses peanut press cake and the orange-spored fungus, *Neurospora sitophila*. The material in the background is fried tempe.

Natto and Related *Bacillus*-fermented Products

Natto is produced by an exclusively bacterial fermentation of the soy bean using *Bacillus subtilis*. In common with most other Japanese fermented foods, it originated in China, where it is named shi. In contrast to the preparation of tempe, the hulls are left on the steamed beans. In Japan, the manufacture is now highly automated and uses carefully selected pure starter cultures.

The cooked beans are inoculated with starter culture, packaged in small, usually polystyrene foam, containers and fermented at a relatively high temperature (40–42 °C) for 12–16 h. The packages are then cooled and held at 0–5 °C for 1–2 days for maturation. The result is a slime-coated product in which the beans remain visible and separate. The major biochemical change is the hydrolysis of protein to peptides and amino acids. Natto is eaten with boiled rice and is also used as a flavoring agent in other dishes.

Slide 3 (see color plate 54) Natto. A Japanese *Bacillus* proteolytic fermentation of whole soybeans producing a characteristically slimy, strongly flavored product.

Slide 4 (see color plate 55) Thu-nuo, dried disks. A traditional Thai *Bacillus* proteolytic fermentation of soybeans.

Similar *Bacillus*-fermented soy bean products are Thai thua-nuo and kinema, made in eastern Nepal, Darjeeling, Sikkim, and Bhutan, but in these cases, the products are still made by traditional methods. Consequently other *Bacillus* spp., as well as non-bacilli, commonly occur in the fermentations, and the products often develop strong ammoniacal odors. Thua nuo is prepared either as a paste or as dried disks, and kinema is sold in the markets as a paste. Neither is eaten directly as a condiment but they are used to flavor soups and stews, etc.

Other Cereal–Legume Fermentations

Cereal–legume mixtures are commonly used as the substrate for fermentations. Whereas, as explained elsewhere, wheat is added in soy sauce manufacture, rice is added in Japanese miso.

In contrast to the above fungal fermentations, from the Indian subcontinent come a number of rice-flour and bean-flour bacterial fermentations. These include two widely used products, idli and dosa.

South Indian Products The beans most commonly used for the Indian fermentations are Vigna spp., the green and black grams: *V. radiata* (L.) Wilcek (formerly *Phaseolus aureus* Roxb.) and *V. mungo* (L.) Hepper (formerly *Phaseolus mungo* L.). *Vigna* is an Old World genus, and the two grams are closely related to the cowpea or blackeye 'peas' (*V. unguiculata* (L.) Walp., formerly *V. sinensis* (L.) Hassk.). These beans may be confused in reports with beans of the unrelated New World genus *Phaseolus*, beans of which are not used. Any process development of grain legumes should be preceded by careful study of the correct identity of the raw material, as many legumes, unlike cereals, are very poisonous when incorrectly or inadequately processed.

Idli The beans and rice are normally milled separately, and water is added to give a thin gruel, or they may be soaked and wet milled, adding about 1% salt to the final gruel. The bean–rice mixture, in which the proportions vary widely from 10:1 to 1:10, is left covered overnight at 28–32 °C. The temperature is ambient shade temperature, although the duration of the fermentation is not as critical as for the tempe fermentation. The mixture may be stirred from time to time but should be kept anaerobic (microaerophilic) to encourage the growth of the heterofermentative lactobacilli. At the end of the fermentation, the slurry is poured on to an idli steamer surmounted by a perforated plate, in which there are shallow, saucer-shaped depressions some 10 cm in diameter and 2 cm deep. A cotton cloth prevents the slurry oozing through the depressions. The cloth also aids removal of the steamed cakes. Cooking for 15–20 min produces the raised cakes of idli, which are then ready to be consumed.

Dosa Similar fermented mixtures, in which lentils (*Ervum lens*) may be used in place of the gram beans, are prepared and poured on to a hot griddle pregreased with ghee, coconut, or other oil, according to culture.

These products are to be found wherever Indian communities have settled. They vary in flavor and in the added spices, but they are all lactobacillic, rather than yeast fermentations, possessing characteristics in common with sour doughs.

Indigenous Products

In contrast to the panoriental group, the indigenous products are a highly diverse group of foods and beverages, springing from the gathering activities of local people who have inherited, or even retained, recognizable Neolithic or bamboo culture traits and have made full use of their habitats rich in diversity of biota.

Cereal–Legume Fermentations

Cereals, principally rice and maize, and various legumes are involved (predominantly of the genera *Glycine, Vigna*, and *Arachis*). However, tree legumes are also used, as in Africa.

Starches of the Rainforest

Edible carbohydrate-containing plants are in short supply in the rainforests. Many plant species are too loaded with additives to be exploited by fauna other than those with specialized guts, such as leaf monkeys. This shortage limits the population carrying capacity. Those that are 'possible foods' may contain poisonous substances associated with their storage organs, e.g., oxalates. The forest and swamp starch-containing plants include the aroids (Araceae), such as the taros (*Colocasia*), the endangered elephant-foot yams (*Amorphophallus*), and the true yams, *Dioscorea* spp.

Tapé (Tapai)

Cassava (*Manihot esculenta* Cranz.) tubers are the most widely used material for the production of the popular sweet and sour alcoholic tapé, but this product is also made from glutinous rice, maize, or millet.

Manufacture The peeled cassava (tapioca in Southeast Asia) tubers or rice grains are inoculated, after boiling or steaming, by dusting with a microbial

Slide 5 (see color plate 56) Tapé in Bandung market, Indonesia. Cooked cassava roots fermented with fungi to produce a slightly soured, slightly alcoholic, and sweetened cassava.

starter powder, ragi. This is a stabilized mixture of yeasts and molds fermented as a dough and dried as small, flat cakes. Many types of ragi cake can be found in Southeast Asian markets, each type being applicable to a particular substrate. The inoculated cassava tubers are incubated in baskets, lined and covered with banana leaves. The inoculated rice is wrapped in small banana leaf or plastic packets. After 2–3 days at ambient temperatures (25–30 °C), the products soften and develop a sweet/sour slightly alcoholic flavor. The product may be sold for direct consumption, or after air-drying. Alternatively, the fermented mass is squeezed, and the paste and exudate are consumed separately; the latter, after further fermentation, is drunk as an alcoholic liquor.

Wines and Acidic or Alcoholic Beverages

Based on the ragi fermentation are the rice wines, such as tuak, of the peoples of Borneo. Some of the wines found in Southeast Asia are derived from the influence of migrating cultures, particularly those wines derived from rice and the inflorescences of palms, such as the coconut and talipot palm (*Borassus flabelliformis*), a feature of the landscape of Sri Lanka and Indo-China. Others, derived from regionally indigenous plants, are considered below. Reference to these is more often to be found in ethnographic and economic botany texts than in books on food.

Tropical forest people often 'tap' plants for a drink, using xylem and phloem saps. The rattans, for example, are a forest source of water. The evolution of fermentation of saps may have followed almost incidentally from the tapping of sugar-rich phloem saps from emerging palm inflorescences.

Products of the Vitaceae are occasionally found, but the Rosaceae of temperate zones are not represented.

Local fermented beverages are made from the saps of a number of genera of palms, such as *Arenga* and *Nypa* as well as from the talipot palm (*Borassus* spp.). Unlike in West Africa, the oil palm (*Elaeis guineensis*) is not tapped in Southeast Asia.

Other true rainforest trees, furnishing sugary and starchy substrates, are the jack and bread fruits (*Artocarpus*) and the durian (*Durio zibethinus*). The local Indo-Malay name for the fermented product of the durian is tempoyak. *Baccaurea grifithii* is another rainforest tree, producing an aromatic resinous fruit that is fermented to a retsina-like product.

Strong-smelling, biologically active, heterocyclic ring, sulfur-containing compounds (extending the 'garlic range' to many other families) are common in rainforest biochemical systems, the above quoted durian being but one example. Like the durian, they are locally exploited but are increasingly rarely encountered.

Fermented Sugar Cane Juice

Sugar cane (*Saccharum officinarum* L.) is indigenous to Southeast Asia, and the juice is fermented by the indigenous forest people, such as the Semelai of Malaysia. The fermentation is controlled by filtering the raw juice through a filter made of the inner bark of a dipterocarp tree, *Shorea curtisii*. The bark is rich in phenolic compounds, some of which are transferred to the liquor.

Detoxification via Fermentation

The recipes for these true forest products, and the plant species themselves, are in danger of being lost as the forests are cleared. The diversity of these forest products is reflected in the range of biochemicals that are detoxified by fermentation. These include the following: alkaloids and other heterocyclic, nitrogen-containing poisons – the nitriles and cyanides (the cause of optical and peripheral neuropathies), an unusual one being that *of Cycas* spp., or false sago, the seeds of which furnish a source of starch; poisonous amino acids, peptides and proteins; steroids; saponins; anthocyanins and related phenolics and organic acids such as oxalic. In the plant, these secondary compounds function as selective attractants, antibiotics, and feeding deterrents. As has been shown in the examples above, the bioactivity of some of these compounds has been exploited to advantage in the preparation of the fermented foods, but, as with so many aspects of tropical plant study, much remains to be recorded and analyzed.

Fermented Fish Products

Fermented, salted, or dried fish and crustaceae are used ubiquitously in oriental cooking. The products used range from solids and pastes to very salty liquids,

the salt being necessary for conservation, more than for culinary purposes. There is clearly a major subdivision into products in which the process solely involves autolysis by fish-derived enzymes, and those in which carbohydrate fermentations, employing microbial enzymes, also occur.

Salt-aided Fermentation

Outstanding amongst the desiccated products is katsuobishi, a mold-fermented product made from tuna in Japan. It is as hard as Parmesan cheese and is used in a similar way.

Belacan is a softer autolyzed shrimp paste from Indonesia and Malaysia; similar intermediate-moisture fish and shrimp pastes occur throughout Southeast Asia.

The salty fish sauces, such as the patis of the philippines, are autolytic products, relying on the enzymes of the fish gut rather than the associated microflora. These salt-aided autolytic products normally contain 14% or more of salt and are thus only of value as relishes to the main dish.

Carbohydrate-aided Fermentation

In some fish pastes and slurries of Southeast Asia, rice, usually as tapé or koji, also plays a part in the preservative process. The rice provides a carbohydrate source for a lactic acid fermentation and allows the use of less salt in the product.

Acceptance

Unlike soy sauce and, to a lesser extent, tofu, miso, and nata (the jelly-like sweet mentioned later), the acceptance of the fish products outside their home markets is limited, possible exceptions being the fish and shrimp pastes, such as belacan of Indonesia. Furthermore, the fish products mentioned above are not easily amenable to modification. Each depends on a particular local fish species, or group of species, and the taste for them is acquired, just as the predilection to the Scandinavian fermented herrings is very much an acquired taste, not even shared by the rest of Europe.

Nevertheless, in a world of increasing protein shortage and with an increasing proportion of by-catch and trash fish in the harvests, owing in part to over-fishing, as well as fish waste from processing, the opportunity to improve nutrition worldwide afforded by some of these products and processes should not be overlooked.

Pickled Fish

Unlike the above-mentioned products, pickled products rely on the addition of acetic acid and sugar, or acid fruit extracts, and do not play a significant role in the regional food supply.

Fermented Meats

Fermented meats are not important in the diet of the peoples of the Far East, in comparison with the fish products, although they are to be found in Thailand, for example.

Microbes as Food

Finally, in this review, the traditional uses of the microbial cultures themselves as the end product are considered. This is quite different from the development of industrial processes for the production of microbial protein, a large-scale, capital-intensive exercise requiring many more process steps than the traditional processes. The traditional foods are derived from bacteria or from fungal fruiting bodies.

Bacteria The polysaccharide and amorphous cellulose coat formed by *Acetobacter xylinum* is eaten in the Philippines under the general name nata. This is made by encouraging the growth of the aerophilic *Acetobacter* on sugar and ammonium phosphate-enriched acetic-acidified (pH 5) coconut water (nata di coco), pineapple (nata di pina), or other fruit juice.

Manufacture The substrate (a nitrogen- or phosphate-enriched sugared juice) is inoculated with the liquid phase of a previous culture (1:10 of substrate), held in a covered (not airtight) container, preferably undisturbed and in the dark. The liquor is maintained at a temperature below 31 °C, preferably about 28 °C, for approximately 2 weeks. The product is a surface cake of a bacterial embedded cellulosic gel, which acquires a particular flavor according to the substrate used. This gel, which can be up to 3 cm thick and is composed of cells plus polysaccharide coat, must be soaked to remove excess acetic acid before use. It is cubed, marketed fresh in a syrup, or marketed in cans, bottles, or plastic pouches.

Use of waste The bacterial process is a convenient way of making a useful product from a range of fruit-processing wastes, the character of which – unlike many of the fermentations mentioned here – is easily adjustable, appears internationally widely acceptable, and is already exported in limited quantities. However, it is a product that could be produced locally without much hazard and is acceptable to a wide range of palates.

Fungal Fruiting Bodies The fruiting bodies of basidiomycetes (and some ascomycetes) are mentioned

here, as they are ubiquitous foods of Southeast Asia, produced by fermentation and exploiting waste or inedible material. The main differentiation is between those fungi with ephemeral (autolysing) fruiting bodies, such as the paddy straw mushroom (*Volvariella volvacea*), and those with durable (dryable) mushrooms, such as the highly prized shiitake (*Lentinus edodes*).

Future

New Applications of Oriental Fermented Foods

The interest of food scientists in traditional fermentations arises not only from the fact that they furnish novel foods and are challenging from the point of view of the techniques needed to effect industrialization, but also from the fact that the unit processes have a wide industrial application. The enzyme, flavor enhancement, color, texture, gel stabilization, and antioxidant properties have come under scrutiny for the production of shelf-stable, intermediate-moisture foods, flavoring agents such as monosodium glutamate, flavor-enhancing nucleotides, and even coloring matters, e.g., the red–purple of *Monascus purpureus*.

Health Hazards

The products mentioned in this review have undergone millennia (to quote Hesseltine) of testing. Nevertheless, in spite of the advances in food hygiene and the current emphasis on care in avoiding contamination at harvest, safe storage, sanitary processing and marketing, the reported incidence of food poisoning has been rising. There are several reasons for this phenomenon, but, in the present context, the following question arises: how have the people in hot, humid countries circumvented microbial food poisoning in the past?

The answer lies in the fact that the traditional techniques for raw material processing, described here, are energy-economical lessons in living with the microbial world; the appearance of mycotoxins and the various bacterial poisons, mentioned elsewhere in this work, are examples of the failure to learn those lessons.

Conclusion

Some of these oriental fermentations, such as soy sauce and, to a lesser extent, tempe, have already found acceptance in the industrial world. Others have yet to be discovered. A further group will be lost forever if steps are not taken to preserve the diversity of the resource base and record the processes of conversion of these resources to food or, better still, to conserve the environmental conditions so that the original inhabitants may continue to practice their art.

Beverages from Sorghum and Millet

J R N Taylor, University of Pretoria, Pretoria, South Africa

Introduction

Throughout Africa, the indigenous tropical cereal grains sorghum (*Sorghum bicolor* L. Moench), pearl millet (*Pennisetum glaucum* L. R.Br.), and finger millet (*Eleucine coracana* L. Gaertn.) have been used since prehistoric times to prepare fermented beverages (Figure 1). In general, these traditional beverages are popular as ever, and in southern and eastern Africa their industrial manufacture has become increasingly common. Although the character of the industrially produced beverages is substantially the same as the traditional products, high proportions of maize (corn), (*Zea mays* L.), which is native to the USA, and even maize alone are normally used in their manufacture.

Figure 1 Sorghum and millet growing together in a field in the Northern Province of South Africa. Courtesy of Beryl Fabian, CSIR, South Africa. Reproduced from Fermenting Foods: Beverages from Sorghum and Millet, *Encyclopaedia of Food Microbiology*, Robinson RK, Batt CA and Patel PD (eds), 2000, Academic Press, with permission.

The fermented beverages may be alcoholic, or substantially nonalcoholic. The alcoholic beverages have many names, including sorghum beer (South Africa), opaque beer (Zimbabwe), jwala (Tswana), utywala (Zulu), Chibuku (southern and eastern Africa), and pito (west Africa). Chibuku is a commerical brand name; the word is from the African 'mine' language Fanagalo and can be translated as 'according to the recipe book.' In this article the term 'sorghum beer' is used generically for the southern and eastern African product. Traditional African beers are very different from European lager-type beer, partially on account of the particular properties of the tropical cereal grains. Sorghum beer is characterized by its opacity due to the presence of semisuspended particles of starch, cereal, and yeast. The starch gives it a viscous consistency. The beer is generally pinkish brown in color due to anthocyanidin pigments from the sorghum or millet. It is sour in taste owing to the presence of lactic acid but, unlike lager beer, is not hopped; and it is consumed while actively fermenting. In contrast, pito is clear or somewhat cloudy and is not particularly sour in taste, but like sorghum beer it is consumed while it is actively fermenting. African beers are generally rather lower in alcohol than lager beer. This is related to the considerably lower β-amylase (EC 3.2.1.2) activity of sorghum and millet malts, in comparison to barley malt.

The substantially nonalcoholic fermented beverages have been less well documented but all involve some form of lactic acid fermentation. Products include kunun-zaki (Nigeria), hulu mur (Sudan), and motoho oa mabele (South Africa). These are made from sorghum or pearl millet; the grain may or may not be malted according to local preference. The best-known nonalcoholic beverage is mageu (mahewu or magou) from southern Africa, which is a lactic acid-fermented gruel, widely produced industrially using almost exclusively maize.

Traditional Methods of Making Sorghum Beer

Sorghum beer is intrinsically linked with African culture, traditionally being brewed by the female members of the family for use at ceremonies including weddings, funerals, and other social gatherings.

The basic sorghum beer process involves the following steps: souring (lactic acid fermentation), cooking (starch gelatinization), mashing (thinning and conversion of gelatinized starch to sugars),

straining (grain separation), and alcoholic fermentation. It should be noted that under home brewing conditions it is very difficult to maintain the brews at the optimal temperatures for each of the steps. This leads to an overlap of the processes across different steps, so that two or more brewing steps may take place at the same time.

Malt is the vital ingredient in brewing. In essence, malting involves germinating the grain for several days to produce enzymes (most importantly, amylase enzymes) not present in the grain, then drying and milling it. In the brewing of sorghum beer, the malt amylase enzymes hydrolyze grain starch to sugars. The sugars are fermented to lactic acid by lactobacilli and, during alcoholic fermentation, yeasts convert the sugars to ethanol and carbon dioxide, producing beer.

In traditional home brewing, the grain is malted by first soaking it for about a day, either in water-filled, clay vessels, or in woven grass baskets placed in a stream. After soaking, the steep water is drained off and the damp grain is allowed to germinate for 2–4 days, depending upon the ambient conditions. Germination is conducted in small baskets or in sacks, allowing the circulation of air. At the end of germination, the germinated grain is spread out in a thin layer on the ground and sun-dried. Once dry, the malt is ground by hand between two stones.

To brew beer, a small portion of ground malt is mixed with hot water; either slurried with the water and then cooked, or added to previously heated water. The warm mixture is then covered and allowed to stand overnight to sour. The following day, the soured wort is diluted with additional water and more milled grain is added. This starch-rich adjunct material is either malt, or more commonly whole, coarsely ground sorghum or millet grain. The entire mixture is then boiled (2–6 h), and then allowed to cool and thicken. The following day, a second batch of malt is added to the now cooled brew. The amylase enzymes in the malt liquefy the mash. Depending upon the taste of the brew and the preference of the brewer, it may be recooked, cooled, and more malt added. As the wort cools, wild yeasts in the environment ferment the brew, giving a bubbling, effervescing liquid. A characteristic of traditionally brewed sorghum beers is their fruity flavor, due to fermentation by wild yeasts. The brew is allowed to ferment for a few days When it is considered to be acceptable, it is strained, traditionally by passing it through a braided grass strainer, or today more generally through a perforated steel sheet. The beer is then served in decorated clay drinking vessels. Figure 2 shows a woman serving out the beer with a ladle made from a plant gourd; the latter may also serve as drinking vessel.

Figure 2 Serving traditionally made sorghum beer from clay pots using a gourd ladle. Courtesy of Beryl Fabian, CSIR, South Africa. Reproduced from Fermenting Foods: Beverages from Sorghum and Millet, *Encyclopaedia of Food Microbiology*, Robinson RK, Batt CA and Patel PD (eds), 2000, Academic Press, with permission.

Modern home brewers may make their own malt, or more commonly they obtain it from large commercial maltsters who produce malt of more consistent quality. Over the years, milled maize or brown bread has tended to replace malted or unmalted sorghum or millet as the adjunct. However, the procedures followed are essentially the same as those of ancient times. Figure 3 shows a modern-day sorghum beer home-brewing recipe.

Traditional Methods of Making Nonalcoholic Beverages

The procedures are substantially the same as used for making sorghum beer, but certain steps are ingeniously optimized to result in a substantially nonalcoholic product. Figure 4 shows a scheme for making kunun-zaki. It is notable that the malt is simply mixed (not mashed) with the cooked adjunct. Alternatively, according to local preference, boiling water may be added to the malt. Both processes limit the amount of enzymic hydrolysis of starch to fermentable sugars and hence favor a lactic acid, rather than an alcoholic fermentation. Further, the high initial temperatures in such processes (approx. 50 °C) enable the growth of thermophilic lactic acid bacteria but not yeast. Later, when the temperature falls towards the range suitable for alcoholic fermentation, mesophilic bacteria take over. Kunun-zaki has a pH of below 5.0 and a

titratable acidity around 0.1–0.2%. The predominant microorganisms are the bacteria *Lactobacillus plantarum* and *Bacillus subtilis*, whereas yeast numbers are low. Zaki means sweet in Nigerian Hausa language and the product is often spiced with ginger, cloves, and pepper, then sweetened.

Industrial Sorghum Beer Brewing

Industrial sorghum beer brewing was initiated by municipal governments in South Africa and Zimbabwe in the early part of the 20th century. However, the adaptation of the traditional craft to factory scale was hampered by technical difficulties. In 1954, the Council for Scientific and Industrial Research (CSIR) in South Africa was commissioned to undertake applied research on behalf of the municipal sorghum beer brewers. This technical assistance aided a spectacular increase in scale from home brewing (approximately 50–200-l brews) to factory brewing (approximately 15 000–27 000-l brews), made possible largely by the development and institution of carefully specified raw material standards and the use of specialized equipment. Modern sorghum beer brewing equipment allows rapid heating and cooling, enabling the key brewing steps to be split into separate unit operations and conducted under optimal conditions of temperature (Figure 5).

Malting

The first major problem encountered in scaling-up sorghum beer production related to the quality of the sorghum malt. At that time, virtually nothing was known about the science and technology of sorghum malting. Because sorghum and millet malt contains substantially lower levels of β-amylase than barley malt and amylase activity can be limiting in sorghum beer brewing, the CSIR researchers developed a sensitive method of determining the

Figure 5 Modern industrial sorghum beer brewery. Courtesy of Traditional Beer Investments of Johannesburg, South Africa. diastatic power (i.e., the joint level of α- and β-amylase activity) of sorghum malts. The assay remains the most important quality parameter for sorghum malt.

The malting process is physically split into three unit operations: steeping, germination, and drying. Steeping is carried out in steel tanks of several thousand liter capacity. The grain is soaked in water for a period of normally between 6 and 24 h. The water is aerated to assist the grain respiration and may be changed at intervals to allow the grain to respire in air and also to clean it.

As sorghum malt of high and consistent quality is required as an ingredient in industrial brewing, today most is produced in modern pneumatic maltings and is referred to as 'conversion' or 'industrial' malt. The steeped grain is germinated indoors, under conditions of controlled temperature, moisture, and aeration to produce malt to a diastatic power specification of 28–35 sorghum diastatic units (SDU) per gram. The principle of pneumatic malting is that air is blown through the bed of grain by means of a powerful fan. The air aerates the grain, removes carbon dioxide, and maintains it at an even temperature. Another type of malt used in industrial brewing, referred to as 'souring' malt, serves as a source of lactobacilli and as a substrate for lactic acid fermentation. Souring malt is generally produced by germinating sorghum grain outdoors on a concrete floor (floor malting) and as a consequence is generally of lower diastatic power than conversion malt.

The malt is normally dried by blowing heated, dry air through it, at temperatures no greater than 50 °C, until the moisture content of the malt is approximately 10%. Drying at this low temperature helps conserve the amylase activity of the malt. Alternatively the malt can be sun-dried.

Modified Reef-Type Brewing Process

Several different industrial brewing processes are used in southern and eastern Africa, as a result of differences in the taste preferences of the customers, and differing levels of brewing skills and equipment in the breweries. The most common is the Reef-type process (Figure 6), originally developed in the gold-mining region of South Africa known as the Reef, and later modified to include a second cooking and mashing stage.

Souring In South Africa, the lactic acid fermentation (souring) is an essential part of the brewing process. Souring is generally performed by incubating a 10% slurry of 'souring' sorghum malt at 48–50 °C. This favors the growth of thermophilic, homofermentative *Lactobacillus delbreuckii* (*leichmannii*). The sour is normally inoculated with a portion of a previous, successful sour containing high levels of viable lactic acid bacteria – a process of backslopping. Some breweries, however, use specially prepared freeze-dried cultures. The lactic acid sour lowers the pH of the beer to below 4.0, which helps to prevent the complete hydrolysis of starch into sugars, slows the rate of microbial spoilage, and inhibits the growth of pathogenic organisms. The sour also contributes to the beer's characteristic flavor. Breweries in other countries generally simply add industrially produced lactic acid during the brewing process.

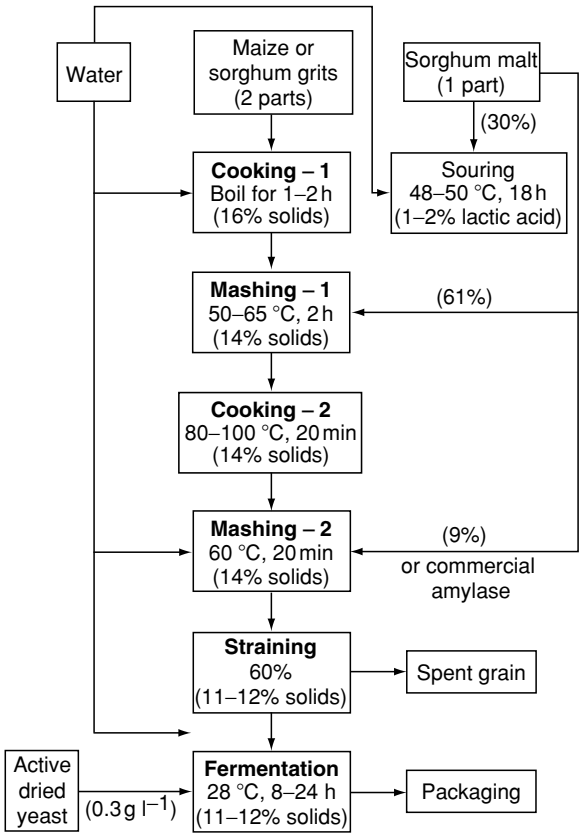

Figure 6 Modified Reef-type sorghum beer brewing process. Reproduced from Fermenting Foods: Beverages from Sorghum and Millet, *Encyclopaedia of Food Microbiology*, Robinson RK, Batt CA and Patel PD (eds), 2000, Academic Press, with permission.

Cooking After the lactic acid fermentation the sour is diluted with water, then maize and/or sorghum meal is added as a starchy adjunct and the mixture is boiled for approximately 1–2 h under atmospheric conditions, or for less time under pressurized conditions, to gelatinize the starch. Industrial brewers in South Africa generally use highly refined maize grits (low-fat endosperm meal) as adjunct. The use of whole, unrefined grain has been largely abandoned owing to the high fat content of the grain, which causes rancidity problems when stored in a milled

form. The high fat content also negatively affects the beer foam. Outside South Africa, the use of less-refined meal, or even whole milled grain is still the norm.

Mashing The mash is cooled to approximately 60 °C with cold water. Conversion malt is then added. As a consequence of the action of the malt α-amylase (EC 3.2.1.1) converting the gelatinized starch to dextrins, the mash is very rapidly liquefied. The β-amylase in the malt hydrolyzes the dextrins to maltose, a fermentable sugar. The low pH of the mash (about 4.0) is below the optimum for sorghum α- and β-amylase activity, which limits starch hydrolysis, preventing the production of too thin a beer and limiting the potential alcohol content of the beer. Some industrial brewers supplement or substitute costly conversion malt with less expensive commercially produced amylase enzymes (α-amylase and/or amyloglucosidase), to facilitate the thinning of the mash and fermentable sugar production. Mashing is carried out for about 2 h at constant temperature (50–65 °C).

Second cooking and mashing The gelatinization temperature of sorghum starch is 68–72 °C. Therefore under the conditions of mashing in the previous step, the sorghum malt starch is not gelatinized. In the modified Reef-type brewing process the mash is recooked (80–100 °C for approximately 20 min). This second cooking stage pasteurizes the mash and also gelatinizes the sorghum malt starch, leaving virtually no ungelatinized starch in the mash. Thereafter, the mash is cooled to 60 °C and a second short mashing period (approximately 20 min) is carried out either with a small amount of conversion malt or commercially produced amylase. The second cooking and mashing steps effectively increase the amount of beer that can be obtained from a given quantity of malt.

Straining Straining removes the coarse cereal particles from the wort, and is normally carried out directly after mashing and prior to fermentation. Industrial brewers strain the mash at elevated temperature using centrifugal decanters and vibrating screens. Before straining there are approximately 14% solids in the mash and after straining approximately 11–12% solids remain in the wort.

Alcoholic fermentation Plate or tubular heat exchangers are used to cool the strained wort to 28 °C. The wort is transferred to stainless-steel vessels and alcoholic fermentation is brought about by pitching with commercially produced yeast (0.3 g l^{-1}). For convenience, active dried yeast is generally used. This yeast is a strain of *Saccharomyces cerevisiae*, specially selected for its ability to ferment sorghum beer rapidly. It is a top-fermenting, nonflocculating type. The pitched wort is then allowed to ferment for 8–24 h. Unlike clear lager beer, sorghum beer is not filtered.

Serving Sorghum beer may be transported by road in bulk (100–500 l) for sale in beer halls as draft beer. Alternatively, the beer is packaged in milk-type cardboard cartons or plastic containers (0.5–25 l) for sale in the retail market. The containers may be returnable and reusable or one-trip, nonreturnable, depending on the market. However, all are characterized by having a small vent in the top to allow the escape of the carbon dioxide produced by fermentation. When ready for consumption, sorghum beer has an alcohol content of approximately 3% by weight. The shelf-life of the product is approximately 5–10 days after straining. Beyond this time, the beer is 'flat' and has settled out, and is frequently spoiled by microbial infection.

Variations in Industrial Brewing Process

In central Africa, the sorghum beer brewing process is much simpler than that described above. Commercial enzymes only are used to convert the adjunct. Whole milled maize is used as the cereal ingredient, although a little sorghum or millet grain may be added for color and flavor. There is no souring step and in some cases no lactic acid addition either. The beer is also often not strained.

Industrial Nonalcoholic Beverage Production

In view of the commercial importance of mageu – some 100 million liters are produced annually – its industrial production will be described, despite the fact that strictly speaking, mageu is an almost exclusively maize beverage, although it can be made from sorghum. Research by scientists of the CSIR and private industry in South Africa in the 1960s led to today's manufacturing process (**Figure 7**). After the maize meal has been cooked to gelatinize the starch, wheat flour (a source of β-amylase to produce maltose) and/or cane sugar is added to promote fermentation. Fermentation is by a commercial thermophilic lactic acid bacteria culture that only produces lactic acid. An interesting development is the widespread use of artificial flavoring in mageu – flavors such as banana, cream, ginger, and guava are popular. The mageu is either pasteurized and/or chemical-preserved to extend its shelf-life and, like sorghum beer,

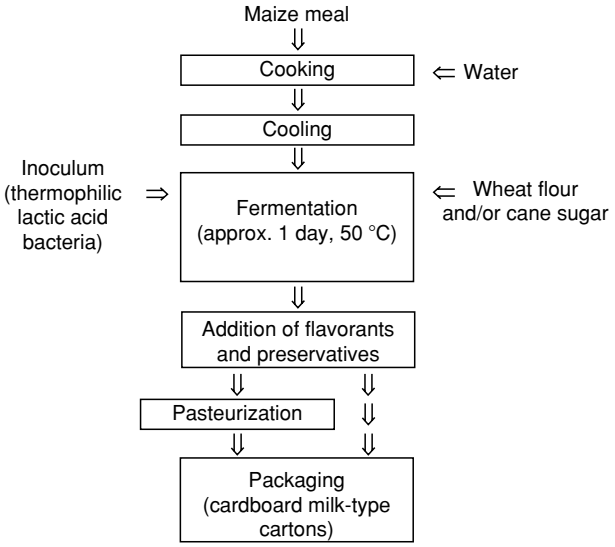

Figure 7 Process for the industrial manufacture of mageu. Reproduced from Fermenting Foods: Beverages from Sorghum and Millet, *Encyclopaedia of Food Microbiology*, Robinson RK, Batt CA and Patel PD (eds), 2000, Academic Press, with permission.

packaged in milk-type cartons. An alternative mageu-making process involves the use of pregelatinized maize meal, produced by extrusion cooking or gun puffing, which obviates the need for cooking equipment. The use of this so-called powder mageu is ideal for preparation in institutions such as mine hostels or hospitals.

Nutritional Aspects

The nutritional value of fermented beverages is influenced to a great extent by two factors, neither of which is associated with fermentation. These are the concentration of cereal solids, and the degree to which the cereal has been refined. The total solids content of commercial mageu is between 5% and 8%, rather lower than the sugar content of many carbonated soft drinks. Higher concentrations are not possible, as the starch would increase the viscosity of the product to that of a porridge. As stated, there is a trend for industrially manufactured fermented beverages to be made with maize endosperm meal rather than partially processed or milled whole grain. Research has shown that brewing sorghum beer with maize grits (the common practice in South Africa) as adjunct substantially reduces its vitamin B and mineral content.

Advantages of Lactic Acid Fermentation

Many nutritional advantages have been claimed for the lactic acid fermentation of cereal beverages and porridges. These include improved starch digestibility, increased protein quantity, improved protein quality and digestibility, increased vitamin levels, decreased antinutritional factors such as tannins and phytate, improved mineral availability, production of bacteriocins and prebiotics, source of probiotic microorganisms, and improved palatability and acceptability. Unfortunately, there are few firm data on the extent of these nutritional improvements. Probably the most unequivocal advantage of lactic acid fermentation is the reduction in pH. Sorghum beer and mageu have a pH of around 3.5. At this low pH, pathogenic bacteria such as *Salmonella typhimurium* are destroyed, heat-resistant bacterial spores do not germinate, and the rate of growth of spoilage bacteria is much reduced. Because many households in Africa still do not have access to potable water and few have refrigerators, these beverages are a valuable safe source of nutrition.

Sorghum Beer

Disregarding the question of whether the consumption of any alcoholic beverage is nutritionally desirable, the nutritive value of sorghum beer is here compared with that of lager beer. There is little evidence, certainly with respect to commercial sorghum beer, to support the often-quoted statement that sorghum beer is more of a food than an alcoholic drink (Table 1). However, sorghum beer has some obvious and not so obvious nutritional advantages. Although the energy content of the two beers is similar, sorghum beer has less ethanol and substantially more complex carbohydrates. The protein content of sorghum beer is much higher, and much of this is yeast protein, which has a better essential amino acid content than cereal protein. The higher thiamin and riboflavin levels are also due to the presence of yeast. The lower nicotinic acid level is due to the use of a high proportion of maize in the grist. The high levels of iron and some other minerals in sorghum beer are the consequence of leaching-out of vessels, because of the low pH of the beer. This can also be disadvantageous. In small-scale brewing where mild steel (as opposed to stainless-steel) vessels are commonly used, excessively high levels of iron have been found in the beer. A benefit of sorghum beer consumption not shown is that, uniquely among beers, it contains measurable quantities of both insoluble and soluble dietary fiber.

Future Directions

As mentioned, these traditional fermented beverages remain popular on the African continent. However, in South Africa there is clear evidence that their industrial production is declining, apparently due to competition from western products such as lager beer and

carbonated soft drinks. The traditional beverages suffer from a number of technical defects, especially variable quality, short shelf-life and inappropriate packaging. These defects are not insurmountable. For example, bottled, pasteurized sorghum beer has been developed. More importantly, however, traditional beverages have a poor image, especially among affluent younger people. The sorghum beer industry in southern Africa is addressing both these problems by attempting to raise the technical standard and status of its personnel to that in the lager beer industry. The CSIR and the University of Pretoria in South Africa run training courses in sorghum malting and sorghum beer brewing technologies. Several hundred people from all over southern and eastern Africa have attended these course and the sorghum beer technology course is becoming a requirement for brewers in the industry.

Because sorghum and millets are uniquely suited to cultivation in the semiarid tropics, there is considerable interest in Africa and India in using them as a replacement for imported barley in the production of lagers, stouts, and distilled beverages. In 1988 the government of Nigeria banned the importation of barley malt. Today in Nigeria, lager beers are produced using unmalted sorghum grain as the sole cereal source. Commercial amylases and proteases are used to produce sugars and free amino nitrogen from the sorghum grain starch and protein. In addition, research and development is being undertaken worldwide to produce clear lager-type beers using malted sorghum, which would itself provide the necessary hydrolytic enzymes.

Soy (Soya) Sauce

M Sasaki and N Nunomura, Kikkoman Corporation, Noda City, Japan

Background

'Shoyu' is the Japanese name for soy sauce. It is made mostly by fermentative methods and is used mainly as an all-purpose seasoning in Japanese cuisine.

In Japan the total production is about 1.04 million kiloliters (kl), against a total population of 125 million. The annual consumption of shoyu per capita is about 8.3 l, of which 3.5 l are consumed in the home and the remaining 4.8 l institutionally and industrially (1999). The consumption volume in Japan is decreasing slightly, but that in American and European area is increasing.

There were 5363 manufacturers in 1957, but by 1999, the number had decreased to 1611. Five large companies together produce about one-half of the total shoyu. Five different types of shoyu are available in Japan: koikuchi, usukuchi, tamari, shiro, and saishikomi.

Koikuchi is made from a mixture of soya beans and wheat kernels in almost equal amounts, and is characterized by a deep reddish brown color and a strong, pleasant aroma. Low-salt shoyu of koikuchi is also enjoyed, and its consumption is growing. It contains half the salt of regular koikuchi shoyu, and it is considered to be healthier.

Usukuchi is characterized by a lighter brown color and milder flavor than koikuchi. It is used mainly for cooking, especially when the original color and flavor of the foodstuff are to be maintained.

Tamari is characterized by a high content of amino acids, and has a dark brown color and distinctive flavor. It is made from soya beans with only a small amount of wheat in the ratio 10:1–2. It is only consumed around the Nagoya region of Japan as a cooking and dipping sauce for several typical Japanese dishes, such as raw fish ('sasimi' in Japanese) and broiled eel ('kabayaki' in Japanese). One of the characteristics of Japanese-type shoyu is the use of almost equal amounts of soya beans and wheat as raw materials. Tamari represents the Chinese type and originates from China. In contrast, shiro is made from wheat with only a small amount of soya beans in the ratio 10:1–2. It is characterized by a very light yellow color, and it has a very low amino acid content and very high sugar content. It is used mainly for cooking and is only consumed around the Nagoya region. Saishikomi is produced from equal amounts of wheat and soya beans in the koji, and raw shoyu is used instead of brine. It is used mainly as a dipping sauce.

Table 1 Production of six kinds of shoyu (Japan Agricultural Standard (1999))

Type	*Amount (kl)*	*Market share (%)*
Koikuchi	686 171	82.9
Usukuchi	115 848	14.0
Tamari	15 233	1.8
Shiro	5 949	0.7
Saishikomi	4 610	0.6
Total production	827 811	100.0

The annual production of the five kinds of shoyu, recognized as being of a quality equal to the Japan Agricultural Standard by the Japan Soy Sauce Inspection Institute in 1999, is shown in Table 1.

As shown in Table 1, about 83% of all shoyu is of the koikuchi type, and thus this type of soy sauce is regarded as the typical Japanese shoyu. The preparation of koikuchi is described below.

History

The origin of shoyu is considered to be from a Chinese food, called 'sho' in Japanese. The first description of sho was found in the book 'Shurai' (in Japanese), which was written in China 3000 years ago. According to this book, sho was made by aging a mixture of mold culture, foxtail millet, dried meat, and a liquor in a bottle for 100 days. The final product was in the form of a mash or 'miso,' which is now one of a number of typical fermented foods in Japan (a semisolid salty food made from soya beans, rice or barley, and salt by fermentation). Soya beans are not described in the book as one of the raw materials of sho, but it is quite possible that soya beans were used, because it is known that soya beans were widely cultured in China 4000 years ago. The first documentation for the clear liquid part of sho is in the Chinese book 'Chin-Min-Yao-Shu' (Saimin-Yojutsu in Japanese) written in the sixth century AD. Sho or hishio was also made from fish and salt at the beginning of Japanese history. Sho made from soya beans is presumed to have been introduced from China into Japan along with other foods by the Chinese Buddhist priest Ganjin (AD 1254). The first record of the name 'shoyu' appeared in 'Ekirinbon-suyoshu' (AD 1595), and it is likely that the basic manufacturing process of today's Japanese-type shoyu was derived by the early seventeenth century. In the Edo era (1603–1867) of Japan, the technology for preparing shoyu developed dramatically and the scale of production increased. However, remarkable improvements in the processing of shoyu have taken place since 1950, with dramatic advances in both biochemistry and technology.

Shoyu was exported to The Netherlands from the port of Nagasaki for the first time in 1668, and, at present, it is exported to 94 countries as a seasoning of world-wide appeal.

Outline of the Manufacturing Process of Koikuchi Shoyu

The process for production of koikuchi consists of five major steps: treatment of raw material, koji making, mash fermentation and aging, pressing and refining, and pasteurization. Among the steps, koji making, mash fermentation, and pasteurization are the most important and difficult processes in shoyu production.

The manufacturing process is shown in Figure 1.

Raw Materials

The amounts of raw materials used for shoyu production in Japan in 1997 are listed in Table 2.

Soya beans Soya beans originated in the East, and the cultivated soya beans, e.g., *Glycine max*, have been derived from *Glycine ussuriensis*, which is a wild species growing in eastern Asia. (*See* **Soy (Soya) Beans: The Crop; Processing for the Food Industry.**)

Whole and defatted soya beans contain approximately 33 and 45% (w/w) protein, respectively. The key component for shoyu production is protein, and about three-quarters of the total nitrogen in shoyu originates from soya beans.

At least 60–70% of the total protein in soya beans is accumulated in particles called 'protein bodies' or aleurone grains in the developing cotyledons. About 90% of the seed protein (about 36% of seed dry weight) is composed of globulins. The globulins are a complex mixture of compounds, and the major difference between the proteins is the molecular size, as separated by ultracentrifugation. The 7S and 11S fractions make up about 70% of the total globulins; the minor constituents are 2S (15%) and 15S (9.1%). The 7S fraction consists of β- and γ-conglycinin (35%), as classified by serological characteristics, whilst the 11S fraction consists of glycinin (41.8% of the total globulins). (*See* **Protein: Chemistry.**) The major components of the soluble carbohydrate fraction in the mature soya bean seed are: sucrose (41.3–67.5%), stachyose (12.1–35.2%) and raffinose (5.2–15.8%). Soya bean oil consists of 94–97% fatty acid glycerides, together with 1.6–2.3% phospholipids. (*See* **Carbohydrates: Classification and Properties; Fatty Acids: Properties; Phospholipids: Properties and Occurrence.**)

Wheat Wheat belongs to the genus *Triticum* of the family Gramineae (the grasses). The origin of the wheat is not entirely certain, but cultured species

Table 2 Raw materials used for shoyu production in Japan (1999)

originated in prehistory. Cultivation of wheat is believed to have originated in the mountainous regions of Syria and the area formerly part of Palestine of the Middle East. (*See* **Wheat**: The Crop; Grain Structure of Wheat and Wheat-based Products.)

Wheat is commercially divided into seven classes on the basis of botanical species, habit of growth and color: hard red winter wheat, hard red spring wheat, soft red winter wheat, soft red spring wheat, hard white winter wheat, hard white spring wheat, soft white winter wheat, and soft white spring wheat.

Hard wheat is more suitable for making shoyu, because the protein content is higher than in soft wheat. The carbohydrates in wheat include starch, cellulose, and sugar. Starch, which is by far the most abundant constituent of the carbohydrate fraction, is important chiefly as a source of energy for the koji mold in the koji-making process. The proteins of the starchy endosperm are largely the gluten-forming proteins gliadin and glutenin, both of which are insoluble in water and in aqueous salt solutions. About a quarter of the total nitrogen in shoyu originates from the proteins in the wheat. (*See* **Starch**: Structure, Properties, and Determination.)

Salt The salt should contain as little iron and manganese as possible, because oxidative browning of shoyu is synergistically accelerated by the presence of these elements.

Water Water for shoyu should be clean bacteriologically and chemically. For the same reason as with salt, low iron and manganese contents are preferable.

Treatment of Raw Materials

Soya Beans

The protein in raw soya beans is native and cannot be hydrolyzed by the enzymes of the koji mold, and it is necessary to denature the protein to render it susceptible to enzyme action. Conditions for denaturing the soya beans affect digestibility, i.e., the ratio of the total nitrogen of a shoyu to that of the raw materials, and hence denaturing methods have been vigorously investigated, including the development of machines. As a result, protein digestibility has increased from 60 to 90%.

There were many problems to be solved in improving the digestibility. For example, if soya bean proteins remain partly undenatured, shoyu becomes cloudy when it is diluted with water or heated for cooking. This cloudiness diminishes its commercial value. However, over-denatured soya protein loses accessibility for enzyme reactions; as a result, digestibility is low. The methods of cooking can be classified into five groups, according to the stages of historical development from the first generation to the fourth generation, as described below. (*See* **Protein**: Digestion and Absorption of Protein and Nitrogen Balance.)

First generation (traditional method) Before the nineteenth century, soya beans were soaked and then boiled or steamed at atmospheric pressure. At that time, the digestibility was about 60% for whole soya beans.

Second generation Around 1938, the method of cooking was changed to autoclaving under pressure. Soya beans or defatted soya bean grits were sprinkled with hot water and then cooked at a gauge pressure of $0.8\,kg\,cm^{-2}$ for about 1 h. After stopping the steam, the cooked soya beans were kept in the cooker overnight with the valve unopened.

The digestibility was, at best, about 66% for defatted soya beans, because of overdenaturation of the protein.

Third generation The method that characterizes the third generation was invented by Tateno and coworkers (1955) and is called the 'NK method.'

Thoroughly moistened soya beans or defatted soya bean grits were cooked in a rotary cooker under a pressure of $0.8\,kg\,cm^{-2}$ for 45 min, and then immediately cooled to below 40 °C by reducing the inside pressure with a jet condenser. This technique considerably increased the protein digestibility from 66 to 87% for defatted soya beans.

This method contributed greatly to the development of techniques for treating the raw material.

Fourth generation (high-temperature/Short-time (HTST) method) (1970) For convenience, this technique is divided into the following two methods.

Method 1 Thoroughly moistened soya beans are cooked under a higher pressure and a shorter time than with the NK method, using saturated steam, i.e., $2.0–7.0\,kg\,cm^{-2}$ for 15 s to 5 min.

The protein digestibility using this method is 84.24 ($2\,kg\,cm^{-2}$, 5 min) to 89.70% ($6\,kg\,cm^{-2}$, 0.5 min) for defatted soya beans.

Method 2 Soya beans are cooked without water using superheated steam at a gauge pressure of $4–8\,kg\,cm^{-2}$ at 220–287 °C for atleast 15 s.

The protein digestibility is almost the same as that recorded for method 1 using saturated steam, but this method has the advantage of making it possible to store the heat-treated raw materials.

Others The treatment of soya beans with water containing ethanol was investigated, but this method was not used because of a large number of problems.

The extruder method has been used and has been found to be suitable for small quantities of material.

Wheat

Wheat kernels are roasted without adding water. In the past, roasting was carried out in an iron pan, but this method was replaced with a continuous roaster at the beginning of the 1900s. Nowadays, the HTST method, described above, is employed. Control of the process is important. If the wheat is insufficiently roasted, the raw starch cannot be digested by the amylase from the koji mold. However, if the wheat is over-roasted, the protein digestibility decreases.

The roasted wheat kernel is coarsely crushed into flour or fine pieces.

Koji Manufacture

The main purpose of this process is to produce the enzymes needed for hydrolysis of the raw materials. Many nutrients for the yeasts and lactobacilli that multiply in the next stage, and some flavor components that influence the quality of shoyu are produced in this process.

Procedure

Nearly equal amounts of cooked soya beans and roasted, crushed wheat (6:4–4:6) are mixed and inoculated with a pure starter culture of *Aspergillus*

oryzae or *A. sojae* – the so-called koji starter or seed mold. The inoculated mixture is then transferred to the equipment for koji cultivation, and spread on to large perflorated stainless steel trays (3 (wide) × 12 (long) × 0.6 (high) m) to a depth of 30–40 cm, and then incubated in a room at 25–30 °C for 2–3 days. During this period, the temperature, moisture, and aeration are controlled to allow the seed mold to grow on the mixture, and to promote the production of enzymes. A temperature above 35 °C leads to a decrease in enzyme production and, sometimes, to death of the koji mold. The temperature of the koji is controlled by stirring. The first stirring is performed at about 20 h, and the second at about 25 h, after inoculation. The resulting end product (clear yellow to yellowish green in color) is 'koji.'

The method described above is a batch system. In recent years, an advanced system for continuous koji cultivation has been developed and employed industrially.

Koji Molds

The koji molds used for shoyu are *A. oryzae* and *A. sojae*. These species differ not only in their conidial morphology, but also in several physiological characteristics of shoyu-manufacturing importance. Generally, *A. oryzae* is characterized by a high productivity of α-amylase, and *A. sojae* is characterized by a high productivity of protease. *A. oryzae* is used not only for shoyu production, but also for the other Japanese fermented foods, such as 'miso' and 'sake.' However, the use of *A. sojae* is limited to shoyu manufacture. However, about four times as many manufacturers use *A. oryzae* than *A. sojae*.

The breeding of koji molds has been investigated, using mutation, crossing, and protoplast fusion, in an attempt to increase their enzyme productivities. At the present time, several koji molds with a high enzyme productivity of protease and amylase are used to ensure a high productivity of the whole process.

Since the discovery of aflatoxin, the question has arisen as to whether or not koji molds produce this carcinogenic mycotoxin. The results of a large number of investigations have proved that no Japanese industrial strains of koji mold produce this toxin. (*See* **Mycotoxins**: Occurrence and Determination.)

Mash Manufacture and Aging

Procedure

The mixing of koji and brine is called 'shikomi' in Japanese, and the mixture is called the 'moromi' mash. The salt content in the brine is 23–25%, and the ratio of brine to koji is usually 1:1.2–1:1.3 (v/v).

The koji and brine are measured simultaneously, and the mixture is pumped into deep fermentation vessels. Wooden casks of 5–10 kl, or 10–20 kl concrete tanks, were once used as fermentation vessels, but recently, they have been replaced with resin-coated, iron tanks of 50–300 kl or fiber-glass tanks of 30–100 kl. This moromi mash is stirred by air pressure to prevent salt-tolerant lactobacilli and wild yeasts from growing.

At one time, shoyu was manufactured over the four seasons. Koji and the mash were prepared in February or March at a room temperature of 5–15 °C, and the mash was fermented and aged from spring to autumn. The shoyu that was brewed under these conditions contained larger amounts of total nitrogen and amino acids, but only a moderate amount of lactic acid. On organoleptic evaluation, it was considered better than shoyu brewed in the other seasons. Nowadays, in modern shoyu factories, in order to produce an excellent-quality shoyu and reduce the fermentation period, the temperature of the mash is controlled; the control simulates the temperature changes of a mash brewed from spring to autumn. The koji is first mixed with brine at about 0 °C to keep the temperature of the mash below 15 °C for several days. Selected salt-tolerant lactic acid bacteria (*Tetragenococcus halophilus*) are added as a starter, and then the temperature is gradually raised to 28–30 °C after 20–30 days. During this period, a salt-tolerant yeast, such as a pure culture of *Zygosaccharomyces rouxii*, is added. After the vigorous alcoholic fermentation has finished, the temperature is dropped again and kept at around 25 °C over the final 2 months. The addition of *Candida (Torulopsis)* yeasts is recommended to obtain a good 'volatile' flavor in the final product. A period of 6–8 months is necessary to complete fermentation and aging. In the past, fermentation was carried out without the addition of lactic acid bacteria or yeasts. Natural conditions controlled the fermentation by adventitious bacteria and wild yeasts. (*See* **Lactic Acid Bacteria**.)

Chemical Changes in Mash Fermentation

In the early stages of mash fermentation, proteins from the raw materials are hydrolyzed to lower-molecular-weight peptides and free amino acids.

Approximately 20% of the starch from wheat is consumed by the molds during koji fermentation, and the rest is retained for the moromi mash. Most of this remaining starch and the other carbohydrates from wheat are converted to hexoses and pentoses in the moromi mash. A proportion of these sugars is subsequently metabolized into lactic acid, acetic

acid, and other organic acids by lactobacilli. As a result, the pH drops from an initial value of 6.7–7.0 to 4.7–4.8.

In the next stage, vigorous alcoholic fermentation (from the action of the yeast *Z. rouxii*) occurs, and the remaining sugars are metabolized into ethanol and a number of minor flavor compounds. For example, *Candida versatilis* or *C. echellsii* converts ferulic acid and 4-hydroxycinnamic acid from wheat to 4-ethylguaiacol and 4-ethylphenol, which enhance the quality of shoyu.

As described above, the dominant species of yeasts found in the mash are *Tetragenococcus halophilus*, *Z. rouxii*, *C. versatilis*, and *C. echellsii*. The major properties of these microbes are listed in Tables 3 and 4.

Pressing

The fermented mash is put into a cloth, and the liquid part is squeezed out under hydraulic pressure, which sometimes reaches 100 kg cm^{-2}, for 1–3 days. The difficulty of pressing shoyu mash is due to the viscosity of more than 300 cps.

The liquid part of the mash is called raw shoyu, or 'nama-shoyu' in Japanese. The residue from the pressing is called shoyu cake, or 'shoyu-kasu' in Japanese. This can be used as an additive in animal feed. The final moisture content of shoyu-kasu is less than 25%. At one time, pressing required large amounts of labor compared with the other processes, but today, very efficient and automatic machines are available.

Refining

The raw shoyu is stored in a tank and separated into three layers: (1) sediment at the bottom, (2) clear shoyu in the middle, and (3) an oily layer at the top. The oil layer is called shoyu oil, or 'shoyu-abura' in Japanese, and is removed by decanting. The middle layer, clear shoyu, is heated at 115–120 °C for a few seconds in a heat exchanger in order to kill any vegetative microbial cells, denature enzymes, coagulate proteins, develop the agreeable reddish brown color, and generate aroma.

The clear shoyu is then filtered, bottled, and marketed.

Retail Product

Chemical Composition

The chemical compositions of various types of shoyu are presented in Table 5.

Aroma and Flavor Compounds

All the production processes are related to the formation of flavor compounds, i.e., the heat treatment of raw material, koji culturing by molds, lactic acid fermentation, yeast fermentation, aging of the moromi mash, and pasteurization. Among these processes, yeast fermentation in the moromi mash and pasteurization contribute most to aroma and flavors. (*See* **Sensory Evaluation**: Aroma; Taste.)

The first attempt to identify the flavor compounds of shoyu was made by Tahara in 1887. Since then, many studies on shoyu flavor have been reported, and, to date, over 300 volatiles have been detected. Among them, caramel-like aroma compounds, such as furanones, and phenolic compounds contribute most to the flavor of Japanese shoyu. (*See* **Phenolic Compounds**.)

4-Hydroxy-2(or 5)-ethyl-5(or 2)-methyl-3(2H)-furanone (HEMF) was isolated for the first time from the natural product (1976). It has an intense, sweet aroma and a shoyu-like flavor. As it is present at high levels (100 p.p.m.) in shoyu and has the lowest threshold of detection in water (less than 4×10^{-5} p.p.m.) among the compounds found in shoyu, the aroma value (the concentration of component/the threshold concentration of component in water) is calculated to be $> 5 \times 10^{6}$. Accordingly, it is a significant contributor to shoyu flavor and is believed to be a 'character impact compound' of shoyu.

In the 1990s, HEMF has been found in various foods such as miso (1991), Emmental cheese (1994), lager beer (1996) and coffee (1993), but the levels in these foods are much lower than that in shoyu. The homologs of HEMF, 4-hydroxy-2,5-dimethyl-3(2H)-furanone (HDMF), and 4-hydroxy-5-methyl-3(2H)-furanone (HMMF) have also been isolated from shoyu. The amount of HDMF in shoyu is very low (about 10 p.p.m.), but HMMF is present at high levels (100 p.p.m.). HDMF is found in many foodstuffs, such as pineapple, strawberries, roasted almonds, and beef broth, and in various model systems, such as the degradation of fructose, the pyrolysis of D-glucose, and roasting of alanine and rhamnose. Similarly, HMMF is found in many foodstuffs, such as beef broth, wild raspberries, and guava fruit, and in various model systems, such as the degradation of L-dehydroascorbic acid, and roasting of glycine and xylose. The formation of these compounds by a nonenzymatic reaction has been proved.

HDMF and HMMF in shoyu are probably formed from sugars and amino acids during heating processes, such as the heat treatment of the raw materials and the pasteurization of the liquid part of the mash. However, HEMF is presumed to be biosynthesized through the pentose phosphate cycle by shoyu yeasts. Not only shoyu yeasts but also the other yeasts employed for alcoholic beverages and single-cell protein can change intermediates, such as D-ribulose 5-phosphate, to HEMF. Moreover, it has been proved that D-xylulose 5-phosphate, one of the intermediates in the pentose phosphate cycle, is present in both the enzymatic hydrolysates of isolated soya bean protein and in shoyu moromi mash before the growth of yeasts in shoyu fermentation, and is the precursor for HEMF.

The amount of HEMF produced depends greatly on the concentration of sodium chloride in the shoyu. The highest productions occurred at a sodium chloride concentration of 17–18%.

HEMF has also been reported to show antitumor activity.

Phenolic compounds, such as 4-ethylguaiacol and 4-ethylphenol, have an important relationship with the aroma of shoyu. These compounds are derived from ferulic acid and 4-hydroxycinnamic acid in koji, respectively, by the action of *Candida (Torulopsis)* yeasts. Based on the results of sensory evaluations, the optimum concentration of 4-ethylguaiacol has been found to be 0.8 p.p.m. in shoyu.

Many aldehydes, such as isobutyraldehyde, isovaleraldehyde, and so on, increase during pasteurization, as a result of the aminocarbonyl reaction and Strecker degradation. The aroma derived from pasteurization is called 'fire aroma,' or 'Higa' in Japanese.

The typical quantitative analysis of koikuchi shoyu is shown in Table 6.

Shoyu flavor consists of HEMF and other minor components, and, whilst HEMF gives the fundamental flavor, many minor components such as 4-ethylguaiacol give the product character.

Color

The color of fresh koikuchi-type shoyu is deep reddish brown, and it is very sensitive to oxidation. The color of shoyu packed in bottles or cans is usually stable but darkens rather quickly after opening the seals. During the brewing process, the development of shoyu color derives mainly from nonoxidative browning reactions, but after opening the seals, it is mainly due to oxidative and nonenzymatic browning reactions between amino acids and sugars, which are

themselves related to flavor in shoyu. In particular, these oxidative reactions give rise to an inferior organoleptic quality of shoyu, in that the existence of oxygen leads to a decrease in the number of 'good' flavor compounds, such as HEMF and HMMF, and an increase in the number of off-flavors resulting from isobutyric acid, isovaleric acid, and many pyrazine compounds. To preserve flavor and color, it is important to store shoyu at a cool temperature. (*See* **Browning**: Nonenzymatic.)

Safety

The main concern with the safety of Japanese shoyu is the long-term effects of consumption, and whether or not shoyu contains mycotoxins and mutagens.

Mycotoxins As strains of *A. oryzae* or *A. sojae* are taxonomically related to aflatoxin-producing molds, the question has arisen as to whether or not the molds produce aflatoxins. Fortunately, chemical, enzymatic, and molecular biological research has shown that none of the koji molds produce aflatoxins. Moreover, the possible presence of other mycotoxins, e.g., ochratoxins, sterigmatocystin, patulin, cyclopiazonic acid, and penicillic acid, in shoyu has been checked, and results have indicated that, with the exception of very few strains that produce cyclopiazonic acid, koji molds do not produce such toxins.

Long-term effects of shoyu consumption The long-term effects of feeding rats shoyu and its effects on the gastric mucosa have been evaluated. Animals fed shoyu were smaller than the controls, but were healthier, more active, and lived longer. Breast tumors developed in 10 control rats, but none developed in those fed shoyu, and it was concluded that shoyu did not appear to be a carcinogen in rats. Moreover, the acute toxicity of shoyu was explained as being due to its sodium chloride content.

Mutagens After an investigation of mutagens in shoyu using the Ames test, it has been found that shoyu treated with nitrite at a concentration level detected in the human mouth, i.e., less than 50 p.p.m., did not induce any mutagenicity, though mutagenic material was formed in shoyu when 2000 p.p.m. of nitrite was present at pH 3.0. It was concluded that shoyu cannot be an inducer of mutagenicity at the level of human consumption.

South-east Asian Countries

China The annual production of soy sauce in China was estimated to be 500 000 kl in 1993.

The manufacture of soy sauce in Peking and Shanghai nowadays is different to the traditional method and is as follows. The koji is prepared by a usual method on a large scale, culturing *Aspergillus oryzae* with a mixture of steamed soybeans and wheat or wheat bran (6–8:4–2), and then mixed with salt water to make a hard mash, with a moisture content of about 80% and a salt concentration of about 6–7%. This hard and low-salt mash is kept at 45–50 °C for 20–30 days for enzymatic digestion. The digested mash is extracted with hot salt water (90 °C, Be 17–19) and then with hot water. The salt-free residue is suitable for animal and bird feed. There is no alcoholic fermentation of mash or pressing of the mash, as there is in Japanese shoyu manufacture. The yield of soy sauce on a nitrogen basis is 70–80%. About 80% of Chinese soy sauce is made by this process. There are four governmental standard grades of soy sauce in China, and the standard of the highest grade is as

follows: total nitrogen 1.6%, reducing sugar 4%, sodium chloride 19% or more, respectively.

Acid hydrolysis of plant protein for soy sauce manufacture was forbidden by law in China 1979, because the contents of arsenic acid and hydrochloric acid were too high.

Taiwan The annual production of soy sauce in Taiwan was estimated to be 12 000 kl in 1994, which is equivalent to 6 l per capita per year.

About 80% is the so-called tou-yu, and this is made from soybeans and wheat originating from China. There were 433 soy sauce manufacturing plants in Taiwan in 1978, of which the eight largest producers comprised at least 45% of local market. Soy sauce products include genuine fermented soy sauce (25%), chemically hydrolyzed soy sauce (5%) and blended soy sauce (70%). There are three national standard grades of soy sauce in Taiwan, and their total nitrogen percentages were 1.4, 1.1, and 0.8 g per 100 ml, respectively, in 1994.

Five to 10% of Taiwan soy sauce is estimated to be in-yu, which is made only from black soybeans and very much resembles Japanese tamari, made only from yellow soybeans. The black soybean koji is washed with water, before being mixed with salt water to make a mash so as to remove the bitter taste of the product.

Fermented soybean sauce similar to in-yu and tamari is also produced in the southern part of China and seems to be the prototype of the soy sauce prepared only from soybeans. Tamari mash is fermented usually in wooden kegs in Japan, but the soybean sauce in Taiwan, Thailand, Singapore, Malaysia, Indonesia, and the southern part of China is fermented in China jars (approximately 150 l in volume) and in the sunshine.

Korea The annual production of soybean sauce in Korea was 420 000 kl in 1996, which included 180 000 kl of industrially produced soy sauce and 240 000 kl of home-made product. The fermented soy sauce produced industrially in Korea is of the Japanese koikuchi type, but about 70% of its production is estimated to be chemically hydrolyzed soy sauce. The home-made soy sauce is prepared by a traditional method, in which cooked soybeans are mashed and made into small balls, which are dried in the sun during the day and kept warm at night for several days in the winter. Molds grow on the surface of the balls and penetrate the interior of the balls, which are then called 'meju.' Sufficiently dried meju is packed in a rice-straw bag for aging for a few months. The aged meju balls are then placed into brine and kept in large China jars in the sunshine for several months for fermentation. The ripened meju–brine mixture is separated into supernatant liquid and sediment residue. The liquid is soy sauce, and the residue is soybean paste, which is sometimes mixed with red pepper. In recent years, better-quality meju has been prepared industrially, in which cooked soybeans are inoculated with *Aspergillus oryzae* mold in a controlled fermentation room. Housewives take the improved meju home and add it to brine to make soy sauce and paste.

Other countries In Singapore, Malaysia, and Indonesia, two types of soy sauce are manufactured: a light soy sauce (in Cantonese 'sung-show' or in Hokkien 'chiuw-cheng'), and a dark soy sauce mixed with cane molasses (in Cantonese 'low-chow' or in Hokkien 'tau-iu'). In Indonesia, soy sauce is called 'keitjap' or 'kecap,' and similarly, two types of kecap are popular in Sumatora and the latter in Java.

The per capita daily consumption of kecap in Indonesia is 10–15 ml. The kecap mash is washed with salt water twice and the mixed extract is concentrated in the sun. The residue from the extraction is used for tauco or miso of an inferior grade, but the genuine tauco is made from soybeans and wheat flour cultured with *Aspergillus oryzae* mold. The molded-cultured material, or 'koji', is dried in the sun, mixed with salt water, and fermented and concentrated in the sun for 3–7 weeks. Tauco is a slurry containing 10% protein, and is sold in glass bottles, thus differing from Japanese miso, which is a paste containing 25% protein. In the aforementioned countries the chemical acid hydrolysate of soybeans and the semichemical or shinshiki soy sauce are also popular, but the amount of extract produced is not known.

FERMENTED MILKS

Contents

Types of Fermented Milks

H Roginski, The University of Melbourne, Werribee, Victoria, Australia

Background

Milk spontaneously fermented with the adventitious microflora has traditionally been consumed in all parts of the world. Historically, fermented milks were made at the same site where the fresh milk was produced, i.e., on farms or near the herds of dairy animals tended by nomadic tribes. Allowing milk to ferment spontaneously was a simple way of preserving milk solids because most spoilage microorganisms do not grow well at pH 4.5 or lower, characteristic of fermented milks. Fermented milk could be stored for an extended period compared with the raw milk. In warm climates, whey was often partly removed from fermented milks to create an environment in which milk solids could be further preserved.

The sensory and physical attributes of traditional fermented milks reflect the local environment and climatic conditions that facilitate the selection of microorganisms that could dominate the microflora of milk. It is a mixed population of lactococci and lactobacilli, and in some cases, also yeasts and molds, which exist together in a protocooperative relationship. As a result of their spontaneous growth, which normally proceeds in a relay-like fashion, where distinctly different groups of microorganisms dominate the milk environment in succession, various metabolites are formed, and these in turn affect the chemical status and physical appearance of the product. The most important of these metabolites is lactic acid, which causes coagulation of casein micelles at pH 4.6. The bacteria that produce lactic acid can be either mesophilic or thermophilic, homofermentative or heterofermentative.

Lactic acid and other metabolites of the milk microflora have a preservative effect on milk, primarily by lowering the pH of milk and, as we now know, through the production of bacteriocins and peptides, some of which may inhibit spoilage microorganisms.

There is archeological evidence that fermentation of milk has been known for millennia. There is also a reference to a fermented milk product in the Bible (Genesis 18:8). Nowadays, a multitude of fermented milks, sometimes also called 'cultured milks,' are produced commercially world-wide. Most of these products reflect long-standing traditions in different parts of the world. Some of these traditional products have gained world-wide acceptance, such as yogurt, which originated in the Balkans, and is now known and produced in most countries.

Also, a number of products have been developed as a result of progress in clinical and industrial microbiology in the last century. Such fermented milks are manufactured with the use of starter cultures for which various health-promoting effects have been claimed.

According to the definition proposed in 1963 by the International Dairy Federation, 'fermented milks are products prepared from milk, skimmed or not, concentrated or not, with specific cultures; the microflora is kept alive until sale to the consumer and may not contain any pathogenic germ.' Such an understanding of the term 'fermented milks' appears to have been commonly accepted in the dairy world. This term implies a liquid or semiliquid consistency of the product and therefore, in common understanding,

does not apply to cheese. The removal of whey in the cheese manufacturing process seems to constitute the most significant demarcation line between 'fermented milks' and cheeses. However, whey is partly removed during manufacture of a small number of products that are traditionally classified as fermented milks.

The majority of known fermented milks are made from cows' milk, but milk from buffaloes, sheep, goats, horses, camels, yaks, reindeer, and asses is also used for this purpose. Fermented milk was originally obtained by mixing fresh milk with the remainder of the previous batch of the product. Most home-made fermented milks are still prepared in this way. Commercial production of fermented milks is not complicated, with the characteristics of the final product being determined chiefly by the metabolic properties of microorganisms used in manufacture and the treatment of milk before the fermentation. A crude empirical selection of cultures for the manufacture of fermented milks began in antiquity, but it was not until the twentieth century that impressive progress was made in starter culture selection and improvement techniques. Knowledge of the physiology of commercially useful microorganisms is still advancing, and this, as well as applications of genetic engineering to starter organisms, will expand the range of technological manipulation of starter cultures and result in a better control of manufacturing process.

Consumption of fermented milks varies widely between different regions of the world. People of Northern and Western Europe have traditionally consumed, for climatic and historical reasons, relatively large amounts of fermented milks. For example, in Finland, the per capita consumption of all fermented milks in 1995 was 38.5 kg, of which 15.5 kg (40%) was yogurt. Consumption of fermented milks is also high in Bulgaria, Israel and several other countries.

Classification of Fermented Milks

Different criteria can be employed as a basis for classification of fermented milks, such as the region of origin, chemical composition and physical characteristics, temperature and type of fermentation, and types of microorganisms involved in fermentation.

Classification of fermented milks proposed by Kurmann, presented below in a modified form, underlies the importance of the starter culture in determining the characteristics of the product:

1. Fermented milks made with thermophilic bacteria, incubation temperature 30/35–40/45 °C.
   1.1. Lactic acid fermentation, without producing appreciable amounts of gas and alcohol.
   Yogurt and similar traditional fermented milks: yogurt (Bulgaria, Turkey, etc.), dahi (India), laben (Saudi Arabia), mast (Iran), matzoon (Armenia), tarho (Hungary), zabady (Egypt). Diluted yogurt: eyran (Turkey), doogh (Iran). Whey-drained (concentrated) yogurt: labneh, lebneh (Lebanon and other Arab countries), kashk, kaskg (Middle East/Iran), tan, than (Armenia), tulum, torba (Turkey), skyr (Iceland). Dehydrated (dried) yogurt: kurut (Middle East/Turkey), karut (Pakistan), quurut (Afghanistan), khurud (Mongolia).
   1.2. Acid fermentation, without producing appreciable amounts of gas and alcohol, using mainly human intestinal bacteria.
   Single-strain fermentation: acidophilus milk, 'bifidus' milk, yakult.
   Mixed-strain cultures of different formulae: AB type (*Lactobacillus acidophilus* and *Bifidobacterium* spp.); ABT type (*Lb. acidophilus, Bifidobacterium* spp., and *Streptococcus thermophilus*); BAP type (*Bifidobacterium* spp., *Lb. acidophilus*, and *Pediococcus* spp.); and other formulations.
2. Fermented milks made with mesophilic bacteria, incubation temperature 10/15–20/30 °C.
   2.1. Lactic acid fermentation with simultaneous production of slime.
   Scandinavian fermented milks: långfil/tätmjölk (Sweden), viili (Finland), tettemelk (Norway), and similar products.
   2.2. Lactic acid fermentation using butter cultures. Fermented milks prepared with butter cultures.
   Artificial buttermilks: 'cultured buttermilk' (which is a type of cultured milk produced in North America) and similar products.
   2.3. Concentrated fermented milks.
   Commercial products, *e.g.*, ymer and lactofil (Scandinavia).
   Traditional home-made milks, *e.g.*, Kellermilch and Lagermilch in German-speaking areas of Europe.
   2.4. Mixed lactic acid and ethanol fermentation.
   Kumys (North Central Asia), leben, laban (Lebanon, Iraq, and Egypt), and other similar products.
   Kefir (Caucasus) made with kefir grains.
   Artificial preparations, *e.g.*, kefir made without grains.

3. Mixed material plant–milk fermentations
   3.1. Products where plant material is a substrate for fermentation
      Kishk (Middle East), niyogurt (Philippines).
   3.2. Products where plant material is claimed to be a carrier of specific microorganisms and/or enzymes.
      Nordic ropy milks.
4. Various unclassified fermented milks.
5. Buttermilks
   5.1. Conventional cultured buttermilk, a byproduct of cultured butter manufacture.
   5.2. Cultured buttermilk obtained by fermentation of a sweet buttermilk.
   5.3. Yogurt buttermilk obtained by churning yogurt into butter and a liquid byproduct
6. Cultured creams

The major classes of fermented milks and their interrelationships can be graphically presented in the form of a 'tree of fermented milks' (see Figure 1), which shows the diversity of these products, further enriched by various physical forms in which fermented milks can be offered to consumers.

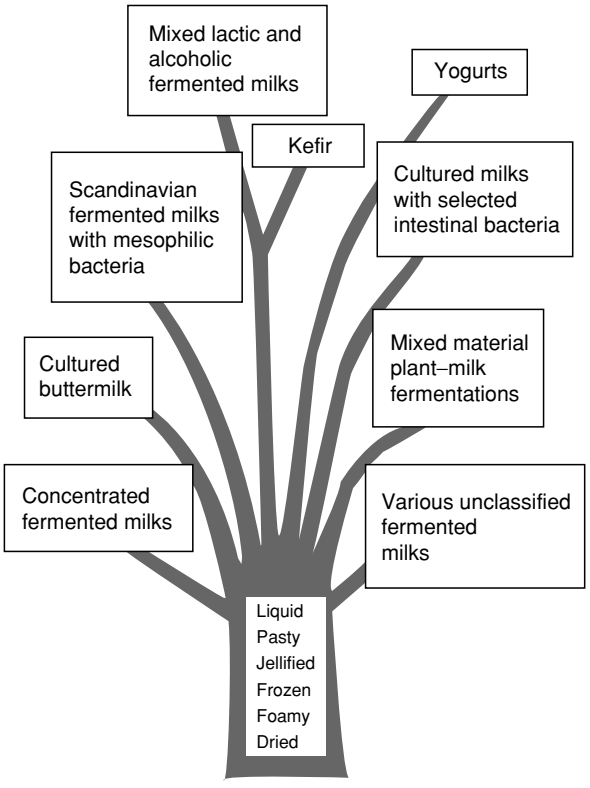

Figure 1 Tree of fermented milk types. From J.A. Kurmann (1984) Aspects of the production of fermented milks. In: *Fermented Milks – Proceedings of an IDF seminar in Avignon*, pp. 16–26. International Dairy Federation Bulletin No. 179. Brussels: International Dairy Federation (1984), with permission.

There are many variations and modifications to these products in different parts of the world, which usually reflect local traditions as well as continuous efforts to develop new products. For example, various types of fermented whey beverages have gained popularity in some European countries.

Taxonomic Location of Starter Cultures

The main thermophilic bacteria used in the production of fermented milks include lactobacilli, *Streptococcus thermophilus* and bifidobacteria. DNA fingerprinting is now commonly used to determine the taxonomic location of these organisms. As a result, important changes have been made to the taxonomic status of certain well-known starter bacteria. For example, organisms previously classified as *Lactobacillus acidophilus* are now divided into the following six species: *Lb. acidophilus*, *Lb. crispatus*, *Lb. gasseri*, *Lb. amylovorus*, *Lb. gallinarum*, and *Lb. johnsonii*. Similarly, the lactobacilli previously classified as *Lactobacillus casei* are now located within either *Lb. rhamnosus* or *Lb. paracasei* ssp. *paracasei*. The extensively studied and well-publicized *Lactobacillus* GG is now a strain of *Lb. rhamnosus*.

The main organisms used in mesophilic starters belong to *Lactococcus lactis* (with subspecies *lactis* and *cremoris*) and *Leuconostoc* spp. Yeasts, belonging mainly to *Saccharomyces* spp., and molds such as *Geotrichum candidum*, are also included in some mesophilic starter cultures.

Manufacturing Technology

Manufacture of fermented milks consists of several basic steps. Most fermented milks can be produced as either 'set' or 'stirred' products, and this feature determines the sequence of major operations (see Figure 2).

Preparation of Milk

Milk for production of fermented milks should comply with the following requirements: low bacterial counts, absence of pathogenic organisms and absence or very low concentrations of various inhibitory substances that may find their way into milk, such as residues of antibiotics from the treatment of mastitis, residues of dairy sanitizers, *etc*.

The first step in milk preparation is usually the clarification of milk, to remove mechanical impurities and somatic cells. This operation is carried out in centrifugal clarifiers/separators, but filtration of raw milk can also be used for this purpose.

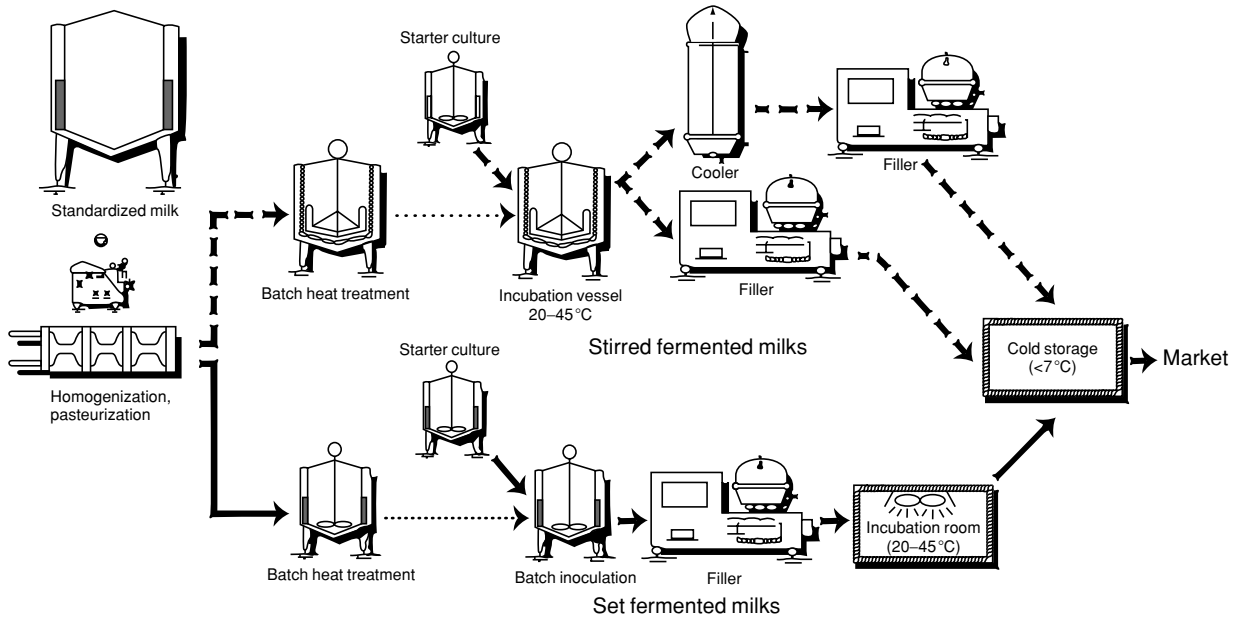

Figure 2 Basic steps in manufacture of fermented milks. From International Dairy Federation (1988) *Fermented Milks – Science and Technology*. International Dairy Federation Bulletin No. 227. Brussels: International Dairy Federation, with permission.

The milk has to be standardized, i.e., its composition altered to meet legal requirements and/or to improve the economy of production and/or to modify the characteristics of the final product. Usually, standardization means adjustment of fat content and sometimes also of nonfat solids (NFS) content. NFS content in milk can be increased by (1) evaporation, which usually removes 10–20% water, (2) addition of skim milk powder, or (3) addition of milk concentrate. Membrane filtration, especially ultrafiltration (UF), is increasingly being used to concentrate milk for production of yogurt and various other fermented milks. The main advantages of using UF retentates in production of fermented milks are: (1) enhanced viscosity; (2) reduced syneresis (even at lower fat content); (3) increased product yield (in manufacture of concentrated fermented milks) due to a partial retention of whey proteins; and, quite often, (4) better taste due to the absence of 'chalkiness' frequently associated with the use of milk powder.

Many fermented milks, including yogurt, can be made from reconstituted or recombined milk. This technique has obvious advantages in locations where it is difficult to obtain raw milk of a consistently high microbiological standard. However, fermented milks made from a totally reconstituted or recombined milk account for only a small fraction of the total production of fermented milks.

The next manufacturing step is homogenization of milk, which, by reducing the diameter of the fat globules, prevents fat separation and has a whitening effect on the milk. Homogenization also improves (1) the stability of fermented milks during storage (by reducing syneresis) and (2) their rheological properties. The usual conditions of homogenization are 10–20 MPa at 50–60 °C. Higher temperatures are sometimes used, e.g., 65 °C in production of filmjölk, a Scandinavian fermented milk.

Homogenization is followed by heat treatment, in order to: (1) pasteurize the product; (2) make the milk a more nutritious growth medium for the starter organisms, through the release of amino acids and other growth factors, reduction of the redox potential and elimination of inhibitory substances; (3) improve physical properties of fermented milks and reduce syneresis; and (4) prevent formation of rancidity through inactivation of lipases. To achieve these objectives, it is common practice to batch-pasteurize milk at 80–90 °C for 20–30 min. Heating of milk to the required temperature in a plate or tubular heat exchanger is followed by pumping into a holding unit where the temperature is maintained for the predetermined period. In some plants, milk is heated in a continuous process in a closed system at 90–95 °C for 5 min or more. Heat exchangers are also used to cool milk to the fermentation temperature. In cases where the only objective of heat treatment is pasteurization of milk, high-temperature, short-time (HTST) pasteurization is usually used.

Another step recommended in manufacture of some fermented milks is the deaeration of milk, which is said to reduce syneresis and improve the consistency of the final product.

Preparation of Starters

Starters for the commercial production of fermented milks can be prepared in several different ways, depending on the type of final product and the type of manufacturing facilities. The majority of fermented milks are now made with defined starters, but for the production of some traditional fermented milks, for example kumys and leben, undefined starters are usually used. In these starters, various lactic acid bacteria and yeasts remain in a protocooperative and possibly also a symbiotic relationship. Traditionally, a starter was a residue from the previous batch that was added to suitably prepared milk. Nowadays, such starters are propagated aseptically in the laboratory to serve as an inoculum for the bulk starter unit.

The majority of fermented milks are made with multiple-strain starters, which are defined mixtures of two or more strains. Apart from enabling manufacturers to make better-quality products, multiple-strain starters can cope better with bacteriophage challenge if suitable bacteriophage-unrelated strains are selected, though this may not always be feasible. A few types of fermented milks are made with defined single-strain starters. Milks fermented with selected intestinal bacteria belong to this category, *e.g.*, yakult, made with *Lactobacillus paracasei* ssp. *paracasei* (formerly known as *Lactobacillus casei* strain Shirota), and acidophilus milk, made with *Lb. acidophilus*.

The importance of the physical characteristics of fermented milks is reflected in the use of microorganisms which synthesize a glycocalyx, a polysaccharide or glycoprotein material which forms 'capsules' around the cells that produced it. Such capsules, sometimes referred to as 'slime' or 'mucus', act as a stabiliser in the product, improving viscosity, disguising syneresis of the milk protein gel, and making the product less susceptible to thixotropic phenomena. Capsule-forming organisms are incorporated into multiple-strain starters used in the manufacture of many types of fermented milks.

In the conventional starter preparation methods, several subcultures in the laboratory are needed to produce, from the initial freeze-dried or liquid culture, the inoculum volume required for the bulk starter unit. This time-consuming step needs skilled personnel to ensure effective quality assurance at all stages of starter preparation. Because of demands on manpower, space and capital, many manufacturers of fermented milks, rather than preparing their own starters, prefer to rely on concentrated commercial starters, which contain up to 10^{11} cells per ml and can be added to the bulk starter unit or directly to the production tank or vat (conventional starters may contain up to 10^{9} cells per ml). Concentrated starters are available in either deep-frozen or freeze-dried form.

Starter cultures selected for the manufacture of fermented milks should not produce appreciable amounts of lactic acid in the product during refrigerated storage. Postfermentation acidification usually leads to product defects such as syneresis of the protein coagulum and the consequent expulsion of whey.

Fermentation

The temperature and time of fermentation can be varied to influence the final product characteristics. The fermentation temperature usually does not differ much from the optimal growth temperature of the starter organisms. It is essential that the temperature remains constant during fermentation. Sometimes, in order to improve the physical properties of the final product, manufacturers choose a lower temperature and a longer time of fermentation to promote the formation of mucoidal capsules by some starter bacteria. For the stirred product, fermentation is carried out in the production tank or vat; the 'set' product is fermented in retail containers.

Cooling

Fermentation is terminated by cooling which, depending on whether the product is stirred or cup-set, can be achieved by different techniques. Cooling of the product, usually to refrigeration temperature, allows the manufacturer to control acidity and initiate the 'cold gelation' of the curd at the appropriate time. The cooling rate is often critical to the quality of the product and is usually determined empirically by each manufacturer. In general, manufacturers aim to lower the temperature of the 'set' product to $< 10\,^{\circ}C$ as quickly as possible, and then continue cooling it at a slower rate to the storage temperature.

In the manufacture of stirred fermented milks, cooling is often carried out in two stages: at first to approximately $20\,^{\circ}C$, at which point the flavor ingredients are added, and the product is packaged into retail containers, and second to the refrigeration temperature. The second stage of cooling is often conducted at a slow rate and may take up to 12 h. This method is said to result in improved rheological characteristics of the product.

Flavoring

Fermented milks are often flavored by the addition of fruit pulp or purée or other flavoring ingredients. Fruit pulp, with a sugar content of approximately 60%, is usually added at the level of about 10%. Pectins present in fruits exert a stabilizing effect on the product, but additional stabilizers may be added

to the product at this stage. These include high-molecular-weight compounds such as gelatin, or various hydrocolloids of plant origin ('gums'), including compounds derived from some seaweeds. For the stirred product, flavoring ingredients are added after or during the cooling stage, whereas the flavoring of the 'set' product is carried out prior to fermentation and filling into retail containers.

Packaging

Fermented milks are packed in containers impermeable to water and odors, insoluble in water, and free from foreign odors. In some applications, impermeability to light, and low permeability to oxygen are also required. Glass, often dyed to reduce the effect of light on the product, was used for a long time as a packaging material for fermented milks, but has now been almost totally replaced by synthetic materials and paper coated with various polymers such as polyethylene. The paper carton, usually formed into a rectangular container, can also be impregnated with resins and/or coated with aluminum or silicone. Synthetic materials ('plastics') are light and can be easily molded into light-weight containers of diverse shapes. The cup is the most common shape of container, but bottles and pouches are also used. Containers for products containing still-viable yeast cells may have a three-layer lid that allows the escape of carbon dioxide generated during storage.

Regulatory Aspects

Fermented milks offered for sale must conform to legal requirements, which, apart from setting microbiological quality standards to safeguard public health, usually define the chemical composition of the product, its shelf-life and, in many cases, the number of viable cells of starter bacteria that must be present in the product at the point of sale. In Japan, for example, a product classified as fermented milk or 'lactic milk drink' must contain at least 10^7 viable cells of lactic acid bacteria and yeasts per milliliter. Standards for fermented milks in some countries include the requirement for the live cells to be present in the product at the end of its shelf-life (declared on the package as the 'use-by' date) but do not specify the minimum numbers. The compositional requirements, usually specified as the minimum content of NFS and fat, differ widely between countries.

The final acidity is often included in the standards as (1) the minimum concentration of lactic acid, (2) the minimum titratable acidity according to an arbitrary scale, e.g., degrees Soxhlet–Henkel (°SH), Dornic (°D), or Thörner (°Th), or (3) the maximum pH of the product.

Products universally known, such as yogurt, are subject to fairly detailed regulations, whereas less well-known products may not have legally binding standards of identity and have to comply with requirements set for other products deemed similar for purposes of control by relevant government authorities.

Health-related Claims

Traditions of folk medicine in many parts of the world have endorsed fermented milks as beneficial not only in the prevention of various health disorders but, sometimes, also as an aid in treatment of these disorders. In addition to traditional products, fermented milks made with 'probiotic' cultures have expanded the range of claimed health benefits. For some of these effects, it would be difficult to separate the effect of starter organisms alone from that of milk fermented with these organisms.

Studies of human intestinal flora are fraught with methodological difficulties. It is not easy to obtain samples of intestinal contents that would accurately reflect quantitative and qualitative relationships in the gut. In addition, the microbial population of the gut is rather stable in healthy individuals and is not affected by the diet. Lactobacilli and bifidobacteria ingested with the diet do not supplant existing intestinal bacteria. However, sufficiently rigorous evidence has now been gathered to suggest that in some disease states, consumption of fermented milks may benefit the host.

In general, health benefits claimed for many types of fermented milks refer to their effect on (1) the microbial ecology of the gut and/or (2) specific ailments unrelated to the gut ecology. Health claims in both these categories include:

- immunomodulatory effects, including enhancement of antitumor activity;
- antimutagenic properties;
- stabilization of gut mucosal barrier, which may lead, among other things, to suppression of allergic reactions;
- prevention and treatment of diarrhea caused by rotavirus and bacterial infections;
- alleviation of radiotherapy-induced diarrhea;
- restoration of normal ecological relationships in the gut after antibiotic treatment;
- alleviation of constipation;
- inhibition of pathogenic organisms;
- alleviation of lactose intolerance;
- lowering of serum cholesterol;
- antihypertensive effects.

It would be reasonable to expect that relationships in the gut can be influenced primarily by the

thermophilic organisms ingested with fermented milks. Beneficial properties of the mesophilic bacteria would be due to their metabolites present in the product before they are consumed, rather than to any lasting effect on the microflora of the gut. In this context, it is interesting to note that an organism known as *Lactococcus lactis* L1A, isolated from samples of fermented milks produced on farms in northern Sweden, was recovered from fecal samples up to 15 days after the consumption of fermented milk containing it had ceased.

During the past few decades, there has been a noticeable revival of popular and scientific interest in 'probiotic' microorganisms and fermented milks. Many of the health benefits claimed for these microorganisms and products still remain to be substantiated by unequivocal experimental and/or epidemiological evidence.

Products from Northern Europe

H Roginski, University of Melbourne, Werribee, Victoria, Australia

Introduction

Fermented milks have always played an important role in the nutrition of people inhabiting northern Europe. In Scandinavia in particular, consumption of fermented milks has a long tradition. Historically, fermented milks, often referred to as sour milks, were made and consumed at home. Most of these products have a characteristic thick consistency and ropiness, and could be kept for weeks or even months in a cool room.

The home production of fermented milks is now much less common in Scandinavia, but many types of commercially manufactured products have the same attributes as their homemade precursors. Consumption statistics provide ample evidence of the continuing demand for Nordic fermented milks, although the growing popularity of yogurt has led to some erosion of this traditional market in recent decades.

Interest in Nordic fermented milks has recently been stimulated by reports of prophylactic and therapeutic effects associated with starter flora and its metabolites, which have been observed in experiments on animals.

General Features

Nordic fermented milks constitute a group of products distinctly different from fermented milks made elsewhere primarily due to their unique physical properties, characterized by high viscosity and ropiness. In the cool climate of northern Europe, homemade fermented milks are the result of the spontaneous growth of mesophilic microflora present in raw milk. Low

temperatures seem to be critical for the domination of the milk environment by encapsulated strains of lactococci. Lactobacilli are isolated only rarely from spontaneously fermented milk in Scandinavia. Molds and lactose-fermenting yeasts grow well in acidified milk and are therefore found in some types of Nordic fermented milks, and influence their properties.

Other traditional fermented products popular in Scandinavia include cultured buttermilk and cultured creams, which have a characteristic aroma and flavor, derived primarily from diacetyl and related volatile compounds. Also popular are concentrated milks, made by the removal of whey from the fresh coagulum or, more recently, using membrane-concentrated milk.

Microorganisms Present

Diverse cultures are used commercially in Scandinavia for various types of fermented milk, and have been derived from traditional products. In many of these cultures, the bacteria responsible for ropiness are indispensable. However, the presence of nonropy organisms is also essential in many cultures to insure the formation of metabolites which impart typical organoleptic properties to the product.

Overall, the following groups of microorganisms have been isolated from various types of traditional Nordic fermented milks:

- Mesophilic bacteria: *Lactococcus lactis* sspp. *cremoris, lactis*, and *lactis* biovar *diacetylactis; Leuconostoc mesenteroides* sspp. *cremoris* and *dextranicum*.
- *Lactobacillus helveticus*. It is significant that the optimum growth temperature of a strain isolated from the Norwegian and Finnish version of tätmjölk was 10 °C lower than that reported for other strains of this species. Thermophilic *L. helveticus* has been isolated from the Icelandic fermented milk skyr.
- *Streptococcus thermophilus* and *Lactobacillus delbrueckii* ssp. *bulgaricus*, found in skyr.
- The yeasts *Candida kefir* and its teleomorph *Kluyveromyces marxianus*, as well as *Torulopsis holmii* and its teleomorph *Saccharomyces exiguus*, have been isolated from various types of Nordic fermented milk. The long shelf-life of ropy milk has been attributed in part to the presence of yeasts, which are inhibitory against a number of potential mold contaminants. The inhibitory compound was inactivated by heat.
- The white mold *Geotrichum candidum* is found in viili, tette, and other products. *G. candidum* isolated from a sample of ropy milk and added to a ropy culture (*L. lactis* ssp. *cremoris*), which was previously not associated with this mold, stimulated the growth of the culture in milk. A cell-free filtrate of the medium (sterile whey) on which the mold had grown had a similar effect.

Forms of lactococci classified as 'intermediate' between *Lactococcus lactis* sspp. *cremoris* and *lactis* (on the basis of their physiological characteristics) have also been found in some ropy milks.

The total number of viable bacteria in these products can be very high. For example, up to 10^{10} cfu g^{-1} have been reported in the Finnish ropy milk called pitkäpiimä. This is a higher concentration of live bacteria than that in some starter cultures used in the commercial production of fermented milks.

Traditional Nordic fermented milks owe their characteristic high viscosity and ropiness to the vigorous growth of capsule-forming lactococci, mainly *L. lactis* ssp. *cremoris*. Encapsulated strains of *L. lactis* sspp. *lactis* and *Leuconostoc* species were also isolated from some products. However, strains of these species which clearly do not produce capsules are also found in Nordic fermented milks.

Glycocalyx

Terms like 'slime,' 'capsule,' and 'mucoidal (Muc^+) phenotype' are used interchangeably in the literature, usually without ascertaining whether the material in question is capsule-type or slime-type. 'Capsule' is defined as a compact layer of polysaccharide and 'slime' as a diffuse layer of polysaccharide, both exterior to the cell wall. As a rule, the capsule of lactococci is tightly bound to the cell that produced it. In cases where the physical nature of the material has not been studied, it would be more appropriate to use 'glycocalyx,' a general term which describes the polysaccharide-containing material lying outside the cell wall, although this term is seldom used.

Figure 1 shows an encapsulated strain of *L. lactis* ssp. *cremoris*.

In some places, the capsular material clearly does not follow the chain of lactococci. It is possible, however, that the detachment from the cells occurred during the preparation of the slide. Slime seems to be produced in particular abundance during the late exponential and early stationary phases of growth.

Normally, both encapsulated and nonencapsulated forms of the same species can be isolated from a product. As an example, the types and numbers of bacteria isolated from pitkäpiimä are shown in Table 1.

L. lactis ssp. *cremoris* was the organism most often encountered in this product. It is worth noting that encapsulated *L. lactis* subsp. *lactis* was found only in samples of ropy milk which did not contain slime-forming cells of *L. lactis* subsp. *cremoris*.

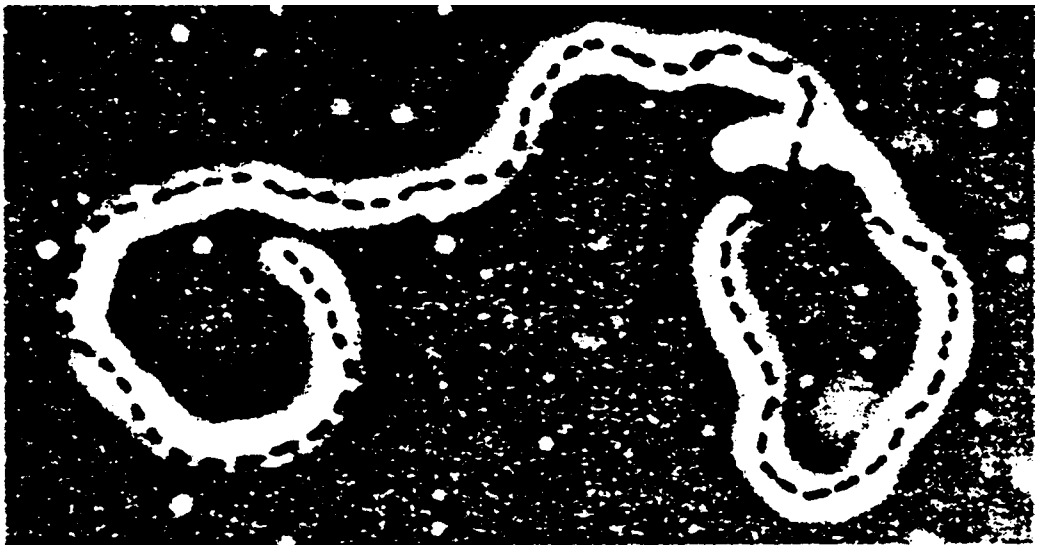

Figure 1 *Lactococcus lactis* ssp. *cremoris*, strain Va, after 6 h growth. Preparation stained with methylene blue, magnification × 1350. From Forsén R (1966) Die Langmilch (Pitkäpilmä). *Meijeritieteellinen Aikakauskirja* 26: 1–76 with permission.

[a]*Streptococus viridansä* physiological group includes *S. thermophilus*, but the result reported above does not imply the presence of *S. thermophilus* in pitkäpiimä.
From Forsén R (1966) Die Langmilch (Pitkäpiimä). *Meijeritieteellinen Aikakauskirja* 26: 1–76 with permission.

The growth of slime-forming lactococci isolated from pitkäpiimä depended on the presence of nicotinic acid and riboflavin in the growth medium. It has also been observed that strains of both *L. lactis* sspp. *cremoris* and *lactis* found in pitkäpiimä were more likely to grow at 40 °C than were the strains of these subspecies isolated from commercial starter cultures for fermented milks. The O_2 demand and CO_2 production of slime-forming cultures of *L. lactis* sspp. *cremoris* and *lactis* from pitkäpiimä has been observed, at 19 °C, to be two to three times higher than that of the strains which do not produce slime.

Characteristics of Capsular Material

Studies on ropy fermented milk using scanning electron microscopy showed that the polysaccharide slime material remains associated with the cells which produced it, while also attached to casein micelle clusters, forming a network responsible for the ropy consistency of the product. Other milk proteins may also be involved. In addition, proteins of bacterial origin may be present in slime. However, the results of studies on slime composition are affected, to some extent, by the technique used to isolate and purify the slime.

In one study, the slime produced by a strain of *L. lactis* ssp. *cremoris* isolated from a Swedish ropy milk was found to contain 47% protein, 20% methyl pentoses, approximately 10% hexose-like sugars, and almost 3% sialic acid. The composition of a phosphorus-containing polysaccharide produced by *L. lactis* subsp. *cremoris* isolated from a sample of the Finnish fermented milk viili is shown in Table 2.

Rhamnose, glucose, and galactose were present in this phosphopolysaccharide at the molar ratio of 1:1.45:1.75. The purification procedure (preparative

sodium dodecyl sulfate–polyacryl amide gel electrophoresis) removed protein, glycerol, hexosamine, sialic acid, and uronic acids from the crude slime material. The phosphate group was attached to the β-D-galactopyranosyl residue. The molecular weight of this phosphopolysaccharide was estimated to be 1.7×10^6 by gel permeation chromatography. The phosphopolysaccharide has a negative charge; it is, therefore, possible that it could form complexes with basic proteins found on the cell surface of lactococci, due to electrostatic interactions.

Determinants of Glycocalyx Formation

Plasmid DNA Observations of the loss of the mucoidal (Muc+) phenotype at higher incubation temperatures led to studies which have demonstrated the involvement of plasmid DNA in the synthesis of glycocalyx by lactococci. The ropy phenotype of strains of *L. lactis* ssp. *cremoris* was found to be associated with a 17-MDa plasmid in Swedish strains and with a 30-MDa plasmid in Finnish strains. This indicates that distinctly different plasmids coding for the ability to produce slime are present in separate populations of starter bacteria. Plasmids on which slime synthesis is encoded can be transferred to strains with no slime-forming ability by a number of currently available techniques, including electroporation or cotransfer involving a bigger plasmid, on which an ability to ferment lactose is encoded.

Proteins of the cell surface Two cell surface proteins of mol. wt 26 kDa and 42 kDa have been shown to be associated with slime formation in lactococci. The synthesis of these proteins is probably plasmid-encoded.

Lipoteichoic acid Experiments demonstrating the presence of lipoteichoic acid (LTA) antigen on the cell surface of *L. lactis* ssp. *cremoris* led to a hypothesis linking LTA with the formation of a capsule or slime. LTA, which was also detected in the growth medium during early stationary phase and during storage at refrigeration temperature, may form associations with proteins and polysaccharides of the slime material. In addition, LTA present on the cell surface inhibits autolytic enzymes of the bacterial cell wall, which has obvious advantages for the shelf-life of the product. LTA also interferes with cell division: 20% of the cells of one particular slime-forming strain were found to have an abnormal morphology due to disturbances in cell division attributed to LTA.

Effect of limiting factors Even in the presence of an energy source, bacterial growth may be affected by some limiting factors, such as an unfavorable physical or chemical environment or the exhaustion of an essential nutrient. It has been suggested that the continuing catabolism of energy substrates can then provide an impetus for the production of polymers, such as the slime material, as either energy reserves or waste products.

Instability of slime production The variable rate at which lactococci produce slime is a well-known phenomenon, especially during incubation at a higher temperature, e.g., 30 °C. In addition, the serial transfer of a ropy strain, even at a lower temperature which normally favors the production of slime material, often leads to the loss of this trait. Sometimes, this unpredictability of slime formation causes difficulties in the commercial manufacture of ropy fermented milks.

Although the loss of the ropiness trait in starter strains has been observed in the commercial production of ropy milks, a similar problem has not been reported in the traditional manufacture of these products, in which a mixture of undefined organisms is used. A mixed population of lactococci and leuconostocs is likely to have effective mechanisms for retention in the culture of the plasmid(s) on which the ability to produce capsular material is encoded, especially if other properties important for the survival of the bacterial population are encoded on the same plasmid(s). The data reported in Table 1 lend support to this concept.

Bacteriophage

Attack by bacteriophages can cause problems in the manufacture of ropy fermented milks. Thirteen phages of different morphology have been found in an extensive study on 90 samples of viili from 20 dairies in Finland. The main morphological type was characterized by an isometric head with a long, noncontractile tail. The host organisms for these phages included strains of *L. lactis* sspp. *cremoris* and *Leuconostoc mesenteroides* ssp. *cremoris*. Some phages differed only in their host specificity.

A phage of nonencapsulated *L. lactis* subsp. *cremoris* isolated from viili was shown to dissolve the capsules of some strains, including a strain of *L. lactis* ssp. *lactis*. The capsules disappeared soon after infection, and maturing phages were seen inside the cells 2 h after infection, appearing as tightly packed bundles. The phage titer declined rapidly after heating for 15 min at 50–70 °C, but particles capable of plaque formation were detected even after heating for 5 min at 100 °C.

Products and Processes

In the domestic production of fermented milks, no heat treatment was applied to milk prior to fermentation, and the milk was inoculated with the residue remaining in the fermentation vessel from the previous batch. In this way, a characteristic flora dominated by lactococci became established in the vessel. Nowadays, in the commercial production of Nordic fermented milks, defined strains of starter microorganisms are used. The types of starter microorganisms have a distinct influence on the properties and shelf-life of these products.

Scandinavian fermented milks fall into six major classes, as shown in Table 3. Not all products in each row are identical to each other; the table is provided as a guide.

Table 3 The major classes of Scandinavian fermented milks[a,b]

Sweden	*Norway*	*Denmark*	*Finland*
Långfil	Tettemelk		Viili
Filmjölk	Kulturmelk	Tykmælk	Talouspiim
Lttfil	Skummet Kulturmelk		Rasvatonpiim
Krnmjölk	Kjernemælk	Kærnemælk	Kirnupiim
Grddfil	Rømme	Crème fraîche	Kermapiim
Lactofil		Ymer	Kokkeli

[a]Each row represents a separate class of products.
[b]There are also many special product names used by commercial manufacturers of fermented milks.

Långfil

Långfil or tätmjölk has a mild, sour taste and a ropy, dough-like consistency produced by encapsulated variants of lactococci. Occasionally, lactobacilli are also found in this product. Traditionally, the leaves of plants such as butterwort (*Pinguicula vulgaris*) and sundew (*Drosera* species, especially *Drosera rotundifolia*) were added to milk before leaving it to sour. They seem to exert a rennet-like action. No relationship has been established between the bacterial flora of butterwort or other plants and the bacterial composition of långfil.

Långfil cultures were preserved for later use by simple techniques, such as dipping a piece of cloth (in Sweden) or birch twigs (tettemelk, in Norway) in the finished product and then allowing them to dry. A new batch was started by immersing the twigs, or placing the dried cloth, in fresh milk.

Viili contains various lactose-fermenting yeasts and *Geotrichum candidum*, in addition to lactococci and leuconostocs. The cream layer is usually covered with the mold. Viili is made from unhomogenized milk and is eaten with a spoon.

Pitkäpiima, which is always ropy, is used as a drink. In domestic production, the cream layer, removed from the pitkäpiima after fermentation, was used to make butter.

Viilipiimä, from which the cream is not removed, also serves as a drink.

The following steps are included in the commercial production of viili:

- standardization of fat content at the minimum level of 3.9%
- heat treatment at 89–90 °C for 15–30 min or 92–96 °C for 4–5 min
- cooling to 18–20 °C
- addition of 4–8% starter culture
- incubation for 18–20 h to reach the pH of 4.6
- cooling to the storage temperature of 8–10 °C.

The final pH, after cooling, is 4.3–4.4 and the shelf-life is between 10 and 15 days.

Cultured Milk

Filmjölk, sometimes also known as kulturmjölk (cultured milk), is a popular Swedish fermented milk characterized by a typical flavor and aroma (derived primarily from diacetyl) and a fairly high viscosity, with a fat content of 3.0%. Filmjölk, which is used as a drink, was developed in the early 1930s. The starter culture contains the acid-producer *L. lactis* ssp. *lactis* and the flavor and aroma producers, *L. lactis* ssp. *lactis*, *L. lactis* ssp. *lactis* biovar *diacetylactis* and

Leuconostoc mesenteroides ssp. *cremoris*. All these strains are propagated together.

In the production of filmjölk:

- standardized milk is often deaerated at 78 °C to prevent or to alleviate defects such as syneresis of the coagulum, granulation, lumpiness, and low viscosity
- the deaerated milk is homogenized at 10–20 MPa and 70 °C, and then heated at 95 °C for 2–6 min
- the milk is cooled to 17–24 °C and inoculated with 1% starter culture
- after 17–24 h, coagulum forms at pH 4.6
- the product is cooled to 8 °C and packaged into retail containers.

Normally, a shelf-life of 10 days at 8 °C is achieved.

Filmjölk with 0.5% fat is called lättfil; the same product is known as skummet kulturmelk in Norway.

Tykmælk, a characteristic Danish fermented milk, is produced commercially in a similar manner to the Swedish filmjölk. It contains 3.5% fat.

Buttermilk

Traditional buttermilk (kärnmjölk, kjernemelk, kærnemælk, kirnupiimä) is made by churning cultured cream which has a relatively low fat content. In this manner, a small amount of cultured butter and a relatively high volume of buttermilk are obtained. A product known as cultured buttermilk is made by the fermentation of skim milk or low-fat milk.

Starter cultures contain, in addition to the bacteria used for filmjölk manufacture, *Lactococcus lactis* ssp. *cremoris*. Slime-producing strains are included in the starter culture for some types of cultured buttermilk made in Finland. The production process involves:

- heat treatment at 85–90 °C/20–30 min or 92–96 °C/4–5 min
- cooling to 20–23 °C
- incubation with 1–4% starter culture
- 15–20 h fermentation
- cooling to 5–10 °C, during which the pH decreases to 4.4–4.45.

The flavor and aroma of cultured buttermilk are very similar to those of filmjölk. The shelf-life varies from 7 to 12 days.

Cultured Creams

Gräddfil, rømme, crème fraîche and kermapiimä are cultured creams made by the fermentation of heat-treated cream with the same cultures that are used in the manufacture of cultured buttermilk. The legal requirements regarding the fat content of cultured creams and production practices vary between Scandinavian countries. For example, in Denmark, production involves:

- the cream being standardized at 9, 18, 38 or 50% fat, and then homogenized
- heat treatment at 90 °C for 5 min
- cooling to the incubation temperature of 20–27 °C
- inoculation with 2% starter culture
- 16–20 h incubation in the tank
- cooling to 5 °C, during which the pH of the final product falls to 4.4.

In two types of Swedish gräddfil, the legally required fat content is 12 and 34.5%; Norwegian rømme contains 20 or 35% fat; and in Finland there are three types of cultured cream, at >12, 35–40 and 42% fat.

Concentrated Fermented Milks

These include ymer, lactofil, kokkeli, and skyr.

Ymer is a Danish fermented milk, which contains at least 11% nonfat milk solids (including 5–6% protein) and 3.5% fat. It is usually produced from the ultrafiltered retentate, which contains about 15% total solids. Production involves:

- blending retentate with cream and homogenization
- heat treatment at 90°C for 5 min and cooling to 20–27 °C
- inoculation with 4% starter culture containing *L. lactis* sspp. *lactis* and *cremoris* and *Leuconostoc mesenteroides* ssp. *cremoris*
- fermentation until the pH reaches 4.5 (after 16–20 h)
- stirring, cooling to 5 °C, and storage for 24 h
- stirring again and packaging.

The product is often cooled in two stages, first to 14 °C and then to 5 °C.

In the traditional process, fermentation of the skim milk is followed by cutting of the coagulum and drainage of the whey at 40 °C. Alternatively, a quarg separator can be used to remove the whey. Pasteurized cream is then blended with the skim product, and this is followed by homogenization, cooling to 12–14 °C and packaging. The shelf-life of ymer is ≈20 days at 5 °C.

Lactofil, produced in Sweden, is similar to ymer. The fat content in lactofil is 5% and the starter culture is similar to those used in the manufacture of filmjölk and karnmjölk.

Kokkeli, traditionally made in eastern Finland, is prepared by warming spontaneously soured milk in an oven and removing the separated whey.

Skyr is manufactured in Iceland from skim milk. Unlike all other traditional Scandinavian fermented

milks, it is fermented by a thermophilic microflora. The milk is then heated to facilitate the syneresis of the protein coagulum. Whey separation is achieved by either straining through linen bags or using quarg separators. Ultrafiltration is now also used to recover whey proteins, which are added to the skyr before packaging. Microorganisms isolated from skyr include thermophilic lactic acid bacteria (*Streptococcus thermophilus, Lactobacillus delbrueckii* ssp. *bulgaricus* and *L. helveticus*) and lactose-fermenting yeasts. Typical skyr contains 17.5% total solids, including >13% protein and 0.4% fat.

Product Composition and Shelf-life

Composition

The total solids and fat content of Nordic fermented milks is prescribed by law. Often, a minimum number of viable microorganisms is prescribed by the food standards.

Starter activity in milk leads to the production of lactic acid, as well as flavor and aroma compounds. For example, *Lactococcus lactis* ssp. *lactis* metabolizes the citrate present in milk to diacetyl, acetoin, 2,3-butylene glycol, and CO_2. Citrate is also metabolized by leuconostocs, mainly to diacetyl and acetoin (at pH $\leq$ 5.5), and acetate (at pH > 5.5).

Differences in vitamin content have been observed between fermented milks and raw milk. For example, viili and cultured buttermilk (containing 1.9% fat) were found to contain more folate than raw milk, by 48 and 65%, respectively. However, their vitamin C content was lower than that of milk, by 58 and 24%, respectively, and their riboflavin was lower, by 12 and 11%, respectively. The concentration of vitamin B_{12} in both products was also lower than in milk, by > 20 %.

Shelf-life

Very high numbers of viable bacteria have been observed in some spontaneously fermented milks. This may be due to the reduced rate of cell autolysis (discussed above).

The shelf-life of traditional ropy fermented milks is exceptionally long, due mainly to the presence of glycocalyx, which improves the rheological behavior of these products.

Features such as the cream layer and the presence of the mold *Geotrichum candidum* on the surface of some products provide added protection from spoilage organisms, thus further extending the shelf-life.

Commercially made products are also noted for their long shelf-life. Even if some preexisting defect reduces the water-holding capacity of the protein matrix, e.g., if proteolysis were allowed to proceed unhindered in raw milk, the presence of glycocalyx would mask the syneresis of the protein coagulum.

Health-related Effects

Considerable progress has been made in demonstrating certain beneficial effects of Nordic fermented milks in experimental animals. However, unequivocal experimental and/or epidemiological evidence still needs to be gathered to substantiate claims of similar effects in humans.

Effect on Immunity

It has been suggested that fermented milks may play an immunomodulating role, for example they stimulate the functions of gut-associated lymphoreticular tissue (GALT), and this effect has been attributed mainly to antigenic structures of the surface of lactococci. In particular, *L. lactis* ssp. *cremoris* isolated from viili has been shown, in studies with human lymphocyte cultures, to stimulate the secretion of immunoglobulins, primarily those of the immunoglobulin M class. In addition, T lymphocytes showed considerable proliferation in response to the same strain.

A substance active as a mitogen of murine B cells was purified from the slime produced by another strain of *L. lactis* ssp. *cremoris*, also isolated from viili. The mitogenic compound was a phosphopolysaccharide, containing rhamnose, glucose, galactose, and phosphorus. Its activity was higher than that of unpurified slime.

A significant induction of the cytotoxicity of peritoneal murine macrophages against sarcoma cells, by *L. lactis* subsp. *cremoris* isolated from viili, has been demonstrated *in vivo*. A single intraperitoneal injection of the freeze-dried cells retarded the growth of ascitic and solid sarcomas in mice. However, the same preparation showed no direct cytotoxic activity against the same sarcoma cells *in vitro*, which suggests that the antitumor effect of this organism is through the enhancement of the cytotoxicity of the macrophages of the host. The exact mechanism of this enhancement is not known, but the slime has been observed to increase glucose consumption *in vitro* by intraperitoneal macrophages.

Freeze-dried preparations of viili, långfil, and ropy yogurt, used as intraperitoneal injections daily for 9 days after the tumor inoculation, also significantly retarded the growth of murine solid sarcomas *in vivo*. The maximum antitumor effect was induced by a dose of 10 mg kg^{-1} of the viili preparation, 50 mg kg^{-1} of the långfil preparation and 100 mg

kg^{-1} of the ropy yogurt preparation. Thus, the effect of both viili and långfil was clearly stronger than that of ropy yogurt. All three preparations significantly enhanced the delayed cutaneous hypersensitivity response to oxazolone, which was depressed in tumor-bearing mice. The antitumor effect of these ropy milks is thought to be mediated by the immune responses associated with host's macrophages and/or T cells.

Antimutagenic Activity

Strains of *L. lactis* ssp. *cremoris* isolated from viili, both ropy and nonropy, reduced the mutagenicity of nitrosated beef extract by 40%, as determined by the Ames test, using *Salmonella typhimurium* as the test organism.

Lowering of Serum Cholesterol

In experiments on rats receiving diets containing viili, nonropy fermented milk, or acidified skim milk, the serum cholesterol level of rats on a viili-containing diet was lowest of the three groups. Their ratio of high-density lipoprotein cholesterol to total cholesterol was the highest of the three groups. The mechanism of this cholesterol-lowering effect is unknown.

Antibacterial Effects

Antagonistic effects of lactic acid bacteria against common pathogens and spoilage bacteria have been well demonstrated *in vitro*. For example, lactococci and their capsular material have been shown to inhibit the growth of *Staphylococcus aureus, Escherichia coli*, and some clostridia.

Future Trends

The future position of Nordic fermented milks in their traditional markets seems assured, despite the popularity that yogurt and probiotic products have gained in the past few decades.

Many types of fermented milks are produced nowadays in Scandinavia and some of them do not clearly fit into the categories outlined above, for example, products which are mixtures of ropy milks with acidophilus milk. With the growing interest in various probiotic cultures, this trend is expected to continue, with more combinations of this kind being offered to consumers.

Introduction

Fermented milks and other related products are available in many different countries worldwide. Some have a long history of consumption while others have been developed more recently due to scientific advances. The microorganisms used to make these products are varied but often feature lactic acid bacteria (LAB) which during fermentation convert lactose into lactic acid. Many of these products are generally good sources of a number of important nutrients such as protein, calcium, and zinc and some also have other beneficial effects (particularly on the gastrointestinal tract (GIT)). Indeed, in some parts of the world these products have a long history of therapeutic use. Due to increased medical interest early in the twentieth century, many products were developed commercially. Currently one of the major areas for growth is the development of fermented products containing specific probiotic bacteria.

History

The true origin of fermented milks is difficult to establish but it is suggested that they originated in western Asia and were carried to the east where new variants were developed to suit the different climate. Recipes for soured milks containing fruits and spices existed in ancient Greek and Roman times and fermented milks have played a role in many different cultures throughout history, e.g., they are mentioned in the Bible and the sacred books of Hinduism. Storable dairy products, presumably cultured, are also mentioned in the archaic texts from Mesopotamia dating back to before 3000 BC. In the preindustrial world, milk and/or dairy products of some description had a place in the diet of most people who had domesticated animals. A combination of chance contamination, climatic conditions, and serendipity probably played a part in the development of traditional fermented dairy products. Fermentation of milk allowed humans to store and use excess milk and to travel long distances. Today, fermentation is used to produce dairy foods with different flavors, textures and health benefits.

Several different factors influence the preparation of traditional fermented milk products, with agricultural factors heavily affecting the process (**Table 1**). Cultured dairy products can be prepared from the milk of different mammals, with cows', buffalos', goats' and sheep's milk being the most common. In some parts of the world the milk of other animals (such as camel, yak, and reindeer) is used.

Yogurt and fermented milk of some description are probably the most popular fermented dairy products. Variations within countries and even within regions are seen due, in part, to different ethnic groups with distinct cultures and preferences. Some of the traditional fermented milks and related products produced in different parts of the world are outlined in **Table 2**.

Table 1 Factors influencing production of traditional fermented milk products

Factor	*Example*
Agricultural	Current farm practices
	Animal husbandry
	Milk availability

Fermented Milks and Other Related Products – Definitions

Generally, fermented or cultured dairy products are made from milk (or its components) and modified by incubation with cultures of microorganisms. The 1997 International Dairy Federation (IDF) international draft standard described fermented milks as milk products fermented by the action of specific microorganisms and resulting in a reduction of pH and coagulation. The microorganisms must 'be viable, active and abundant (at least 10^7 CFU g^{-1}) in the product to the date of minimum durability.' The standard further controls the type of microorganisms to be used as being nonpathogenic and nontoxic to produce either a pure fermentation (a lactic acid fermentation) or a mixed fermentation (containing also an alcoholic fermentation). Specific cultures are required to be used for the production of certain defined products, such as cultured buttermilk, yogurt, and Acidophilus milk. There is some disparity among different countries regarding the legal definition of some fermented milk products. Some countries have prescriptive legislation, in line with the above IDF standard, while many others do not.

Some definitions for fermented milks and/or related products imply or state (in legislation or industry standards) that live microorganisms should be present in the final product. This is true in countries such as Japan, the Netherlands, Denmark, and Austria, which stipulate that there must be a high proportion of viable microorganisms in the product (often $\geq 10^7$ ml^{-1}). In contrast, a few countries such as the UK, Germany, and Sweden also recognize products that are heat-treated after fermentation as long as the appropriate consumer labeling is used.

Currently changes are being proposed by the Codex Committee on Milk and Milk Products to the standard for fermented milks. The forthcoming standard will cover all fermented milks (including yogurt and composite products), give descriptions of the different products, essential composition and quality factors, food additives, contaminants, hygiene, and labeling. Issues currently under discussion include at what point the viable organisms should be controlled (e.g., at point of sale to the consumer, when the product leaves the manufacturer, or at the date of minimum durability); the definition, composition, and minimum acidity for mild yogurt; the definition of composite fermented milk products, and the labeling of heat-treated products. The standard still has several hurdles to overcome before it is adopted.

Below are some descriptions for fermented products that are currently used.

Yogurts

Yogurt is traditionally produced from milk and/or cream through the action of two particular strains of LAB – *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. Codex currently defines yogurt as a milk product obtained by fermentation using these two specific strains with or without optional additions (such as milk powder, other LAB, and sugar). In many countries (e.g., Sweden, France, Belgium, Portugal, Spain, USA) legislation exists allowing only *L. bulgaricus* and *S. thermophilus* to be used to produce yogurt. In the UK yogurt can be made using both of these strains or just one of them. In other countries (e.g., Switzerland) strains such as *L. acidophilus* and bifidobacteria may be used in addition to the traditional yogurt strains. It is likely that the

new Codex standard will build on the draft definition currently used for mild yogurt (a product made from *S. thermophilus* and lactobacilli other than *L. bulgaricus*). In Japan no separate legislation exists for yogurt and so it is not obligatory that the two traditional strains are used, either collectively or separately. Similarly, in Finland there are also no compositional regulations for any milk products.

Soft Cheeses

Cottage cheese is a high-moisture, unripened soft cheese made from skimmed milk. Most of the microorganisms used in its manufacture (including species of *Lactococcus lactis*) are destroyed during the process, which involves scalding the curds. After washing, the curds are then mixed with a creamy dressing, which has usually been ripened with a flavor-producing culture. Cream cheese is a soft cheese that is made from cream. A starter culture of *S. lactis* and two species of *L. lactis* is used to produce a rich, full, and mildly acidic flavor and a soft texture. Cream cheese can be made from cream of various fat contents. Crème fraîche is a lightly fermented cream with a rich nutty flavor. Cultured or sour cream is also prepared from cream. After pasteurization and homogenization, it is incubated with a mesophilic starter to produce a thick tangy product. Fromage frais is made from fermented milk and has a mild flavor. It is thicker and more concentrated than yogurt as some water is removed after fermentation. Quark or quarg is a soft, unripened cheese made in a similar way to cottage cheese. Its production often involves heating after coagulation by the starter culture.

Probiotic-Type Products

Probiotic products contain live microbial food ingredients that are beneficial to health. Bacteria of human origin are often used in probiotic products intended for humans. Species of lactobacilli and bifidobacteria are most common but bacteria of nonhuman origin and yeasts such as *Saccharomyces boulardii* are also used. In some countries *Streptococcus thermophilus* and *L. bulgaricus* are considered probiotic strains. Fermented milk drinks and yogurts are popular forms for probiotic foods, although nondairy fermented products also exist, such as fruit juice drinks.

Other Fermented Drinks

The proposed Codex standard will characterize certain fermented milks, including Acidophilus milk, kefir, and kumys, by their specific microorganism(s). However there are a number of other products which are described elsewhere. Acidophilus milk is a product made using the probiotic bacteria *L. acidophilus*, a bacterium from the flora of the normal GIT. It and related products (such as Acidophilus yogurts) are popular in the USA.

Cultured buttermilk was originally made using buttermilk (the byproduct of churning fermented cream into butter) but it has an unpredictable quality and short shelf-life since the whey often separates out and off-flavors develop. Modern equivalents are made from skim or low-fat milk and fermented with acid and flavor starters such as *S. lactis* and/or *S. cremoris* together with *S. paracitrovorous*. Buttermilk is often used as an ingredient in the baking industry.

Laban is a cultured milk drink, usually based on cows' milk and consumed in many Gulf countries. Similar products exist in Egypt, Tunisia, and Morocco. Homemade traditional laban contains a mixture of LAB, molds, and yeasts. Three strains of LAB are used in its commercial preparation. Lassi is a yogurt drink from East India that may be sweetened and flavored with rosewater or fruit. Kefir originated in Russia and is now also popular in Poland, Germany, and Sweden. This traditional product is usually made using cows' or goats' milk and kefir grains which contain a complex mixture of microorganisms including bacteria (such as streptococci and lactobacilli), yeasts, and a polysaccharide of microbial origin. Koumiss (kumiss, kumys, kumyss) also originated in Russia but is based on mares' milk. *L. bulgaricus* and lactose-fermenting yeasts are used in its production. Ropy milks, popular in Scandinavia, use starters that produce slime (mucus), giving a unique viscous quality to the final product.

Frozen Products

There are a few frozen products, like tsutsugi from Mongolia, made from naturally fermented cream, and a number of newer products like Acidophilus icecream in the USA, which contain probiotic strains. Although viability may decrease slightly during freezing, it is still possible to achieve levels of 10^6–10^7 CFU ml^{-1} in frozen products. Frozen yogurt has become popular since the 1970s, especially in the USA. It is made by freezing regular stirred yogurt after the addition of stabilizers, sweeteners, and fruit and flavorings.

Other Related Products

Some fermented products are made using nondairy ingredients such as soya milk, coconut milk, grains, and rice as a base, e.g., boza, a nonalcoholic drink made from cereal (such as wheat, rye, maize, or millet) and widely consumed in Bulgaria and the Balkan peninsula. Acidified milk products (such as sour cream) can be made by direct acidification using organic acids. Nonfermented products also exist,

such as nonfermented Acidophilus milk, available in the USA where *L. acidophilus* is added to freshly pasteurized milk and the product is then kept refrigerated to prevent bacterial growth. In this way the milk acts as a carrier for the microorganism but it does not have the sour taste usually associated with fermented dairy products.

Microbiology

Originally the microorganisms involved in fermentation were used to preserve food of animal and plant origins. As other methods are now available (e.g., refrigeration and pasteurization), microorganisms are used for other reasons – to change the flavor of the raw material (possibly to produce a more acceptable product), to improve the nutritional value of the raw material, and to produce a food which offers beneficial health effects (e.g., probiotic products).

The microorganisms used in the starter culture determine the characteristics of the final product. More specifically, the product's quality and characteristics are dependent on the way the chosen microorganisms utilize the nutrients available in the medium.

Historically, fermented dairy products were made using starter cultures containing a heterogeneous mixture of LAB and yeasts, using one batch to inoculate a subsequent one. This wild fermentation can lead to products of variable quality and taste, due to contamination and the genetic instability of some microorganisms. Although this traditional method is still used in many parts of the world (especially for home production), starter cultures containing known microorganisms have been available commercially since the beginning of the twentieth century. The starter cultures act in a known way, giving greater control over the end product in terms of safety, quality, and taste.

Specific starter cultures are often used in geographical regions, for example, ropy, sour milks containing only streptococci or streptococci and lactobacilli predominate in northern Europe. The type of starter culture can be used to classify fermented milk products in the following manner (Table 3).

LAB are Gram-positive nonsporing cocci, coccobacilli, or rods. Lactobacilli are generally recognized as safe because of their extensive use over the centuries and more recently their role in food technology, with negligible problems. LAB involved in the production of fermented milks and related products are distributed over a large number of bacterial species and include species of *Lactobacillus*, *Streptococcus*, and *Bifidobacteria* genera. Lactobacilli have greater difficulty growing in milk that is neutral or slightly alkaline compared to streptococci. In a mixed culture of these two species, the streptococci may establish growth in neutral or weakly alkaline milk, and from their acid production make the milk suitable for subsequent lactobacilli growth.

Table 3 Classification of fermented milk products by starter culture

Starter culture used	*Example of fermented dairy product*
Thermophilic

LAB use the lactose in milk as an energy source. During fermentation lactose is cleaved by bacterial enzymes to produce galactose and glucose. The glucose formed is then further fermented to produce pyruvic acid, which is metabolized to lactic acid. There are no traditional products made solely using yeast but some products such as kefir and koumiss use yeasts as well as LAB in their manufacture. The yeasts produce CO_2 via an alcoholic fermentation. This CO_2 may be utilized by the other microorganisms and therefore is not usually present in the final product.

Many products have been developed over the last 100 years due to advancements in microbiology, increased understanding of the fermentation process, and increased knowledge of the impact of nutrition on health. Unlike products which often rely on spontaneous fermentation, newer products use selected strains of bacteria for specific qualities. Some commercialized products may be copies of traditional products, for example, using different microorganisms to produce a product similar to a traditional one.

Probiotics

Most microorganisms in fermented milks and related products do not survive transit through the GIT. The body has a number of different mechanisms (e.g., stomach acid, bile, and mucous secretions of the GIT) to decrease or prevent the movement of microorganisms through the GIT. Only robust strains (usually of human origin) such as those termed probiotics can survive and reach the large intestine in a viable state. Here they can modulate the gut flora, leading to specific health benefits.

The word probiotic is derived from the Greek, meaning for life. The concept was used by von Ferdinand in 1954 to describe gut flora modulation using lactobacilli and bifidobacteria. The definition has evolved and recently probiotics for use in human nutrition were redefined as 'live microbial food ingredients that are beneficial to health.' As such a probiotic may consist of a single strain or mixture of microorganisms, its activity is not limited to the GIT but may affect microbial communities at other sites, such as the urogenitial and respiratory tracts; it may have nonmicroflora-mediated effects, e.g., effects on immune parameters.

A number of microorganisms are used in probiotic products, including strains of lactobacilli (e.g., *L. acidophilus, L. casei*, and *L. plantarum*), bifidobacteria (*B. breve, B. longum*, and *B. bifidum*), other LAB (e.g., *Enterococcus faecium*) and non-LAB species such as strains of *Escherichia coli*.

Although viability has been stressed as an important criterion for probiotic microorganisms, recent studies have shown that nonviable probiotic organisms and their cellular components may be efficacious in certain situations. Research in this area is ongoing but, from a commercial perspective, viability of the microorganisms in probiotic products continues to be a key issue.

Nutritional Aspects

Fermented milks and related products reflect the nutritional composition of the milk or base ingredient from which they are made. Generally those made from milk are good sources of a wide variety of nutrients but their nutritional composition often varies from milk due to changes during fermentation (Table 4).

Cultured products are more digestible compared to unfermented ones. In some communities fermented products are used as weaning foods for this reason. During fermentation acid is produced slowly, allowing small particles to form and increasing the surface area for later human enzyme digestion.

Table 4 Effect of lactic acid bacteria on composition of fermented milk

Before fermentation	*After fermentation*	
	Decreased	*Increased*
Lactose	Lactose	Organic acids Lactic acid Galactose, glucose Polysaccharides
Protein	Protein	Peptides Free amino acids
Fat	Fat	Volatile and long-chain free fatty acids
Vitamins	Vitamins	Vitamins (e.g., folate)

Adapted from Nakazawa Y and Hosono A (1992) *Functions of Fermented Milk Challenges for the Health Sciences*. London: Elsevier.

Fermented milk products have lower lactose levels than milk, normally ranging from 30 to 50%. This is because lactose is hydrolyzed by microbial beta-galactosidase during fermentation to produce galactose and glucose, making fermented products useful for the substantial number of people with a lactase deficiency (absence or decreased production of the enzyme needed to break down lactose). Also live bacteria from fermented products that survive the gastric acid release their microbial beta-galactosidase into the small intestine, aiding lactose digestion.

A larger proportion of free amino acids and peptides will be present in fermented milk products due to microbial digestion, although the overall amino acid concentration will be similar to the base ingredients. This may not be of major importance, as most people have no difficulty digesting protein.

The vitamin content of the final product will depend on the base ingredients used, the starter cultures, and the processing conditions (especially heat treatment). LAB can synthesize vitamins such as folate *in vitro* and *in vivo*. Therefore, there may be increased vitamin levels in some fermented products. It is doubtful, however, whether these vitamins would affect the vitamin status of healthy adults as their bioavailability in the GIT is currently unknown.

The fermentation process does not generally affect the mineral content of the product, although there is some suggestion that bioavailability may be enhanced. Like dairy milk, fermented dairy milk products are excellent sources of a range of minerals such as calcium, phosphorus, and zinc.

Traditional fermented milks and related products can make a considerable contribution to the nutritional status of some groups, particularly in developing countries, where they provide a good source of nutrients (particularly protein) at a low cost.

Other Benefits

Fermented milks and other related products may have other benefits above and beyond their nutritional content. Traditional products (such as laben from Syria) have been used therapeutically for decades for disorders of the stomach, intestine, and liver, and for stimulating the appetite long before the existence of bacteria and other microorganisms was recognized. Both koumiss and kefir are used therapeutically in Russia.

The glucose liberated from the lactose hydrolysis during fermentation is converted into lactic acid, which contributes to the taste of the products. It also helps preserve fermented foods by acidifying the product and preventing or decreasing the growth of pathogenic organisms. Certain probiotics may have a similar effect within the human GIT either by changing the environment (decreasing the pH) or by colonization resistance (preventing other microorganisms from adhering to the GIT), thereby decreasing the incidence and/or duration of intestinal infection. It has also been established that some probiotic bacteria are capable of producing bacteriocins – substances that are toxic to other (usually related) strains of bacteria. Other probiotic components may also have beneficial effects on unwanted microorganisms, for example a supernatant of one probiotic has recently been shown to downregulate *Helicobacter pylori* infection in humans.

A number of health effects have been established for probiotics, including reduction of duration of rotavirus diarrhea, alleviation of the symptoms of lactose intolerance, reduction of harmful intestinal microbial enzyme activities, immune enhancement, and decreased fecal mutagenicity. However, it cannot be assumed that all probiotic strains of even a specific species have the same or even any desirable properties.

In some countries where yogurt has not been part of the normal diet, the consumption of fermented dairy products is generally low. However, their popularity has increased in recent years (**Figures 1** and **2**).

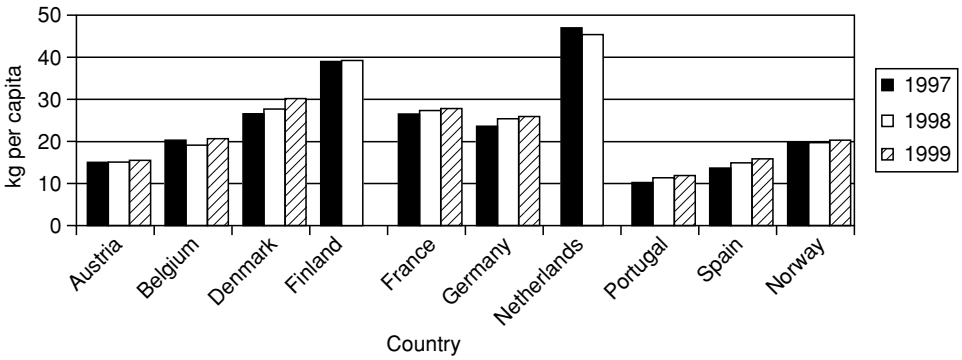

Figure 1 Consumption of milk drinks and fermented products, including yogurt: part 1. Aadapted from IDF (2000) The world dairy situation 2000. *Bulletin of the International Dairy Federation* 335: 8.

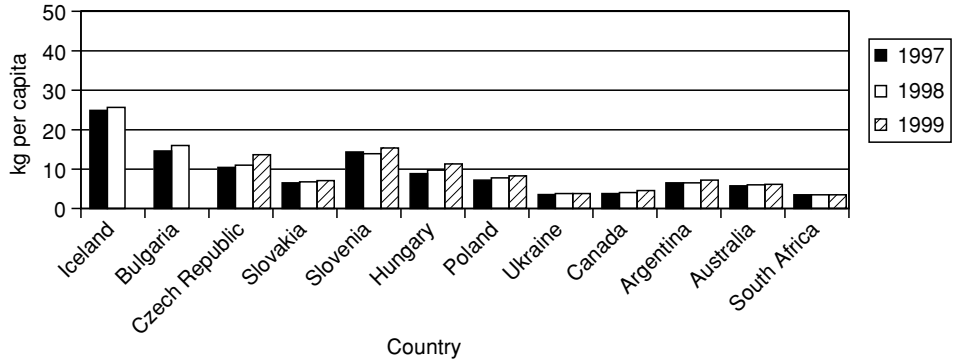

Figure 2 Consumption of milk drinks and fermented products, including yogurt: part 2. Adapted from IDF (2000) The world dairy situation 2000. *Bulletin of the International Dairy Federation* 335: 8.

This may be due to the wide variety of products now available, their simple production technology, their low cost, their long shelf-life, and their healthy image.

The growth area for fermented milks and related products appears to be in the added-value and health sector of the market – probiotic, functional, and fortified products. A number of factors will influence the acceptance and further growth of the market, including the introduction of more specialty products, quality and sensory improvements, development of fermented products using plant material, genetically engineered strains, and continued or increased interest in 'healthy' foods.

Background

During the past 80 years, considerable attention has been directed sporadically on benefits derived from the consumption of milk products containing lactic acid bacteria (LAB). The role of fermented milks (FM) in human nutrition is well documented. Man knew the virtues of these fermented foods, even during the early days of civilization. In earlier days, these foods were produced by natural fermentations with the main objective of preserving milk. In Europe, Asia, and Africa, sour milk was known to be more stable than fresh milk. It preserved the high-quality nutrients present in milk in a relatively more stable form. From prehistoric times, Man learned to use milk as food, and, although the origin of the art of preserving dairy products by lactic acid fermentation is lost in antiquity, biochemical and microbiological knowledge of fermentation is comparatively recent. On the Indian subcontinent, the conversion of milk in every household by souring with the left-overs of the previous day's sour milk has been a common practice ever since the Aryans inhabited the land. In this way, the life and utility of milk nutrients were extended. Today, the practice of preserving milk by fermentation has become a routine household technology, and these products are almost compulsory on this subcontinent. As far as the Western countries are concerned, FMs like kefir, koumiss, leben, skyr, crowdiss, and yogurt produced by lactic fermentation of milk have been consumed by people either as refreshing beverages or as nutritious or therapeutic foods and dietary adjuncts.

The milk of several species, including the cow, buffalo, goat, sheep, mare, camel, and reindeer, has been used for the preparation of FMs. Each type of FM has its own characteristic texture, body, flavor, and composition, depending on the type of milk used, the type of starter cultures (LAB with or without aroma producers and yeasts), and the procedures followed in its preparation. The FMs popularly used in various countries may be classified broadly into four categories: (1) moderately sour types with a

pleasant aroma associated with diacetyl, e.g., cultured milk; (2) sour and very sour types owing to high acid production, e.g., yogurt and dahi; (3) ethanol in addition to lactic acid, e.g., koumiss and kefir; and (4) probiotic fermented milks, e.g., acidophilus milks especially prepared with human strains of *Lactobacillus acidophilus*.

Fermentation with LAB is one of the oldest methods of food processing and food preservation used by mankind. In many areas of the world, the fermentation process is initiated by adventitious indigenous microorganisms or through 'backslopping' with mixed or unknown cultures. Often, this type of fermentation may be slow or unpredictable. Nevertheless, it affords a vital means of preserving highly perishable foods, especially where refrigeration is lacking. In developed countries, fermentation is initiated with pure starter cultures that have predictable performance potentials. Recent scientific and technological advances in starter-culture management and process control have yielded a variety of products with superior chemical, physical, nutritional, and sanitary qualities. A number of FMs, cereals, and beverages are prepared through the action of lactobacilli. Nearly every civilization has consumed FMs. Over the past two decades, the per-capita consumption of FMs has increased more than 35-fold owing to their image as nutritious and healthful foods. Likewise, the per-capita production and consumption of cheeses have seen notable growth in the USA, Europe, and the Indian subcontinent. Thus, FMs have been, and still are, of extreme importance in the nutrition of people throughout the world.

Table 1 Changes in milk constituents resulting from fermentation

Constituents	*Changes*
Milk proteins (3–4.5%)	Coagulated into a smooth curd with casein particles finely dispersed; partially peptonized (0.1–0.7%) and utilized for microbial growth, resulting in the build-up of microbial cell proteins, increase in non-protein nitrogen and release of peptides and amino acids
Lactose (4.5–5%)	Utilized (1–2%) by starter bacteria producing mainly lactic acid (0.6–2%), volatile acids, flavor compounds, and CO_2 may also be formed by heterofermentative types; alcohol and CO_2 may be produced by lactose-fermenting yeasts
Milk fat (3.5–7%)	Fermentation leads to partial digestion of lipids
Mineral matter (0.7–0.8%)	No direct appreciable change
Vitamins	No change in fat-soluble vitamins A, D, and E; slight decrease in B-complex vitamins, depending on the strains used

Nutritional Significance of Fermented Milks

Lactobacilli use the nutrients in milk for their own metabolism and growth, and multiply from one to 10 million cells per milliliter. The microorganisms are present in the FM, not only as viable cells, but also as autolyzed cells that give rise to primary and secondary metabolites and enzymes that they may have produced during fermentation and storage.

The nutritional value (NV) of a FM depends on the availability and digestibility of nutritive constituents, and the changes in these constituents resulting from microbial growth and fermentation processes (Tables 1 and 2). Similarly, the NV of fermented food also depends on the nutrient content and the bioavailability of the nutrients. Generally, the energy value of a FM is similar to that of the milk from which it was prepared, yet it is claimed that the FM are more nutritious (the compositions of milk and yogurt are given in Table 2). Fermentation makes some of the nutrients more available for absorption. The interactions between milk nutrients and starters are detailed below.

Table 2 Composition of milk and yogurt (per 100 g)

Nutrients	*Whole milk*	*Whole-milk plain yogurt*	*Low-fat plain yogurt*	*Very-low-fat/low-calorie flavored yogurt*	*Greek yogurt*	*Plain fromage frais*
Energy (kcal)	66	79	56	41	115	113
Protein (g)	3.1	5.7	5.1	4.3	6.4	6.8
Fat (g)	3.9	3.0	0.8	0.2	9.1	7.1
Calcium (mg)	115	200	190	130	150	89
Zinc (mg)	0.4	0.7	0.6	0.4	0.5	0.3
Phosphorus (mg)	92	170	160	110	130	110
Magnesium (mg)	11	19	19	13	12	08

Predigestion of Protein and Protein Quality

The proteins in milk are of an excellent quality biologically, and both caseins and whey proteins are well endowed with essential amino acids (EAA). The fact that the protein content of FM, like yogurt, is often elevated by concentration or addition of skim milk solids means that it is an even more attractive source of protein than liquid milk. It is important that the proteins in FMs are totally digestible, because some degree of initial proteolysis is caused by the starter organisms. The extent of this breakdown depends on the strains of bacteria being employed, but, in general, at least some release of amino acids and peptides can be expected during incubation and storage. FM products contain significantly higher levels of free amino acids (FAA) than milk, because the heat treatment and proteolytic activity of the starter organisms. The native milk proteins, which form a hard curd in the stomach, are converted into a soft curd containing finely dispersed casein particles resulting from the action of starter organisms in the FM. The FM proteins are useful to children, old people, and those with stomach ulcers, because the soft curd in FM is easier to digest than the milk.

It has been observed that rats fed with diets containing FM products had a higher feed consumption, greater weight gains, and a more efficient utilization of their feed. Some medical practitioners advocate the use of dahi and buttermilk by children not only for treatment of common intestinal ailments but also for their general nutrition. In tropical countries like India, where milk is exposed to heavy bacterial contamination because of the tropical atmosphere and low standards of hygiene, leading to rapid spoilage, it is better to convert milk into FM in order to preserve its NV.

Predigestion of Milk Fat and Fat Quality

Although much of the FM sold in industrialized countries is produced from skim milk, traditional materials have always contained some 3–4% milk fat. It has been proposed that the digestibility of fat is improved via the action of the bacteria present during the fermentation process, but whether this effect really exists is highly debatable. The overall energy content of FM reflects both the fat content of the milk from which it was made and whether or not ingredients such as cream or sugar have been added. Humans have a double requirement for lipids. Lipids act as a storage fat, which is composed of saturated fatty acids, and serve as a source of energy or as a protection for vital organs. In addition, they play an important role by acting as structural fat, which, together with proteins, forms many of the essential membranes in animal cells, particularly in areas like brain and nerve cells. These are essential to many physiological processes. Some essential nutrients are fat-soluble and are found primarily in foods that contain fat. These nutrients are essential fatty acids (EFA) and fat-soluble vitamins. Shahani and Chandan (1979) cited the fact that the LAB possess lipase activity, as evidenced by lipids in cultured products being partially degraded. Their assays for lipase activity, however, were performed using culture organisms with tributyrin emulsions as a substrate, and they did not prove that the bacterial lipases acted on lipids in the cultured products. A significant increase in free fatty acids over the milk has been observed in FM. The lactic acid fermentation and enzymic degradation of amino acids also produce small quantities of volatile fatty acids.

Predigestion of Lactose

The milk carbohydrate, lactose, causes intestinal problems in a number of persons who are lactose-intolerant. These persons are deficient in the intestinal enzyme, β-galactosidase, and thus must restrict their intake of milk and dairy products. Milk does not contain this enzyme. Lactose intolerance is normally defined as the occurrence of gastrointestinal symptoms after administration of a single test dose, about 50 g of lactose in aqueous solution. In a large proportion of the world's population, β-galactosidase activity is low or absent. This enzyme is present in sufficient quantities in lactic fermented milks. Consequently, the lactose level in FM can be lower than in milk, although this is not always the case, as skimmed milk powder or non-fat milk solids are sometimes added during the manufacture of some of these products; during fermentation, 20–50% of the lactose in milk is hydrolyzed to its component monosaccharides, glucose and galactose, by the starter culture organisms. The production of β-galactosidase increases during the fermentation of yogurt, reaching a maximum after 4 h of incubation. This enzyme may be released from the microbial culture during digestion, thus indicating that it may be present in the intestine of persons consuming FM. Lactose-intolerant subjects have a much lower rise in blood glucose and thus a much lower lactose utilization efficiency. A lower lactose content would presumably help tolerance of the product to those with a reduced ability to digest lactose. But clearly, the explanation is not this simple, because FM with a fairly high lactose content is also better tolerated by such individuals than the equivalent amount of lactose in milk. Lactic

acid is produced as a byproduct of the fermentation process. It acts as a preservative, influencing the physical properties of casein curd by inducing a finer suspension, which improves the digestibility of casein. It also improves the utilization of calcium and other minerals, and inhibits the growth of potentially harmful bacteria.

Effect of Fermentation on Vitamin Content

Milk is a rich source of vitamins, particularly A, D, and some B-complex vitamins. Breed, diet, climate, geographical location, age and stage of lactation and other factors can influence the vitamin content of the milk and, in turn, affect the vitamin content of the FM. There is conflicting evidence about whether there is an increase, decrease, or no change in the level of vitamins during the fermentation of milk. Various manufacturing treatments may affect the content of labile vitamins, whereas there is metabolism of vitamins by the LAB during the log-growth phase and their subsequent synthesis by the same bacteria. An indication of the changes, resulting from heat treatment, fermentation, and storage, is given by the International Dairy Federation (1983). The vitamin content of FM varies with the type of milk used (particularly the fat content of the milk, which influences the amount of vitamin A and other fat-soluble vitamins present), with the strain of bacteria and with fermentation conditions. Vitamin C is heat- and light-labile, but it is more stable in the acidic conditions of FM than in normal milk. The levels of some B-complex vitamins are reduced, owing to the requirement of some of the LAB. Losses of up to 90% of vitamin B_{12} have been reported with specific bacterial strains, but losses are not always this great and can be reduced considerably by the use of a 'supplementary culture' capable of synthesizing significant amounts of vitamin B_{12}. However, several cultures are able to synthesize the folic acid, increasing the level of this vitamin present in the final product; e.g., *Propionibacterium freudenreichii* ssp. *Shermanii*, which is used as a starter culture in some of the cheeses, is known to synthesize vitamin B_{12}.

In the current climate, in which there are concerns about the folate intake of women during the early stages of pregnancy, this aspect may prove to be a nutritional advantage. Increases in vitamin B and P (riboflavenoid) group vitamins have been observed in kefir, as a result of the activity of yeasts and acetic acid bacteria. Fermentation has been reported to increase folic acid in buttermilk, sour cream, yogurt, bifidus milk, kumiss, dahi, lassi, laben, skyr, and kefir. The effect of fermentation on the vitamin content is given in Table 3.

Table 3 Effect of fermentation on vitamin content (μg per 100 g)

Vitamins	*Whole milk*	*Buttermilk*	*Sour cream*	*Yogurt*	*Cottage cheese*
Thiamin	30	34	35	44	21
Riboflavin	170	154	149	214	165
Niacin	100	58	67	114	128
Pantothenic acid	300	275	360	591	215
Vitamin B_6	40	34	16	49	68
Folacin	6	trace	11	11	12
Vitamin B_{12}	0.40	0.22	0.30	0.56	0.63

Effect of Fermentation on Mineral Absorption

Most experiments performed recently did not confirm the improved absorption of calcium because of the more acid pH in the intestine following consumption of FM. When the bioavailability of essential minerals and trace elements was investigated in rat experiments using diets based on milk, yogurt, pasteurized yogurt, and a commercial diet, it was observed that the bioavailability (as measured by intestinal absorption, urinary excretion, and bone content) of calcium, phosphorus, magnesium, and zinc from all diets was superior to that from the commercial diet. In experiments with albino rats, the availability of calcium and phosphorus from FM was increased by about 7 and 11%, respectively, compared with milk. These results are explained by the fact that colloidal calcium complexes and lactic acid, both present in FM, enhance calcium absorption.

Bioactive peptides derived from the tryptic hydrolysates of casein, known as caseinophosphopeptides (CPP) possess physicochemical properties that enable chelation of various bi- and trivalent minerals to be carried out, thereby enhancing mineral solubility in the lower small intestine. It has been suggested that moderate and exchangeable binding of calcium to CPP is responsible for the high absorbability of calcium from milk. Results of experiments conducted at the University of Melbourne School of Dental Studies have proved that there is a significant reduction in the tooth decay in laboratory animals fed with CPP.

Nutritional Significance of Single-cell Proteins in Fermented Milks

In recent years, the nutritional importance of microbial cell protein has received considerable attention. When FM is consumed, a large number of bacterial cells (about 10^7 CFU g^{-1}) and the products released from these cells enter the digestive tract. Most of the

living cells are inactivated in the stomach by the action of hydrochloric acid and pepsin. It has been estimated that about 60% of the microbial cell nitrogen content (excluding cell wall material and nucleic acids) can be utilized by the body. The EAA content of microbial cell proteins in FM ranges from 2.0 to 6.5 mg per 100 g of product. The cells of some bacteria were found to be rich in methionine, lysine, and cystine. Studies on amino acid patterns of acid hydrolysates of microbial cell proteins have revealed the presence of all the known amino acids. Cells of mixed cultures contained higher concentrations of many amino acids than those found in cells of individual cultures. There were also considerable species variations in the pattern of amino acids in the microbial cells. When the cells were subjected to proteolytic enzymes, simulating to some extent the conditions during passage in the alimentary canal, significant differences were found between species with regard to the extent of hydrolysis and concentration of EAA released. Cells of *Lactobacillus acidophilus* and of mixed cultures of *Streptococcus salivarius* ssp. *thermophilus* and *Lactobacillus delbrueckii* ssp. *bulgaricus* released the highest concentrations of EAA. The biological activity of many EAA in FM protein is much higher than that of corresponding amino acids in milk. These results indicate that the microbial cells of starter bacteria consumed along with FM are likely to be hydrolyzed partially or fully in the digestive tract, releasing EAA, and some of the starter cultures are more useful than others in this respect.

Biological Value of Fermented Milks

The cumulative effect of the available EAA from milk proteins and from microbial proteins is reflected in the protein quality (biological value) of the total protein content isolated from FM prepared with different cultures. The protein quality of Indian FM, dahi was assessed by microbiological assay using *Streptococcus zymogenes* as the test organism. It was found to be higher (3–30%) than that of milk used for preparing dahi. Samples prepared by using mixed cultures of *Lactococcus lactis* ssp. *lactis*, *Lc. lactis* ssp. *cremoris*, *Str. salivaricus* ssp. *thermophilus*, and *Lb. delbrueckii* ssp. *bulgaricus* gave higher values than those containing other cultures. Incorporation of the culture of *Propinobacterium freudenreichii* ssp. *Shermanii*, along with the starter cultures, produced a further improvement in protein quality. It has also been found that there is increased secretion of digestive enzymes by salivary glands when stimulated by the curd particles, and that the FM proteins are twice as digestible as milk proteins.

Biopeptides in Fermented Milks

Several of the peptides derived from milk proteins represent 'extranutritional' substances, which display significant physiological influence. During the microbial fermentations milk proteins undergo controlled proteolysis under the combined influence of native microflora (comprising several spore-producers) and the starter bacteria. In addition, proteinases produced by the starter organisms could complement the complex enzyme system of starter microorganisms, leading to the accumulation of beneficial peptides. Cheeses and processed cheese products, therefore, offer the potential for developing specialized functional food products displaying prophylactic properties, besides their natural nutritional virtues. This represents a hitherto unexplored area of food research, which has tremendous future potential, from both an academic and commercial perspective.

The folklores regarding the nutritional, healthful, and therapeutic aspects of FM have been amply substantiated through recent biochemical, nutritional, and physiological research. With the growing awareness of beneficial attributes of such products, there has been a tremendous growth of market for probiotic FM products in the Western countries, especially in Japan and developing countries. Prospects for the genetic modification of starter organisms to enhance the NV and probiotic attributes have opened challenging vistas for the new product development and diversification. FM as a potential carrier for natural source of biological peptides is a fascinating area for technological development.

FIGS

K K Sinha, T.M. Bhagalpur University, Bhagalpur, India

Background

Along with date, vinifera grape, and olive, the fig was an important food crop for the ancient civilization of the eastern Mediterranean region. It has been referred to in many legends and songs of historical and mythological background. It has also been mentioned frequently in the Bible. Theophrastus was also familiar with its several varieties, as is indicated in his 'Enquiry into Plants.'

The edible or common fig, *Ficus carica* L., is a member of the family Moraceae, which includes more than 1000 species distributed throughout the world. Some well-recognized ornamental species of the genus *Ficus* include *Ficus benghalensis* L. (Indian banyan), *F. elastica* Roxb. (Indian rubber fig), *F. pumila* L. (Climbing fig) and *F. religiosa* L. (Peepal tree).

The fig is thought to be a native of southern parts of Arabian peninsula, Italy, the Balkan peninsula, and Russia. It was brought into cultivation probably in the southern parts of the Arabian peninsula by 3000 BC. Later on, it spread into Iraq, Syria, and Turkey, and into all the Mediterranean countries. During the age of exploration by Columbus, the fig was taken into most subtropical areas of the western hemisphere. It is widely cultivated in the tropical, subtropical, and warm temperate areas of the world. The major production is found in the Mediterranean region, from Turkey in the east to Spain and Portugal in the west. It is also grown commercially in parts of the USA and Chile and, to a small extent, in Arabia, Iran, India, China, and Japan.

Greece is now the leading fig-producing country, followed by Algeria, Morocco, Syria, and Italy. Turkey is, however, the largest producer of dried figs.

General Habit

The fig is a small to moderate-sized deciduous tree, 5–8 m high, with a short twisted trunk crowned with irregular branches. Shoots can also develop frequently at the base of the trunk. The bark is pale gray. Leaves are broad, ovate or nearly orbicular, more or less deeply (3–5) lobed, rough above, and pubescent below, long stalked, leaf blade 10–25 cm long, dark green with pronounced venation. The female fig plants have larger, denser, and more spreading crowns of leaves than males. Moreover, leaf fall begins earlier in males.

Fruit Morphology

Fruits are mostly solitary, axillary, green, yellow brown, purplish, or even black, depending on the cultivar and more or less pear-shaped with either a velvety or glabrous skin. Normally, these fruits are of moderate size, but in certain cultivars, these may be up to 6 cm in diameter. The plastid pigments in the fruit skin of fig are chlorophyl *a* and *b*, β-carotene, lutein, violaxanthin, and neoxanthin.

The edible fig is a multiple fruit that is botanically known as syconium. It consists of a fleshy hollow receptacle with a narrow aperture at the tip and numerous small flowers lining the inner surface. The true fruits, which are small achenes, are borne on short stalks on the inside of the syconium (**Figure 1**).

Types and Cultivars

Depending upon the nature of the flowers and the method of pollination, figs can be cronologically distinguished into four different classes:

1. Common fig or Adriatic fig
2. Caprifig
3. Smyrna fig
4. San Pedro fig.

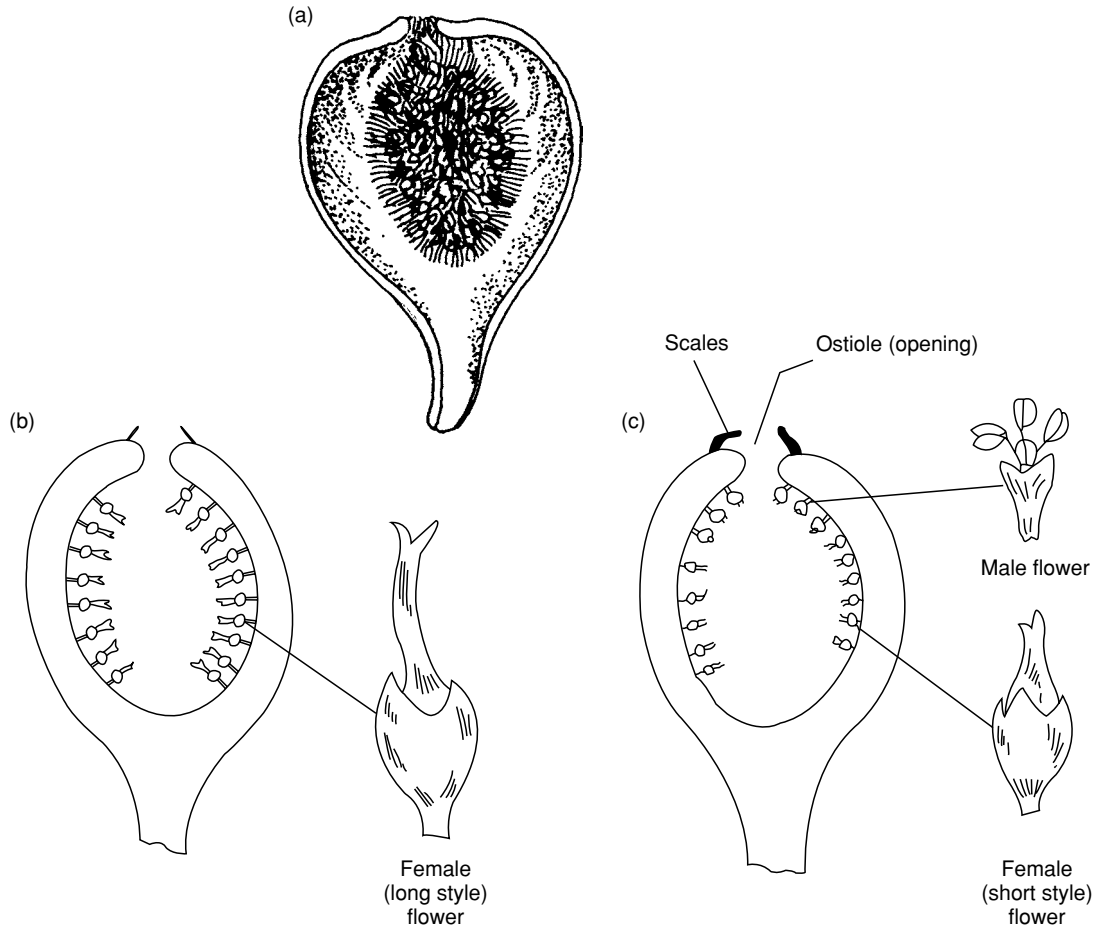

Figure 1 Longitudinal sections of fig fruits. (a) Edible fig fruit. (b) Edible fig fruit (diagrammatic). (c) Capri fig fruit (diagrammatic).

Common Fig

In this type, the individual flowers are pistillate (female), and consequently, the fruits develop without pollination and fertilization (parthenocarpic) and have no seeds. Two crops are produced annually. The first crop (*brebas*) is larger and more juicy, and is usually eaten fresh. The fruits are borne on the old wood. The second crop is produced in the axils of the leaves, and the fruits are used fresh or dried. Some common cultivars of this type are Kadota (Dottato), Mission, Adriatic, Brown Turkey, Celeste, and Conadria.

Caprifig

The caprifigs are wild figs that grow naturally in the Mediterranean region and Western Asia and probably represent the primitive type. Although the fruits do not have any commercial value, they are cultivated in most fig-raising countries, as they are essential for the development of Smyrna fig. The life history of the caprifig is closely connected with that of a small wasp (*Blastophaga psenes*), which brings about cross-pollination.

Caprifigs produce three crops of fruit in a year. The spring crop (Profichi) contains staminate (male) flowers and the so-called gall flowers. These are similar to pistillate flowers but have short-styled ovaries. The fig wasp enters the young figs and lays eggs in the gall flowers. In about 2 months, the new generation of wasps hatches out and emerges from the fig having pollen grains throughout the body surfaces. By this time, the summer crop of figs (Mammoni) are produced, which contain mostly gall flowers. The wasps again enter these figs and deposit eggs in most of them. Although these flowers are pollinated by wasps, the presence of the larvae without eggs may develop fertile seeds. Late in the season, the winter crop of figs (Mamme) is developed and remain on the tree over winter after the wasps visit on them. The larvae mature in April, when a new crop of spring fig is ready to receive the wasps, and the annual cycle is resumed.

Smyrna Fig

No staminate flowers are produced in Smyrna figs, and these are absolutely dependent on cross-pollination from caprifigs. This process is known as 'caprification' and is brought about artificially. Branches of caprifigs of the spring crop are suspended on the Smyrna tree. The wasps coming from Spring crop enter the developing Smyrna figs and affect pollination. The ovaries of Smyrna figs have longer styles that prevent the wasp from depositing eggs at the proper site. The ovules thus develop normally after fertilization. Smyrna figs have a superior nutty flavor owing to the presence of fertile seeds. They are the most important fig of commercial value and are extensively cultivated in Asia Minor, Greece, Algeria, and parts of Portugal and California. Early attempts to cultivate Smyrna figs in California and other places met with continued failure until the spring crop of caprifigs and the fig wasp were introduced. Calimyrna is the most common and widely grown cultivar of Smyrna type. Some cultivars like Krymskii 43 and Bianco Grosso have also been recommended for cultivation in Southern Uzbekistan.

San Pedro Fig

This is an intermediate type of fig that has two crops annually. Like the common fig, the first crop (breba) is completely parthenocarpic and does not require pollination and fertilization of flowers, but the second crop develops only when the flowers are pollinated, as in the case of Smyrna fig. San Pedro, King, and Gentile are some of the common cultivars of this type.

The common fig is the only type that is grown in India. It is considered to be a hybrid between the imported *F. carica* and the indigenous species. A large number of cultivated forms are known in which the fruits vary in shape, size, color of skin, color and flavor of flesh, and period of ripening. Some of the cultivars grown in India are Black Ischia, Brown Turkey, Turkish White, Kabul, and Marseilles. The figs grown in many parts of India are named after the locality and exhibit no special distinction to warrant varietal names. Poona fig is of a medium size, bell-shaped and light purple in color with a rosy flesh. In South India, Poona fig and Marseilles are commonly cultivated, the latter thriving well on the hills above 1500 m. The fruits of Marseilles are medium-sized and pale green on the rind with a whitish sweet flesh.

Fig Cultivation

Soil

The fig tree does not require a very rich soil for cultivation. Alluvial or loamy soil or yellow or reddish brown colour, with a rocky or murum bed, prevents the roots from penetrating deep into the soil, and favors the side-growth of rootlets, which is very desirable. Fig trees also thrive well in clayey soil, but the land must be well drained. Rich black soil is unsuited to fig trees because the plant grows tall and runs to leaf, and the fruit is considerably inferior in both size and taste.

The fig is also one of the salt- and drought-tolerant crops. It can tolerate a fairly high level of sulfate or chloride salts, but it can be injured when even a small amount of sodium carbonate is present in the soil. In highly alkaline soil, the leaves show tip burn, and there is considerable leaf fall. A red loam with a live substratum and about a meter deep is considered best for figs in South India.

Heavy and poorly drained soils usually produce fruits of inferior quality. Soils with a high lime content produce fruits of better quality suitable for drying.

Climate

The fig is a subtropical fruit. In the dormant condition, the mature trees can withstand temperatures as low as -12 to $-9.5\,^{\circ}C$ depending upon the cultivar, but the young trees may have to be protected during winter because they are not very hardy. Low temperatures of about 1.5–4.5 °C at the time when the trees are not dormant are very much damaging. Similarly, early autumn frost or spring frost when the plant starts sprouting causes considerable damage to the tree. In India, the temperature of commercial fig growing areas in Southern and Western parts of the country seldom falls below 4–5 °C, and therefore, there is no damage resulting from low temperatures. In Northern India, where the temperature falls to freezing, the plants remain dormant at that time and normally are not damaged. Figs grow well when the temperature range is 15.5–21 °C.

The climate also greatly influences the characteristics of fig fruits. It affects the shape and size of the fruit, as well as the color of the skin and pulp, quality, and tendency towards parthenocarpy. The best-quality figs are produced in regions with a dry climate, especially at the time of fruit development and maturation. High humidity coupled with a low temperature usually results in fruit splitting and a lower fruit quality. Fruits exposed to warm breezes in hot areas, though slightly sweeter, remain small in size. By contrast, mild temperatures result in large, succulent fruits.

Propagation

The plant is readily propagated by cuttings, although all types of budding and grafting as well as air-layering

are successful. Hardwood cuttings, 20–30 cm long and 0.5–0.7 cm thick, taken from 1–2-year-old shoots in late summer are selected for this purpose. These cuttings are treated with root-promoting substances, stored in packing material like sawdust at room temperature for about 4 weeks, and then planted. Cuttings taken from the base of the shoot and lower part of the crown give better results. In about 2 months, they begin to throw roots and shoots and make a few leaves. If they are properly taken care of, the plants become fit after a year for transplantation, otherwise they may take a further 10–12 months. After a 12–15 months, they are transplanted into orchards. The spacing varies depending upon the size of the tree, variety, and type of culture adopted.

Figs can also be air-layered successfully, and monsoon is the best time for it. One-year-old branches, if layered in June, can be planted in the field in August–September. Top working to change the variety of established trees is sometimes possible and may be done by shield or patch budding or cleft or bark grafting. Micropropagation of figs is also possible.

Pruning and Training

Fig trees are pruned annually and trained to the desired height and shape to keep the plant most productive and to facilitate harvesting and other orchard operations. As the tree normally bears two crops in a year, the first pruning is done on the wood of the previous season and the second on new wood of the current season; the time and the amount of pruning are adjusted according to the type, habit of growth, and bearing capacity of the tree. The main aim of pruning is to induce the growth of fruit bearing wood and so improve the yield of fruits. In addition, pruning increases the fruit weight in early cultivars. Besides pruning, some special methods like notching are also adopted to stimulate the production of laterals on vigorous upright branches.

Irrigation and Manuring

Fig is fairly drought-resistant, and it is seldom irrigated in many fig-growing countries. However, reports from Cairo indicate a greater shoot growth and yield of fruits in irrigated fig plants. In some cases, fruits from irrigated trees have been found to 13–16% heavier. In India, the fig is irrigated only during dry months. However, care should be taken that at the time of ripening of fruits, no irrigation is given, because that may result in the production of insipid fruits. Excessive water in the soil may also cause splitting of fruits. The plant also responds to manuring, but the type and amount of manure vary in different areas.

Fruit Development and Harvesting

The fig tree begins to bear a fair crop from the second or third year after planting, though rooted cuttings and layered plants are known to bear fruits even in the first year of planting. Under favorable conditions, the trees continue to bear fruits for 12–15 years, after which they show a marked decline in yield. Normally, the trees bear two crops in a year, but in some types, even a third crop is obtained.

The figs commonly grown in India are parthenocarpic in nature and do not need any cross-pollination with wild caprifig (caprification), which is very common practice in other countries. However, fruit setting is also inhibited under certain conditions. It has been suggested that parthenocarpy is favored or inhibited in a given type by climatic condition of the growing area. The parthenocarpic fruits develop to a normal size and have a desired sugar content, but as they are completely seedless, the baking industries do not want to use it, because they lack the crunchy quality imparted by fig seeds.

As fresh figs are extremely perishable, fully ripe fruits cannot be transported to distant markets. It is better to harvest the crop when the fruits are slightly immature (ripened). Ripe fruits are picked either from the tree by twisting the neck at the stem end or by cutting it or gathered after they drop on the ground. In the major fig-growing countries, special devices are employed for collecting fruits from the tree, and the pickers are protected against the acrid juice.

Drying

Fresh figs do not keep well even under cold storage (0 °C) for more than a month. Fully matured figs can be either frozen or dried if they have to retain their flavor and color for several months. Details of the process of drying and curing differ in different countries depending largely upon the variations in varieties cultivated.

Dried figs are the most important fruit product of fig. In one method of drying, the fruits are firstly subjected to sulfur fumigation and then dried in an electric drier at a temperature of 70–72 °C. In another method, the fruits are initially soaked in boiling salt water for 30 s, then dried for few hours in the sun and for 8 days in the shade.

Pests, Diseases, and Disorders

The following major pests have been reported from fig trees:

- Stem-boring beetles (*Batocera rufomaculata, B. rubrus*)
- Leaf defoliators (*Adoratus duvauceli*, *A. versutus*)

- Scale insects (*Aspidiotus lataniae*)
- Fig flies (*Lonchaea aristella*).

In addition, dried figs have been found to be damaged by fig moth (*Ephestia cantelia*) and the Indian meal moth (*Plodia interpunctella*). Some of these pests can cause more than 50% losses in yield. The fig leaf roller (*Phycodes mina*) has been reported in Haryana (India), for which excellent control was obtained with trichlorphon (0.05%) and chlorpyrifos (0.03%).

Figs are also susceptible to root-knot nematodes, which can be controlled by using DD-mixture.

Leaf rust is an important disease of figs in all the fig-growing countries of the world that is caused by *Cerotelium fici* (Syn. *Uredo fici*). Rust-affected leaves show small, round, brownish to black eruptive lesions mostly on the lower surface. The affected leaves drop off prematurely and, in severe cases, affect the yield of fruits. This disease can be controlled by dusting with sulfur or spraying with zineb or Bordeaux mixture.

Anthracnose (caused by *Sphaceloma fici-caricae*), a leaf spot disease (caused by *Cylindrocladium scoparium*) and mosaic disease (caused by virus) of fig have also been reported from different parts of India.

Some important diseases of fig fruits are caused by *Botrytis cinerea, Alternaria fici, Aspergillus niger, Fusarium moniliforme*, and *Cladosporium sicophilum*, which can be controlled by using some effective fungicides. Rhizopus rot (caused by *Rhizopus stolonifer*) of fig is also quite common among storage rots and can be controlled by dipping the fruits in a solution of aureofungin and copper sulfate.

Sunburn and fruit splitting are the important disorders of fig plants. Newly planted young trees are mostly affected by sunburn in which the affected parts crack, and the bark peels off. Heavy pruning exposing the trunk and branches is responsible for sunburn. Whitewashing of exposed parts can prevent this malady. Fruit splitting usually occurs if there is a shower during ripening of fruits. Fruit splitting damages the fruit, making it completely unfit for consumption.

Uses

Figs are consumed fresh, dried, preserved, canned, or candied. Fresh figs are delicious and can be used as a dessert or for jam. The great bulk of the crop is consumed as dried fruit. Better grades of dried fig are used for making fancy packs, whereas other grades are used for the production of alcohol and wine. Figs are also roasted like coffee beans and can be used as a substitute of coffee. Other fig products are spiced or pickled figs, fig bread, fig meat, and fig brownies.

Fresh figs generally consist of 84% pulp and 16% skin. The chemical composition varies with type. The average nutritional composition of dried figs (per 100 g) has been recorded as follows:

Energy: 220 cal
Protein: 3.3 g
Carbohydrate: 48.0 g
Fat: 1.5 g
Fiber: 12.4 g
Sodium: 62 mg
Potassium: 970 mg
Vitamin C: 1 mg
Thiamin: 0.08 mg
Riboflavin: 0.1 mg
Nicotinic acid: 0.8 mg
Pantothenic acid: 0.5 mg
Folic acid: 9 μg
Vitamin B_6: 0.26 mg
Calcium: 250 mg
Iron: 4.2 mg
Phosphorus: 89 mg
Magnesium: 80 mg
Copper: 0.3 mg
Zinc: 0.7 mg

Figs owe their food value chiefly to their mineral and sugar contents. The total mineral content is two to four times that of most other fresh foods, and only cheese and a few types of nuts have a higher calcium content. They are richer in iron and copper than nearly all fruits and vegetables and most other dried fruits. The nutritive index of fig in comparison with that of other fruit is reported to be as follows: fig, 11; apple, 9; resin, 8; date, 6; pear, 6.

The fruit, fresh or dried, is valued for its laxative property. It is diuretic, demulcent, emollient, and nutritive, and is used in the form of confection and syrups. Figs are considered useful in the prevention of nutritional anemias. The ash of figs is highly alkaline.

The fig tree yields a latex that is used as an anthelmintic. It is toxic when administered parenterally to animals but has no toxic effect when administered orally. The anthelmintic action has been traced to ficin, a proteolytic enzyme that has the remarkable power of digesting living helminths. This ficin also reacts with protein of the skin, causing dermatitis. Some individuals are adversely affected by such materials and cannot ingest fresh figs without skin eruptions around the mouth. Many field workers in fig orchards suffer from dermatitis on the arms and body if they brush against the limbs and leaves, or as they handle the fresh fruits. Gloves and protective aprons are generally provided for such workers.

Fresh fig latex also shows milk-clotting activity, which may be 30–100 times greater than that of the animal rennet prepared from calf stomach mucosa.

FILTRATION OF LIQUIDS

J Keifer, Formerly of Filtrox-Werk AG, St Gallen, Switzerland

Introduction

Filtration and separation play an important role in the preparation of beverages, especially beer and wine, which, as the products of a fermentation process, require an extensive reduction in microorganisms and haze-forming substances at the end of the production cycle. The aim of this clarification step is to obtain a product which does not contain any harmful microorganisms, is visually bright, and has the required shelf-life.

Selection of the clarification process necessitates a careful analysis of the separation problems involved. Not only is the result of the clarification process itself a criterion, but additional factors also have to be taken into account.

The clarification processes commonly used in the brewing and wine-making industries are kieselguhr filtration, sheet filtration, cross-flow microfiltration (for wine) and dead-end membrane filtration. The first two processes are the dominant filtration technologies.

Kieselguhr Filtration

Kieselguhr or diatomaceous earth filtration in the brewing and wine-making industries is a precoat filtration with the addition of further kieselguhr as body-feed. In brewing, it is always a pressure filtration to maintain the carbonation of carbon dioxide content of the beer; in wine-making, it may be pressure or vacuum filtration.

The application of kieselguhr filtration is restricted to a maximum solids content of about 0.2%. Feeds with higher solids contents always require pretreatment.

Basic Technology of Kieselguhr Filtration

Microorganisms and haze particles are much smaller than the sieve aperture of that part of the filter's structure used as a mechanical support for the kieselguhr cake. Therefore, several precoat layers of coarse kieselguhr are applied to obtain a tight cake which retains the body feed and beer/wine solids. Continuous dosing of body feed prevents a rapid pressure increase by dilution of the solids and, therefore, results in longer filtration runs.

The relationship between filtration pressure, filtrate flux, or specific flow rate (flow per unit area), cake thickness, and cake permeability is obtained from Darcy's law and its derivations.

One derivation of Darcy's law, containing the parameters of cake porosity, specific gravity, and thickness, is:

$$U = \frac{\Delta P}{\mu a \rho s (1 - \sum) L}. \qquad (1)$$

As ρs and Σ are constants for a specific cake, the expression can be simplified to:

$$U = \frac{\Delta P}{\mu a c_k L}, \qquad (2)$$

where U is the filtrate flux (m s^{-1} or m^3 s^{-1} m^{-2}), μ is the filtrate viscosity (N s m^{-2}), ΔP is the differential pressure (N m^{-2}), a is the specific filtration resistance (m kg^{-1}), ρs is the specific gravity of the cake-forming particles (kg m^{-3}), Σ is the filter cake porosity, c_k is the filter cake constant (kg m^{-3}) ($=\rho s(1 - \Sigma)$), and L is the cake depth (m). This expression can be applied to model the different means of operating a kieselguhr filter, that is:

- constant flow, variable pressure;
- constant pressure, variable flow; and
- variable flow, variable pressure.

The first of the above is commonly used in practice for beer and wine filtration.

Kieselguhr Filtration of Beer

A typical beer plant consists of the components shown in Figure 1. The process starts with the kieselguhr filter unit filled with water. Then, after a two-step precoat, as specified in Table 1, the water is pushed out by incoming beer; a portion of the resulting diluted beer is collected and blended back to the unfiltered beer during the production run. (*See* **Beers:** History and Types.)

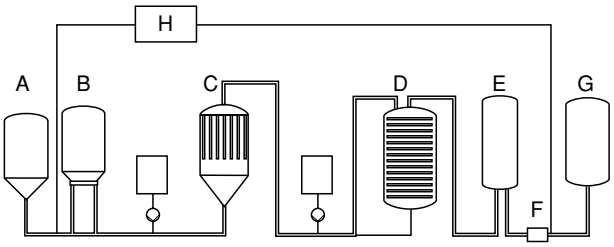

Figure 1 Components of a typical beer filtration plant: A, storage tank for unfiltered beer; B, buffer tank for unfiltered beer; C, kieselguhr filter including dosing unit; D, polyvinylpolypyrrolidone stabilization unit, including dosing unit; E, buffer tank for bright beer; F, carbonation unit; G, bright beer tank; H, cleaning-in-place (CIP) station.

Table 1 Kieselguhr permeabilities for different process steps

Process step	*Permeability*	*Examples*
First precoat	1.2–1.5 Darcy	Manville Hyflo Ceca Dic B Dicalite Speedplus
Second precoat	100–250 m Darcy	Manville Standard Supercel Ceca CBR Dicalite Speedflow
Bodyfeed	30–250 m Darcy	Manville Filtercel Ceca CBL Dicalite 215 Also types from second precoat

The beer in the filter plant is then recirculated for several minutes to stabilize the filtrate haze level. At the end of this step, the beer should reach a clarity of no more than 0.6 European Brewery Convention (EBC) units. At the end of recirculation, the collection of filtered or bright beer can start.

Quality Parameters of the Filtrate

Microbiology Normal beer before filtration contains about 1–10 million yeast cells per milliliter. Kieselguhr filtration can reduce this figure to a maximum of 5 yeast cells per 100 ml – a reduction by a factor of 2×10^7 to 2×10^8. Bacteria – if present – are reduced by a factor of 10^3–10^4.

Haze The total haze is formed by the optical effects resulting from the presence of yeast cells, proteins, and a lot of other high-molecular-weight substances. In brewing, the haze level is measured in EBC units. A level of 0.6 EBC or less is acceptable; less than about 1 EBC is detectable only by accurate measurement of the portion of a light source scattered at a 90° or 25° angle by the suspended particles.

Oxygen pick-up A low dissolved oxygen content of the packaged product is important to maintain its shelf-life, that is, to avoid changes in its appearance or sensory characteristics within the consumption period. Normally, an oxygen pick-up of less than 0.1 mg l^{-1} beer is acceptable.

Process conditions Only typical ranges of values for the process parameters are given below since beer is a natural product which is available in many varieties. Batch sizes, for example, show variations by a factor of about five.

Filtration speed and batch size The filtration speed (or flux) strongly influences batch size; the higher the speed, the smaller the batch, the volume of which is often measured in hectoliters (hl).

The filtration speed cannot be standardized. Normal values – depending on the filter system and the type of beer – vary from 2.5 to 10 hl m^{-2} h^{-1}. The higher filtration speeds are normally obtained by using vessel filter systems, preferably candle filters or horizontal leaf filters. The traditional plate-and-frame filter is operated at lower filtration rates.

The filter is precoated at 7–10 hl m^{-2} h^{-1}.

Batch sizes normally range from 15 to 70 hl m^{-2} filter area. Large batch sizes can be obtained by the

use of enzymes to degrade β-glucan, thus reducing bodyfeed requirements. β-Glucan in its gel form leads to beers of extremely poor filtrability. The filtrability can be measured by the so-called Esser test, a membrane filtration test.

Temperature The filtration temperature is less than 1 °C, ideally −1 °C. Lower temperatures are better, as so-called chill hazes comprising proteins and other high-molecular-weight substances are precipitated and, therefore, removed by the filtration.

Additional treatment Together with kieselguhr filtration, beer is treated sometimes by the addition of silica gel or polyvinylpolypyrrolidone (PVPP) to improve the colloidal or haze stability. The space consumed within the filter by this additional processing aid leads to smaller batch sizes. Therefore, the PVPP treatment is mostly performed in a second, separate filter unit with a regeneration station for the PVPP.

Filter types The traditional filter for kieselguhr filtration, that is, the plate-and-frame filter, is being replaced more and more by modern vessel filters which can be easily automated and require less manual work.

Vessel filters can be classified by the kind of kieselguhr support: candle filters with vertical, cylindrical filter elements, hanging from a perforated plate into the vessel; horizontal leaf filters with centrifugal sludge discharge; and, uncommonly, vertical leaf filters. Candle filters are preferred, because of their excellent filtration characteristics and the absence of any moving parts.

Performance ranges from 30 to 1000 hl h^{-1} for the horizontal leaf filter and from 100 to 1000 hl h^{-1} for the candle filter.

Kieselguhr Filtration of Wine

For wine filtration, the same principles as for beer filtration are valid. The process parameters differ: the filtration speed is higher, ranging from 10 to 20 hl m^{-2} h^{-1}, due to the better filtrability of wine; the temperature is higher, at up to 20 °C; and different grades of kieselguhr are used. (*See* **Wines**: Production of Table Wines; Production of Sparkling Wines.)

Several stages of filtration can be differentiated in wine production: the first filtration after the main fermentation, a second after the use of finings, and a possible third as a prefiltration stage prior to membrane filtration just before bottling. The kieselguhr types vary from coarse, at the first filtration, to very fine, at the last.

The filter types normally used are the plate-and-frame, the horizontal leaf filter and, for smaller units, the vertical leaf filter. Candle filters are normally not used, because of the numerous types of wine and the risk of mixing taking place upon batch change. The horizontal leaf filter can be emptied and filled again with the new variety; this reduces the extent of mixing.

The performance of typical plants ranges from 10 to 600 hl h^{-1}. The plants are much smaller than beer filters and normally are operated manually.

Sheet Filtration

Sheet filtration is normally used as a second filtration for polishing or obtaining a further reduction of microorganisms. In the wine industry, it is also used for prefiltration. For these purposes, a wide range of filter sheets is available, from a coarse prefiltration to a final filtration with bacterial reduction up to a factor of 10^8. Figure 2 shows an electron micrograph of a filter sheet.

In brewing, filter sheet grades vary only over a narrow range; for polishing (reduction of haze level), for obtaining yeast-free beer and for reduction of bacteria. Tighter filter sheets, with bacterial reduction by a factor of 10^6–10^8, are not used in the brewing industry, mainly for economic reasons; the presence of colloids shortens sheet life.

The process conditions for sheet filtration depend on the type of sheet. A survey is presented in Table 2.

The permeability value for filter sheets is given in liters per square meter per minute (1 m^{-2} min^{-1}), measured at 20 °C and 100 kPa with prefiltered water. Filter sheets with permeabilities lower than 30 l m^{-2} min^{-1} are only used as pharmaceutical grades.

The typical life span of a filter sheet depends on its porosity, the quantity and kind of solids to be removed, and the filtration speed. Typical values for beer filtration vary from 50 to 200 hl m^{-2}.

The filter sheets commercially available consist of cellulose, kieselguhr, and, sometimes, perlite. Asbestos-containing sheets are no longer available, due to the well-known problems caused by the use of asbestos.

The disadvantages of filter sheets include so-called drip losses through the exposed edges of the sheets, especially with high-value products, and the high manual input required in handling.

Recent developments of vessel filter systems, incorporating the use of filter sheet material as the filtration medium, eliminate these problems. Filter sheets formed in so-called lenticular cartridges permit a filtration free from drip losses. The handling of such cartridges is very easy; up to 3.6 m^2 are combined in a single unit, as opposed to an absolute maximum of

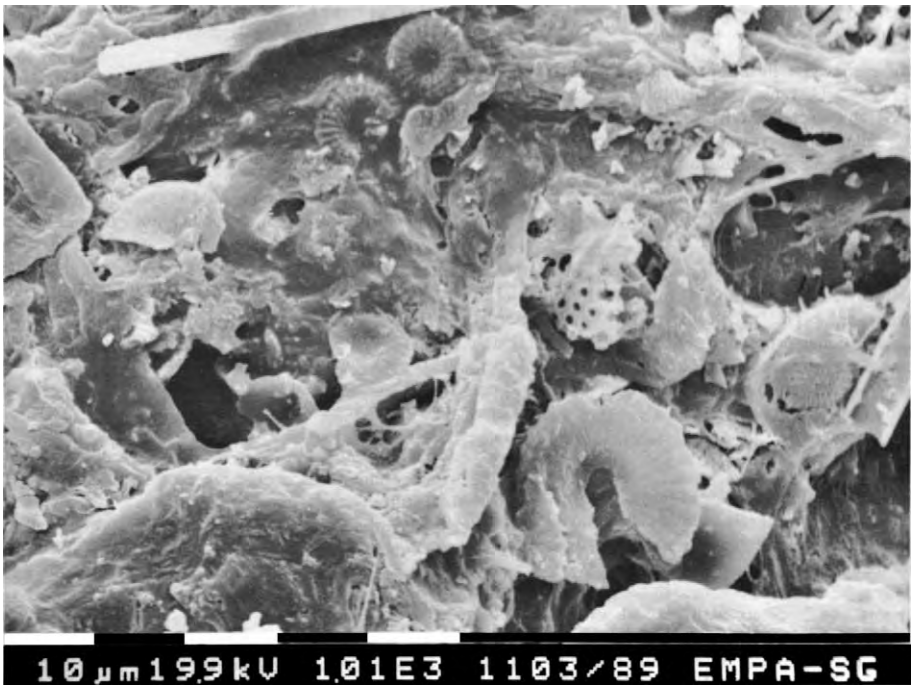

Figure 2 Electron micrograph of a filter sheet.

Table 2 Typical filter sheets

Permeability ($1\,m^{-2}\,min^{-1}$)	*Flux ($hl\,m^{-2}\,h^{-1}$)*	*Use*	*Examples*
300	6	Prefiltration of wine	Seitz K200 Filtrox K30 Carlson XE150
150	2–3	Polishing and filtration of beer	Seitz K150 Filtrox 71H Carlson XE280
130	4	Polishing and filtration of wine	Seitz K150 Filtrox K70 Carlson XE280

30	2	Removal of bacteria from wine	Seitz EK1 Filtrox St 140

$1.4\,m^2$ per individual sheet. Under typical process conditions, it is possible to attain about double the filtration speed of the normal sheet filter.

Final Filtration of Wine

As a last step before bottling, wine can be treated by membrane filtration. The removal of all harmful bacteria requires membranes with a pore size of 0.45 μm. Such a membrane is expensive and therefore requires a very effective prefiltration. This can be achieved by using a lenticular cartridge with its deep-bed filtration medium, or by cartridge filters, constructed from wound cotton, glass, or polypropylene fibers or nonwoven fibrous polymeric media, which may be pleated for optimal filter surface per volume.

Integrity checks of the final membrane are possible.

Cross-Flow Microfiltration

All the techniques described above are based on consumable materials such as kieselguhr, filter sheets, or

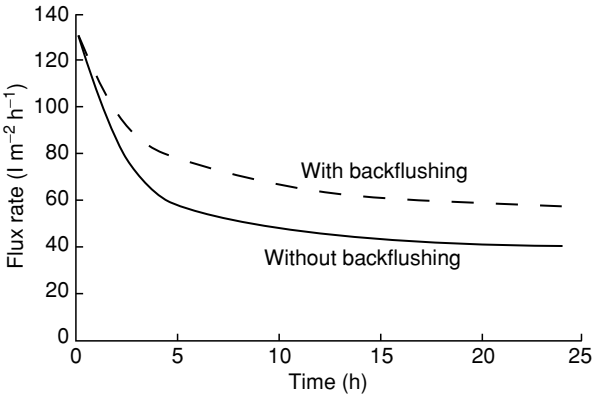

Figure 3 Typical behavior of a cross-flow microfiltration plant used in wine production.

different cartridges. A technique that can combine several filtration stages into a single operation, hence reducing wastage, is cross-flow microfiltration, based on the well-known cross-flow or tangential flow principle. The application of pore sizes of 0.1–1 μm allows an alternative to the systems used until now.

Cross-flow microfiltration systems are based either on capillary or tubular membranes (internal diameter 0.8–4 mm), or flat sheet membranes in conjunction with a special turbulence-promoting mesh. Various polymeric materials are used and ceramic membranes have been tested.

The process conditions should provide a turbulent flow, to prevent concentration polarization and, hence, rapid membrane clogging.

In wine filtration, cross-flow units have found some application (Figure 3). Typical values for the filtrate or permeate flux are 30–80 l m^{-2} h^{-1}, and run times vary from 6 to 30 h. The main problem is the prevention of a rapid flux decay. The reduction in flux can be prevented to an extent by backflushing or other fouling-reducing techniques.

In beer filtration, the cross-flow technique is still not economic due to low process temperatures and the high colloidal fraction of the solids, which results in flux rates of only 20–30 l m^{-2} h^{-1}; and the large volumes of beer involved. Further investigations into the use of membranes will lead to the attainment of better fluxes in the future.

Prospects and Conclusion

The long-term preservation of a food or beverage is a critical requirement of the future consumer. Additionally, chemical or thermal treatments of food are no longer accepted by an increasing number of consumers. For the microbiological stability of beer and wine, filtration in the submicro-meter range is gaining more importance.

Filter media with guaranteed properties, guaranteed solids- or dirt-holding capacities, and microorganism separation characteristics are required as the final step of treatment.

Environmental concern will cause the substitution of waste-producing techniques by others; for example, cross-flow technology and filter media will replace kieselguhr and sheet filtration.

Economic implementation of new techniques will probably arise from the increasing costs of waste disposal, not from any additional advantages in quality, handling or energy consumption. In contrast, the cost savings associated with a reduction in waste will be balanced by a higher energy consumption.

FISH

Contents

Introduction

Q Bone, The Marine Laboratory, Plymouth, UK

Kinds of Fish used as Food

An extraordinary diversity of different kinds of fish and fish products are used as food, from jawless lampreys to lungfish (and, at times, even coelacanths), but the most abundant kind of fish, the bony ray-finned teleosts (like carp and cod), make up the great majority of fish used directly as food. The teleosts also make up the greater part of fish used as fish meal, which we eat indirectly after it has been used as animal feed or plant fertilizer, for most fish meal is made from small pelagic teleosts. Some 20 000 teleosts are known presently, but new species are still being described from both marine and freshwaters, and the final total may well exceed the present estimate of 30 000 (with around 12 000 from freshwater). Many of this grand total are naturally too inaccessible, too rare, or otherwise unsuitable for use as food, but most of the different teleost families contain food fish species, and some families like the Clupeidae, Gadidae, and Salmonidae are of special importance. In contrast, the other major fish group, the sharks and rays (elasmobranchs), has only some 800 species, almost all entirely marine. Relatively few are of significant importance as food, though flesh from small sharks (dogfish) is much used in the UK as rock salmon, whilst other elasmobranchs provide liver oils. Apart from the teleosts and elasmobranchs, the only other food fish important for their flesh (and, in particular, their eggs) are the ray-finned sturgeons, one of the small number of surviving Chondrostean fishes.

Elasmobranchs and Teleosts

The general structural features of the two main groups of food fish are shown in Figure 1. The elasmobranch body is covered with hard denticles, often variously ridged or pointed; in the jaws, these form formidable successions of teeth. In contrast, teleosts are covered with bony scales (sometimes lost or minute, as in eels), and these too may be variously sculptured and ridged, although they are usually more or less circular. In both groups, the general body plan is the same, with two sets of paired fins as well as dorsal and ventral unpaired fins. The paired fins are attached to the pectoral and pelvic girdles, the former linked to the central vertebral column. On either side, serial myotomal muscle blocks (the main edible portion of most) are separated by tough connective tissue myosepta, which attach to the vertebral column and to the connective tissue layer underlying the skin.

However, the design of the fins and axial skeleton is different in the two groups: in sharks, the skeleton is cartilaginous (strengthened by granular or prismatic calcifications where necessary); the vertebral column is simpler than in teleosts, and the ribs are small. The unpaired fins are attached to basal cartilages. Shark fins are supported by jointed cartilaginous elements at their bases and by thin elastoidin rods (ceratotrichia) along their length, which stiffen the outer border of the fin. Lacking the bony rays of teleost fins, the supporting elements of shark fins

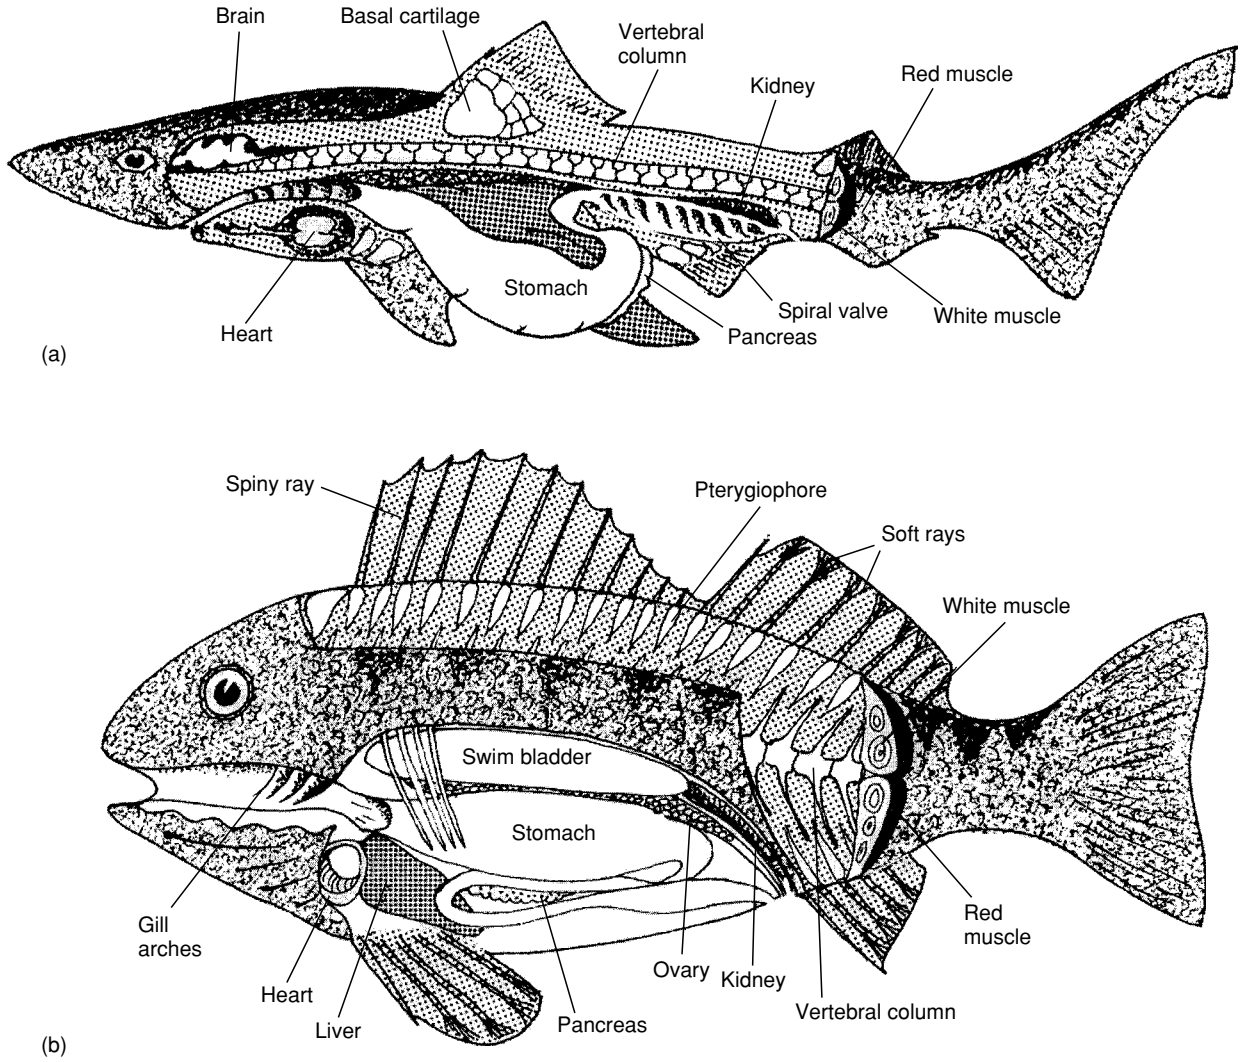

Figure 1 General features of (a) a shark and (b) a teleost fish. Note the absence of a swim bladder and less prominent skeletal elements in the shark, and the presence of a large liver and spiral valve. In both, the myotomal muscle consists of an outer layer of dark flesh and an inner white layer (see text). (a) After Lagler KF, Bardach JE, Miller RR and Passino DRM (1977) *Ichthyology*, 2nd edn, pp. 506. Chichester, UK: Wiley. (b) After Dean B (1895) Fishes living and fossil. An outline of their forms and probable relationships. In: *Columbia University Biology Series*, vol. 3. London and New York: Macmillan and Co.

can be sufficiently softened by cooking to be eaten as an expensive delicacy. They are much less flexible than teleost fins and, unlike the latter cannot be furled and used for delicate fanning and flapping movements. The pectoral fins act in almost all sharks as lifting foils, like aeroplane wings, and they can adjust their angle of attack and be swung back and forth to some extent; the other fins of sharks can only bend stiffly from their bases. Rays differ from sharks because their pectoral fins (which they use for swimming) are greatly enlarged and supported by jointed cartilages to their tips, so that they are much more flexible and can make delicate flapping movements. Naturally, the fins are highly muscular; hence, it is the pectoral muscles rather than the reduced myotomal muscles that are used as food, and they are easily separated from the supporting cartilages when cooked.

In teleosts, the skeleton is much more prominent than in elasmobranchs: the vertebrae have neural and hemal spines; in addition, the unpaired fins are attached to bony, spinous pterygiophores, and there may also be intramuscular bones in the myosepta, as in clupeids such as herring (*Clupea harengus*) and the shads (*Alosa* spp.), which are irritatingly obvious when they are eaten. Teleost fins are very different to those of elasmobranchs, for they are supported by flexible, jointed rays (lepidotrichia) controlled by

muscles at their bases moving individual rays, and hence can be furled or make most delicate movements (e.g., in seahorses or knifefishes).

Internally, the chief differences between teleosts and elasmobranchs are as follows: many teleosts have a gas-filled swim bladder, used for buoyancy (and also in some for sound production and reception, and in some freshwater species for respiration); the gills are of a slightly different design; all elasmobranchs and only a few teleosts have a spiral valve in the intestine, and the reproductive apparatus is different. Only a very few teleosts (e.g., damsel fishes, Pomacentridae) have internal fertilization (universal in elasmobranchs) and, except in bottom-dwelling species, store lipid in the large liver for buoyancy.

A notable physiological difference between the two is that elasmobranchs are close to osmotic equilibrium with seawater by virtue of high concentrations of urea and trimethylamine oxide (TMAO) in the body fluids, whereas in marine teleosts, the body fluids are much more dilute than seawater, and hence they lose water and gain ions across the gills and other permeable surfaces. In fresh water, of course, the reverse occurs. The high urea and TMA0 content of elasmobranchs naturally has important consequences for spoilage.

Fish as Food

Both adult and larval teleosts form the basis of special fisheries as do the eggs of certain species (e.g., sturgeons), but elasmobranch fisheries concern adults only. Even in adults, whilst myotomal muscular tissue is the chief food source, other nonmuscular tissues, such as fins, gonads, and livers, may be important foods (of economic, if not always of much nutritional, importance, e.g., shark fins). In some instances where the bones are eaten (e.g., sardines and whitebait, and, in Japan, the roasted vertebral columns of certain larger species), these are important sources of dietary calcium and phosphorus. Fish are also a valuable source of the vitamins nicotinic acid, riboflavin, and vitamin B_{12}. Refer to individual nutrients.

Above all, however, fish are important as an excellent protein source, for muscular tissue makes up a larger part of the fish body than in terrestrial vertebrates, from 37 to 68% of the total bodyweight. What is more, in all food fish except rays, the locomotor musculature is arranged in serial myotomal blocks along the body so that, at least in larger fish, it is an easy matter to gut the fish and separate the flesh from the skeleton as fillets. The relatively larger muscular mass in fish, and their importance as a protein source, is directly related to their life in water. Because most fish are well streamlined, the major drag force opposing their forward motion is skin friction drag, proportional to the square of forward speed. Thus, the power output required from the musculature is (approximately) proportional to the cube of swimming speed. Even modest swimming speeds require a large mass of locomotor muscle, but only a small weight penalty is incurred by the large amounts of (edible) musculature needed for locomotion, since the water in which fish live is not much less dense than the musculature. Even those fish that do not reduce their density (or achieve neutral buoyancy) by storing gas or fat for static lift only weigh in water around 5–7% of their weight in air.

The locomotor muscle is divided in almost all fish into a lateral red component, used during cruising, and a much larger white or pale yellow mass, which is active during short bursts of higher speed. A similar division is seen in the pectoral muscles of skates and rays. The two types of muscle have a different enzyme spectrum and metabolism, and also differ in lipid content and vascular bed. In yellowfin tuna (*Thunnus albacares*), for example, the red muscle contains twice the amount of lipid than the white muscle, as well as a large amount of myoglobin absent from the white muscle. The functional division into two muscle types of different composition (most simply distinguished by color) is sometimes reflected in the use of the muscles as food. For example, the internalized red muscle mass of the porbeagle shark (*Lamna cornubica*) is regarded as a delicacy when smoked, whereas the larger white portion of the myotomes is cooked and eaten unsmoked.

Raw fish muscle contains around 20% protein (the contractile lattice of actin and myosin and various sarcoplasmic proteins) so that protein forms the major energetic component of the fish, as shown in Table 1.

Table 1 Protein energy as percentage of total energy of some food fish and meat

Food	*Protein energy (%)*
Cod fillet (*Gadus callarias*)	95
Albacore (*Seriola lalandi*)	90
Haddock (*Melanogrammus aeglefinus*)	96
Sole (*Solea vulgaris*)	85
Flounder (*Pleuronectes flesus*)	95
Halibut (*Hippoglossus hippoglossus*)	66
Herring (*Clupea harengus*), an oily fish	41.5
Chicken (white meat)	76
Lean beef	69
Medium-fat beef (cooked)	27.4
Medium-fat pork (cooked)	13.9

From Geiger E and Borgstrom G (1962) Fish protein – nutritive aspects. In: Borgstrom G (ed.) *Fish as Food*, vol. 2, p. 128. London: Academic Press.

In comparison, even lean beef has relatively less protein energy. It is the high protein content of fish flesh that permits the preparation of increasingly important surimi products (*See* **Fish**: Miscellaneous Fish Products). Some fish also offer a useful lipid source, because, as well as the liver oils and lipid in ovaries, there can be much lipid in the muscles themselves, especially in scombroids and clupeids. In mackerel (*Scomber*), adipose cells between the muscle fibers and lipid droplets within the fibers make up 17% of the cross-sectional area of the lateral strip of red muscle. Unsurprisingly, fresh mackerel fillets contain some 16% lipid (protein: 19%), so that lipids make up the greater part of the total energy. As important as content is the nature of the lipid, for fish lipids contain ω-3 polyunsaturated fatty acids, shown in a number of studies to confer significant benefits in the prevention of cardiovascular diseases. Some fish contain lipids that are unsuitable for human consumption; for example, the castor oil fish, *Ruvettus*, gains its name from the purgative qualities of the low-density oil it stores for buoyancy purposes, and since it is abundant in oil sacs within the skeleton, naïve consumers are warned not to suck the bones. (*See* **Fatty acids**: Dietary Importance.)

Both fisheries and aquaculture are crucial for providing protein in many communities, some 5% of all protein eaten per capita in low-income countries. In addition, fish protein fed to animals provides indirectly for further human protein food. It is hardly surprising that fish form an important part of the diet in many countries, and that as well as being hunted with ever more sophisticated equipment, fish are farmed on an increasing scale. The annual per capita consumption ranges from over 20 kg to less than 5 kg, being highest in countries with a coastline facing a productive sea, such as Iceland or Japan, and lowest in such countries as Switzerland and Turkey. The average annual per capita consumption in 1996 was some 13.3 kg (excluding China). The most recent worldwide statistics available (2000) show that fish continue to increase in importance as a food source.

Of these different fish, the overwhelming majority are teleosts, as they are in numbers of species. The total elasmobranch catch is less than 1% of the marine fish caught.

History of Fish as Food

Fish have been used as food from ancient times, and quite a wide variety of fish skeletal remains are known from middens and spoil heaps, including both freshwater and marine species. The presence of marine fish remains in inland Late Old Stone Age refuse heaps (around 40 000 BC) in the Dordogne, France, implies that, even at that date, some means of preservation (possibly drying over smoky fires) must have been used to counter the rapid perishability of fish flesh. Air-drying, smoking, salting, and pickling in brine were probably developed around 4000 BC and permitted the wider availability and use of fish as food. The preservation treatments used varied according to the kind of fish: air-drying and salting were suited to leaner fish, whilst oily fish, such as herring or salmonids, had to be covered in brine to prevent rancidity owing to lipid oxidation. Today, more rapid transport of fresh fish and improved techniques of chilling and freezing are of much greater importance than these other means of preserving fish flesh, although curing in various ways may be important in increasing monetary value, as manifested, for example, in the price difference between fresh herring and kippers. (*See* **Preservation of Food**.)

Preparation

Different storage, preparation, and cooking methods may profoundly alter the value of fish as food, since they greatly influence important constituents of fish flesh, such as lipid and vitamin content. These effects will not be considered here. (*See* **Fish**: Processing.)

Problems in using Fish as Food

Ensuring the safety of seafood (fish and fish products and shellfish) requires government regulation and expense, but several Hazard Analysis Critical Control Point programs are now being put in place to minimize and avoid illness and disease caused by seafood, and consequent difficulties in import and export of seafood products. Two special cases of the problems with fish as food are where some or all of the fish may be dangerously poisonous. The puffer fishes (Tetraodontidae) contain high concentrations of the Na^+-channel blocker, tetrodotoxin (TTX), which is an exceedingly powerful nerve- and muscle-blocking agent. Such fish (a delicacy in Japan) are carefully prepared by licensed chefs to remove the tissues containing the highest concentrations of TTX before consumption in special Fugu restaurants; nevertheless, between 1987 and 1996, there were 32 deaths from eating puffer fish. Connoisseurs apparently require the initial symptoms of low doses of TTX (tingling of the lips) to enjoy the delicacy. The second special case is that of tropical marine fish. Herbivores may accumulate ciguatera toxin, apparently of algal origin, which also passes to carnivores such as barracuda, *Sphyraena*, when they eat the contaminated herbivores. The liver and viscera are particularly liable to be poisonous, and as yet, there is no reliable

test to distinguish fish with ciguatera toxin (apart from feeding portions to animals such as kittens).

Future Trends

Despite overexploitation of many fish stocks and consequent (if belated) control measures, it is clear that fish will continue to play an important role as food, chiefly as a consequence of improved methods of farming both of freshwater and marine species. A better understanding of fish stock management will be important in keeping capture fisheries at around present levels, which are probably not far from the maximum sustainable. In contrast, aquaculture (which provided 28.8 million tonnes in 1997) will increase steadily. In 1996, over a quarter of the world supply of food fish for human consumption came from aquaculture (mainly Chinese carp and other cyprinids). It also seems likely that there will be an increasing amount of fish and fish products entering international trade, particularly from developing countries, where exports almost doubled in value between 1990 and 1995. Future trends here seem likely to show different methods of keeping fish free from spoilage such as by the use of controlled atmosphere packaging using mixtures of N_2, O_2, and CO_2, and a large increase in the use of such products as surimi. An entirely different reason for the future importance of fish as food arises as the result of dietary studies, which have either demonstrated or suggested the value of fish diets in preventing some common diseases in developed countries. For example, fish are generally low in cholesterol and, compared to meat, have a much more complex spectrum of lipids high in polyunsaturated fatty acids. Of particular importance is the high proportion of the ω-3 series of fatty acids in oily fish, contrasting with the ω-6 fatty acids of vegetable origin. Epidemiological studies indicate that significant reductions in coronary heart disease may be obtained by the weekly consumption of only 300 g of such fish. There are also possibilities of modifying the diets of farmed fish to augment the levels of other components valuable for the human diet. (*See* **Fish Farming**.)

Catching and Handling

P Chattopadhyay, Jadavpur University, Calcutta, India

Introduction

The devices used to catch fish are known as gear, i.e., hooks, baits, nets, and rope. Fishing gear of numerous designs is available for use in commercial or sport fishing. Many factors have to be taken into consideration when selecting the method and gear to be used to catch a particular species of fish in a specific area. The choice depends on the species being fished, value of the individual species to the fisherman, the depth of water, and the characteristics of the sea bed. The different species of fish have different habits, movements, and reaction to stimuli. Demersal species are usually found near the sea bed, whereas pelagic species are found anywhere between the sea bed and surface. The movements and habits of each species are controlled by water temperature, salinity, spawning habits, migration, available food resources, and the temperature barriers that exist in any particular location. A few methods of catching fish are discussed below.

Net Methods

Trawling

A fishing method in which a boat is dragging a large net through the water is called trawling. When the net is somewhere in the water column, it is called midwater trawling, but when the net is dragged along the

ocean floor it is known as bottom trawling. Many important species are caught with the bottom trawl. Large 'doors' are used ahead of the net to keep the net down yet opened wide (Figure 1). There are many designs of these doors. The most common are otter doors. Fuel consumption can be reduced by cutting holes into the doors in appropriate places. Trawling therefore requires a strong boat to pull the fishing gear through the water as well as the fish. It disturbs the bottom of the ocean but is still an efficient method of catching large quantities of bottom fish. The doors used for midwater trawls are much lighter than those used for bottom trawling.

If two boats are used, each dragging one side of the net, the same opening of the net could be achieved without using any doors (Figure 2). For this, cooperation between two boats is necessary. Pair trawling is a fuel-efficient method. The ability of smaller fish to escape is controlled by the size of the net mesh. However, as the bag fills up with fish, and the larger fish block the net holes, small fish become trapped deep inside the net and are unable to escape. Regulating the mesh size of the net may be partially effective in minimizing the catch of undersized fish. Recent research suggests that the shape of the net mesh may affect its efficiency: a square mesh may allow for better escape of undersized fish than the traditional diamond mesh.

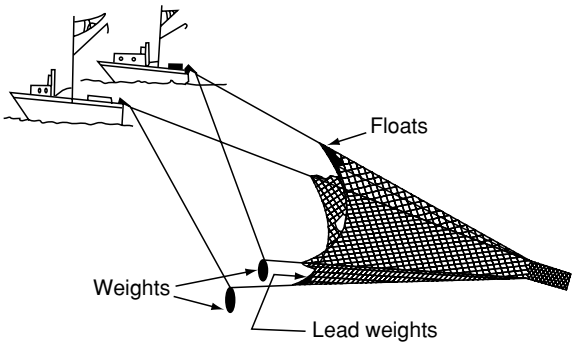

Figure 2 Two-boat midwater trawl.

Table 1 shows some data on the relationship between fish length and weight. Table 2 relates the mesh size of a net to the length of fish retained. The lengths given represent the size at which about 50% of the fish are retained and 50% can still escape through the net. The data can also be expressed for a particular fish (Table 3).

The popularity of trawling has been expanded with the development of factory ships with facilities for on-board freezing.

Seining

Seine nets are often used to catch schooling fish (Figure 3). Pelagic fish, for example, mackerel, are most easily caught in this way. These are upper-water-column fish and swim large distances. Small boats, sometimes two boats, set off from the mother ship and carry a relatively small mesh net which is set around the school of fish. If the net is a 'purse' seine, a string on the bottom is then pulled tight so that the bottom of the net can be closed off. The net is then hauled in until most of the fish are in a small area of water. This is called hardening of the net. The fish are then removed from the water, with hand nets or with

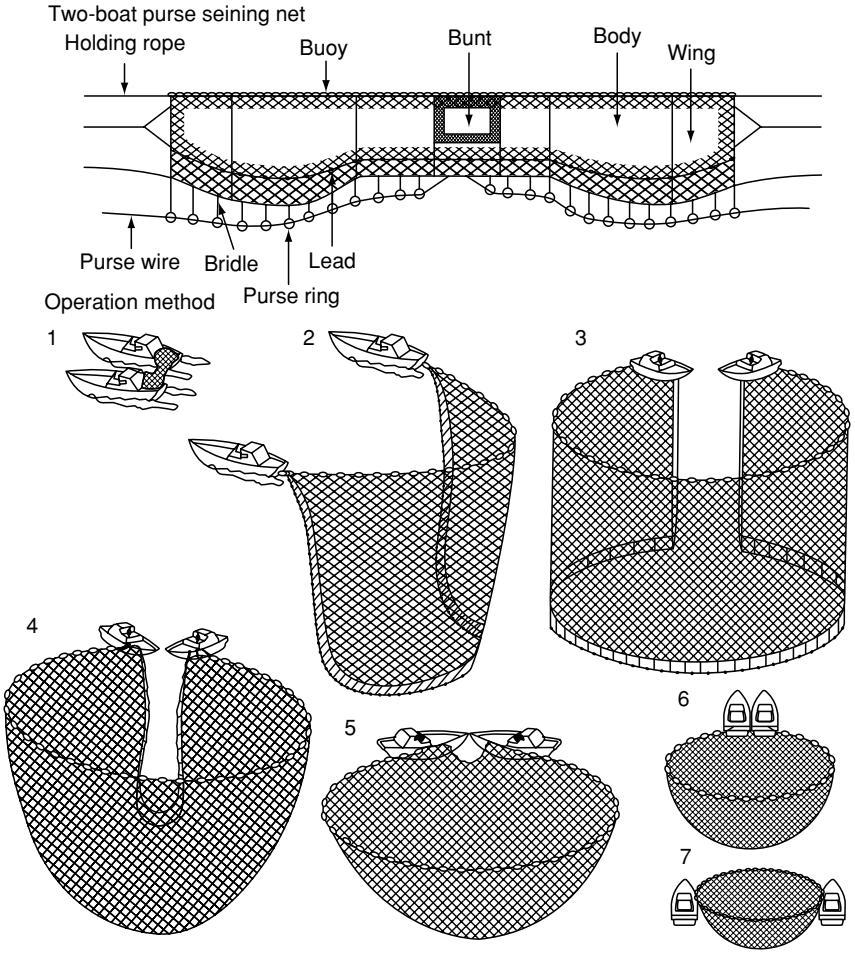
mechanical unloaders (pumps). Purse seining is used for the capture of species utilized in bulk reduction processes such as fish meal or species of high value. The greatest damage is done to the fish at the time of unloading from the boat because of the postmortem physicological changes that have occured in the fish. Fish in rigor should not be pumped. A modification of the seining method is practiced from the shore. The mother ship becomes a land-side attachment and the net, after setting, is hauled to shore by either people or a vehicle. This method is often used for more valuable species such as blue fish, striped bass (in New York), or for salmon (in Scotland).



1. Sharing the load of a net and moving forward with their bows linked.
2. Separating from each other and casting a net where a school of fish is located.
3. Surrounding the school.
4. Pursing begins.
5. and 6. Net hauling.
7. The bunt is positioned between two boats and fish is scooped with a big dip net.

Figure 3 Seine nets. Reproduced from Yamaha Motors (1986) *Yamaha Fishery Journal Composite*, p. 178, with permission.

Gillnetting

Gillnetting involves stretching out a net to intercept fish (Figure 4). The net can be set at any level in the water column by manipulating the rope length and by the use of anchors and floats. Placement is often chosen to intercept natural fish migration. The fish do not see the net and simply swim into it. Once their gills go through the net, they can no longer escape, and they drown. The thrashing of fish prior to death leads to both external and internal bruising. If the nets are not well attended, the dead fish will be untreated for too long and will be of poor quality. For this reason, gillnetting is one of the least desirable ways to catch fish from a quality standpoint, even though it is extremely efficient. It is an easy method to use with small boats, for example, for salmon in Alaska. The nets are generally hauled from one side of the boat and immediately sent back to fish on the other side, or a drum is used to wrap the net around as fish are simultaneously removed by hand.

Gillnetting has become controversial because of 'ghost fishing'. With modern net materials like nylon, these nets are difficult for fish to see and may continue to catch fish after the fisherman has lost them.

Cast Nets

Weighted cast nets or variations thereof are usually used by the artisan fisherman. These are simply thrown out to sea from land or a small boat; the weight around the net causes them to sink and trap (catch) the fish.

Herding devices

Another net-based catch method involves the use of traps, and weirs (Figure 5). These devices herd fish into an area where they can then be easily removed. This fixed gear is expensive and time-consuming to build, and also depends on the fish coming to the trap rather than a boat going to the fish. Thus, traps work best when the migration of the desired fish species can be predicted accurately. They often work best in rivers or streams or close to the shore where natural terrain features channel fish movement. The fish can be caught live simply by hand-netting them out of the

trap. Otherwise fish can be kept alive in the traps for some time and harvested when needed. Large pound nets are used along the shore to collect and harvest these fish.

Hooking Methods

Longlining

Longlining is simply the use of a long fishing line with lots of hooks, usually evenly placed (e.g. every 1 m) along the line (Figure 6). This method can be used on rougher grounds (bottoms) where a trawler cannot be used. This system has many important benefits over trawling, including the potential for size and species selectivity by the proper choice of hook size and shape, and bait; lower energy cost; and less damage to the ocean bottom.

Placing the bait on to numerous hooks is very labor-intensive. New forms of mechanical baiters have been developed that replace the tremendous effort involved in hand baiting. It is also labor-intensive to remove the bait and fish from the line as it is hauled back on board. Equipment to do this automatically has been developed. If longlining is done properly, the fish can be processed on board one at a time as they are brought on board.

Figure 6 Examples of longlines. (a) Drift longline; (b) bottom longline; (c) vertical line bottom longline. Reproduced from Yamaha Motors (1986) *Yamaha Fishery Journal Composite*, p. 219, with permission.

The hooks used for longlining must be of the appropriate size for the fish that is to be caught. The choices of hook size and bait make this form of fishing very selective (Figures 7 and 8). Since each hook is designed to catch fish above a certain size, this technique is particularly effective in avoiding undersized fish. Hook shape may also affect species selectivity as well as the amount of bait needed (a major expense with longlining). The Mustad Company of Norway has developed the most advanced longline systems appearing on the market.

Trolling

Trolling is usually done close to the water surface. The boat moves through the water with a number of lines each attached to a pole (Figure 9). A number of hooks are attached to each line. The fish are almost always landed live. Trolling allows for selective handling of fish and thus leads to a very high quality. Troll-caught salmon are particularly prized, especially if they are to be smoked subsequently. The absence of either internal or external bruising maximizes the appearance and the recovery (weight) of this extremely expensive product. It must be noted that subsequent careful handling is important to preserve the higher initial quality.

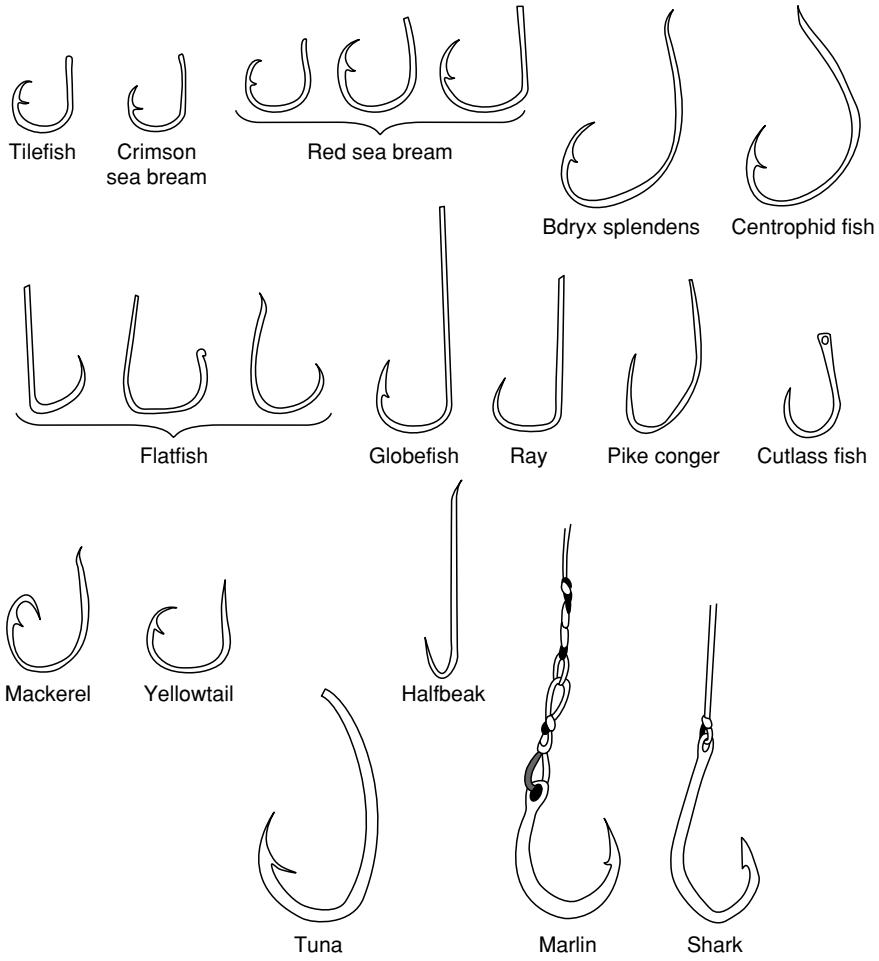

Figure 7 Various fishing hook shapes. Reproduced from Yamaha Motors (1986) *Yamaha Fishery Journal Composite*, p. 220.

Jigging

Jigging was first developed commercially in Japan. When fish are caught by this method, bait and/or special lights (at night) are used to attract the fish to an area (Figure 10). The fish tend to bite on any flashing item including the many hooks present in the water. Some part of the catch may also be snagged on the hooks. The system of powerful lights on the boat coupled with brightly colored jigs and small in-the-water lights is particularly attractive to certain species of squid. Bait is an important cost in all the hooking methods, particularly longlining. Each longline hook uses about 45 g of bait. Therefore, there is an interest to develop appropriate baits, i.e., those that can withstand the physical constrains of the mechanical system and also attract the appropriate fish. Research is being done currently on taste preferences of fish, i.e., flavor attractants. This will help to develop appropriate artificial baits.

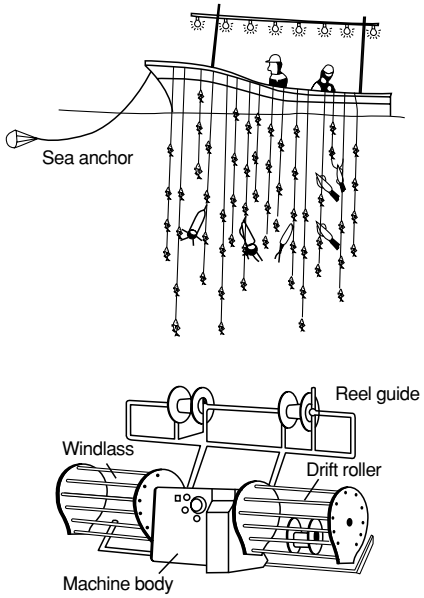

Figure 10 Automatic squid-fishing jigs. Reproduced from Yamaha Motors (1986) *Yamaha Fishery Journal Composite*, p. 24.

Other Techniques

A number of more unusual techniques may also be used. Spears and harpoons may be used for some of the larger fish. Fishermen sometimes simply detonate a bomb in the water and then collect all the dead fish – usually of low quality. A wide variety of other catch methods are used for shellfish. These animals often live below the ocean floor and thus require techniques like surface dredging (Figures 11 and 12) or raking and tonging to recover the product (Figures 13 and 14). A dredge has steel teeth that scrape and stir up the ocean floor. The scallops are then caught in a large steel bag behind the dredge. Tongs are really a pair of forks with a center pivot that are used to pick up clams or oysters from the ocean floor. Classical rod

and reel fishing can be used commercially for larger, more valuable fish like tuna and swordfish.

There are many other methods used to catch fish as well as a variety of other types of equipment, such as pots and traps for shellfish (Figure 15). Most of these methods are adopted to the specific fish and local fishing conditions.

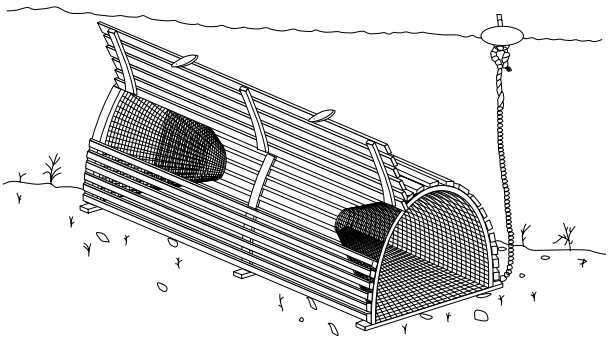

Figure 15 A New England loster pot. Reproduced from Wheaton FW and Lawson TB (1985) *Processing Aquatic Food Products*. New York: John Wiley, p. 85, with permission.

Traps are often used in areas through which fish regularly move or congregate. Traps are set in relatively shallow water adjacent to the land. They may be of many sizes and configurations, but all aim to prevent fish from leaving once they enter; any vessel can set and attend a trap.

Pots are used to capture crustaceans whose principal movement is by legs on the sea bed; pot fishing may be inshore or deep-sea. Pots of different sizes and configurations are set out and attract the species by means of baits, either cut-up fish or other sea creatures, or in a prepared, packaged form. Once the animal enters the pot through a specially designed entrance, it is unable to exit again and is trapped.

Harpooning can be used commercially on large species having high individual value. Work and time involved in searching, capturing, and bringing aboard each fish restricts the operation to valuable species. A retrieving line runs from the pole of the harpoon to the operating vessel; both the hunting and retrieving lines are run out from coils or tubs positioned on the vessel's foredeck.

Handling and Preservation on Ships

Handling of fish on ships needs special care. Fish begin to spoil immediately after death. Since the rate of spoilage is increased by any rise in temperature, the refrigeration of the catch by chilling or freezing is necessary. Spoilage is caused by enzymic, bacterial, and oxidative changes. Enzymes are present in the flesh and stomach of the fish, and the gut wall and the neighboring flesh, which are penetrated and softened by these enzymes after death, are thus easily invaded by spoilage bacteria. For this reason, in trawl, seine, and line fisheries for demersal fish, the fish is gutted and washed immediately after catching. In pelagic fisheries, where small fish are caught in greater numbers and not gutted, the spoilage is

quicker. Rancid odors and flavors are produced when atmospheric oxygen combines with fat in the fish, and temperature is the most important single factor affecting the rate of spoilage.

Chilling

The chilling system should maintain the lowest possible temperature. Considering the problem of quality, length of voyage, labor, and investment, chilling in melting ice is the most common method. An alternative to this is the use of chilled or refrigerated sea water (CSW or RSW), which has the additional advantage of handling the catch. The landing deck or container must be kept clean to prevent contamination of each haul by previous landings, and constant attention to hosing the landing deck area is necessary. Baskets, boots, and other items in contact with the catch should be thoroughly washed before the fish are landed. Fish should be carefully handled on the deck to avoid bruises and cuts; after landing, they are shifted to holding bins and mixed with ice to cool them. Gutting is done manually or by automatic gutting equipment on board. Gutting should remove all the guts and liver, and the belly cavity should be opened sufficiently to make the washing effective. After washing, the gutted fish are stored in melting ice to bleed; this insures that the flesh is free from discoloration. Chilling of fish in ice is done through stowage in bulk, in boxes, in pens, or in shelves.

In bulking, the fish and ice are mixed in intimate contact in order to achieve maximum storage life. It is carried out in a hold divided into pens fitted with removable shelves of wood or metal. Bulking to a depth greater than 40 cm is not recommended and, with some species, the limits are lower; otherwise, there would be excessive weight loss owing to the pressure. With bulking, there are difficulties in unloading the catch owing to the problem of separating the ice and the fish, a process which may involve a large amount of labor. Sometimes, for this reason, substantial water is added and fish are pumped out with a centrifugal pump.

The boxing of fish is usually preferred to bulking because of better cooling, and the elimination of handling of the fish (bruising and injury) at the dock, leading to an improved quality of product at the point of consumption. Boxing involves placing ice and fish in a container (box) of standard dimensions (normally 30 and 65 kg capacity) and stowing the box in the hold. The only real disadvantage is that boxing requires more hold space per unit weight of fish; return of reusable boxes may also be a problem.

In the shelf stowage system, the fish is stowed in single layers, gut cavity down, on a bed of ice. Sometimes a little ice is spread on top. This insures complete bleeding and retards spoilage by chilling, but it is a process which is not widely used on vessels because it is not space-efficient and the fish may become dehydrated as a result of the movement of air over the unprotected fish.

In pen stowage, fish and ice are placed in alternate layers to a depth of 70 cm, a second pen board is placed over the bottom pen, and the same process is repeated. This storage system is widely used for stowing fish in ice. In general, crushed or flaked ice is used in the chilling of fish on board. The storage life of fish in ice can be slightly extended through the use of antibiotics or salt-water ice. Antibiotics such as chlorotetracycline and oxytetracycline in concentrations up to 5 p.p.m. in ice are permitted in some countries to inhibit bacterial action. Separation of salt and water during freezing or melting is a problem with salt-water ice. Immersion of fish in CSW or RSW is used as an alternative to ice for the chilled storage of fish. The sea water may be chilled by the direct addition of ice (CSW), or by mechanical refrigeration with a heat exchanger (RSW). Storage of fish in CSW or RSW helps in unloading the fish from the vessel, as they can be pumped out and into a holding tank.

Freezing

Freezing at sea is necessary if the vessel remains at sea for a period up to 90 days. Storage in ice, or by other means of chilling, is adequate up to 15 days, after which the fish rapidly become inedible. If fish are frozen on board and stored at low temperature, the fishing vessel can remain at the fishing grounds until the hold is full. This improves the economics of fishing, and the general quality of fish landed. Depending on the facilities available on board and the markets, fish may be frozen in the round, gutted, gutted and headed, or in the form of fillets. A number of conventional freezers may be used at sea with little modification. The freezer and its refrigeration system have to conform to national regulations and insurance requirements for a fishing vessel. Many countries do not allow the use of ammonia as a refrigerant in fishing vessels. The design, operation, and type of refrigeration system must take into account the movement of the vessel, vibration, sea-water corrosion, and the extra rough usage under conditions at sea. Fish to be frozen and iced fish are handled in the same way, except that the former are frozen rather than merely cooled. Filleting is the step before freezing, and the fish should be held at chill temperature, below 5 °C, from catching to freezing, in order to retard spoilage and avoid the ill-effects of rigor mortis.

Rigor mortis, or death-stiffening, is the physical change that occurs in all animals, including fish, as a result of a series of complex reactions that go on in

the flesh tissue after death. It is one of the factors which, after a certain period of time, retards the postmortem autolytic and bacterial decomposition of the flesh and its protein, and thus extends the shelf-life. Rigor mortis in fish starts 1–7 h after death and its peak in slaughtered fish, kept in ice, lies between 5 and 22 h after death; the total duration of the rigor is 30–120 h. A prolongation of the rigor mortis period is of great economic importance, and harvesting and on-board handling practices should aim to extend rigor and maintain fish quality. Rigor mortis lasts longer when the fish has exerted less muscular activity prior to death, as it is refrigerated immediately. Immediate slaughtering of the fish after capture also appreciably extends rigor. The onset of rigor mortis is quicker at higher temperatures, and may occur only 10–20 min after death at about 30 °C. It is therefore essential that the fish is chilled quickly to avoid problems arising from rigor mortis during freezing. If possible, it is desirable to freeze fish before rigor mortis begins. Freezing in rigor can damage the fish, and only poor-quality frozen fillets or blocks can be made from such fish. However, while some fish can be frozen postrigor, others become quite unsaleable. In addition, prerigor frozen fillets are sometimes subject to contraction upon thawing; they should be transferred to the cold store immediately on removal from the freezer.

Handling in Port

Containers, boxes, and the portable sections of a fish room are handled by cranes. The discharge of a large vessel stowing its catch in pens and shelves is achieved by filling a basket with fish, attaching it to the end of a rope, hoisting it up and swinging it ashore; this operation may be mechanized using bucket elevators and ship-to-shore conveyors. In the chilled or refrigerated sea-water systems of stowage, pump unloading is convenient and widely used. The fish which are frozen on board are unloaded by standard, endless looped-canvas elevator belts. After landing, the fish should not be exposed to warm ambient temperatures of the auction market. Fish can be sold, after taking random samples from the boxes, containers, or shelves, as soon as the vessel arrives in the port, so that the fish can be unloaded directly on to the waiting transport. Cleanliness, care, and cooling are most important for first-class fish.

It is common to land fish at a market (fish pier) where it is put up for auction. This is also convenient for the ship and secures maximum prices for the fish. However, since these auctions can cause delay in the further distribution of the fish, affecting its quality, there should be several sales during the day and a corresponding distribution system (e.g., special fish trains) to avoid such problems. This will help to insure that the fish reach inland wholesale or retail dealers in time for further sale. Fish should always remain in ice throughout the period in the market, and special market boxes or kits can be used. Fish intended for distribution fresh and uprocessed are usually brought from the market or other landing points to a packing house. They are iced or reiced and packed in nonreturnable or returnable containers with the requisite insulating properties for transport to the inland wholesaler or retailer.

Fish as Food

G Lozano and A Hardisson, University of La Laguna, Tenerife, Canary Islands, Spain

Background

Seafood plays an important role in human nutrition, contributing near 125 000 million tonnes per annum of finfish, shellfish-molluscs, shellfish-crustaceans, and a few other edibles, both from fisheries catch and from aquaculture production. New technologies in fish manipulation, conservation, and manufacture have ensured a constant distribution and high quality of products all year round, and actual aquaculture bloom imply the local appearance of new species on

the market that were not common previously for the local population feeding habits or were even relatively unknown.

Fish (bony fish and elasmobranch fish) represent a large amount of marine-origin meals for direct human consumption and support a wide series of transformation techniques for subproducts or by-catch such as oil, flour, protein, and concentrates production.

Fish and Nutrition

For many centuries, fish has been one of our main foods and at present supplies almost 10% of the animal-origin proteins eaten at mealtimes; this proportion is much higher in developing countries, where fish may be the only source of animal protein. Japan, Norway, Iceland, Spain, and the UK are examples where fish, fishing, and aquaculture play an important role within the population's socioeconomic and feeding activities (Tables 1 and 2).

It is possible to divide fish into two large groups according to the forms of feeding advantage: primary products and secondary or subproducts. The former include fresh, frozen, smoked, salted, and canned fish, and the latter include oil, protein concentrates, and hydrolyzed products.

Two different types of fish are traditionally considered (in this case, exclusively finfish) under the generic denominations of white and blue fish. The first includes those species that have a white or whitish musculature, without the strong presence of darker-colored lateral muscular fascicles, and corresponds to the group of lean and semifat fish (with a fat content no more than 1.5 and 8–10%, respectively), such as cod (*Gadus morhua*), salmon (*Salmo salar*), and hake (*Merluccius merluccius*). The second type is characterized by its darker muscular tissue, the presence of a high degree of vascularization in the lateral muscular fascicles (Vogt's musculature, of fundamental importance on fish swimming in oceanic migratorial species as tunnids), and a high fat content (over 10%), which makes them fatty fish, e.g., the sardine (*Sardina pilchardus*), herring (*Clupea harengus*), mackerel (*Scomber scombrus*), and eel (*Anguilla anguilla*).

However, this distinction between lean, semifat, and fatty fish should be used with some caution, since a large number of species, e.g., the sardine (fatty fish) or hake (semifat fish), can have an enormous range of seasonal variation in their fat content owing to feeding-habits variation and sexual-products elaboration.

The food industry supplies a wide range of different fish types and products (finfish, shellfish-molluscs,

[a]Preliminary estimation.

Data from FAO (1999) *El estado mundial de la Pesca y la Acuicultura 1998*. Versión en español. Parte 1, pp. 1–18. Rome: FAO with permission.

shellfish-crustaceans), both catch and aquaculture production, and marine, salty, or continental in origin:

- fresh and cold storage fish;
- frozen fish;
- dried fish;
- salted fish;
- smoked fish;
- conserved fish (canned or tinned fish);
- semiconserved fish (canned or tinned not pasteurized);
- Japanese traditional products (Neriseihin) as surimi and kamaboko;
- krill (euphausiids);
- trepang (dried sea cucumber);
- fish oils;
- fish flour and meal;
- hydrolyzed fish (siloed fish);
- fish protein concentrate.

Cold-temperature preservation can be achieved through a wide range of systems, from refrigeration by simple addition of ice to cryogenic ultrafreezing. Preservation may be increased by storage in modified-atmosphere conditions, ionization and vacuum packaging. Some species require special conditions for freezing such as sardine (superficial freezing: superchilling), tuna (brining solution of calcium chloride), or shrimp and prawn (brining solution of sodium chloride with sugar adding).

Refrigeration can be carried out by three different methods: cold sea water (CSW), refrigerated sea water (RSW) or a combined method of CSW/ice or RSW/ice, with or without the addition of antibiotics to water and ice. Freezing is based on very cold air flow, surface–plate contact and brining solutions (euthectic solutions), although air flow and cryogenics are the best techniques. All of these cold-freezing systems can be adapted for two different purposes: maintenance of a high-quality product along a determined, specific short time, or obtaining an acceptable quality in the long term.

Dried, salted, and smoked fish are short-term edibles in which only water loss and salt concentration ensure preservation, smoked fish being more durable due to semi-cooking of meal and adsorption of some preservative salts from wood (as tanines) during the smoking process.

The differences between packed fish (jarred, canned, tinned, etc.), conserves and semiconserves depend on the heat used first to prevent microbial spoilage (sterilization of cans involves the use of temperatures up to 105 °C for 30 min). Anchovies in olive oil is a good example of a tinned fish semiconserve, as fish fillets are salt-pressed and oil-soaked, but no sterilization is carried out after canning.

Neriseihin products, such as surimi and kamaboko, are a very important world-wide market, as they form the basis for a few new marine preparation foods as cheap sustitutives of more expensive natural meals: 'lobster tail,' 'crab sticks,' and 'young eels' are popular products.

Fish oils, flours, meals, hydrolyzed solutions and protein concentrates may be obtained from specific fisheries (Peruvian anchoveta (*Engraulis ringens*)) or as subproduct or bycatch of other principal catches. Ecuadorian and Peruvian flours, which are used for production of aquaculture feed, show fundamental differences in general characteristics (high quality and low cost) compared with European flours, as the latter product is a result of damaged specimens discharged for human consumption, or specimens of no commercial interest by primary demand, all with a low-quality composition and similar cost to that of the Peruvian and Ecuadorian counterparts.

Other types of seafood (and continental water species) should be mentioned, although their importance is local or anecdotal, for example, sea urchins (genera *Echinus, Paracentrotus, Sphaerechinus*). A few species are traditionally caught and consumed in Spain and France, thus increasing demand and initiating the introduction of specific aquaculture industries, which produce both fresh specimens for direct consumption and manufactured products commercially denominated 'sea urchin caviar,' presented as jarred or tinned semiconserves.

Among all these food sources, the krill fisheries that exploit different species of the genus *Euphausia, Thysanoessa, Meganictiphanes*, and *Nictiphanes*, with a total catch of 160 000 tonnes in 1996, are good examples of a new component of human nutrition and aquaculture feed, although their fundamental role in the marine trophic systems must take total catch quotas under strict controlled management.

General Chemical Composition

From a nutritive point of view, the most interesting chemical components of fish (comprising finfish, cephalopods, shellfish-molluscs and shellfish-crustaceans) are proteins and fats (Tables 3–5 and Figure 1), as well as water, which can constitute 70–80% of the total composition, mineral salts (usually refered to as ash), and vitamins. Carbohydrates and fiber are practically nil in fish.

Proteins and Nonprotein Nitrogen Substances

The value of fish proteins is very high. It is better than meat protein and, although inferior to milk and egg protein, has a stable composition of essential amino acids, with slight deficiencies of methionine and

threonine, and an excess of lysine – very important if we take into account the fact that this latter amino acid is lacking in cereals.

The protein content of a species depends on many biological and environmental circumstances (sex, age, sexual maturity, nutritive conditions, etc.); this variation can be rhythmic, periodic, or nonperiodic. Finfish can show a wide range of variation between ~10 and ~30% in wet weight.

The biological coefficient value of protein (B_{vp}) compares retained nitrogen (N_r) with gastrointestinal absorbed nitrogen (N_a):

$$B_{VP} = N_r/N_a \times 100.$$

Nonprotein nitrogenous substances are important in the taste of the fish, with the highest concentrations being found in migrant and elasmobranch fish. The nitrogenous substances are mainly free amino acids, peptides, purine bases, urea and trimethylamine oxide.

Fats

Fats are mainly composed of unsaturated fatty acids, including oleic acid (18:1*n*-9) and high unsaturated fatty acids such as linoleic acid (18:2*n*-6) and linolenic acid (18:3*n*-3), among others. These have an

important role in the control of blood cholesterol levels and in the prevention of cardiovascular problems of arteriosclerotic origin. This is an important feature in the case of blue fish, such as sardine, anchovy (*Engraulis encrasicolus*), herring and bluefin tuna (*Thunnus thynnus*), as well as other species of pelagic fish. As in the case of proteins, fats undergo high seasonal variations in their content, in this case related to trophic and genetic periods and migrations.

Recent studies show increasing interest in deep-sea shark fisheries because of the high levels of unsaturated hydrocarbon compounds in shark liver oils. Squalene ($C_{30}H_{50}$) and the hydrogenated form squalane ($C_{30}H_{62}$) play an important role as lubricants and emolients and as a base for a range of products in the pharmaceutical and cosmetic industries, because they help through-the-skin absorption and avoid water loss.

Carbohydrates

Carbohydrate concentrations are very low (0.1–1%) in fish, and their contribution to the diet is insignificant.

Vitamins

Fish is a rich source of fat-soluble vitamins, such as vitamins A and D. In lean fish, they are found almost exclusively in hepatic oils (the best example being cod liver oil), but in the case of fatty fish, they are also present at high levels in muscular tissues. Vitamins B_1, B_2, and B_{12}, and nicotinamide are also found in significant proportions in the liver and gonads.

Minerals and Heavy Metals

Fish contain many important minerals, mainly located in the viscera, muscles, and bones. Among the most abundant elements are sodium, potassium, calcium, iron, chloride, phosphate, sulfate and iodine. Iodine is very important in the treatment of illnesses caused by the malfunction of the thyroid gland, which can cause delays in growth and/or dwarfism.

In terms of the alimentary structure of fish, the heavy metal content present in the edible parts is an important factor because of the toxic characteristics of these cations and their slow accumulation in the organisms of the trophic chain by bioaccumulation or biological amplification (Table 6). Mercury, lead, tin, cadmium, and vanadium are particularly important heavy metals and are regulated, as far as the maximum total content permitted for consumption, acceptable daily intake, etc., are concerned, by the World Health Organization and national organizations working together on health problems.

Digestibility

A significant advantage of fish as a food is its easy digestibility, which results from the special configuration of the muscular structures. These are composed of short muscular segments (myotomes) separated by conjunctive covers (myosepts), which together produce short muscular fibers. Myosepts are more easily transformed to gelatines at 65–70 °C, causing the destruction of muscular structures, and improved access to fibers, than in other animal meats.

Fatty fish are less digestible than lean fish but provide more energy to the consumer. With a mean content of 18–20% protein, fatty fish provide up to 1302 kJ per 100 g, compared with 336 kJ per 100 g in lean fish. Taking into account losses after removal of the head and internal organs (up to 50–60% of the fresh weight), these values are reduced to 357 and 155 kJ per 100 g, respectively.

The digestibility coefficient (D_c) compares absorbed nitrogen (N_a) with ingested nitrogen (N_i) as follows:

$$D_c = N_a/N_i \times 100.$$

D_c values range from 70% (ray) to 100% (cod and hake) in finfish, 75–85% in molluscs, and 70–90% in crustaceans.

Popular Varieties and National Preferences

In general, it is difficult to list the entire range of species or groups of species that comprise the fishing resources of a country, region, or specific geographical area, given the number of variables of differing importance, such as industrial and small-scale fishing, fleet type and

catch methods, the oceanographic and biological characteristics of the environment, migrant and sedentary species, coastal and oceanic areas, insular systems, and national and local gastronomic traditions.

The number of variables increases in the case of nations whose fishing activity includes freshwater species (in the strict sense of the term, or combining marine and freshwater characteristics) and which can boast aquaculture potential in one or many of its varied forms. The situation in such cases is clearly complex when it comes to handling data concerning catches, fishing effort, and production.

Denmark's fishing and production are based on gadoids, pleuronectids, clupeids, and scombrids; Australia's on lobsters, crabs, tuna-like fish and sharks; Uruguay's on squids and hake (*Merluccius* spp.); Mexico's on lobsters, scombrids, anchovy (*Engraulis ringens*) and sardine (*Sardinops* sp.); Japan's on scombrids and lobsters (with, in this case, considerable aquaculture production); and Norway and Greenland's on salmonids and gadoids; USA's on salmonids, cyprinids, anguilids, clupeids, gadoids and scombrids (although one should not overlook the importance of shark-fishing in the deep waters of the Pacific coast); Germany's on salmonids, cyprinids, anguilids, clupeids, gadoids, and scombrids; the UK's on gadoids, merlucids, clupeids, flat fish, and salmonids; and Spain's on, among others, anguilids, cyprinids, salmonids, scombrids, sparids, gadoids, merlucids, flat fish, cephalopods, and crustaceans (Table 7).

Preferences for Lean, Semifatty, and Fatty Species

Local preferences for a particular type of fish (lean, semifatty, or fatty) depend on many factors. Some of these are seasonal and biological (catching species on a massive scale as they migrate during a given period, presence near areas of reproduction, disappearance and replacement of species), whereas others have more to do with traditions and culture (consumption of a species during a short period, even though it is present in the fishing zone for all or part of the annual cycle) or social, economic, and political considerations (moving to other fishing grounds, changes in selling price, employment complications in the sector, the imposition of reduced catch quotas, etc.).

In the western Mediterranean countries (Spain, for example), species of white fish (lean and semifatty) are consumed throughout the year, whereas the greatest consumption of blue fish is in the summer, the most important species being bluefin tuna (*Thunnus thynnus*), bonito (*Sarda sarda*), skipjack (*Katsuwonus pelamis*), albacore (*Thunnus alalunga*) and yellowfin tuna (*Thunnus albacares*). In winter, the mainstays are mackerel (*Scomber scombrus*), chub mackerel (*Scomber japonicus*), sardine (*Sardina pilchardus*) and anchovy (*Engraulis encrasicolus*). The same is true, to a large extent, of other neighboring Mediterranean (France and Italy) and Atlantic areas (Portugal).

This pattern is also seen clearly in the Canary Islands (central-eastern Atlantic), where multispecific small-scale fishing is practiced for white fish and crustaceans (demersal species) between October and April, whereas during the period May to September, activity centers almost exclusively on bluefin tuna, skipjack, albacore, bigeye (*Thunnus obesus*) and yellowfin tuna (pelagic species), which are also caught by large Russian, Korean, and Japanese fleets.

Turkey deserves special mention, since, despite its extensive scombrids, clupeids and flat fish resources, it is not a fish-consuming country. In spite of strenous efforts by the government, the traditional cultural situation has remained unchanged. Thus, an extremely important source of food, for both internal consumption and export earnings, is still untapped because Turkey is not a fishing nation.

Usage of Marine versus Freshwater Species

As mentioned earlier, the harnessing and use of marine or freshwater species depends on a wide range of circumstances, most notably, in the case of freshwater fish, the presence of rivers, lagoons, and

lakes in the fishing area. This enables the resource to be extracted and distributed without any great difficulty, given that, for the most part, marketing of this type of fish tends to be limited and is almost never exported.

Nevertheless, both manufactured products (particularly smoked fish) and species, which are produced by means of aquaculture, are opening up new markets for freshwater fish in countries, or regions, where previously they had been rejected or unknown, and where consumption was practically nil.

Manufactured products are derived from eel, sturgeon (*Acipenser sturio*), salmon and trout (*Salmo* spp.), and, in the case of aquaculture species, tilapia (*Tilapia* spp.), tench (*Tinca tinca*), carp (*Cyprinus* spp.), salmon and trout. All of these form part of a sizeable range of widely distributed and economically important species.

The most important characteristic of aquaculture is its capability of producing high-quality edibles, both nutritional and health properties at an almost constant market price, irrespective of seasonal or socioeconomic situations or politics (migrations, weather condition, political restriction to foreign fleets to fishing in national fishing grounds, bans owing to biological reasons, total allowable catches).

Of special significance is the controlled addition of modified diets to species in order to increase their growing rates, condition factor, and certain biological characteristics (e.g. resistance against diseases), thus creating an improved food for human consumption. Components such as folic acid, ascorbic acid, and L-carnitine are being used in new types of foods.

In the EU member states, all production (marine and continental) is regulated under the 'Sectorial Program of Coastal Fisheries and Aquaculture' that assures management, assessment, market procedures, and scientific aid in quinquennial programs. Some species that were not accessible via aquaculture a few years ago are now being consumed in great quantities. For example, turbot (*Scophthalmus maximus*) has seen an extraordinary increment in production to 10 000 tonnes in 1999 (4400 tonnes in Spain alone).

Problems of Supply and Demand

The complex nature of the various sectors of the fishing industry, catches, distribution, processing, and marketing, can be explained by a series of factors. In some cases, a small number of species are fished for a particular type of industry (e.g. canning or smoking factories), or in order to supply a traditional and unchanging market requiring a constant level of quality catches throughout clearly defined periods.

These circumstances may vary considerably as a result of resource modifications produced by natural or artificial causes (variations in the environment, changes in the recruitment rate, overfishing) or by changes in eating habits (varying in demand caused by the introduction of species produced through aquaculture, or caught in areas previously not fished by the fleet). Such species displace or at the very least compete commercially with those that are traditionally consumed. The crises affecting the anchoveta in Peru (only 200 000 tonnes caught in 1985), cod in Greenland (7000 tonnes in 1986), the demise of the European herring, or the Saharan Bank sparids, are prime examples of resource modifications, whereas cases of aquaculture include the introduction of salmon, trout, tench, and eel farming in Spain.

Demersal Species of Temperate Climates

G D Khedkar and B V Jadhao, Dr. Babasaheb Ambedkar Marathwada University, Aurangabad, Maharashtra, India
C D Khedkar, College of Dairy Technology, Warud (Pusad), Maharashtra, India
N V Chavan, Adarsha College, Hingoli, Maharashtra, India

Background

Fishes of many families, shapes, and sizes obtain their food in the near-bottom zone and show morphological and behavioral adaptations for life on or near the seabed. These are the demersal fishes, comprising both benthic and benthopelagic species, the latter usually performing vertical migrations to feed. Demersal fishes occur at all depths and in all near-bottom habitats of the oceans. In this article, emphasis is given on demersal species such as cod, haddock, plaice, and sole, which live on or near the bottom of the sea; the continental shelves along the coasts of Europe, Greenland, Iceland, and North America. Worldwide, about 85% of the total continental shelf area has sandy or muddy substrate. Only about 6% is rocky or gravelly, and the remaining areas are coral reefs or shell beds. However, there are both latitudinal and depth-related patterns. Corals are almost entirely confined to low latitudes where organically enriched muddy areas are also most extensive, particularly near the mouths of major rivers or below highly productive upwelling areas. Sandy, rocky, and gravelly sediments are more common at high latitudes. Regional and local modifications of the distribution and character of soft sediments are common as a result of water currents flushing the shelves. In addition to offering a range of physical habitats to fishes, continental shelves are usually highly productive, and especially in temperate and boreal regions, demersal species of the shelf waters are very abundant and support some of the world's major fisheries. Of the approximately 13 500 marine fish species, 1000–2000 species inhabit continental shelf-water of temperate zones. The majority of these are demersal species.

Taxonomic Diversity, Geographical Patterns, and Assemblages

A wide range of families, including both cartilaginous and bony fishes, have demersal representatives in shelf-waters. There are several rather consistent geographical patterns, however, on both a worldwide and regional scale. The abundance and biomass of demersal fish are considerably higher at high latitudes, i.e., in temperate climates, normally due to the high abundance of a few species, especially gadiform fishes such as hakes (Merluccidae) and cod-like fishes (Gadidae), but also flatfishes (Pleuronectiformes) and rockfishes belonging to Scorpaenidae (Figure 1). Predominant differences between the oceans have evolved, the gadiform fishes being more diverse on temperate Atlantic shelves than on North Pacific shelves, where scorpaenids are very diverse and few gadiforms occur. Narrow shelves tend to have fewer demersal species than wide shelves and shelf seas. The highly productive upwelling areas associated with eastern boundary currents have few demersal species, and most are benthopelagic. Hakes are very well adapted to these environments and live both demersally and pelagically, mainly feeding on other fish.

Adaptations of Demersal Fishes

One adaptation apparent in demersal species is in response to the vertical gradient in light intensity. Many species can adjust their body coloration to their environment almost continuously, while some species like Atlantic cod (*Gadus morhua*) have different persistent color varieties depending on the habitat in which they grow up and live. Most shelf and upper slope fishes are countershaded. They have dark backs to reflect enough of the strong downwelling light to match the dim upward component of the ambient light, with silvery flanks to mirror the background from all visible angles. However, bright sunlight in the clearest oceanic waters penetrates to only 1000 m or so, and in turbid slope waters, penetration is reduced to considerably less than this. Therefore, the great bulk of the ocean is unlit by the sun, resulting in a reduction in countershading for protection, often accompanied by an overall darkening in body colour, with increase in the living depth of the species. Because the red end of the spectrum is most readily absorbed by sea water, darkening of the body at depth can be achieved either by black or by red pigmentation. Most demersal species tend to be blackish, but striking examples of red camouflage are found in the orange roughy, *Hoplostethus atlanticus*, and in *Sebastes* species. The rapidly diminishing intensity of light with depth in the ocean has resulted in the refinement of a range of sensory systems in demersal bottom fishes. Surprisingly, there is no general trend towards a reduction in eye size as occurs in pelagic fishes.

Unlike the pelagic fishes, which are slender and often torpedo-shaped, the typical demersal fishes are

not so well adapted in terms of body shapes or physiology for prolonged fast swimming. However, many shapes ranging from an eel shape to the more classical fish shapes of the cod, sparids, and rockfishes have proven successful (Figure 1). Regulating buoyancy may not be as important to demersal fish as to pelagic organisms. Demersal fish species come in all sizes from small gobies, reaching a length of only a few centimeters, to the Atlantic halibut (*Hippoglossus hippoglossus*) and Greenland shark (*Somniosus*

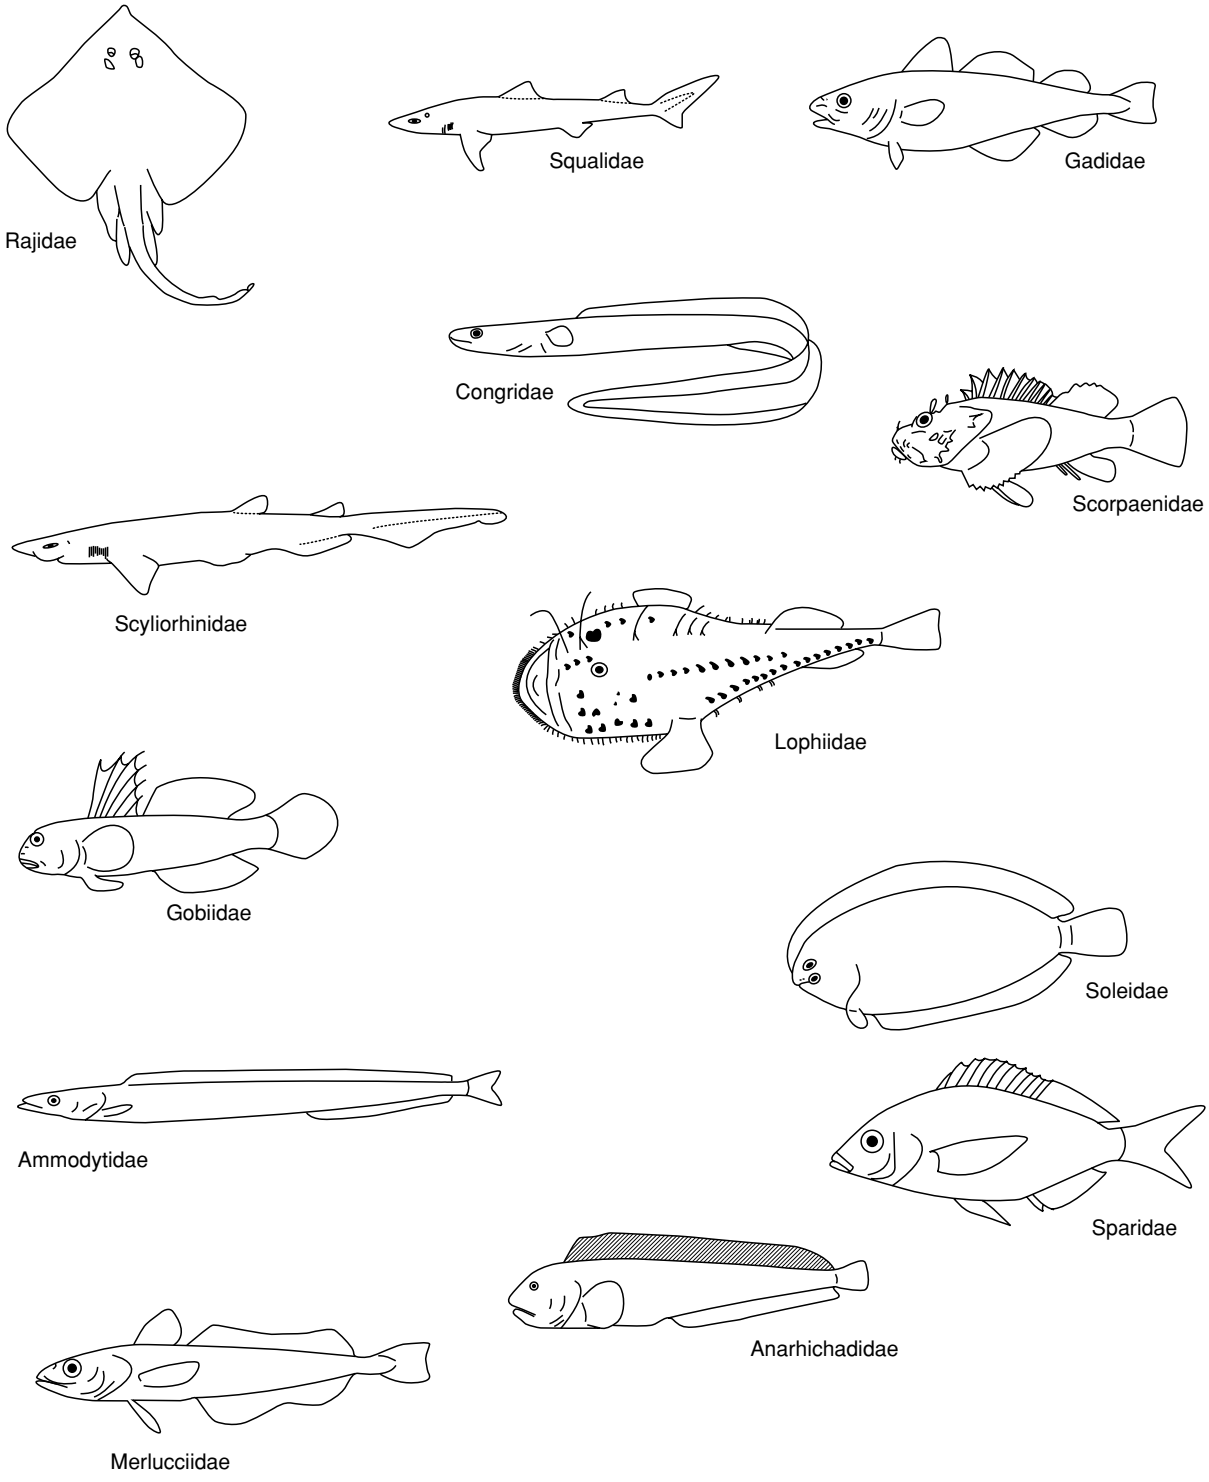

Figure 1 Body shapes of fish from selected demersal families.

microcephalus), which may reach 2 and 6.5 m in length, respectively. Many modes of life are possible in the demersal environment. Some fishes are sluggish and have evolved a typical 'lie-and-wait' strategy, while others are very active, and some almost behave as pelagic species. Flatfishes and several rays spend part of their time buried in the sand and may only emerge for certain times of the day or tidal cycle to feed. Most of the demersal species are more active during the night or at dusk and dawn. Camouflage may be attained in many ways, i.e., through body shape, skin coloration, and modification of skin into the appendages resembling algae or debris. The retention of functional and substantial eyes, together with specialized adaptations, must surely be in response to the widespread phenomenon of the biological light, which is produced by very many organisms in the deep sea, including those associated with the sea floor. In contrast to the pelagic oceanic fishes, relatively few deep-sea demersal fishes have evolved elaborate light-organ systems of their own. For example, there is no need for ventral camouflage in bottom dwellers or bioluminescent lures in a habitat at the sediment–water interface where food ultimately collects and is thus found more easily simply by foraging.

Feeding and Diets of Demersal Fishes

Most of the demersal species of temperate region are carnivores, customarily grouped into three categories, piscivores, benthophages, and zooplanktivores, that predominantly eat fish, benthos, and zooplankton, respectively. Many demersal fishes depend on pelagic production by feeding on vertically migrating nekton and zooplankton entering or inhabiting the near-bottom layer. Piscivores usually have the capacity to deal with live prey that are large compared with their own body size, and so they tend to have large gapes. Some swallow their prey whole, and others tear and bite the prey into smaller pieces. However, the techniques vary widely between species within the demersal fish group. Piscivores generally have several rows of conical backwardly pointing teeth both on the jaws and within the mouth and pharynx. These primarily prevent the prey from escaping and aid swallowing. Benthophagous fishes also have several prey capture methods. Some apply suction after detecting prey on the surface of the sediment or within the sediment, and others bite off the siphons of buried bivalves. Others feed on shelled animals and have strong, muscular jaws. Zooplanktivores often lack dentition on the jaws and rely on suction for ingesting their rather small prey whole. Most species probably pick their prey one at a time rather than filter-feed as clupeids and mackerels do at high prey densities. In most demersal species, there are significant ontogenetic changes in diet and feeding ranges. At metamorphosis, when larval characters are lost, and most demersal fish take up a demersal life style, pronounced diet changes from feeding on planktonic crustaceans to feeding on benthic or benthopelagic prey may occur. As a fish grows in size, larger or more energy-rich prey are needed to satisfy its energy requirements. Many species therefore go through a succession of feeding modes during their lifetime, usually starting as planktivores and ending as piscivores or benthofages. For a given species, pronounced diet shifts tend to occur at rather fixed sizes, but habitat shifts may happen concurrently, and it is sometimes difficult to determine which is more significant. Many species are quite opportunistic, and their diet varies greatly between habitats and seasons, often depending on the food availability.

Major Demersal Species

The major species of demersal species include the Gadiformes or cod-like fish (sometimes called the Anacathini – fish without spines). These include commercially valuable species like the cod (*Gadus morhua*), haddock (*Melanogrammus aeglefinus*), ling (*Molva molva*), and whiting (*Merlangius merlangus*).

Cod

The cod belongs to the family, the Gadidae (genus *Gadus*), represented by at least 19 species in the demersal habitats. They can be distinguished from other genera in the family by having three dorsal and two anal fins. There are 10 species, of which six possess a barbell, a sensory process that hangs down, or may be extended forwards, from the lower lip. In four of these species, the upper jaw is larger than the lower jaw: the cod, *Gadus callarias*, green–yellow with a number of dark spots and a white lateral line; the haddock, *G. aeglefinus*, gray with a prominent black blotch on the shoulder and a black lateral line; the bib or pout, *G. luscus*, very deep in the body and copper-colored, with some dark irregular bands, and the poor cod, *G. minutus*, similar to the last, but smaller and not so deep in shape and brownish yellow with no bands. Then there are the two species that have a barbell but whose lower jaw is larger than the upper jaw: the coal-fish or saithe, *G. virens*, with very dark skin on top, almost black, but a white lateral line and the teeth in the upper jaw all about the same size; and the pollack-whiting, *G. esmarkii*, with the teeth on the outer margin of

the upper jaw stronger than the others; this is a small fish with a beautiful golden color. The geneva that have no barbell include the whiting, *G. merlangus*, with silvery sides and a black spot at the root of the pectoral fins and the pollack, *G. pollachius*, dull green with a lower jaw longer than the upper jaw, the blue whiting, *G. poutassou*, which is like a whiting, but has a very long first anal fin and is smaller; and the silvery cod, *Gadiculus argenteus*, which lives in deep water over the edge of the continental shelf. The cod is undoubtedly the most important demersal food fish of our seas, and not only around the British Isles, but in the Arctic waters of Iceland, northern Norway, and Bear Island.

A large cod may produce as many as four million eggs at one spawning. All members of this family lay floating eggs; their small transparent spheres then drift with the moving waters and develop into the young fry. The spawning period is February to April, and the principal areas are those of the Great Fisher and Ling Banks, and Long Forties and Flamborough grounds. These have been determined by the charting of eggs and fry caught in plankton nets and from the landings of ripe and spawning fish. The fry, which are only 6 mm long when they hatch, spend about 2.5 months as part of the plankton, and are subject to the same hazards of shortage of food or excessive abundance of predators as the young of other species. They feed almost entirely upon the small crustaceans (copepods) of the plankton. During this period, circulating currents keep them within the North Sea, and when they are just over 2 cm long, they seek the bottom. Once on the sea-bed, they are extremely difficult to catch, especially as the nursery regions contain a good deal of rough ground. Still feeding upon crustacea, but now the bottom-living amphipods, isopods, and small crabs, the young cod grow quickly on the typical nursery grounds and begin to be caught by the commercial trawlers when they are 1.5–2 years old and 30 to 36 cm length; in some deeper regions of the North Sea, however, growth is slower, and they may not enter the fishery until they are 3 years old. The age of a cod is generally determined from its scales and not its otolith. Cod do not begin breeding until they are about 5 years old and have reached a length of some 69 cm.

Adult cod feed mainly upon fish, particularly herring, mackerel, small haddock, and sand eels; they also take mollusks, crustaceans, and bristle worms to a lesser extent. There is a marked contrast between the feeding of the cod and that of its close relative, the haddock. This is interesting in view of the well-established rule that two closely allied species cannot remain competing with one another in the same habitat: one, if slightly the more efficient, will certainly eliminate the other. The cod and haddock exist together on the same grounds but have distinctly different food preferences. Whereas the cod feeds mainly on fish, the haddock, except for sand eels, feeds almost entirely upon invertebrates: bristle worms, crustacea, mollusks, and particularly brittlestars, and small sea urchins. The haddock food is limited to rather small slow-moving animals found close to, or burrowing in, the bottom. Cod and hake eat larger and more quickly moving animals, even considering only fish of a comparable size. The nature of the mouths of these three species is significant. The mouths of hake and cod are much larger than those of haddock and practically, if not absolutely, terminal. They are provided with sharp teeth, and all the mouthparts are strong. Haddock, however, have a small mouth positioned somewhat ventrally. Their mouthparts are soft, and the teeth are ordinarily dull. They are, however, provided with better-developed muscular lips. Cod and hake are well equipped for capturing large or fast-moving objects, but haddock, with their smaller, ventrally positioned mouths, are best equipped for picking small animals off or out of the bottom. In addition, the heaviest built portion of the haddock is the anterior part of the body, and this may help them to remain more easily in a forwardly tilted position while feeding.

Haddock

The haddock is perhaps commercially second in importance to the cod among the trawl-caught fish. It is very abundant in the North Sea, particularly in the northern half, and further north to the Faeroes, Iceland, and the Barents Sea, but it does not go as far north towards Spitsbergen as does the cod. On the western side of the Atlantic, the haddock is also abundant on the coastal banks from Cape Cod to the Cabot Strait, and large concentrations are found on the southern hald of Grand Banks of Newfoundland. The main spawning period of haddock, like that of cod, is from February to April. The haddock is smaller than the cod, becomes mature much earlier, when only 2 years old, and is less prolific. A 2-year-old fish of about 25 cm in length will produce some 30 000 eggs, a 3-year-old (30 cm long) some 100 000, and a 6-year-old (only about 40 cm long) some 280 000. Haddock in the trade category 'extra large,' i.e., over 152 cm in length, are rare today; occasionally, however, much larger 'jumbos' are caught. For both cod and haddock, there is quite a marked difference in the growth rates of fish from the northern and southern halves of the North Sea. In the north, a 5-year-old haddock will have an average length of only 32 cm, whereas in the south, a haddock

of the same age will measure 39 cm. The sea-bed to the southern North Sea is warmer than that of the northern North Sea, and this is not simply because of the difference in latitude but because of the greater depth. The deeper water of the north is cut off in summer from the warmer zones by the formation of a discontinuity layer. In the much shallower south, where the water is more disturbed, no marked separation of upper and lower layers takes place, and so the sea-bed is kept warmer, and the fish grow more quickly.

Spawning takes place at various points in the very large area over the northern North Sea and in a much smaller isolated patch just north of the Outer Hebrides. It is still not known to what extent the Hebridean spawners are linked to the main North Sea stock. The positions of spawning within the large area are not fixed; their centers shift from place to place in different years.

Until the small embryo fish begin to produce their characteristic pigment, it is exceedingly difficult to distinguish the eggs of the haddock from those of the cod, and they are often found floating together. They drift and develop, as do those of the cod, but the fry remain in the plankton longer and so do not seek the bottom until they are over 5 cm long. Since the young haddock are larger than the young cod when they first settle down to a bottom-living life, they can be caught more easily.

Whiting

Among the four members of the genus *Gadus* that lack the barbell, the whiting, *G. merlangus*, is the most notable. It forms a considerable part of the catch of North Sea trawlers and seiners and is also abundant in the English Channel and Irish Sea; indeed, it is the most important demersal species for the fishermen of Northern Ireland. The catches in the North Sea have indeed been increasing since 1982, and it has been estimated that the total European catch for human consumption from this area was 140 000 tonnes with, in addition, some 30 000 tonnes of smaller fish taken for fishmeal. The whiting spawns principally in April and May throughout the North Sea but mainly within the 90-m line. In their pelagic phase, after reaching 2 cm in length, the young whiting associate with jellyfish, particularly *Pelagia cyanea*, which become very abundant in June; they shelter under the bell and appear to swim among the tentacles without coming to any harm. When almost 6 cm in length, they go down to the bottom. In their first 2 years, they are found in greatest numbers between the latitudes of 55 and 57° N. Like the hake and cod, the whiting feeds largely upon smaller fish, but at times may also take large quantities of the more active swimming crustaceans, such as shrimps, prawns, mysids, and euphausiids.

C D Khedkar, College of Dairy Technology, Warud (Pusad), India

N V Chavan, Adarsha College, Hingoli, Maharashtra, India

Background

The pelagic species found in summer throughout the waters of the European continental shelf are continually on the move in search of food; they feed on small fish such as sprats and sand eels, as well as on krill plankton. These species move between the surface and lower layers of the sea (2–400 m), depending upon the season and topographical features of the sea-bed. As surface-feeders, they have long provided a useful and easily caught source of food. Although the individual species are distinct, the group overall has a number of unifying features that tend to influence its exploitation and utilization by humans.

Mackerel

The scientific name of the mackerel caught in the north Atlantic is *Scomber scombrus*. Other species of *Scomber*, and species of *Scomberomours, Auxis*, and *Restrelliger*, are also described as mackerel in many parts of the world. The name mackerel is used in the UK principally for the species *Scomber scombrus*, but the name can also be used in the UK for any species of *Scomber* offered for retail sale. *Scomber scombrus* is sometimes called Atlantic, northern or Boston mackerel, to distinguish it from *Scomber japonicus*, which is variously called chub, Pacific, or Spanish mackerel. A small mackerel is sometimes called a cock mackerel, a joey or a little boy in England, or a pinner in Scotland.

Distinguishing Features

The Atlantic mackerel has a rounded, elongated body with two widely spaced back fins, the first with 11–13 spiny rays, the second with soft rays; the club mackerel has nine or 10 spines in the first back fin. There are four to six (usually five) finlets between the second back fin and the tail, and between the anal fin and the tail. There is a small keel on each side of the tail stub. The tail is forked. The back of the mackerel is a brilliant greeny blue, and the head is a steely blue–black with a small yellow patch behind the eye. There are 23–33 dark wavy bands across the back of the fish down to the midline. The sides have a silvery or coppery sheen, the belly is silvery white, and there is a broken black line just below the lateral line. The scales are small, and the skin feels velvety. There is a swimbladder in the chub mackerel but not in the Atlantic mackerel.

Life History

At the start of the winter, the mackerel migrate to overwintering areas. These are not well defined, but three are known around UK, one in the North Sea along the Norwegian Deeps, another along the edge of the continental shelf in the western Celtic Sea, and a third close to the south coast of Cornwall. The first two are typical overwintering areas and are similar to those off the east coast of North America; the mackerel are mixed with other species, for example scad in the Celtic Sea and Norway pout in the North Sea. Off Cornwall, the pattern is different. Large shoals of mackerel with few other fish among them move close inshore into relatively shallow water, although separate shoals of pilchard and scad are found in the area. The Cornish stock of winter mackerel was unknown before the mid-1960s, presumably because it was not there, and it is assumed to be an unstable offshoot of the stock in the Celtic Sea. Should the unknown factors that attracted the shoals suddenly change, there is always the possibility that they may withdraw just as suddenly from the area; nowhere else in the north Atlantic are adult mackerel found in a comparable position. Mackerel do not feed while overwintering, but they are not totally inactive. They form large dense shoals near the sea bed during daylight but rise and disperse during darkness. Occasionally, they disperse for no obvious reason and reform hours or even days later many miles from their previous position. Mackerel begin to move away from the overwintering areas in the spring to spawn and to start their feeding migrations. Spawning begins along the edge of the continental shelf in southern Biscay during February. By late March, spawning occurs throughout the Bay of Biscay and the Celtic Sea, and to the west of Ireland, and continues until June, but at all times, the greatest concentrations of eggs are found along the edge of the shelf. The older, larger fish start spawning first and, when spent, start swimming northwards along the edge of the shelf towards Shetland. Smaller, younger fish start spawning later and do not migrate so far. The youngest fish remain in the Celtic Sea throughout the summer. The spawning season in the North Sea is later, from May to August, and is most productive north of the Dogger Bank. Those that spawn south of the Dogger Bank are part of the western overwintering stock that spawns and feeds in the southern North Sea. Once spawning is completed, the North Sea mackerel mix with the older fish from the western stock around Shetland until the winter migration begins. Each female mackerel spawns on average about 300 000 eggs, which, when fertilized, are about 1 mm in diameter. Each contains a large oil globule that helps it to float in the upper water layers until it hatches. The larvae, 2–3 mm long, hatch after 4.5 days at 15 °C, or 8.5 days at 10 °C, and by the end of the first year, the young mackerel are 15–20 cm long. Growth continues to be rapid, and by the end of the first year, the young mackerel are 28–34 cm long. The growth rate is then considerably reduced, and mackerel 35–40 cm long may be anywhere between 5 and 20 years old. While a large fish is usually an old fish, one mackerel 57 cm long was found to be only 6 years old.

Length and Weight

An adult mackerel 30–35 cm long weighs 300–500 g before gutting. A joey mackerel, 20–25 cm long and probably in its second year, weighs 100–200 g. Mackerel weighing more than 1 kg are exceptional.

The Mackerel Fishery

Large, dense shoals may be found near the surface all round the UK in the summer and autumn, but their occurrence is sporadic in the southern North Sea.

The English summer mackerel fishery was traditionally from April to September; this has now been extended from February to October so that, coupled with the huge winter fishery now established in the southwest from October to March, mackerel supplies are available throughout the year. The Scottish mackerel fishery from June to August could also possibly be extended. Mackerel fishing methods have changed dramatically over the past 50 years. Before 1939, mackerel were caught mainly in the spring by drift net, an interim occupation for drifters between the winter and summer herring fisheries. After 1945, mackerel landings were small for some years, and the catch was taken mainly in the southwest during the summer by feathering, that is, small boats using hand lines with colored lures made from feathers or plastics. Once the mackerel shoals were found to remain in Cornish waters throughout the winter, the hand-line catch increased considerably in the late 1960s. As the market for mackerel improved, trawlers began to engage in mackerel fishing, using midwater mackerel in quantity off the west of Scotland in late summer.

Composition of Mackerel

The mackerel is a fatty fish, and the fat and water content vary with season. The fat content of mackerel caught off southwest England is lowest in May after spawning and reaches its peak between October and December after the fish have fed during the summer and autumn. A typical range of fat content throughout the year is 6–23%, and the protein content is 18–20%. The fat content of mackerel caught off the west coast of Scotland during August and September is similar to that of Cornish mackerel during December and January.

Herring

The herring, *Clupea harengus*, is the most plentiful fish found in the north Atlantic. *C. pallasi* is a closely related herring species found in Pacific. So important is it in sea life that it is given pride of place. It is known as a creature very well adapted for living in the upper water layers. Its blue–green back matches the color of the depths when viewed from above, and its silver flanks, seen from the side or below, mirror the varying lights and shades of the surrounding waters.

Distinguishing Features

The body of the herring is deeper than it is thick, and the length of the fish is about five times the greatest depth. The upper part of the body is dark blue–green or steel blue, the snout is blackish blue, and the sides and belly are silvery. The lower jaw protrudes slightly beyond the upper jaw. There is a single short back fin, a short anal fin near the tail, and a deeply forked tail fin. The pelvic fins are behind the start of the back fin, whereas on the sprat (*Sprattus sprattus*), they are in front.

Life History

Nearly all the other sea-fish of commercial importance lay eggs, which float freely in the water, drifting as part of the plankton; the herring is an exception and deposits its spawn in masses on the sea-bed, particularly on a gravel bottom, thickly plastering stones, shells and even the backs of crabs with it. As soon as the eggs are laid, they sink and stick to whatever they touch. In the summer when the fish are feeding, they are perhaps in smaller shoals, but now it seems that these combine together as the spawning time approaches. Some shoals are said to be 13–15 km long and 3–5 km wide. Each herring lays at least 10 000 eggs, and so the quantities of spawn produced by a shoal are enormous. The spawning grounds are an attraction to many bottom-living fish, especially haddock, which gorge themselves on this rich food. The eggs are fertilized in the water by the male herring, which discharge their sperm at the same time as the females lay their eggs. In North America, native Indians have long collected these eggs as a seasonal delicacy, and nowadays, an entire industry is centered on the collection of herring eggs for export, mostly to Japan. The eggs are about 1 mm in diameter and are incubated for 10–30 days depending on the sea temperature; 14–20 days is typical for the North Sea. The newly hatched fry or larvae, with yolk sacs attached, are 6–10 mm long and planktonic, and drift with the current. Since they depend upon nearby supplies of plankton for food, population levels can be directly affected by changes in the availability of the zooplankton. When the larvae reach a length of 40 mm, they begin to develop scales, take on a silvery sheen and move to inshore nursery grounds. Here, they are often caught, together with the young of other fish. The small fish now collect together in shoals, and tend to come in towards the coast into shallow water and sometimes large estuaries like the Thames or the Wash in the UK. In the Thames estuary, enormous shoals of whitebait are fished by so-called stow nets, which are huge conical nets lowered below anchored vessels and streamed out with the ebb and flow of the strong tides. After a sojourn of some 6 months or so in the estuaries and coastal regions, the herrings appear to scatter over the North Sea. They do not join the main shoals until they become sexually mature for the first time, and this, curiously enough, occurs in different individuals from the ages of 3–5 years.

Body Length

Most of the herring landed in the UK are between 230 and 300 mm long; herring caught off Norway and Iceland are often larger, up to 360 mm. Occasionally, herring can reach a length of about 430 mm, but this is exceptional.

Herring Fishery

In Scotland, there are several small fisheries at the beginning of the year. In the Minch, between the Outer Hebrides and the mainland, there is a fishery first for spent fish, then for recovering spents, and later on, in February and March, a stock of early spawning fish comes in. In the Firth of Forth area, there is a fishery for full and filling fish in January, extending to one for spawning fish in March. In Ireland, there are two fisheries for full and filling herring and later for spawners, one at the north and one in the southeast; both are over by the end of February. April and May is a lean period of poor fisheries, mainly for recovering spents. The small fishery at Lowestoft does not always materialize. In Ireland, too, they catch recovering spents in both the north and south in May, and sometimes in the south in April. During June to August, there is the great summer fishery in the northern North Sea for good-quality full and filling fish, the herring having nourishing themselves on the rich crops of zooplankton. In England, the drift-net fishery is confined to the North Shields area, where immature and recovering spents are caught in June, and full and filling fish in July and August.

The ring nets are employed for the herring fishery. A shoal of fish is located either by echo-sounding or by a feeling wire (a wire that gives a tremor when it is hit by the passing fish) and then surrounded by a net cast out as the boat circles around. Herring do not spend all their time near the surface; for a good part of the daytime, they are near the bottom, and a knowledge of this habit has led in recent years to another new and very considerable development: fishing for them with special fast trawls that skim over the bottom and have their head ropes kept very high by extra floats or underwater kites. The Germans were the pioneers in this and, for many years, have operated a large fleet of herring trawlers, working particularly on the Fladen grounds. During July and August, some of the companies in Hull, UK have also adopted this type of fishing in the North Sea. Fishing off the Yorkshire coast is in full swing during September, with landings at Whitby, Scarborough, and Grimsby, but by the end of September, all the drifters are concentrated at Yarmouth and Lowestoft ready for the great October and November fishery for the immense shoals of fine-quality full and filling that flood the East Anglian grounds prior to spawning in the Channel. This is the climax of the year; there is no more important herring fishery elsewhere in the world.

Processing and Preservation of Pelagic Species

Pelagic fishes are fatty and are not normally gutted at sea; they therefore spoil quickly unless they are chilled immediately after catching and kept chilled. They develop off odors after 1–2 days at 10 °C, become soft and spoil rapidly after 3 days, and become putrid after 5–6 days. Stale or noticeably spoiled fish should not be used for processing. In stale fish, the eyes are sunken, cloudy, and discolored red or brown. The skin loses its bloom, and its colors lose their intensity and brilliance, giving a washed-out appearance. The gills are dark red or brown, and a dark blood red mucus oozes from the gill covers. The odor of the gills and body is sour, sweaty, or strongly oily; sometimes a smell of ammonia is also present.

Chilling and Freezing

For freezing, the fish should be chilled immediately after capture and frozen within 24 h. Frozen fish should be properly glazed and kept in cold storage at −30 °C, which will keep it in good condition for at least 6 months. The cold-storage life can be extended up to 1 year if the fish is packed in polyethylene bags topped up with water and frozen in vertical freezers. The block is doubly protected against deterioration in storage by the encasing ice and packaging. Gutting before freezing is not necessary and may be a disadvantage. The fish can be hot-smoked to give a ready-to-eat delicatessen product, and the flesh of the hot-smoked fish can be used as a basis for a pâté. It can also be split or filleted and then kippered in cold smoke in a manner similar to herring. For a product of good eating quality, a fish with a fat content of at least 10% should be used. The smoked product can be whole gutted fish, with or without the head on, or fillets. Smoked whole fish is gutted, or headed, and gutted as required, the gut cavity cleaned, and the black bellywall lining removed. For hot-smoked fillets with skin left on are cut from the whole fish. Brining requires some care. In order to minimize the risk of food-poisoning organisms growing in the finished product, it is recommended that the salt concentration in the water phase of the product be at least 3%. This concentration, expressed in terms of water plus the solid components of the flesh, is less than 3%. To measure the salt concentration in the water phase, it is also necessary to measure the water content of the product. A salt concentration of 3% does

not render hot smoked fish unacceptably salty to the consumer. The rate of uptake of salt during brining depends principally on the size of the fish; large fish take longer to brine than small fish. Thus, to achieve a reproducible uptake of salt, all the fish in a batch should be of roughly the same weight. The brined whole fish can be tied by the tails in pairs and hung over tenter rods for smoking, or hung individually by the tails in keyhole slots cut in metal frames designed for the purpose. Fillets are laid on trays made of nylon-coated or stainless steel wire mesh. Full tenters, speats, or trays are loaded on to trolleys, which, when fully loaded, can be left to drain for 1–2 h or wheeled directly into the kiln without draining. In kilns with more than one trolley, the first loaded trolleys should be positioned at the air-outlet end, and the last loaded trolley at the air-inlet end. The smoking procedure in a mechanical kiln is as follows. With the kiln thermostat first set at 30 °C, the air-inlet half to threequarters open, and the main fan and chimney fan on, the smoke producer is set to produce maximum smoke, the recirculation damper being set to balance the smoke pressure in kiln. This predrying and smoking period takes about 1 h, during which time, surplus moisture dries off the surface of the fish, and the skins begin to set. The thermostats are then reset at 50 °C, the air inlet reduced to a quarter open, and the smoke pressure balanced by resetting the recirculation damper. The temperature and humidity in the kiln begin to rise, and the fish start to cook; high humidity prevents excessive weight loss. Once the temperature reaches 50 °C, it should be kept at that temperature for 30 min. The skin of the fish then becomes firm, and color begins to develop. For the final cooking stage, the order of the trolleys is reversed. The thermostats are reset at 80 °C, the air inlet closed, and the recirculation damper opened only just enough to relieve any back-pressure on the smoke producer. By the time the kiln temperature reaches 80 °C, small fish need a further 40–45 min to complete the process; larger fish need about 75 min. As a rough guide, the whole smoking process should take about 3 h. The fish attain a dark golden brown color, and the skin is dry with a silky sheen. The flesh should be completely cooked; the thickest part of the flesh at the shoulders of a whole fish should be opaque, with no jelly-like flakes.

Canning

These fishes may be canned as steaks, as fillets in a variety of sauces, or as a cold-smoked product. To make canned steaks, the whole fish are headed and gutted, and the belly cavity is cleaned out. The black skin is removed from the belly wall, and traces of blood along the backbone are brushed away. The fish are then cut into steaks of a length to suit the pack. The pieces are packed vertically in the can to give a product that resembles a middle-cut steak of a large fish. After adding 3 g of salt, the can is closed and heat-processed for 90 min at 115 °C. Vegetable oil or tomato sauce can be added to the can before closing. The finished cans should be stored for about 1 month before labeling and distribution; there is no further significant change in flavor or texture during storage after that time.

Salting

Quantities of fish were at one time pickle-cured in barrels for export, and small amounts are still packed in this way. A typical process is as follows. Fresh fish are split along the back and opened with a jerk to break the ribs. For hot-smoked fillets, skin left on is cut from the whole fish. Guts, gills, and any protruding bones are removed, and blood is washed away from the backbone. The fish are then soaked in fresh water for up to 2 h, rinsed, drained, and then dipped in dry salt. The fish are packed in barrels in circular fashion with tails to the center, and salt is sprinkled on each layer. The first two or three layers are packed skin downwards, and successive layers skin upwards. About 1 kg of salt to 3 kg of fatty fish or 4 kg of lean fish is required throughout the pack. When the barrel is full, it is closed, laid on its side, topped up with brine through the bung, and left for 10–12 days, further brine being added, if required, to keep the barrel full.

Tuna and Tuna-like Fish of Tropical Climates

G D Khedkar and B V Jadhao, Dr. Babasaheb Ambedkar Marathwada University, Aurangabad, Maharashtra, India
C D Khedkar, College of Dairy Technology, Warud (Pusad), Maharashtra, India
N V Chavan, Adarsha College, Hingoli, Maharashtra, India

Background

Over the last two decades (1981–2001), tuna has become one of the most commercially important fish species, a source of foreign exchange earnings for many developing countries. Initially, larger fishing nations dominated the industry, but with the introductin of the 200-mile (roughly 320-km) exclusive economic zone, an increasing number of developing countries now take advantage of their tuna resources. Important fisheries exist throughout tropical and temperate areas of the world's oceans. Although tuna constitutes less than 3% of the world fish production, it is one of the most valuable fisheries. The southwest Pacific is the main tuna fishing area and accounts for one-third of total catches. The eastern Central Pacific was overfished in the early 1980s, leading to a drop in production in 1984. There was a subsequent fleet movement to the southwest Pacific. As a result, yellowfin resources recovered. Tuna has many uses in the Western nations. A number of tuna utilization possibilities have emerged in the tropics. Internationally, tuna is traded fresh, frozen, or canned. Japan remains virtually the only major market for fresh tuna, much of which is consumed as sashimi. Tuna for the sashimi market is deep frozen to temperatures below −40 °C. The sashimi market is sensitive to quality-size, fat content, and method of handling the fish. Normally, larger fish with a higher fat level are preferred. Most of the frozen tuna internationally traded is eventually canned. Canned tuna is generally presented in the following product forms: solid, chunk, flakes, grated, and smoked. A small quantity of tuna is traded for use as pet foods, oil, and tuna meat. Principal uses of internationally traded tuna are canning, other forms of processing, or special Japanese products. Different parts of the fish are used for different product types. For canning, the firmer loins are used for 'solid pack,' and those less firm or broken are used for 'chunks.' The scrapings, which are not blood, meat, or skin, are collected and sent to the flake or grated lines.

Table 1 lists the characteristics of several commercially important tropical species of tuna.

Characteristics of Major Tropical Species of Tuna

Skipjack (*Katsuwonus pelamis*)

Skipjack is usually 45–80 cm in length and 3–6 kg in weight (Figure 1a). This species is primarily frozen and used as a raw material for canning. In Japan, skipjack is also smoked and dried for katsuobushi production. The landings of this fish have increased steadily over the last 40 years from 25% of world tuna production in 1965 to 32% in 1975, 48% in 1988, and 51% in 1997. Skipjack replaced yellowfin as the most important component of total tuna landings in 1972 and has since consistently accounted for the majority of total landings. Japan has traditionally been the most prominent producer of this fish, but in recent years, the USA, France, and Spain have increased their operations. Several developing countries such as Indonesia and the Philippines have also emerged as important producers. Thailand has emerged as a major market for fresh and frozen skipjack in recent years, importing an estimated 250 000 tonnes in 1988 and surpassing the USA as the world's most important frozen skipjack import market. Major markets of canned skipjack are the USA, UK, and Germany.

Yellowfin Tuna (*Thunnus albacares*)

Yellowfish tuna is usually 70–150 cm in length and 7.2–150 kg in weight (Figure 1b). A major use of this fish is freezing and processing as canned fish for markets in western Europe, the USA, and Japan. Japan also uses yellowfin on the sashimi market. The landings of this fish have increased in recent years, due to new purse seine fisheries in the Western Indian Ocean and the Pacific. The largest importer of frozen yellowfin is Italy. In 1987–88, Italy imported 100 000 tonnes as a raw material for its canneries. Japan and the USA are the second and third most

Table 1 Some commercially important tropical species of tuna

Common name	*Scientific name*	*Size*	*Weight*
Yellowfin	*Thunnus albacares*	160–200 cm	40–130 kg
Bigeye	*Thunnus obesus*	90–180 cm	20–80 kg
Bluefin			
Northern bluefin	*Thunnus thynnus*	160–200 cm	40–130 kg
Southern bluefin	*Thunnus maccoyii*	160–200 cm	40–130 kg
Skipjack	*Katsuwonus pelamis*	48–80 cm	3–6 kg
Albacore	*Thunnus alalunga*	40–90 cm	4–15 kg

important markets: Japan imported 50 000 tonnes annually in addition to its domestic production during the 1980s, while the USA imported 40 000 tonnes.

Albacore (*Thunnus alalunga*)

Albacore usually weighs 4–15 kg, with a length of 40–90 cm (Figure 1c). This is a cosmopolitan fish, occurring in tropical waters of all oceans. At least two stocks (northern and southern) exist in both the Atlantic and the Pacific oceans, with little or no interchange across the warm equatorial waters. The northwest Pacific is the most important fishing area, followed by the northeast Atlantic and eastern Central Pacific. The landings of this species varied between 180 000 and 225 000 tonnes from 1975 to 1988, but a general decline in annual production is evident. Japan and Taiwan each account for approximately one-third of the world's annual albacore production. Most of the albacore production is in canning in the USA as solid whitemeat tuna. The USA is a major importer, averaging 70 000 tonnes annually. Some albacore is sold as fresh and canned fish, and consumed in local markets in France and Spain.

Southern Bluefin (*Thunnus maccoyii*)

Southern bluefin typically weighs 40–130 kg, with a length of 160–200 cm (Figure 1d). It occurs in southern oceans at a latitude of 39 °S. The fishing areas south of Australia, in the Tasman Sea, and in the Eastern Indian Ocean account for 70% of total annual production. The catch varied between 33 000 and 47 000 tonnes annually during 1975–88. Management measures were introduced by Australia in the 1980s to prevent overexploitation of the species, and production levels have since declined to 19 000 tonnes in 1989. Australia and Japan are the principal producers, consistently accounting for more than 85% of total production worldwide. The fish is generally sold fresh on the sashimi market in Japan, where it may fetch as much as US$35–45 kg^{-1}.

Bigeye tuna (*Thummus obesus*)

Bigeye tuna typically weighs 20–80 kg and is 90–180 cm in length (Figure 1e). This species is

distributed in tropical and subtropical seas but is absent from the Mediterranean. World production of this fish during 1980–90 was approximately 200 000 MT annually. The eastern Central Pacific has traditionally been the most important area, accounting for a third of the total bigeye production. Japan, South Korea, and Taiwan are the only producers with selective fishing gears targeting bigeye, and Japan is the largest consumer of bigeye. Although some of the production is frozen, most is sold as fresh fish and sold on the sashimi market.

Quality Requirements for the Tuna Market

The raw material must be handled carefully so as to prevent bruising and damage to the flesh. Thus, long lining is the best method of catching tuna for export, since damage is minimal. The flesh of fish killed under stress undergoes chemical changes, a condition called 'burning,' which causes the flesh to become mushy and inedible. Speed and accuracy are needed in processing tuna for export. Fish has to be bled, gilled, gutted, and chilled rapidly. Tuna for the sashimi market is graded not only on visual characteristics such as a bright/clear skin, clear and moist eyes, elastic skin, and undamaged smooth abdominal walls but also on the fat content of the flesh. A small flap is cut in the tail region to inspect the color and feel for the oil content.

In most buyer countries, tuna imports are generally covered by food-safety regulations applicable to fresh/frozen fish. The limits for heavy metals vary: in Italy, the upper limit for mercury is 0.7 mg kg^{-1}, and in Japan, it is 0.4 mg kg^{-1}. The permissible limit for cadmium is 0.5 mg kg^{-1} in most buyer countries, while lead levels vary from 0.5 to 2.0 mg kg^{-1}. Internationally, traded tuna is also tested for histamine, a tuna muscle protein that causes vomiting, diarrhea, and skin irritation if ingested at high levels. For most buyer countries, the permitted levels vary from 200 to 500 mg kg^{-1}.

Internationally Traded Tuna Products

Internationally traded tuna products include the following

- chilled, deheaded and gutted, or gilled and gutted;
- frozen, deheaded, and gutted, or gilled and gutted;
- canned, 'solid packs' (a mixture of pieces of tuna);
- canned, 'chunks' (a mixture of pieces of tuna);
- canned, 'flakes' (smaller pieces of tuna);
- oil and meals;
- pet food and animal feed.

The canned products are packed in oil, brine, or sauce. A range of flavoring and seasoning additives are used in canning, including salt, monosodium glutamate, hydrolyzed protein, and various spices. Smoked tuna products are also internationally traded to a small extent.

Sashimi

The Japanese tuna market is distinct. It is centered on raw consumption in a form called sashimi. The sashimi market demands large species such as bluefin, bigeye, and, to a lesser extent, yellowfin. The sashimi market is sensitive to quality-size, fat content, and method of handling the fish. Normally, larger fish with a higher fat level are preferred. The highest-quality northern bluefin is used exclusively for high-class restaurants, while the lower-quality product is used for household sashimi. Southern bluefin is used mostly by the restaurant trade, while bigeye use is split between restaurants and households. Sashimi processing involves progressive cutting of the flesh into cuts and portions illustrated in Figure 2. Different sashimi cuts (Figure 3) from different species have various market values, depending on the fat content. Those with a higher fat content have a lighter color. Prime sashimi is 'otoro' (pink), followed by chutoro (darker pink). Otoro and chutoro are types of toro and have a fat content of about 25%. Inner muscle blocks, more reddish in color with 14% less fat are marketed as akami. Prices vary according to size, season, freshness, moisture content, flesh texture, and taste.

Dried/smoked tuna products, called fushi in Japan, constitute a smaller but important percentage of Japanese tuna products. Katsuobushi refers to skipjack fillets that have been boiled then broiled over charcoal several times, dried, and then inoculated with a mold during processing. Shavings of katsuobushi fillets are marketed as kezuribushi. Arabushi is

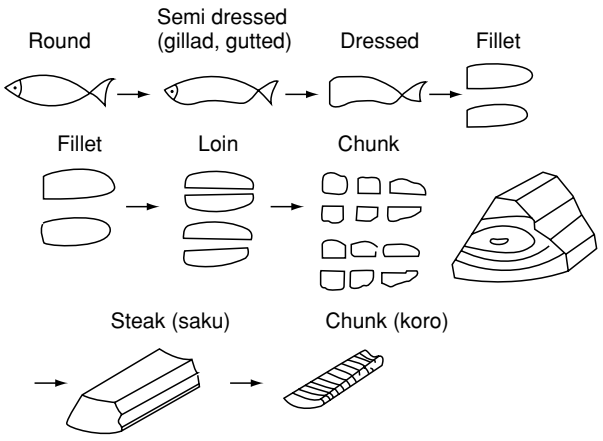

Figure 2 Stages in the preparation of sashimi portions.

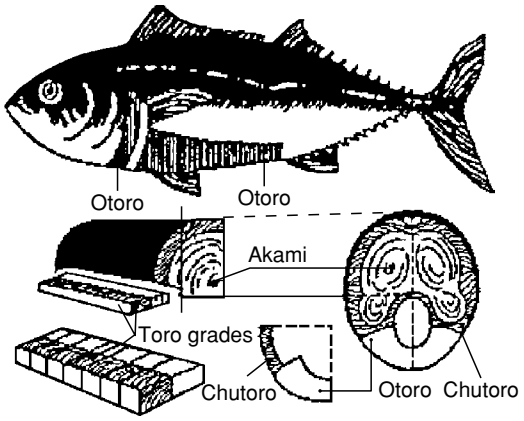

Figure 3 Distribution of cuts in tuna.

produced by drying and smoking skipjack loins, using fish caught by pole and line. Namaribushi is similar to arabushi, but the basic softness of the product is retained by reduction of smoking period. Imports of fishery products are in the form of arabushi, with the final processing including mold inoculation being done in Japan. Other products include tsukudani, a tuna pickle made out of skipjack flesh, boiled and seasoned with a solution of soya sauce and other flavoring materials. Shiokara, a fermented product, is produced from the viscera, stomach, or low-fat meat of skipjack by a process of salt fermentation.

Nutritive Value of Tuna

Tuna is very rich in high-quality protein. It is richer than beef or chicken and is one of the best sources of amino acids (Table 2). Tuna flesh contains substantial quantities of vitamins A, B_{12}, and D. It is also a very rich source of phosphorus, iodine, and fluorine. Studies of tuna have shown that *Katsuwonus pelamis* muscle consists of 69–72.6% moisture, 22.4–25.5% protein, 1.6–2.6% lipid, and 1.5–2.4% ash; a lipid content of up to 4.1% has been reported for some temperate species. Anatomical fractionation has yielded 69.7% meat and a total waste (head viscera) of 30%, a meat–bone separation has yielded 84% mince, and after heat processing and canning, the amino acid content has been found to remain essentially the same except for histamine and the sulfur amino acids. Hence, the protein quality can be said to be unaffected by precooking and retorting of canned tuna. Thiamin shows about 5% retention in the canned product. Nicotinic acid and riboflavin have also shown some reduction, and minerals assayed have shown a low retention. These losses might be due not only to heat destruction but also leaching of vitamins and minerals into the liquid portion of the canned product.

Table 2 Comparative appraisal of nutrients in raw and canned tuna

Nutrients	*Raw tuna*	*Canned tuna*
Essential amino acids (mg per 16 g of N)		
Histidine	6.59	5.07
Isoleucine	4.49	4.47
Leucine	8.24	8.33
Lysine	8.79	8.67
Cystine	1.62	2.72
Phenylalanine	3.62	1.47
Threonine	4.57	3.81
Tryptophan	4.57	1.19
Valine	5.31	5.33
Vitamins and minerals (per 100 g)		
Thiamin (μg)	189	11
Riboflavin (μg)	305	152
Nicotinic acid (mg)	28	19
Sodium (g)	0.27	2.39
Potassium (g)	0.91	0.63
Calcium (mg)	2.94	0.80
Iron (mg)	8.76	5.59
Copper (mg)	2.54	0.63

Global Supply Trends for Tropical Tuna

The world catch has steadily increased since the 1980s due to fishing by fleets in Latin America and Asian developing countries, the move of French and Spanish purse seiners to the western Indian Ocean, and increasing exploitation of western Pacific resources. Japan is the largest producer, even though its catch of high-value species has declined. The catches of Spain, France, Indonesia, Mexico, and South Korea have experienced the most growth. Skipjack continues to be the main species caught; 1.2 million tonnes were harvested in 1989. Yellowfin catches increased from 500 000 tonnes in 1980 to 905 000 tonnes in 1989. The major fishing grounds are in the southwest Pacific, accounting for about one-third of the total worldwide catch. Other major areas in order of importance are: eastern Central Pacific, western Indian Ocean, Northern Pacific and eastern Central Atlantic. The total canned tuna production increased more than 50% from 602 000 tonnes in 1980 to 1 099 000 tonnes in 1989. More than 80% of all catches are canned, 16% are consumed as sashimi, and the rest are cured. The leading country in canning remains the USA, which produces around 275 000 tonnes per year. Thailand's canned production grew the most during the 1990s. The share of developing countries in total canned production increased from 16% in 1980 to 44% in 1989. Trade in fresh and frozen tuna reached 1.3 million tonnes in 1989, representing about 75% of

all tuna trade. Increase in the Japanese demand for sashimi and canned yellowfin doubled fresh and frozen imports from 1980 to 1989. Thailand is now the largest importer of frozen tuna as it imports practically all the raw material for its canneries. Similarly, Italy and the Ivory Coast, both dependent on raw material imports, expanded purchases of frozen tuna. The main suppliers of fresh chilled and frozen tuna continue to be South Korea and Taiwan, mainly selling to the Japanese sashimi market. Prepared/preserved tuna exports reached 411 269 tonnes in 1989. Nearly 40% of total canned tuna production entered international trade in 1989.

Global Demand Trends for Tropical Tuna

Japan continues to be the main tuna-consuming country – sashimi consumption has declined over recent years, whereas canned tuna and katsuobushi have expanded. The total per capita supply has increased somewhat from 5.60 kg in 1980 to 6.35 kg in 1988–30% canned, 25% katsuobushi, and the remainder sashimi. Per capita consumption in the USA increased only slightly, from 2.4 kg in 1980 to 2.7 kg in 1988. In Spain and France, per capita consumption of canned tuna almost doubled. In Italy, canned tuna accounts for about 20% of total fish consumption.

Canned tuna is the most interesting product form to watch. Despite dramatic adjustments in the industry during the past decade, canned tuna's share of total consumption has remained at 80%. In Japan, consumption is likely to expand further on the wave of occidental food. By 2005, a per capita consumption of 2.7 kg is predicted. The USA, however, has reached saturation.

Prospects for Developing Countries

Loining operation is one of the prospects for developing countries, especially for those in the Caribbean and South America. In an attempt to contain production costs, US canners operating in Puerto Rico are actively considering options for loining tuna in lower-wage countries. Bumble Bee and Star-Kist are already importing frozen loins from Mexico, Equador, Costa Rica, and Thailand. The preparation of loins for canning is a labor-intensive operation. The cost squeeze for US canners could provide the impetus to perfecting the technology to allow loining to take place away from the cannery location. US canners have the advantage in that the main product form for lightmeat tuna is chunks. Therefore, quality control of imported frozen loins is relatively easy when compared to solid packs. The import duty of frozen tuna loins is 0%, the same as that for frozen whole tuna imports. Developing countries, especially those in the South Pacific should closely watch developments in loining technology, as this might provide a good opportunity to obtain a better yield from their resources.

Demersal Species of Tropical Climates

G D Khedkar and B V Jadhao, Dr Babasaheb Ambedkar Marathwada University, Aurangabad, Maharashtra, India
N V Chavan, Adarsha College, Hingoli, Maharashtra, India
C D Khedkar, College of Dairy Technology, Warud (Pusad), Maharashtra, India

Introduction

Demersal fishes have been a major source of protein for people all over the world for thousands of years. Worldwide, about 85% of the total continental shelf area has sandy or muddy substrate. Only about 6% is rocky or gravelly, and the remaining areas are coral reefs or shell beds. However, there are both latitudinal and depth-related patterns. Corals are almost entirely confined to low latitudes where organically enriched muddy areas are also most extensive, particularly near the mouths of major rivers or below highly productive upwelling areas. Sandy, rocky, and gravelly sediments are more common at high latitudes. The tropical waters contain a greater number and diversity of fish species than waters of the higher latitudes. Demersal fish of economic importance are concentrated on the continental shelf and on the continental slope down to about 500 m. They live on or near the bottom of the ocean. A regular landing from a deep-sea trawling session would include catfish, croakers, soles, groupers, shinynose, snappers, mullets, and megalops. World catches of demersal species increased rapidly during the first three-quarters of the 20th century. Since then the catches from some stocks have declined, due to overfishing, while other previously underexploited stocks have increased their yields (Table 1). The limits of biological production have probably been reached in many areas. In order to maintain the fisheries and to protect the ecosystems which support them, careful management is needed.

Migration in Demersal Species of Tropical Climates

Diurnal migrations, either vertically or horizontally, are common in demersal fishes. More fascinating, however, are the long-distance seasonal migrations associated with reproduction, feeding, and sometimes overwintering. Many examples were already well described several decades ago, based on traditional tagging data. But nowadays scientists are employing the application of modern electronic tagging techniques, whereby perfect positional information can be derived after retrieval of the tag. The traditional tagging experiments have provided evidence of migrations across deep-sea areas. Even transatlantic crossings have been recorded for cod. Although such basin-wide migrations may not occur regularly, they certainly show that demersal fishes are quite capable of considerable movements over long distances.

Sensory Systems in Demersal Fishes of Tropical Climates

The shelf environment is generally well-lit and most demersal fishes have well-developed vision. In addition demersal fish may use mechanoreceptors (sense of pressure, motion, and sound), chemosensory (olfaction and gustation) and electrosensory (i.e., ability to detect electric fields) systems. Different systems may play essential roles during different stages of important processes such as prey detection, capture and handling, predator avoidance, or reproduction. In general, mechanoreception by the acousticolateralis system (lateral line organ and ear) tends to be most important for the detection of predators, conspecifics, and other physical disturbances in the environment. Olfaction is very important to benthofages that have to search the substrate for food, whereas planktivores

Table 1 Total world catch of major demersal fish species (1990–2000)

Scientific name	*Common name*	*Catch (tonnes)*

Trisopterus esmarkii	Norway pout	299 145

and piscivores tend to rely more heavily on vision. Gustation is most important after capturing prey. Benthofages may have elaborate adaptations of their olfactory system. In addition to a well-developed nose, they may have barbells on the snout (e.g., gadids, zoarcids) and modified and extended first rays of their pectoral fins (e.g., Triglidae) densly packed with olfactory sensory cells. The electrosensory system is particularly well developed in some sharks and rays, and they may primarily use this system for prey location, but also for orientation and navigation.

Life History Characteristics of the Demersal Fishes of Tropical Climates

Life history strategies are best examined in the context of the assemblage or community within which the fish operates. No species lives in isolation, but interacts with and influences the activities of all the other species it regularly encounters. Ecological understanding ultimately grows out of the study of communities, and this perspective is the one most deep-ocean ecologists have adopted. Comparative study of several systems, when possible, can be very insightful. The samples required for this sort of study, however, are not easily come by. Large numbers are required, which, in the best case, should encompass most life stages and time series over seasons, over years, and over space. A single sampling gear rarely suffices, and even a suite of different nets, for example, might also be complemented with cameras and other 'snapshot' devices. For deep-sea fishes, it is hard to find any area where such requirements are met. One that comes somewhat close is in the deep abyssal region of the eastern Atlantic.

Most demersal teleosts (bony fishes) are oviparous and produce free-floating eggs. Mating and spawning happen at the same time, often in mid-water. Some notable exceptions are the viviparous redfish (Sebastes) that release numerous pelagic larvae, and the wolfish (Anarhichadidae) which deposits a cluster of large eggs that is guarded until hatching. Sand eels (Ammodytidae) also have demersal eggs but do not protect the eggs. Most teleosts have no parental care other than making sure that they mate and spawn in an area and habitat that enhances the survival probability of their eggs, larvae, and pelagic juveniles. Most pelagic teleost eggs are small, i.e., a few millimeters in diameter, and fecundity is high, i.e., thousands to millions of eggs per female. Batch spawning is common in the highly fecund species, e.g., cod may spawn 10–13 batches of its very small eggs within a spawning season.

Demersal sharks are either oviparous or viviparous, whereas rays and chimaeroids are oviparous, attaching their few large encapsulated eggs to debris or macroalgae. All species produce rather few young in each batch, i.e., from a couple to a few tens of eggs/juveniles, and lifetime production is very low compared with most teleosts. Upon hatching or birth, the young resembles the adults. Spawning seasons vary in duration, and the general rule is that the more seasonal the production cycle, the more fixed and limited is the spawning season. High-latitude fishes and those living in monsoon or upwelling regions have comparatively short spawning seasons, whereas tropical and subtropical fishes have protracted seasons or year-round reproduction. Larvae hatched from small pelagic eggs have a yolk sac that may provide sufficient nutrition for a few days or weeks, after which they depend on exogenous feeding, usually on small crustacea such as copopod nauplii. The mortality in this perod is very high indeed, and only a minute fraction of the total number of eggs spawned will eventually result in a surviving demersal juvenile. The teleost postlarvae pass through metamorphosis upon reaching a certain size. Characters such as fins and juvenile pigmentaion develop, and sense organs also become fully developed. In flatfishes, the eye migration occurs. In general, the larva is transformed into a fish which is morphologically and behaviorally adapted for demersal life. Associated with this change is the settling on the seabed, at least for parts of the diurnal cycle. Settling areas are often, but not always, separated from the feeding areas of the older fish. This reflects the different habitat and food requirements of juveniles and adults, but may also reduce cannibalism. In the majority of teleost species, the demersal nursery areas are shallower than feeding grounds of older conspecifics. Estuaries and offshore shoals are typical nursery areas, also rocky shores where the substrate and macroalgae offer protection and a variety of prey. Tidal flats and sandy beaches are typical habitats of juvenile flatfish. A gradual ontogenetic shift in depth distribution happens as the juveniles grow larger.

The expected longevity of demersal species of tropical climates varies greatly. A general pattern is that longevity increases with increasing adult size, but there are many exceptions to this rule. Some species, i.e., redfishes, can probably live for at least 30–40 years, but this is unusual for shelf species. Small species such as Norway pout may live for 5–6 years at most, but in exploited areas this seldom happens. In most shelf waters, the fisheries have influenced age distributions to the extent that life expectancy is significantly reduced.

Somatic growth patterns also vary widely among demersal fishes of tropical climates. In fast-growing species living in strongly seasonal environments, the overall growth trajectory may show seasonality either because food supply and feeding rates vary, or because the somatic growth is influenced by reproductive activity/gonad growth. Growth rate usually declines significantly when the fish becomes mature, but never ceases entirely. Attempts have been made to classify species into *r*- and *K*-selected types (*r* and *K* are coefficients expressing rate of reproduction and somatic growth, respectively). The *r*-selected types are those with short life spans but fast growth and rather small adult size. They mature at a small size and young age, and can rapidly take advantage of short and unpredictable favorable environmental conditions by increasing their numbers. The *K*-species, however, tend to invest more energy in somatic growth by growing more slowly and maturing later in life, when they are capable of producing many young. The populations of such species comprise many age groups, and they are not, like the *r*-species, so vulnerable to repeated recruitment failures due to low survival of young over a range of years. There are many species that do not readily fit into these classes, and it is unusual for demersal species of tropical climates to have the extreme *r*- or *K*-strategies seen among epipelagic fishes and demersal deep-sea fishes, respectively.

Species Distribution

The vast extent and inaccessibility of the near-bottom oceanic environment have resulted in extremely patchy sampling and arguably therefore a quite restricted, and no doubt biased, view of overall demersal fish distribution and community composition. Slope areas in certain regions, especially some parts of the North Atlantic, are notable exceptions yet, on the basis of relative areas, the proportion of the abyssal floor of the world ocean that has ever been trawled is so minuscule that any evenly distributed species represented in collections by more than 20 specimens *in toto* is potentially more numerous across the globe than in humanity! The relative uniformity of physical features, such as temperature and salinity at considerable depth, could allow very widespread distribution patterns to occur. The detailed knowledge of the distribution of most of the demersal species of tropical climates, however, remains obscure. Such knowledge is largely derived from taxonomic and rare zoogeographic studies. Rarely does it come from studies of full assemblages where species, ecology, and interrelationships are taken into account. Yet it is these investigations that contribute most to our understanding of the deep demersal environment and the community ecology of fishes there.

Important Species of Demersal Fishes of Tropical Climates

The Clarias

Clarias gariepinus, also known as the African mud catfish, exists in the wild but it is also cultivated in ponds, cages, and pens and is of great commercial importance. This is an omnivorous fish with a preference for a planktonic diet. It also feeds on other types of food items such as insects, insect larvae, pupae, fish, and fish remains. It also has a propensity for being carnivorous. Propagation of these fishes is widely practiced in the tropics. Peak production of eggs by the female and hatching of the fertilized eggs are known to take place during the rainy season. A production mean of about 28 000 eggs and a hatching rate of 86.4% have been recorded during the rainy season. A low propagation yield at other times has been attributed to the resting period in the ovarian cycle of the animal. Induction of spawning has been carried out with 11-desoxycorticosterone acetate or carp pituitary suspension. Some of the processed products made from Clarias include fermented, dried, and hot-smoked products. The nutrient content of *Clarias* spp. is given in Table 2.

The Ariomma

Ariomma bondi and *A. melanum* are the two species. The former is found in 200–400 m depth of water; it is silvery and has a big head with small eyes. *A. melanum* inhabits 200–600 m of water, is brown in color, and has a small head with small eyes. The drift fish (*A. bondi*) is a relatively unexploited deep-sea fish found in tropical West Africa from Senegal to Gabon and in the western Atlantic from Nova Scotia through to the Gulf of Mexico. The length range is about 10–19 cm, with a corresponding average weight of 31.88 g. Size is an important technological property of a fish, of significance to its fishery and subsequent utilization. The nutrient content of *Ariomma* spp. is given in Table 2. The length–weight measurement, as well as the weight composition, has been found to

Table 2 Nutrient content of *Ariomma* and *Clarias* spp.

Nutrient	*Composition*	
	Clarias spp.	*Ariomma spp.*
Moisture	70.5–72.0	75.5–77.5
Protein	18.2–18.6	19.47–20.12
Lipid	6.7–7.1	3.32–3.39
Ash	2.6–2.9	2.67–2.71

meet the technological requirements of canning. In canned *Ariomma*, the edible portion increases from 51.66 to 59.38% when the whole, headless fish with the soft bones and fins are canned, consequently increasing the calcium and phosphorus content of the product. Canned *Ariomma* will be cheaper than canned tuna since it is relatively inexpensive and has a lower processing cost.

Demersal Fisheries

Demersal fisheries use a wide variety of fishing methods to catch fish on or close to the seabed. It is defined by the gear used, type of fishing activity, and varieties of fishes which are caught. A very wide range of fishing gear is used in demersal fisheries, the main ones being bottom trawls of different kinds, which are dragged along the seabed behind a trawler. Other methods include seine nets, trammel nets, gill nets, set nets, baited lines and long lines, temporary or permanent traps, and barriers. Catches from demersal fisheries make up a large proportion of the marine harvest used for human consumption and are the most valuable component of fisheries on continental shelves throughout the world.

Demersal fisheries have been a major source of human nutrition and commerce for thousands of years. Models of papyrus pair trawlers were found in Egyptian graves dating back 3000 years. The intensity of fishing activity throughout the world, including demersal fisheries, has increased rapidly over the past century, with more fishing vessels, greater engine power, better fishing gear, and improved navigational aids. Many demersal fisheries are now overexploited and all are in need of careful assessment and management if they are to provide a sustainable harvest.

The products of demersal fisheries are mainly used for human consumption. The species caught tend to be relatively large and of high value compared with typical pelagic species. Demersal fisheries are also known as ground-fish fisheries.

The five demersal marine fish with the highest average catches over the decade 1990–2000 are Alaska pollock, Atlantic cod, sand eels, blue whiting, and Argentine hake (Table 1). All these species spend a considerable proportion of their time in midwater. Sand eels spend most of their lives on or in the seabed. The vast majority of demersal fisheries take place on the continental shelves, at depths of less than 200 m.

Management of Demersal Fisheries

It is necessary to manage the demersal fisheries for biological, social, and economic purposes. Biological goals used to be set in terms of maximum sustainable yield of a few main species, but a broader and more cautious approach is now being introduced, which includes consideration of the ecosystem within which these species are produced and which takes account of the uncertainty in our assessment of the consequences of our activities. The most important biological goal is to avoid extinction of species. At a global level it is evident that economic goals are not being achieved because the capital and operational costs of marine fisheries are about two times higher than the gross revenue.

There are large numbers of examples of adverse social impacts of changes in fisheries, often caused by the effects of larger, industrial fishing operations on the quality of life and standard of living of small-scale fishing communities. Biological management of demersal fisheries has developed mainly from a single-species 'yield-per-recruit' model of fish stocks. The yield is controlled by adjusting the mortality and size of fish that are caught. In many shared international fisheries, such as those governed by the European Union, the annual allocation of catch quotas is the main instrument of fisheries management. This requires costly annual assessment of many fish stocks, which must be added to the operating costs when looking at the economic balance for a fishery.

The instruments for limiting the size of fish caught are mesh sizes, minimum landing sizes, and various kinds of escape panels in the fishing gear. These instruments can be quite effective, particularly where catches are dominated by a single species.

There are two classes of economic instruments for fisheries management: corrective taxes and subsidies and property rights. The latter demands less detailed information than the former and may lead to greater stakeholder participation in the management process, because it fosters a sense of ownership.

The management of demersal fisheries will always be a complex problem, because the marine ecosystem is complicated and subject to change as the global environment changes. Management will always be based on incomplete information and understanding and imperfect management tools. A critical step towards better management would be to monitor performance in relation to the target objective and provide feedback in order to improve the system.

One of the changes which have taken place over the past few years is the adoption of the precautionary approach. This seeks to evaluate the quality of the evidence, so that a cautious strategy is adopted when the evidence is weak. Whereas in the past such balance of evidence arguments were sometimes applied in order to avoid taking management action unless

the evidence was strong, the presumption now is that in case of doubt it is the fish stocks rather than the short-term interests of the fishing industry which should be protected. This is a very significant change in attitude, which gives some grounds for optimism in the continuing struggle to achieve sustainable fisheries and healthy ecosystems.

Introduction

Of the total world catch of over 80 million tonnes of fish, roughly 36 million tonnes are accounted for by groups of typically pelagic fish. Of the total fish catch, approximately 25 million tonnes are used for reduction purposes and it is likely that a very high proportion of this comes from pelagic fish landed in bulk. The production of fish meal from oily fish is around 6 million tonnes, with an associated 1.4 million tonnes of oil, implying a conversion ratio of about 3.4:1. Allowing for approximations, these figures imply that about 70% of tropical pelagic fish caught are used for purposes other than direct human consumption. In addition to meal and oil, over 1.7 million tonnes of canned pelagic fish products is produced.

The landmass between the tropics of Capricorn and Cancer (32°28′S and N) is considered as the tropical region. Most of this region, barring some desert areas in Africa and the Indian subcontinent, is considered to be lush with vegetation and animals and is characterized by a climate predominantly determined by annual monsoon rains. From a socio-economic point of view, the tropics, in spite of its expected lushness, has some of the poorest and least developed countries in the world. The great bulk of mariculture in the tropics takes place on land-based ponds, which draw sea water through natural inlet channels, and in shallow bays. Unlike in temperate regions, offshore culture facilities using large floating and/or submersible cages are virtually nonexistent. In particular, the almost exponential growth of the shrimp culture industry in the last 15 years or so, and the adverse environmental influences this development has had on the coastal environment, and the future potential in mariculture development in the tropics as a means of closing the projected gap in supply and demand for aquatic products, especially for the upper end of the market, by year 2015, have created a fresh awareness of tropical mariculture.

Pelagic Environment

Microscopic planktonic organisms of the oceans form the basis of marine food chains and the more complex food webs. A bucketful of tropical sea water may contain several thousand microscopic plants and animals. Microscopic plant life includes all the members of the phytoplankton that provide food for herbivores. The phytoplankton is composed of various types of unicellular algae, which range from a few microns to several hundred microns in size. The major groups of algae include the diatoms, which are the dominant type of phytoplankton. It is essential for diatoms to remain in the surface waters to carry out photosynthetic processes, and therefore these algae have developed a variety of adaptations to prevent sinking. Other common types of phytoplankton include the dinoflagellate algae and coccolithophores.

Since all the oceans are connected with one another, and temperature appears to be the most important factor that limits the distribution of marine fish, there is basic similarity in the families throughout the tropical belt (Table 1). Pelagic fish are those which live at or near the surface of the sea. There are two categories of pelagic marine fish which form important fish resources in the tropics: those that occupy the open ocean, further from the shore and from the surface (to a mean depth of about 150 m), are generally large, swift, carnivorous species, such as tuna, as well as smaller species: the second category comprises fish which occupy the surface or near-surface waters of the continental shelf. These fish are also found in large inland lakes and reservoirs in the tropics, where species such as clupeids or cyprinids are important in commercial and artisan fisheries. These species have been introduced there because of an increasing demand for fish, and to allow better utilization of available water resources in such places (Table 2).

Important Characteristics of Pelagic Species

There are more kinds of surface-living fish in tropical and subtropical waters than those of higher latitudes. The pelagic species are the predominant catches in the tropics with a total exploitable potential of about 15–45×10^6 tonnes. Their common characteristics, including abundance and density, allow efficient mass fishing. Each species has different characteristics, which sometimes fluctuate with seasons. The continuity of fisheries for pelagic fish depends not only on the abundance of the stocks but also on their distribution. Pelagic fish, being more dependent on the body of water they are in than on the type of sea bed, show variable patterns of migration. It is in warmer seas that the larger members of the mackerel family (Scombridae) – the tunnies, bonitoes, and albacores – abound, likewise Coryphaena, the sailors' 'dolphin' and shoals of flying fish (Exocoetidae) and the smaller lantern fish (Myctophidae), upon which these larger fishes prey. The opah or moonfish (Lampris), the larger sunfish (Mola), and the swordfishes (Xiphiidae) are also typical of milder conditions. The northern boundary of these subtropical waters is usually taken to be a line at the sea surface having a mean annual temperature of 12 °C; this isotherm, as such lines are called, skirts the south-western tip of Ireland and the entrance to the English Channel, so that from time to time in summer some of these exciting exotics stray into cooler parts. One of the tropical species which shows a marked variation in chemical

composition is the West African shad (*Ethamalosa dorsalis*). This fish shows a range in fat content of 2–7% (wet weight) over the year, with a maximum in July. It has also been observed that the oil content of some of these species varies with size. A range of products can be obtained from the pelagic species of tropical region. The limitation in utilization is their small size; nevertheless, these are converted to low-cost products such as meal and oil.

Examples of Pelagic Species of Tropical Climates

Sardines

Sardine is a generic term applied to a number of different kinds of small saltwater fish which are prepared, cooked, and packed in a special way. Sardines are actually canned herring and the Maine sardine is the Atlantic herring, *Clupea herengus* (Figure 1). The edges of the scales on the belly of these fish are rough. These species lay their eggs on the seabed; Atlantic herrings usually lay their eggs at depths of 40–200 m and in some cases intertidally on gravel and small stones and the Pacific herring spawns on seaweed between tidemarks. Both species spawn on narrow strips. They mature at about 3–4 years of age and their annual fecundity amounts to 40 000–100 000 eggs. Throughout life the total fecundity would be about 10 times greater and only two survivors are needed to replace the stock. Hence the annual mortality each year of the eggs, larvae, and juveniles is high; indeed, it is approximately the inverse of the annual fecundity. The natural mortality of the adults is that sustained under predation in the absence of fishing and, as might be expected, it is rather difficult to establish; that of the herring might be about 10–20% of numbers per year.

These fish travel in huge schools and live in the open ocean, ranging from Greenland to North Carolina. The smallest of these herring, 12–17 cm in length, are dressed and canned as sardines, while larger ones are cut into small steaks and packed as 'fish steaks' or filleted and smoked to make kippered snacks.

Figure 1 The Maine sardine (*Clupea herengus herengus*).

Sardinella longiceps is the most important and widely distributed of all the species in the tropical environments. Sardines provide a tasty, low-calorie package. They provide valuable protein, minerals, vitamins, and cholesterol-reducing omega-3 fatty acids. Herring has been canned since the early 1780s when Napoleon recognized that there was a need to preserve food. Even today with the convenience of the refrigerator and the freezer, sales of canned food have been rising yearly. Sardines are also processed without preservatives as they are sterilized by heat in a sealed aluminum can.

The Maine Sardine

The Maine sardine is recognized as the world standard for excellence in sardines. Around the globe there are more than 20 varied species packed as sardines, but it is the tropical sardine that is unsurpassed for quality. This versatile little fish has long been an important resource to the state of Maine, longer in fact than Maine has been a state. Weirs, crude brushwood traps, were used to capture the small fish as they swam in shallow coastal waters. In the nineteenth century, Maine commercial fishermen adopted very similar fishing techniques and set stationary weirs in coves and along coastal areas that are often visited by young herring – the fish come in at night with the flood tide and are left trapped in the weir when the tide goes out.

Today, modern technology has refined the sardine fishing industry to include the use of large boats called seiners that take advantage of sophisticated detection equipment such as depth recorders, echo-sounding devices, and even light airplanes to watch for the flash of silver that marks nearby schools of small herring. The seiners use large nets to encircle schools efficiently, then a drawstring is pulled to close the bottom and trap the fish within. The use of modern-day seines gives fishermen the flexibility to follow the fish offshore rather than wait for them to enter stationary shoreside weirs. To insure that only the freshest product reaches the public, netted fish are quickly dispatched to modern canneries for careful processing.

The Maine sardine industry had its real beginning as a result of the Franco-Prussian War of 1870. At that time, for the US supply of the very popular oil-fried canned French sardine, it became increasingly important that the brand should meet high standards before being released for sale. Every case lost is meticulously inspected and carefully evaluated for strict adherence to 21 quality factors and it is operated under the rigorous Hazard Analysis Critical Control Point program monitored by the Food and Drug Administration. The nutrient content of tropical

sardines is as follows: moisture 65%; fat 14%; crude protein 18%; ash 1.7%; inorganic phosphorus 175 mg; and amino nitrogen 105 mg. These characteristics are important to the canning industry.

The Sprats

The sprats, *Clupea sprattus* (L.), are small clupeoids about 10–13 cm in length. They live for about 5–7 years, but the most abundant age group is the third year. Like other clupeoids, they feed on copepods and other plankton animals. They spawn in spring and summer, but in the northern Adriatic they spawn between December and March. They mature from the end of their second year to the end of their third year and lay between 10 000 and 40 000 eggs each year. The natural mortality is probably high. There are major spawning grounds in the southern North Sea and in southern Norwegian fjords. The eggs, larvae, and juveniles are fully pelagic. Sprats are found in the Baltic, in the North Sea, in the northern Adriatic and off Romania in the Black Sea. Fisheries were established in the Scottish firths, between Bergen and Stavanger in Norway, off Brittanny in France and around the English coast, particularly in the Wash and in the Thames estuary. In the main, these are winter fisheries worked with drift nets and stow nets, i.e., bag nets hung from fixed poles in the tidal streams.

The Mackerel

The common mackerel of tropical climates, *Scomber scombrus*, is the most important pelagic fish. It occurs in large shoals and is caught, as the herring is, in driftnets when it is in its plankton-feeding phase of spring and early summer. Mackerels are larger than herring, reaching as much as 40 cm in length or more. They spawn in the midwater in productive seas where the larvae and juveniles grow up, and they spend the rest of their lives there. They feed on copepods and other plankton animals. They swim quickly and some of the larger ones are predatory. The natural mortality of mackerels is perhaps high, up to 30% of numbers per year. They do not shoal as herring do but there may be small and transient aggregations.

The catch of mackerel has been increasing within the past few years. The catches have reached as much as one million tonnes from two stocks, one in the North Sea and the other to the west of the British Isles. They are found in the Mediterranean but catches have only amounted to about 30 000 tonnes each year. Considerable catches of Atlantic mackerel have been made off the eastern seaboard of the USA. The stock of Atka mackerel in the North-west Pacific yielded annually about 100 000 tonnes. The Pacific mackerel yielded large catches for a period, after which they declined. The horse mackerel (*Trachurus trachurus* L.) has usually been caught in trawls. It is somewhat larger than the common mackerel.

Mackerel meat has higher enzymatic activity than other fish, and the decomposition of substances related to adenosine triphosphate (ATP) is quick. The successful storage of raw mackerel for processing is, therefore, subject to the temperature used. Frozen storage at −18 to −30 °C could give a storage life of about 2–3 months. Storage with crushed ice (0 °C) would keep the fish fresh for about 48 h. Due to the higher variations in its fat content and its high enzymatic activity, mackerel present problems during processing and utilization. The nutrient content of fresh mackerel shows moisture content of 76%, crude protein 18%, fat 4%, carbohydrate 0.7%, and mineral 1.3%.

The Menhaden

The menhaden (*Brevoortia* spp.) comprise a group of species found in the tropical and subtropical west Atlantic. The most important species is the Gulf menhaden. *B. patronus* found in the Gulf of Mexico. Landings of menhaden showed a slow but steady increase up to 1993 (1.3 million tonnes) and have subsequently leveled off at a slightly lower level.

The Capelin

The capelin (*Mallotus villosus*), an arctic fish found north of the polar front, is caught off the Canadian seaboard, around Iceland and Greenland and in the northern parts of the Norwegian and Barents seas. Landings first became prominent in the mid-1960s and increased to a peak of 4 million tonnes in 1977. They have since decreased progressively to only just over a million tonnes in 1987, partly as a result of the collapse of the Barents sea stock.

Preservation of Pelagic Fish Quality on Board and Ashore

Overall, the world fisheries biological potential is about 120 million tonnes and fishery resources around the world are close to maximum catch limits. Many of the recent global changes in landings appear to be more the result of climatic fluctuations of stock size than of fishery development of management processes. There has been a steady increase in landings during the 1990s; 1997 (110 million tonnes) was slightly more than the record catch in 1996 (108 million tonnes). Much of the increase is accounted for by three pelagic shoaling species (Peruvian anchovy, South American sardine, and Japanese sardine) and the semi-demersal Alaska pollock. Pelagic fishing usually gives a single-species catch. When

caught in coastal fishing by smaller boats, mixed catches may demand species sorting as well as size grading. Traditionally, offshore fishing with big vessels has been for fishmeal and oil production, while the coastal fisheries have supplied the fresh-fish market and the processing industry, especially canning.

The increasing demand for high-quality raw material for all types of production has put pressure on fishermen to utilize all available knowledge and organize the processes on board in an attempt to optimize quality, value, and efficiency to satisfy the market. Special grades of fishmeal demand the highest degree of freshness, thereby requiring rapid and efficient chilling for this type of production. The interest in using small pelagics as raw material for animal feed, either as silage or as whole fish frozen in blocks, is also a challenge for the on-board handling and storage of fish. Byproducts are of increasing interest, e.g., roe production and collection of other raw material for biotechnological utilization. The choice of using ice or chilled/refrigerated sea water depends on fish species, the quantity of fish to be handled, and the type and value of product to be produced on board or ashore. The use of ice when boxing pelagic fish for human consumption was long regarded as uneconomical, but the development of methods for automatic addition of ice has made this more attractive. Likewise, improved methods of internal transport and storage using new methods for identifying and labeling each box, which can be monitored and recorded by microprocessor techniques, are important developments.

Filleting of fish on board is a specialized process and increases the product value, but sets certain limits on fishing capacity and often on processing flexibility. The advantage of on-board processing is that freshness can be assured. Also, the question of full utilization of the catch is important; today dumping is too easy and fish are wasted in an effort to store only the most valuable products.

Highly specialized vessels for surimi production based on pelagic fish have been developed but, so far, this venture has not been successful due to many technical problems and limited availability of suitable fish resources.

Chilling

Many of the pelagic resources are found close to the shores, giving small vessels the opportunity to participate in the fisheries. The need for chilling is important, particularly when temperatures are high (> 15 °C), while low temperatures may allow bulk transport if the distance is short. Sorting of fish is necessary ashore due to both damage and autolysis, which increases at high temperatures. Often only a small part can be utilized for consumption. Small vessels can improve handling and increase quality of the catch by using boxes or small insulated containers with ice or CSW. It is important to avoid anaerobic conditions in containers without circulation. Therefore the system of pumping air via perforated pipes into the bottom of the containers can be used. Many such installations have been tried out and proven to be beneficial. To reach a practical solution to benefit the fishermen, quality must be paid for; otherwise new investments will not be made. The Food and Agriculture Organization has been heavily involved in giving advice and is undertaking projects to increase the utilization of small pelagics for human consumption. In some cases when small pelagics are intended for curing or salting and sun drying, the process may start on board. Containers with brine, or chilled brine, can be used, starting the brining on board so that high-quality raw material can be brought back for sun drying. The best results are achieved when small fish are chilled and brined rapidly. Bigger fish (> 25 cm) should be gutted if the brine is not chilled.

Canning

In many countries canning is the most important utilization of small pelagics. The many different products of sprat, sardine, herring, mackerel, pilchard, and tuna are well accepted. This is important in the market due to good storage stability and high nutritional value. Fish for canning must be of the highest quality, and because most small pelagic fish are very delicate, damage due to handling often results in a high degree of postharvest losses. Also, the many old purse seiners operating without chilling make substantial losses, especially in areas with high temperatures such as India, California, Chile, or Peru and South Africa. Autolysis in combination with rough handling results in belly bursting, which is very dependent on storage time and temperature. Reducing storage time and temperature can greatly improve the quality of the raw material. Chilling is of the utmost importance and only a few hours' delay at 15–20 °C will reduce storage ability by several days. This means that the quality of landings of small pelagic fish for canning is dependent on season and fish species, on the chilling rate on board, and on the loading or unloading method. The bigger fish can often withstand rough handling. Disintegration of fish results in lower productivity in the processing plant. In a Mexican canning plant the quantity of sardines nabbed by machine decreased from 160 to 60 kg per person per hour when the proportion of belly burst increased from zero towards 100%. For the small fatty species,

oxidation must also be avoided. For fresh consumption and canning it is not a problem if chilling is done properly and if fish is utilized within 2–4 days, as is usually the case.

Important Elasmobranch Species

J P H Wessels, Danhof, South Africa

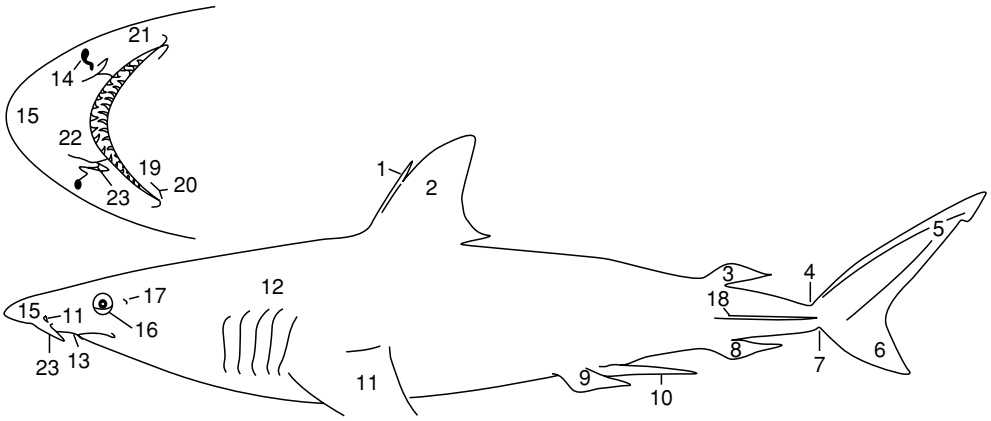
Introduction

There are economically important fish species in both subclasses of the cartilaginous fish (class Chondrichthyes: **Figure 1**). These two subclasses are Elasmobranchii (previously referred to as Euselachii), which include sharks, skates, and rays, and Holocephali or chimeras. Holocephali differ from Euselachii in respect of the number of gills (they have one gill slit compared with 5–7 in sharks, skates, and rays) and in the fact that their teeth are fused to form plates. The economic use of shark and ray flesh and other portions such as livers is widespread and is not a recent development. Traditional oriental uses for flesh and fins abound: the flesh of many different sharks and rays are used in the western world, Central America and in some South American and African countries and traditionally by the Aborigines of Australia. Like other natural oils, shark oil was used as fuel for lamps, even in lighthouse towers.

Of the total 1994 world catch of fish (just under 100 million t), 730 784 t was reported to consist of sharks, rays, and chimeras. Of this quantity, the chimeras (elephantfish, or St Joseph shark) represented only 5032 t. More than 190 000 t of skates and rays were caught during 1994. Of the species identified, the following sharks were most plentiful in the world catch: *Carcharhinus falciformis*, the silky shark (15 400 t): *Mustelus schmitti*, the smooth houndshark (11 450 t); and *Squalus acanthias*, the spotted spiny dogfish (20 589 t). Catches recorded during 1994 were 1763 t for the basking shark (*Cetorhinus maximus*) and 1049 t for the porbeagle (*Lamna nasus*). The whiptail ray (*Dasyatis akajei*; 4041 t), the cuckoo ray (*Raja naevus*; 2822 t), the thornback skate (*R. clavata*, 1298 t), and the spotted ray (*R. montagui*; 827 t) were dominant catches amongst the rays. Catches recorded for the guitarfish species (*Rhinobatus percellens* and *R. planiceps*) were 1110 and 30 t respectively and for unidentified guitarfish 1559 t.

Table 1 lists the countries that catch and process sharks, rays, and skates. This table shows that fishing activities are not limited to specific geographical areas. **Table 1** also lists the major products of shark, ray, and skate exploitation. Apart from the countries shown, Ivory Coast and Senegal featured as producers of shark products in previous years, while Hong Kong is reported to have produced 3 t of dried salted shark fin during 1989. Shark oil and shark liver oil are recorded as products of Korea and the Maldives, where an estimated 20 t of shark oil and 18 t of shark liver oil were produced in 1989. A further 18 t of shark oil of unknown origin was traded.

Apart from the countries listed, considerable landings of elasmobranch fish were made in France and Brazil (more than 20 000 t in 1991), Argentina and Spain (more than 15 000 t in 1991), Australia, Nigeria, and the former Soviet Union (3100–7600 t in 1991). While Japan is the world's major producer of shark, ray, and skate products, trade statistics reveal that Hong Kong and Singapore are the major centers for trade in shark fins. A large portion of the world's elasmobranch catch is bycatch, i.e., a byproduct of



1. Dorsal fin spine.

some directed fishery such as a trawling, longline, treknetting, or seining industry. Where elasmobranch fishing is directed, use is made of lines (even handlines) and hooks.

Commercial Products Derived from Elasmobranch Species

Shark and Ray Flesh (Fresh, Chilled, or Frozen)

The smaller species of shark are generally used as sources of fresh, chilled, or frozen meat, while the larger sharks provide fins and hides. In the world context, the spotted spiny dogfish (*Squalus acanthias*), which grows to a length of 1 m and which, unlike most other sharks, is readily skinned, constitutes the major source of shark meat. The relatively small smooth houndstooth sharks (*Mustelus canis, M. manazo*, and *M. mustelus*), the blue shark (*Prionace glauca*, which grows to almost 4 m in length), the porbeagle (*Lamna nasus*, which reaches 3 m in length), and the mako shark (*Isurus glaucus*, of similar potential size as the porbeagle) are also important sources of shark meat. However, in the case of larger specimens of these species, the flesh would be used mainly as an ingredient of fish pastes, or sold as steaks, or included in smoked or minced form of bacalao. In Japan the flesh of the porbeagle, the gummy shark (*Mustelus* spp.), and the whiptail ray (*Dasyatis akajei*) are the only elasmobranch species readily eaten as fresh fish. It is reported that these species do not acquire an ammoniacal taste shortly after being caught.

The elephantfish (*Callorynchus* spp.) is a source of particularly fine flesh of a good white color which, like the flesh of some noncartilaginous fish, is lean. The low-fat content has consumer appeal in countries where there is an awareness of the detrimental effect of a high-fat intake. Low-fat levels of 0.1–0.3% are recorded in the flesh of various shark species. Low muscular fat levels are usually associated with high levels of fat storage in the liver; also in noncartilaginous fish. Certain of the smaller *Carcharhinus* species are of importance in some areas, e.g., the black-tipped shark (*C. limbatus* or *C. johnsoni*) and, in Italy and France, even the large dusky shark (*C. obscurus*) has importance. The tiger shark (*Galeocerdo cuvieri*), which grows to a very large size, is used as a source of shark flesh in several areas of the world. The thresher shark of the Caribbean (*Alopias vulpinus*) is a large shark: it's meat is perceived to be of very good quality and is said to resemble swordfish.

In Japan, it appears that little shark flesh is eaten as fillets or cutlets, but shark flesh has found its way into what might be called surimi-based products. For this purpose certain gel-forming properties are required. Of the major species mentioned above, three appear to have found use in chikuwa and kamaboko-type products: *Prionace glauca, Mustelus manazo*,

Table 1 Products (t) derived from sharks, skates, and rays produced by different countries during 1989

Country	Fresh or chilled fillets	Frozen fillets	Frozen sharks	Sharks dried, salted, or in brine	Sharks, rays, etc. (dried not salted)	Shark fins (dried, not salted)	Shark fins (dried and salted)

and *Isurus glaucus*. Shark flesh is not necessarily used on its own in these products, but rather as a substitute for traditional white fish types. *Lamna nasus* and *Prionace glauca* are said to produce weak (nonelastic) gels, but the flesh of most sharks and rays has good elastic properties. Good gel-forming is associated with a high myosin content, myosin being that portion of the muscular protein that solubilizes in 1.2–1.5 mol l^{-1} sodium chloride solution.

As far as skates, stingrays, and guitarfish are concerned, there is no indication that specific species are more suitable for certain products. Whole gutted skate and skate wings, skin-on or skinned, and skate nobs (chunks of flesh), used fresh and in the frozen form, are world trade commodities. Stingrays are sold alive or fresh in Japan. In as far as rays tend to be more limited in distribution than sharks, there is a tendency for some species of rays to predominate in the catch from specific areas.

The flesh of skates and rays passes through rigor mortis more rapidly than that of cod, for example, and it is not inclined to suffer from the gaping phenomenon that occurs in some fish fillets.

Of 16 shark species studied as a source of flesh, some of the better known species have high fillet yields, in excess of 45% of the original body mass. These include *Squalus acanthias, Mustelus manazo*, and *Carcharinus falciformis*. The yield of the hammerhead shark (*Sphyrna tudes*), at 54.4%, is almost as high as the best, i.e., the blacktip shark (*C. limbatus*).

Canning of Shark Flesh

Some years ago a small shark-canning industry was set up in Murmansk, a port on the Barents sea.

Smoked and Salted and/or Dried Flesh of Sharks and Rays

Flesh of the shark species listed above is smoked and salted and/or dried in various countries. Some of the larger sharks appear to be only used in this manner. The hammerhead sharks (*Sphyrna tudes* and *S. zygaena*), which are not favored as a source of fresh meat, are used for the production of salted and dried meat in the Caribbean and South America. A notable exception is schillerlocken, a smoked product

produced in Germany from the belly flaps of a small shark, the dogfish; in addition, some smoked shark delicatessen products are made in Italy from shark of popular species and size. Shark flesh appears to be consumed primarily in salted form in some South and Central American countries, but it is also used in the fresh or chilled form and for freezing.

The flesh of the ray is hot-smoked, while a fermented product, subsequently salted, is made in Iceland. Rays of the genus *Gymnura* (a butterfly ray) are dried (unsalted) in Indonesia, while the ray is also used in this manner in Gambia, and guitarfish are dried and salted in India. (*See* **Smoked Foods**: Principles; Applications of Smoking.)

Mercury and Ammonia Formation in Shark Flesh

There are two aspects which cannot be ignored in a discussion on the use of the flesh from different cartilaginous fish. The first is the mercury content of the flesh of sharks, which is sometimes raised, and the second is the postmortem formation of ammonia.

Mercury Content

Relatively high contents of mercury, up to about $8\,mg\,kg^{-1}$ of flesh, have been recorded in shark flesh, while values of up to $1\,mg\,kg^{-1}$ are on record for skates, and $0.3\,mg\,kg^{-1}$ for chimeras (*Callorynchus* spp.). This chemical property is shared with other long-living, wide-ranging finfish such as swordfish and marlins. Cartilaginous fish, however, often contain very low levels of mercury. In one particular laboratory the mercury contents of 1003 samples of *Isurus glaucus*, measured as total mercury, ranged from 0.02 to 8.29 mg per 100 g, with a mean of 0.54 mg per 100 g of flesh, while 163 samples of *Galeorhinus galeus* yielded 0.2–3.75 mg per 100 g of flesh (mean of 0.88 mg).

Maximum limits for the mercury content of flesh – operative in the world fishery market at present – lie between 0.5 and $1\,mg\,kg^{-1}$ of flesh. As these animals are generally quite mobile, i.e., not restricted to narrowly defined geographic areas, one expects that the age of the fish would be the major determinant of the level of mercury that will have been taken up and retained by the body. This great mobility is thought to be one of the reasons for the high mercury content of shark flesh; they take in more water than would a slower-moving fish of similar size. Also, for reasons not understood, sharks secrete the heavy metal at a lower rate than they take it up. (*See* **Mercury**: Properties and Determination; Toxicology.)

Ammonia Formation

While ammonia production owing to bacterial action is a common feature of fish flesh, the effect is exaggerated in the flesh of cartilaginous fishes. These fish possess, in addition to the trimethyl amine oxide of fish blood and muscle, a further nitrogen-rich compound, urea (carbonyl amide), which functions in osmoregulation to maintain the fish in balance with its salt-water environment. Bacteria that come in contact with the blood or flesh of the fish after death break down these compounds to release amines and, in the case of urea, ammonia with its characteristic pungent 'fishy' smell; the release of ammonia is a first step in the breakdown process, resulting from bacterial urease activity. (*See* **Amines**.)

Bleeding of sharks is recommended as soon as possible after death, a step which is not practiced in some of the *Squalus acanthias* fisheries – hence the reddish color of the flesh in such cases. Rapid cooling by icing or freezing and strict hygiene are further recommended practices. Urea can also be removed by leaching with water or brine, while in the case of salted, dried flesh the urea content will have been reduced. Even if no bacterial action takes place during the earlier stages of salting which will result in urea breakdown, the leaching effect which accompanies salting results in considerable loss of urea from the flesh.

The urea contents of the flesh differ between and within species. According to one source, *Squalus acanthias* lies at the low end of the range with 1570 mg urea per 100 g of flesh and smooth hammerhead shark (*Sphyrna zygaena*) is at the higher end with 2038 mg per 100 g. Skate fall in the same class as sharks in terms of their urea content, in the range 1–2%. The few values available for St Joseph shark range from 1.4% to 1.8%.

Utilization of Shark Fins for Soup

One set of shark fins usually consists of two pectoral fins, the first dorsal fin (and in large sharks with two dorsal fins, the second) and the lower lobe of the tail fin. These fins are either dried or salted and dried and used in the Orient and by Chinese communities elsewhere to produce shark fin soup. Small sharks do not yield suitable fins, while some larger species do not produce fins of desirable quality. In general, however, the fins of any shark longer than 1.5 m can be used.

Of the sharks of suitable size, only nurse shark (*Ginglymostoma cirratum*) fins and the sawshark (*Pristiphorus mudipiunis*) pectoral fins appear to be of no commercial value.

The preferred shark species are the hammerhead, the mako, and the blue, mentioned above, and the tope or soupfin, *Galeorhinus galeus*. Fins from many of the large and the very large sharks are used, however, including those of the great white shark (*Carcharodon carcharias*), the fibrous meat of which, incidentally, is eaten in part of northern Japan. The very large tiger shark (*Galeocerdo cuvieri*) is also listed as a source of good-quality shark meat. Several *Carcharinus* species provide fins for processing in Pakistan.

Shark Hides for Leathermaking

Shark skins used for leathermaking must be removed from the fish in a very fresh state. Only sharks larger than 1.5 m are skinned for leather, with the exception of the small Pacific Ocean shark species, the brown cat shark (*Apristurus brunneus*), the hide of which is used to prepare the special boroso leather.

The nurse shark (*Ginglymostoma cirratum*) is the species of first choice, except in Japan, where preference is for the skin of the blue shark (*Prionace glauca*) and that of members of the Rhinobatidae family (guitarfish) which have relatively small skin dentiles. These species do not produce suitable hides as far as the shark leather industry of the USA is concerned. In the USA the tiger shark is seen as having a good hide. If properly cut and prepared, however, the hide from any other larger shark species is acceptable. This situation prevails since technical advances in shark hide tanning were made by the Ocean Leather Corporation of Newark in New Jersey, USA. These advances permitted the production of softer leather rather than the rough sandpaper-like skins produced earlier from shark skin.

The Food and Agriculture Organization has drafted a code of practice for the utilization of sharks for food and for skin production.

Sharks' Teeth

Sharks' teeth represent another potential product, similar to leather, in the sense that the end products are consumer goods. There is at present no established market for sharks' teeth, except on a small scale in some holiday resort areas, where mako shark teeth are sought after as tourist items.

Other Products

Other shark products that remain to be discussed represent the result of further extensive processing or are a nutrient source or products with pharmaceutical or other uses.

The Japanese Product Meikotsu

The soft cartilage of shark or skate is diced, boiled, and cooled in water, the remaining muscle and hard cartilage are removed, and the soft cartilage is again boiled and then sun-dried. This product is made in Japan for export to China. Shark cartilage in powder or tablet form is available for treatment of various cancers and autoimmune conditions such as arthritis. While there is strong evidence of dramatic beneficial effects in some instances, the medical fraternity seems to be skeptical.

Extraction of Chondroitin

Chondroitin is extracted from the hard and soft cartilage of the shark. The chondroitins are mucopolysaccharides composed of glucuronic acid and galactosamine units.

Shark corneas have been used to implant on to human eyes, at least in the USA and Australia.

Shark Liver Oil, Vitamins A and D, and Squalene

Shark flesh is virtually free of oil. On the other hand, the livers can contain high but variable levels of oil. The size of the livers varies greatly with the species; larger sharks tend to have larger livers while within species heavier sharks have relatively larger livers. (*See* **Fish Oils**: Dietary Importance.)

The liver constitutes about 17.5% of the mass of the large tiger shark (*Galeocerdo cuvieri*), against 2.9% of that of the soupfin shark, in this instance *Galeorhinus japonicus*. Some deep-water dogfish sampled in Australia contain relatively large livers. For the Portuguese shark (*Centroscymnus coelolepsis*) a mean of 27% of body mass was recorded and for the leafscale gulper shark (*Centrophorus squamosus*) 23%. There is seasonal variation in the relative liver mass and oil contents of the livers, with an upper limit of liver mass in the large sharks about 20% of the body mass.

Marine oils are usually used as raw materials for products such as baking fats and margarines. The oil of the cartilaginous fish is often not made up predominantly of triacylglycerols. The fatty acids in such nontriacylglycerol-rich oils are associated with diacyl glyceryl esters which may contribute considerably to the nonsaponifiable fraction of such oil.

The fatty acid composition of shark oils is not well documented in modern literature. Oil of the head or the liver of the spotted spiny dogfish (*Squalus acanthias*) has a relatively low content of saturated

fatty acids in comparison with most fish oils, i.e., 20% or less, and high levels of C_{20} and C_{22} highly unsaturated fatty acids. Head oil, for example, was reported to contain 10.4–15.5% eicosapentaenoic acid and 17.7–21.8% docosahexaenoic acid, the two fatty acids claimed to be dietary essentials. Amongst the best defined actions of these fatty acids in the human body are reduced blood pressure, thinning of the blood, reduced blood triacylglycerol levels and brain development and visual acuity in very young children. An oil (probably a body oil) from the porbeagle (*Lamna cornubica*) contained an even lower level of fully saturated fatty acids and a higher level of docosahexaenoic acid. The monoenoic fatty acid content of this oil was lower than that of the dogfish head oil (45–47%). Also, the liver of the dogfish is rich in monoenoic acid compared with the oil from the flesh of the same fish. Three elasmobranch species (*Carcharias melanopterus* 31%, *Galeocerdo cuvieri* 40%, and *Pristis cuspidatus* 37%, of the Rajiformes order) are listed as having oils with a high content of saturated fatty acids. (*See* **Fatty Acids**: Dietary Importance.)

Interest in shark oils lies not in the fatty acids of which the oils are composed, but primarily in the fact that some of the oils contain high levels of vitamin A and others high levels of a long-chain hydrocarbon called squalene.

The kitefin (*Dalatius liche*) and hammerhead (*Sphyrna tudes*) sharks with their large livers yield oil with high vitamin A potency, while the liver oil of the relatively small blacktip shark (*Carcharinus limbatus*) also has a high vitamin content. These vitamin contents are higher than those of other somewhat larger species of the same genus: *C. obscurus* (dusky shark), *C. plumbeus* (sandbar shark), *C. falciformis* (silky shark), *C. leucas* (bull or Zambezi shark), *C. brevipinna* (spinner shark) and *C. taurus* (sand shark, Taiwan). Smooth houndstooth shark (*Mustelus manazo*) and mako shark (*Isurus glaucus*) oils are also high in vitamin content, as are oils from the black shark (*Galeus glaucus*) and the soupfin shark (*Galeorhinus japonicus* and *G. galeus*). The vitamin content values are reportedly up to 100 000 IU of vitamin A per gram of dogfish oil and even up to 156 000 IU in oil from the liver of adult *G. galeus*. In general, values are only about 10% of these, with much lower values (< 100 and 180 IU) reported for the basking shark (*Cetorhinus maximus*) and the chimerid *Hydrolagus colliei* (ratfish). Compared with the liver oils of most finfish, the elasmobranch oils contain very low levels of vitamin D: 1 IU g^{-1} for the above-mentioned ratfish to 25 IU g^{-1} for the oil from the liver of the skate, *Raja inornata*. (*See* **Retinol**: Physiology.)

The importance of natural vitamin-rich oils in the diet of humans and farm animals has declined greatly since the last world war as a result of the successful synthesis at competitive costs of synthetic vitamins A and D. The focus of the shark oil market has therefore moved to Japan and some western countries, where squalene is extracted from suitable shark oils. After hydrogenation of the almost fully saturated hydrocarbon (C_{30}) to squalane, this material is used as an ingredient of cosmetics. (*See* **Cholecalciferol**: Physiology.)

Elasmobranch oils have been classified into three groups on the basis of their content of unsaponifiable matter. The first group is similar to the majority of finfish oils, in the sense that they have a low nonsaponifiable material content, i.e., up to 2%. In these oils, cholesterol would be the major nonsaponifiable material. The second class of elasmobranch oils contains 10–35% nonsaponifiable material which, in addition to cholesterol, largely consists of long-chain alcohols naturally present as diacyl glycyl esters. Ratfish oil is in this category. The third group is the high-squalene group. The nonsaponifiable material of the liver oils from the sharks in this group is obviously high.

The basking shark (*Cetorhinus maximus*) is one of the sharks of which the liver oil contains the highest content of squalene, i.e., 45–75% expressed as unsaponifiable matter (another source gives a range of 22.8–55.3%). Deep-sea shark species which have oils with very high unsaponifiable matter contents are *Squalus mitsukurina, Centrophorus squamosus, C. calceus, C. acus, C. atromarginatus, C. lusitanicus*, and *C. niaukang*. The cosmopolitan kitefin or seal shark (*Dalatias licha*) is also said to produce oil with a very high content of unsaponifiable matter.

A small amount of shark oil is traded in view of its use in industry. Special physical properties of such oils render them suitable for use as additives in certain lubricants and polishes.

Processing

M W Moody, Louisiana State University, Baton Rouge, LA, USA

Introduction

From earliest recorded history, humans have used fish and fishery products for sustenance, recreation, and many other positive aspects of developing society. Today, fish – and the associated fish-processing industry – remains an important economic segment of nearly every modern culture. Countries controlling water and coastal resources vehemently protect their interest. So sensitive are the issues of fisheries management and harvesting rights that disputes have been the source of international conflicts, embargoes, and even wars.

There are hundreds of species of fish. Nearly every large body of environmentally sound water, both fresh and salt, is currently producing or has the potential to produce commercially important fishery products. Although most of the fishery resource is harvested from wild stocks, aquaculture is becoming increasingly important as a stable and reliable source of fin fish. Worldwide landings of fin fish approach 122 million metric tons. In 1996, the top fish-producing countries were China, Peru, and Chile. China alone harvested more than 33 million metric tons of fish, more than 25% of world production. Because of the great diversity and distribution of fishery stocks and specific consumer demand for processed-fish products, the international trade of processed fishery products is significant. The estimated annual per-capita world consumption of fish and shellfish (estimated live-weight equivalent) for human food is an estimated 15.2 kg.

This article reviews the basic concepts of basic fin fish processing and associated quality considerations.

Fin fish can be processed into human food, animal food, or into components for industrial applications. Such inherent characteristics as oil content, flesh color, bones, size, and unit cost will usually determine the suitability for the final product.

Onboard Handling

Fin fish are harvested by various capture methods, including nets, trawlers, seines, traps, and hook and line. In many cases, regulations will dictate approved methods if conservation is an issue. The degree that fish are properly handled or mishandled at the time of capture will directly affect the quality of the final processed product. Fish should be quickly and thoroughly chilled and properly stored prior to processing.

Most fish are initially landed on to fishing vessels for temporary storage and transport to shore processing facilities. Depending upon time and distance, the fish may be iced, chilled, or frozen. In some instances, the harvesting vessel is designed and equipped to process fish on board the vessel.

Processing Plant Operations

In its simplest form, fin fish processing may involve only simple evisceration. It may also be complex, requiring specialized and expensive equipment, such as in the value-added production of fish analogs. Fin fish can be processed manually, with automated equipment or, more typically, by using a combination. Automated processing is more suited to processing fish that are uniform in dimension and where high volume is a consideration. Automated fish-processing equipment can be expensive and may require a high degree of maintenance. Manually processed fish, on the other hand, generally provide the highest meat yield, and this technique is used where product appearance is a major consideration.

Although there can be many varied steps and techniques used in fin fish processing, the common steps that may be used include grading or sorting, heading, evisceration, scaling, skinning, cutting, trimming, filleting, and one of many methods of preservation. A processing line is commonly used for fin fish operations. The raw material, usually whole, live, or drawn fish, is introduced into the plant and moves from one processing step to another until that day's delivery has been completed. Each processing step must be synchronized to avoid bottlenecks and delays in processing. Fish harvests can be seasonal or unpredictable, and processing plants must cope with daily shortages or gluts. The objective of fin fish-processing operations is to maximize meat yield and product

shelf-life, size and grade product accurately, and generate the minimum amount of waste. Meat yield is the bottom line and will depend upon the species being processed and the method of processing used.

Fish come in all sizes and shapes. Consequently, the final product can vary greatly in size, shape, and weight. There can be variability within the same species. Markets, however, require product sizing uniformity and consistency. In the last few years, there have been significant developments in sizing and grading technology. Computers, using advanced optic and weighing systems, can sort fish fillets and other meat cuts quickly and accurately. Fin fish-processing operations generate a significant amount of waste in the form of viscera, skin, bones, and unrecoverable meat. This is a growing problem since disposal options are becoming more restrictive. Fish processors are subject to governmental regulations, as is any food manufacturer. Fish nomenclature, fish-processing regulations, and international trade requirements are all challenges to modern fin fish processing. The following discussion considers some of the significant preservation methods and value-added products for processed fish.

Fresh Processing

Fish products processed and offered as fresh have a relatively short shelf-life. Depending on the quality of the fish and the conditions of storage, the shelf-life can be as short as a few days or as long as several weeks. Typical fresh products include whole drawn, headed, fillets, and other meat cuts. There is a direct correlation between the temperature of fresh fish products and the shelf-life. For maximum shelf-life, fish should be stored at temperatures near the freezing point of water (i.e., 0 °C). At this point the flesh will not freeze, but bacterial and enzymatic activities will be minimized. As storage temperatures rise above 0 °C, bacterial and enzymatic activities can increase significantly, dramatically shortening the shelf-life. Where applicable, crushed ice is used to hold fresh fish. The ice maintains the desired temperature of the fish. Water from the melting ice 'washes' microorganisms from the product, thus extending shelf-life. Little or no sophisticated packaging is required for the product. Most fin fish can be processed for fresh markets. (*See* **Storage Stability**: Parameters Affecting Storage Stability.)

Frozen Processing

To reach worldwide markets effectively, frozen fish processing is becoming increasingly important. Not all species of fish are suitable for freezing. Fish with a high fat content may become rancid in a relatively short time. In some cases, there may be undesirable textural changes or discolorations. There are a variety of frozen fish products, such as frozen fish blocks and breaded products, that are not available using any other method of preservation. Modern fish-freezing technology and equipment are economical, efficient, and specific for fish products. Bulk frozen products, such as frozen fish blocks (fillets, mince, or other meat cuts frozen as a single unit), are normally frozen using a direct-contact freezer such as a plate freezer. Individually quick frozen (IQF) products use the efficiency and speed of cryogenic freezers. Other types of freezers used in fish processing include blast and immersion freezing (brine freezing). Regardless of the type of freezing equipment used, there are common factors that have an impact on the product quality. (*See* **Freezing**: Blast and Plate Freezing; Cryogenic Freezing.)

Rate of freezing Rapid freezing produces smaller ice crystals than slow freezing. These smaller ice crystals are responsible for less structural damage to the fish flesh. In addition, rapid freezing minimizes the destructive concentration of cellular constituents. Rapid freezing is encouraged when processors use thin, prechilled packages of fish, and high-capacity, low-temperature freezers. (*See* **Freezing**: Principles.)

Freezer storage temperature There is no significant microbiological activity in frozen fishery products, but enzymatic activity can have a pronounced effect. Most frozen fishery products must be maintained at extremely low temperatures to negate enzyme destruction. Research shows that storage temperatures in the range −23° to −29°C are acceptable for most fishery products. Lower temperatures are even better but, at some point, economic considerations are prohibitive.

Packaging Frozen fish products are packaged to minimize dehydration and oxidation. Desiccation of poorly packaged frozen fish is a serious problem. Over a period of time, a highly undesirable drying condition (freezer burn) may occur. Fish fats and oils are easily oxidized in the presence of air. The resulting rancidity is responsible for undesirable flavors and color. Fish processors depend on commercial packaging materials and wraps to serve as effective barriers to minimize dehydration and oxidation. The fish-freezing industry has made great use of ice glazes for minimizing these same effects, especially in IQF products. Typically, ice glazes are formed by immersing or spraying frozen fish fillets or other fish products in chilled water immediately after emerging from the cryogenic freezing equipment. In this manner, a

coating of ice is formed around the product. The fish-processing industry also uses modified-atmospheric packaging (MAP) and vacuum-packaging to extend shelf-life and maintain quality. However, in the USA the use of such technology may be restricted without approved controls on fresh, unfrozen fish products because of potential growth of anaerobic pathogens such as *Clostridium botulinum*. (*See* Storage of Frozen Foods; **Freezing**: Structural and Flavor (Flavour) Changes.)

Fish Canning

Fish has been successfully canned commercially for more than 100 years. However, with the advent of improvements in freezing technology, transportation, marketing, and storage facilities, the percentage of canned fish products has been declining. One of the major advantages of canned fish is the relatively long shelf-life when stored at ambient temperatures. At the same time, canned fish is notably different from fresh and frozen fish. Canning requires subjecting fish to high temperatures to produce commercial sterility. The resulting product is fully cooked. Salmon, tuna, and herrings (including sardines and anchovies) are species of high commercial value that are traditionally canned. Fish may be delivered to the canning facility fresh (salmon and herrings) or frozen (tuna). Generally, fish are processed for canning by first heading, eviscerating, scaling, and cleaning. Additional processing steps can be quite variable, depending on the species and the desired end product. For example, salmon are packed raw into cans and, although the fins are removed, the skin and bones, which soften and are edible after processing, are considered part of the pack. Tuna and some of the herrings are cooked before packing the cans. Cooking removes excess water from the fish tissue and improves the appearance of the final pack. Bones, skin, and dark-meat portions are removed from tuna before packing into cans. (*See* **Canning**: Principles.)

Canned fish may or may not be packed with additional ingredients, such as oils, water, or sauces. Salmon are not generally packed with any additional media. Tuna may be packed in vegetable oil, water, or broth. Sardines and herrings may be packed in oils, flavors, or a number of sauces such as mustard or tomato. Cans used in the process are of many sizes and shapes. Metal cans are sealed with double-seaming machines that exhaust the head space to produce the proper vacuum. Hermetic sealing is essential if product integrity is to be maintained throughout heat processing, cooling, and storage. Leaks will cause spoilage and jeopardize product safety. Canned fish are low-acid foods and, consequently, will readily support the growth of most microorganisms. *Clostridium botulinum* is a heat-tolerant microorganism capable of growing and producing a highly potent toxin in canned fish that has been underprocessed, or contaminated as a result of container leaks. For this reason, most countries require minimum heat process times and temperatures to destroy all microbiological vegetative cells and spores to commercial sterility. Properly sealed and packed cans are heat-processed using steam under pressure in a retort. The processing time depends on can size, initial temperature of the fish at the time of processing, and the internal temperature of the retort. After processing, cans are quickly cooled in cold chlorinated water, labeled, and packed in shipping containers. Canned fish are subject to deteriorative changes during heat processing and subsequent storage. For example, meat discoloration may occur if the product is overprocessed. Struvite, a harmless glass-like crystal of magnesium compounds, may develop in canned tuna after an extended storage period; the use of appropriate food additives, such as chelating agents, usually minimizes the problem. (*See* **Canning**: Quality Changes During Canning; ***Clostridium***: Occurrence of *Clostridium botulinum*; Botulism.)

Dried, Salted, or Smoked Fish Processing

Curing and drying fish with salt and smoke were among the earliest methods used by humans to preserve fish. Over the years, these products have developed traditional markets and today represent a relatively small but important commercial segment of the processed fish industry. These products depend on low water activity to minimize the growth of microorganisms. Dried salted fish are processed by increasing tissue surface area, usually by splitting the fish, packing in salt to reduce tissue moisture quickly and, finally, air drying to achieve a moisture content low enough to provide product stability. Smoked fish can be processed using a variety of techniques and types of equipment. There are two basic types of smoked fish: cold-smoked and hot-smoked. Cold-smoked fish, as the name implies, is generally processed at lower temperatures than hot-smoked fish over a longer period of time. The salt content may be higher and the texture drier. Hot-smoked fish is succulent and is processed in a significantly shorter period using much higher temperatures. (*See* **Preservation of Food**; **Smoked Foods**: Principles; Applications of Smoking.)

There are several important steps in the processing of most smoked fish. Salting the raw fish before smoking firms the texture, adds a desirable flavor and, in some cases, may serve as a preservative. Soaking fish in a brine solution is the most desirable method of adding salt. This procedure provides

control and uniformity. Several factors directly affect the rate at which salt is absorbed, such as: (1) the strength of the brine solution; (2) the amount of exposed tissue (skin retards salts penetration); (3) the fat content of the fish (the higher the fat content of the fish, the slower the salt penetration); (4) the size of the fish or pieces of fish (the larger the pieces, the slower the penetration); and (5) the amount of agitation and temperature of the brine. After brining, but before smoking, the surface of the fish is air dried to facilitate 'pellicle' formation.

Drying is performed by a skilled individual and usually within the oven that will be used to smoke and cook the fish. A properly formed 'pellicle' will produce an attractive finished product. Smoke particles will cling to its surface, imparting a pleasing golden or bronze color. After drying, the fish is smoked and then cooked to the required internal temperature for a specified period. Cooking time and temperature will vary, depending on the final salt concentration and the use of other food additives. Modern smoking ovens have automatic controls that carefully monitor critical parameters. *C. botulinum* is a microorganism of great concern to smoked fish processors. In some countries, cooking times and temperatures and salt concentrations are established by regulations to eliminate the risk associated with this organism. In addition, the final product must be held under suitable refrigeration to prevent the growth of microorganisms.

Further Processing

Full use of the fish resource is a difficult challenge for the processing industry. There are many species that, because of economics and demand, are not suitable for traditional processing. In addition, fish frames and other filleting wastes resulting from processing operations represent a significant source of recoverable meat. Mechanical flesh-separating equipment can be used to recover meat economically. Most systems work by forcing edible meat through a perforated surface. In this way, the fish flesh is separated from the skin, bones, and other unwanted fish waste materials. The resulting comminuted material is paste-like and is called fish mince. Ideally, the mince should be as white in color as possible, but mince can be dark if it contains blood, organs, or pigments. Mince has many potential uses. Its primary use may be as an extender in other fish and seafood products. Fish mince may also serve as a base material for the manufacture of analogs and other fabricated seafood and meat products. Surimi is made from mince that has been washed in water to remove many of the solubles, including color, to render a highly functional material. Surimi can be processed and formed into various imitation seafood products, such as shrimp, crabmeat, and lobster meat. The production of these imitation seafood products from surimi is highly technical and requires expertise and sophisticated equipment. The process begins with the addition of certain functional ingredients that will give desired properties to the final product, including water, starches, protein, fats, and other ingredients. In addition, various natural and artificial colors and flavors may be blended with the surimi to mimic the desired seafood product. Ingredients including color and flavors used must be in compliance with food regulations and laws. The resulting product is extruded into the desired shape, cooked, and packaged.

Quality Considerations

Fish and fish products are among the most perishable of all foods. Decomposition and spoilage can begin shortly after harvesting, and can be minimized only with extreme care and diligence on the part of the fisherman and processor. The two primary causes of spoilage in fish are microbiological and enzymatic. Bacteria are the primary microorganisms that affect fish quality but molds and yeasts can also be responsible for spoilage of fishery products. Large numbers of microorganisms are found naturally in the gut and body slime of living fish. When fish die as a result of harvesting or when they are butchered during processing, bacteria are introduced into muscle or organ tissues and cause spoilage and decomposition. Under favorable conditions, bacteria can grow and reproduce extremely rapidly. Unchecked, decomposition is quick. Proper temperature controls and sanitation procedures can provide the maximum shelf-life for most seafood products. Fish may harbor a large variety of bacteria, even some pathogens. However, since fish are generally cooked prior to consumption, most do not pose an immediate health hazard. Processing techniques used to process fish require individual evaluations to determine control methods. Please refer to the previous example of *C. botulinum* and the use of vacuum or MAP packaging.

Processors are concerned not only about the number of microorganisms and controlling their numbers, but also about contamination by specific types of microorganisms. Pathogens, even in small numbers, are capable of causing disease or producing toxins. Naturally occurring proteolytic enzymes cause spoilage, called autolysis, by producing undesirable textural and flavor changes. Like microbial spoilage, the undesirable effects of enzymes are minimized by proper handling and temperature control. However, unlike microbial spoilage, enzyme activity may occur during frozen storage.

Several natural toxins may occur in processed fin fish products. Ciguatera and scombroid (histamine) are, perhaps, the most well known. Ciguatera is most commonly associated with reef fish in tropical zones. Fish flesh is made toxic as a result of fish consuming the benthic dinoflagellate *Gambierdiscus toxicus*. Scombroid poisoning is caused by the ingestion of fish containing a high level of histamine. Histamine is produced in fish flesh by enteric bacteria after harvesting. In most cases, this condition can be traced to improper cold storage of the fish. Scombridae (tuna and mackerel) and Scomberesociadae fish are more commonly associated with scombroid poisoning, although other families have been implicated. Other naturally occurring fish quality considerations include paralytic shellfish poisoning and parasites.

Fish Products

Products resulting from fin fish processing are diverse and complex and yet most of the world production can be summarized within several categories (Table 1). One reason for the complexity is product and species nomenclature. The common name of a fish or fish product in one region may not be the same as in another. In addition, there is the large number of fin fish species. A consistent and meaningful nomenclature system of fish and fish products is necessary for international trade. Although there have been attempts by various organizations and governmental agencies to standardize fish nomenclature, this issue remains a major problem not only in international trade but also within commercial domestic trade. Quality and sanitation are other major considerations for fish products. Microorganism count and species under certain conditions may give an indication of the overall quality of the finished product and under what conditions it was processed. These microbiological requirements and standards, however, may vary considerably among countries and nationalities. In general, most countries involved in international trade will consider aerobic plate count, enteric microorganisms, and pathogens as microbiological indicators of food quality and sanitation. Mandatory government fishery inspection programs are becoming increasingly important. In the USA, the Hazard Analysis Critical Control Point (HACCP) concept is being considered as the basis for a national fishery inspection program. HACCP requires processors to evaluate all processing steps and to identify those steps where hazards could occur if the step is not controlled. Control systems, monitors and records are required to insure that the processing of the fish is in compliance with requirements. (*See* **Hazard Analysis Critical Control Point**.)

Table 1 World fish products, 1996

Product	*Metric tons*
Fish, frozen whole and fillets	16 720 040
Fish, oil	1 395 204
Fish, cured (salted, dried, smoked, spiced, marinated, vinegar- or sugar-cured)	4 490 446
Fish, canned and prepared (packed in containers: fermented, sausages, balls, salads, paste, roes livers)	5 447 264

Miscellaneous Fish Products

T Motohiro, Formerly of Kagoshima University, Kagoshima, Japan

Background

Fish and shellfish have long been consumed by some maritime tribes for their protein source. However, a finding that the highly unsaturated fatty acids in

marine oils have been related to prevention of heart disease is noteworthy in modern Western societies conscious of their health, and the consumption of seafood is increasing significantly. (*See* **Fish Oils**: Dietary Importance; **Shellfish**: Commercially Important Crustacea; Commercially Important Molluscs.)

The majority of fish and shellfish are safe as food, but there are some species that are naturally toxic or poisonous and may cause illness or even death if they are consumed. This article reviews raw-fish dishes of Japan (e.g., *Fugu*), nature and risks from ciguatoxins, caviar and its production, and eels and their uses.

Raw-fish Dishes of Japan

Raw-fish dishes – sliced fish flesh called *sashimi* in Japan – have been served with vinegar for more than 1000 years, but are now more popular eaten with soy sauce and grated Japanese horse radish. Flesh from freshly caught fish is in the majority, but frozen–thawed flesh is often supplied to the dishes. Bluefin tuna (*Thunnus thynnus*), sea bream (*Pagrosomus major*), striped bonito (*Sarda orientalis*), yellowtail (*Seriola quinqueradiata*), and flounder (*Paralichthys olivaceus*) are the species mostly consumable in all seasons, and tiger puffer (*Fugu rubripes*) is considered a prize delicacy in winter. The flesh for the dishes should be of top quality regarding color, flavor, taste, and texture.

Freshly caught bluefin tuna and striped bonito are normally subjected to deep freezing, at a temperature as low as −45 °C, at sea to prevent myoglobin, the dominant pigment in fish muscle, from turning to metmyoglobin, which is a cause of meat discoloration. Thus, the thawed flesh of deep-frozen tuna and bonito is suitable to be served as raw-fish dishes.

More than 100 species of puffer fishes (family Tetrodontidae) are broadly distributed from temperate to tropical waters, but only about 10 species have been consumed as human food by a handful of countries, principally Japan. There are marked differences in toxicity among species, some being virtually nontoxic. Fresh flesh and some parts of the puffer fish may be enjoyed as raw or cooked dishes if properly prepared, but other parts, such as ovary and liver, are extremely toxic (**Table 1**). Only licensees may prepare and serve dishes of the puffer fish for consumers, under conditions specified by the Ministry of Health and Welfare, because the major cause of food-poisoning deaths is ingestion of toxic puffer fishes.

The responsible toxins are tetrodotoxin (TTX) and related compounds (**Figure 1**). The lethal dose of TTX for people is estimated to be 10 000 mouse units, equivalent to 2 mg of TTX. Poisoning as a result of eating puffer fishes is serious, and causes neurological symptoms: tingling in the lips and extremities, paralysis, and death by respiratory arrest and cardiovascular collapse. The cardiovascular effects account for the relatively high lethal rate in puffer-fish intoxications.

Table 1 Toxicity of puffer fishes

Species	*Ovary*	*Testes*	*Liver*	*Skin*	*Intestine*	*Muscle*
Fugu niphobles	A	C	A	B	A	C

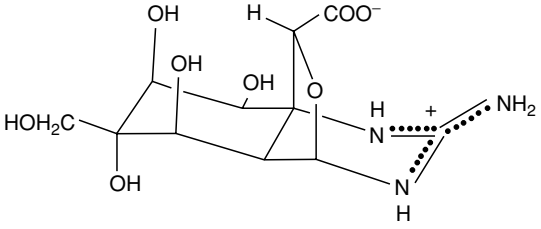
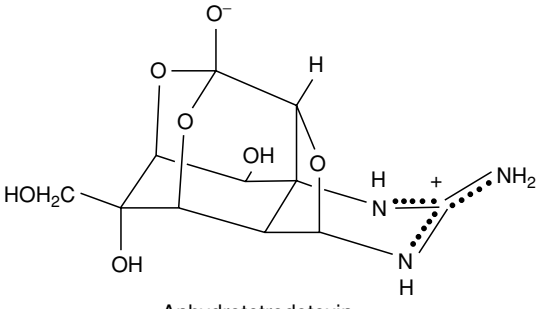
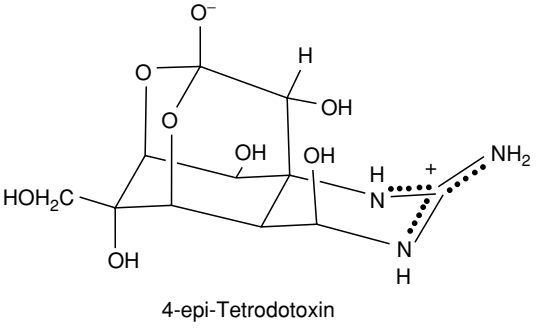
Tetrodotoxin



Tetrodonic acid



Anhydrotetrodotoxin



4-epi-Tetrodotoxin

Figure 1 Structures of tetrodotoxin and related compounds. From Nakamura M and Yasumoto T (1985) Tetrodotoxin derivatives in puffer fish. *Toxicology* 23: 271–276, with permission.

TTX has been demonstrated to be produced by intestinal bacteria of TTX-bearing animals, as well as some species of marine bacteria. This fact, along with the distribution of TTX in nature, made it possible to suggest the mechanism involved in the toxification of TTX-bearers (Figure 2).

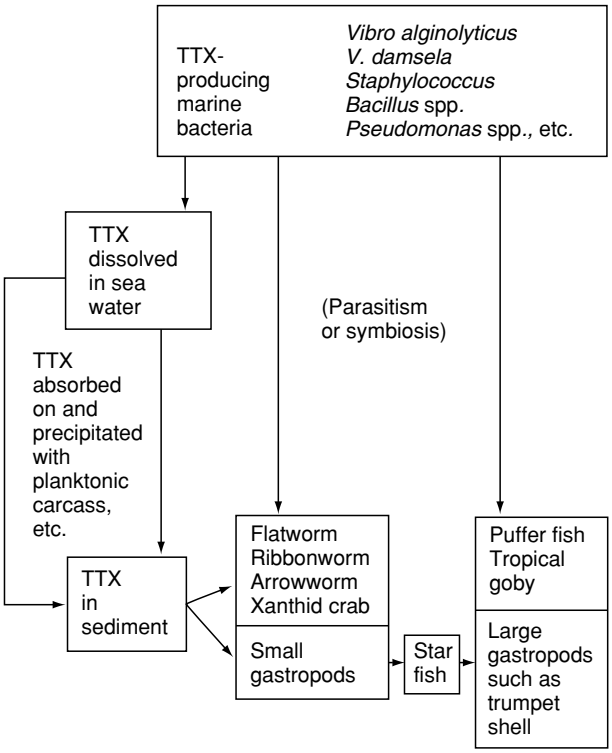


Figure 2 Assumed mechanism of toxification of TTX-bearing animals. From Noguchi T, Arakawa O and Hashimoto K (1989) Tetrodotoxin with special reference to its origin and the mechanisms involved in toxification of puffers. *Journal of the Food Hygiene Society (Japan)* 30: 281–288, with permission.

Nontoxic or slightly toxic puffer fishes have been successfully cultured, and an increase in demand is likely.

Nature and Risks from Ciguatoxins

About 300 species of fish and shellfish, inhabiting shallow waters around coral reefs, have been known to cause ciguatera, a poisoning with unique symptoms. Fish apparently become toxic and lose the toxicity rather more slowly. Although the name ciguatera is derived from the Spanish term for a marine snail, the syndrome is currently recognized as the result of consumption of certain tropical fish. The risk of ciguatera is highest from the consumption of herbivorous reef fish or of the carnivorous fish that feed on them.

It is thought that the principal source of ciguatoxin, the most important toxin, is the benthic dinoflagellate *Gambierdiscus toxicus*, which tends to cluster on the surfaces of certain tropical seaweeds. Because of this growth habit, the benthic dinoflagellate is efficiently accumulated by herbivorous reef fish. Ciguatoxin was isolated from *G. toxicus* obtained directly from

coral reef seaweeds. Cultures of *G. toxicus*, however, have been found to produce primarily a different toxin, maitotoxin, the structure of which is not yet clarified. Other benthic dinoflagellates, with growth habits and distributions similar to those of *G. toxicus*, may also be involved. The known differences between ciguatoxin and brevetoxin lie in the longer duration of the effects of ciguatoxin in human victims. Symptoms are nausea and neurological deficits similar to those of paralytic shellfish poisoning, but more severe and enduring. Victims of ciguatera occasionally complain of relapses, in some cases precipitated by consumption of alcohol, for months or even years after the initial attack. Deaths are rare. The neurological dysfunction includes a reversal of the sensations of hot and cold, called 'dry-ice' sensation. The distribution of ciguateric fish cannot be defined strictly, but distinct zones of toxicity are known by local fishermen. In notorious carnivorous fish, such as barracuda, which are capable of both migrating and accumulating high levels of toxin, it would be difficult to discriminate toxic fish from others.

Although the characterization of ciguatoxin has been a long-standing matter owing to the complexity of the molecule and the difficulty in obtaining adequate material, instrumental analyses with purified material have elucidated the complete structure (Figure 3). Chromatographic evidence indicates that several other related toxins are also involved in ciguatera poisoning.

Caviar and its Production

The eggs of many fish species, and of some other aquatic animals such as sea urchin, are sought as a food item. Caviar is one of the most well-known names, especially in connection with sturgeon (*Acipenser medirostris*) eggs. Caviar and other fish egg products are considered a specialty food and thus tend to bring a high price.

Fish eggs have a substantial food value. On a dry-weight basis, eggs contain 45–48% protein, 11–32% lipid, and 1.3–4.5% ash, respectively. To produce caviar, live mature fish have to be used; from dead sturgeon, it is difficult to remove the eggs as they adhere firmly to the ovary sac. The belly is cut open, from the pectoral fins to the anus. The ovary is then drawn out and processed immediately. The general procedure used in caviar processing begins with washing the ovaries to remove most of the blood and slime. The ovaries are then cut open to extract the eggs. The egg-membrane tissue of the sturgeon is normally hyperplasic and muscular, but it can be softened enzymatically by the action of lysozyme. The eggs are typically salted, using either dry salting or a salt brining. For dry salting, 10% (w/w) of salt is added to the eggs as they are passed through a 33-mm sieve; stirring may ensure faster and more effective penetration of the salt into the eggs. After 3 h of salting, the eggs are drained on a wire net. In the case of salt brining, the eggs are allowed to stand for 1 h in saturated brine, then drained upon a wire net overnight. For further dehydration, the salted eggs are pressed in a cotton bag. The salt-cured eggs are packed in a container, tightly sealed, and stored at 5 °C for aging.

Salted salmon eggs are called red caviar. The quality of red caviar depends on species, maturity, and freshness of the eggs. The eggs should be of spawning

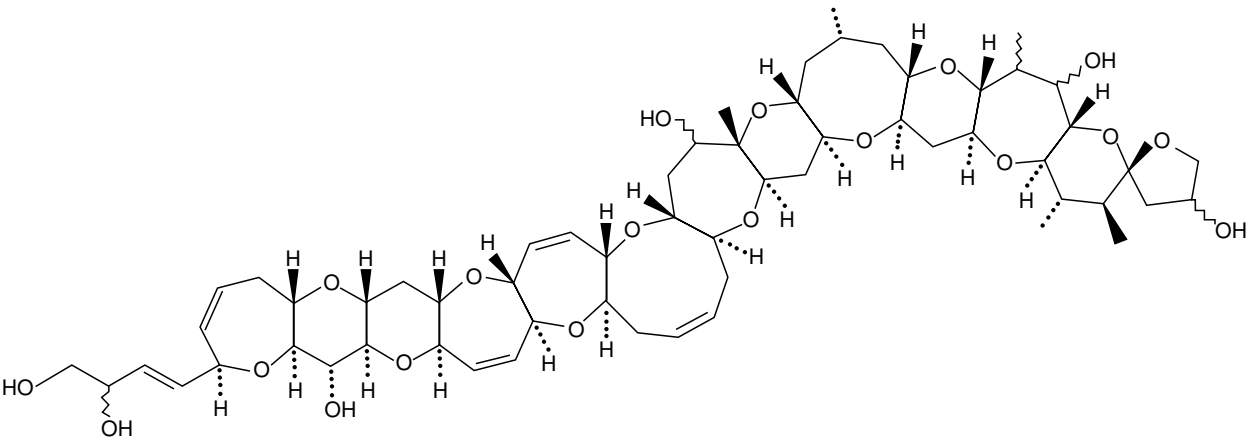

Figure 3 Structure of ciguatoxin. From Murata M, Legrand AM, Ishibashi Y and Yasumoto T (1989) Structure of ciguatoxin and its congener. *Journal of the American Chemistry Society* 111: 8929–8931, with permission.

salmon caught from coastal waters and be extracted within 2 h of catching. Egg-membrane tissue in a mature ovary is naturally hyperplasic and muscular, and results in a low-quality product. It is also inadequate if eggs are used from the salmon late in the fishing season, or immediately before spawning. A high-quality red caviar is attributed to the use of eggs of pink salmon (*Oncorhynchus masou*).

Once separated from the raw salmon, the ovaries are washed thoroughly in fresh water to remove blood vessels and slime, then rubbed through a gauze cotton net to isolate the eggs. An apparatus consisting of gauze cotton net, a sloping wire net, and a receiver is useful for commercial purposes. The eggs that have been separated through the gauze cotton net run down the slope and fall into the receiver. The mass accumulated in the receiver is put into a tub containing saturated salt brine (which has been boiled and cooled prior to use), stirred for 20 min, removed and put into a basket, drained for 24 h, packed in a barrel or a wooden box, and cold-stored for aging.

The oil content of salmon eggs averages 12% on the basis of total weight. Salmon eggs yield a light-colored oil. The oil contains about 45% of highly unsaturated fatty acids with molecules having 20–22 carbon atoms. About one-third of the total fat is phospholipid, probably lecithin. The protein of salmon eggs is of a high quality. It contains all of the eight essential amino acids (isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine) in substantial amounts. Salmon egg protein is relatively high in lysine, methionine, and isoleucine. (*See* **Amino Acids**: Metabolism.)

Eels and their Uses

Eels are difficult to sell in the USA but are highly prized in Europe and several areas of the Far East, including Japan. The major species of food eels are freshwater eels (Anguillidae), pike eels (Muraensocidae) and conger eels (Congridae). Of the 16 species of *Anguilla* eels found worldwide, most are in the waters around Southeast Asia. *Anguilla japonica* and *A. marmorata* are the inhabitants in the waters around Japan, while *A. rostrata* and *A. anguilla* are in the Atlantic. For food eels, the important species are *A. japonica* and *A. anguilla*. *Muraenesox cinereus* is the commercially valuable species of pike eel. Conger eels number about 110 species in the world, but white-spotted conger (*Conger myriaster*) is the only species prized as food. Eels are mostly processed to produce 'spitchcock' with seasoning juice. Eels weighing roughly 200 g are put into a basket and subjected to cut-feed for a couple of days in running water. In producing 'spitchcock,' back-cutting, meat separating, and sizing are the initial processes, performed manually. The spiting and broiling processes are carried out mostly by machines.

In the broiling process, an infrared ray burner is commonly used. The broiling time depends on the flame temperature and the size of the slices of flesh, but generally, 4–5 min is long enough for the first broiling without seasoning juice, then 5–10 min for the second broiling with the juice. A seasoning juice is brushed over the flesh surface during an automated run from the first to the second broiling processes. The broiling process greatly affects the food quality: either insufficient or excessive broiling gives a bitter or burnt flavor to the product. The seasoning juice consists of soy sauce, sugar, and sweet liquor, in a ratio of 1:1:0.5.

Smoked eel is another type, traditionally popular in Europe, and is widely consumed. Preliminaries for processing smoked eels are almost similar to those for 'spitchcock.' The fresh fillets are cured in 5–10% salt brine for about 10 h; salt concentration and curing time are controlled according to the size of the fillet. The cured fillets are then subjected to trimming, washing, draining, and drying. Smoke drying is important in processing smoked eel and is performed at a controlled temperature within 60–80 °C for 5–6 h, using hardwood or sawdust. A gradual increase in temperature, using adequate amounts of sawdust, is required to prevent the flesh from scorching. The half-finished product is taken out from the smoking kiln, any soot is swept off, and the fillets are arranged in a carton box to equalize the water contents.

The 'spitchcock' eels are the traditional food of Japanese people during the hottest period of the summer. They contain (per 100 g of eel) 47.1 g of water, 23.0 g of protein, 24.4 g of lipid, 3.1 g of non-fibrous carbohydrate, 2.4 g of ash, 150 mg of calcium, 300 mg of phosphorus, 0.8 mg of iron, 510 mg of sodium, 300 mg of potassium, 150 μg of retinol, 5000 IU of retinol potency, 0.75 mg of thiamin, 0.74 mg of riboflavin, and 4.1 mg of niacin. Refer to individual nutrients.

Pike eel is a white-flesh fish, which is rich in fat and taste, and consumable as 'spitchcock,' soup, or 'vinegared' products, or, after processing, to *surimi* (ground meat), as the base for a high-quality fish-gel product. However, a number of tiny bones remaining in the flesh are disadvantageous in processing any type of marine food.

Spoilage of Seafood

P Dalgaard, Technical University of Denmark, Lyngby, Denmark

Background

The world's annual production in capture fisheries has remained at ~ 90 million tonnes during the last decade, and only aquaculture production in marine and fresh water has allowed for global increases in raw material for fishery products. At the same time, international trade in seafood is increasing, and optimal utilization of available resources and prevention of losses during storage and distribution are more important than ever. Most seafoods have a short and variable shelf-life, and the increasing interest in marketing of less preserved products makes prevention of spoilage an important challenge.

The flesh of most fresh fishes has a high pH of 6–7 *post rigor* and a high content of free amino acids in the muscle extractives. Many marine and some freshwater species contain trimethylamine oxide (TMAO), resulting in a high muscle redox potential, and some species contain high levels of polyunsaturated fatty acids. Furthermore, fish and shellfish often harbor a natural psychrotolerant microflora. These specific properties result in microbial activity and lipid oxidation being responsible for spoilage of most fresh and lightly preserved products. This explains the short shelf-life of these products (**Table 1**). Postharvest losses of food have been estimated to be as high as ~ 25% resulting from microbial activity alone, and this problem is particularly relevant for seafood. To reduce losses resulting from spoilage and to insure that products are safe at the time of consumption, knowledge about product shelf-life under different storage conditions is important. Storage temperature, packaging, hygienic standard of raw material, and gutting are the most important factors influencing the shelf-life of seafoods (**Table 1**).

When new seafoods are developed, or existing products are modified or stored under new conditions, shelf-life must be determined by sensory methods. However, product attributes, to be measured by instrumental methods, are useful when industry and national or international authorities need to evaluate raw material or products. Development of such instrumental methods and techniques to predict shelf-life can rely on information about reactions responsible for product spoilage. The present article concerns these microbial, chemical, and biochemical spoilage reactions and methods to determine and predict shelf-life of seafood. In addition, safety hazards related to seafood consumption are presented.

Sensory Changes and Shelf-life

Sensory properties of seafood, as determined by the senses of sight, smell, taste, and touch change during storage, and a series of phases can be identified in most products. Fresh fishes typically have a species-specific taste and odor that disappear after a few days of chilled storage. Later, off-odors and off-tastes, i.e., off-flavors, which are often ammonia-like, fishy, sour, sulfurous, or yeasty become notable, increasing in intensity and finally resulting in overt spoilage. Sensory methods relying on panels of trained assessors are used to determine the shelf-lives of products based on the degree of sensory changes.

Sensory methods frequently used with seafoods include the Torry scheme, various simplifications of this method, EU schemes for freshness grading, and the quality index method (QIM). The Torry scheme, developed in Scotland in 1948 for fresh fishes, relies on the assessment of raw appearance, raw odor, raw texture, cooked odor, cooked texture, and cooked flavor of samples. Each quality attribute is scaled by five or 10 descriptive terms. Numerous less extensive sensory schemes have been used to determine the shelf-life from the appearance, odor, taste, and texture of raw or cooked products. Often, sensory changes are expressed as a simple overall grading (I, II, or III) and shelf-life determined as the time when the percentage of samples in grade III reaches a defined level. The EU requires numerous fish and shell-fish to be graded by specific EU schemes if marketed within the community. Assessments of appearance, odor of skin, outer slime, eyes, gills, and peritoneum are carried out with whole or gutted fish. Assessments are typically carried out in auctions by trained personnel, and fish are placed into grades Extra (E), A, B or Unfit (C), based on schemes for

Table 1 Shelf-life of selected seafoods

Product	*Storage temperature (°C)*	*Packaging*	*Shelf-life (days)*
Fresh seafood			
White-fleshed from temperate/cold waters	0	Air or VP	12–18

MAP, modified-atmosphere-packaging; VP, vacuum-packaging.
Modified from Dalgaard P (2000) Fresh and lightly preserved seafood. In: Man CMD and Jones AA (eds) *Shelf Life Evaluation of Foods*, 2nd edn. pp. 110–139. Gaithersburg, MD: Aspen.

different groups of species. These freshness categories do not allow the remaining product shelf-life to be determined directly, and the demerit point or QIM can be used to obtain this information. The QIM relies on sequential evaluation of a relatively large number of fish attributes. Demerit or QIM points of a sample, i.e., the sum of the attribute scores, increase linearly with product storage time, and rates of spoilage at a constant storage condition can be calculated easily. QIM schemes allow the remaining shelf-life of whole or gutted fish of several species to be determined. Evaluation of fish fillets remains difficult, and further studies are needed to validate QIM for determination and prediction of the shelf-life of fresh fish above 0–5 °C, i.e., when products are temperature-abused.

Microbiological, Chemical, and Biochemical Changes

Sensory methods are always needed to determine the shelf-life of new or modified seafoods. Unfortunately, sensory methods relying on a panel of assessors are expensive to use and difficult to calibrate. Therefore, it is desirable to supplement or replace sensory evaluations by instrumental analyses. Instrumental methods are important, e.g., to determine whether the characteristics of seafoods comply with specifications as part of purchase agreements or with standards and guidelines established by national or international authorities.

Microbial activity is responsible for spoilage of most lean fresh and lightly preserved seafood. Chemical reactions, primarily oxidation and activity of autolytic enzymes, become important spoilage reactions when microbial activity is reduced by processing or preservation (Table 2). It is noteworthy that the range of product characteristics and storage conditions within which a particular spoilage reaction actually limits product shelf-life remain poorly described for practically all seafoods.

Microbiological Changes

Fish and shellfish are poikilotherms, i.e., their body temperature is similar to that of their surroundings,

Table 2 Seafood spoilage indicators

Spoilage indicator	*Sensory property*	*Spoilage reaction*	*Examples of products where compounds are formed*
Trimethylamine (TMA)	Ammonia-like	Microbial	Most marine fishes and in some fresh water fishes like Nile perch and tilapia that contain TMAO
Ammonia	Ammonia	Microbial and enzymatic	Particularly in cephalopods, crustaceans, and dark-fleshed fishes
Histamine	Pepper-like[a]	Microbial	Tuna, mackerel, mahi-mahi, herring, anchovies and other seafoods with a high level of free histidine, particularly when stored $>5\,^{\circ}C$
Cadaverine, putrescine, and tyramine	Putrid, rotten[a]	Microbial	Most fresh and lightly preserved seafoods
Volatile sulfur compounds	Sulphurous, rotten	Microbial	Aerobically stored fresh fish, temperature-abused fresh and lightly preserved products, but also sporadically in sous vide cooked and chilled fish where very high levels can be observed
Short-chain alcohols and carbonyls (ethanol, propanol, butanol, 2-methylbutanal, 3-methylbutanal, 2,3-butadione)	Solvent-like, malty	Microbial	Most fresh and lightly preserved seafood
Hypoxanthine (Hx)	Bitter taste	Enzymatic and microbial	All fishes, but rates of Hx formation vary markedly between species owing to differences in activity of the autolytic enzymes that generate the substrate precursor inosine. As examples, Hx formation is very rapid in redfish, modest in cod, slow in mackerel, and very slow in swordfish
Dimethylamine (DMA)	Ammonia-like	Enzymatic	TMAO containing seafood and particularly in hake when stored frozen at $>-20\,^{\circ}C$
Free fatty acids (C_{16}–C_{22})	Rancid, oily, bitter and metallic	Enzymatic	Fatty fishes stored at conditions of temperature abuse as well as in both lean and fatty fishes during frozen storage at inappropriately high frozen storage temperatures
Propanal	Solvent-like	Chemical	From oxidation of *n*-3 fatty acids
Pentane, hexanal		Chemical	From oxidation of linoleic acid and useful at indicator for this type of oxidation
Cis-4-Heptanal	Cardboardy, paint-like	Chemical	During frozen storage of cod
2,4-Heptadienal, 2,4,7-Decatrienal	Stale, whale oil flavor	Chemical	Fatty fishes and fish oil containing products

[a]As a result of high flavor detection thresholds, biogenic amines contribute to the spoilage of seafood only when present in extremely high concentrations.

and the often complex microflora on their outer surfaces to some extent reflect the microbiology of the water in which they live. However, only some of the numerous species of microorganisms on live fishes are important in seafood spoilage. In fact, a pattern of microbial growth and activity during storage of seafood is frequently observed; the so-called specific spoilage organism (SSO) concept (Figure 1). On newly processed, fresh, or lightly preserved seafood, the SSOs are usually present in very low concentrations and constitute only a minor part of the total microflora. During storage under particular conditions of temperature, atmospheres, NaCl, available water, preservatives, etc., SSOs, which are often a single microbiological species, grow faster than the remaining microflora, produce metabolites responsible for off-flavors, and finally cause sensory rejection of a product (Figure 1). SSO are typically present at levels of about 10^7 colony-forming units (cfu) g^{-1} when products become sensorily spoiled. In contrast to SSOs, the spoilage microflora, i.e., the microflora found at the time of sensory product rejection, are frequently a mixture of microbial species, some of which can be unimportant in terms of spoilage. The substantial importance of microbial activity in seafood spoilage has been established by comparing off-flavor development in sterile and naturally contaminated blocks of fish muscle. Identification of a SSO relies on a comparison of product spoilage characteristics with those of isolates from the spoilage microflora. Spoilage potential and spoilage activity are evaluated as the qualitative and quantitative ability, respectively, of isolates to produce off-odors and spoilage metabolites. The yield factor for production of a metabolite by a microorganism is a measure of the amount of metabolite produced per cell. Yield factors are most useful to determine whether the levels of cells and metabolites in a seafood correspond to the spoilage activity of an isolate from the spoilage microflora, i.e., if the isolate is likely to be the SSO. Evaluation of proteolytic activity need not be included in SSO identification, because microorganisms metabolize seafood extracts, primarily free amino acids and TMAO, and causes sensory product spoilage before protein degradation is detected.

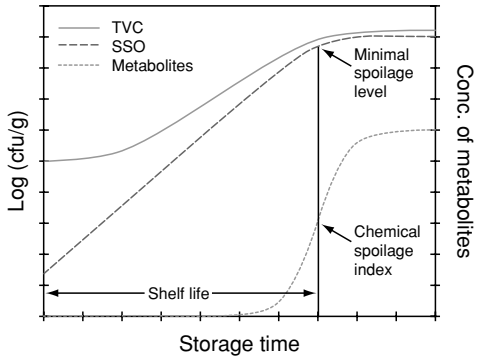

Figure 1 Specific spoilage organism (SSO) concept. Typical changes in total viable counts (TVC), SSO, and metabolites produced by SSO during storage of fresh seafood. Modified from Dalgaard P (2000) Fresh and lightly preserved seafood. In: Man CMD and Jones AA (eds) *Shelf Life Evaluation of Foods*, 2nd edn, pp. 110–139. Gaithersburg, MD: Aspen with permission.

As shown in Figure 1, the level of SSO and their metabolites can be used as indices of product spoilage. Furthermore, product shelf-life can be predicted from the initial level and from the growth rate of an SSO. Finally, it follows from the SSO concept that targeted inhibition of a SSO can be used in the development of new products that have an extended shelf-life.

The SSOs of a number of seafoods have been identified and habitats of the live fishes, product characteristics, and storage conditions clearly determined the microorganisms responsible for product spoilage (Table 3). The specific parameters that allow certain microbial species to become dominant in the spoilage microflora can be determined by studying SSOs in pure cultures. As an example, *Shewaenella putrefaciens*-like bacteria grow vigorously at the pH of most fresh seafoods but are substantially inhibited at pH values below 6. This explains why *Pseudomonas* spp. are more important SSOs in aerobically stored fresh seafoods with a pH of ~ 6 or below. *S. putrefaciens*-like organisms, *P. phosphoreum*, *Aeromonas* spp., species of Enterobacteriaceae and *Vibrio* spp. reduce TMAO to trimethylamine (TMA) in anaerobic respiration. This facilitates their growth in vacuum or modified-atmosphere-packed seafoods and explains the development of TMA in different fresh and lightly preserved packed products. Spoilage of these products, however, can also be caused by lactic acid bacteria, although these are unable to reduce TMAO to TMA. Gram-positive microorganisms are generally more resistant to heat, frozen storage, salt, low water activity, low pH, high carbon dioxide levels, and irradiation than Gram-negative microorganisms. However, existing data for the quantitative effect of environmental parameters on growth kinetics of microorganisms are insufficient to predict precisely the microbial species that become the SSO in a seafood, where combinations of product characteristics or storage conditions have not previously been evaluated in storage trials with naturally contaminated products.

Shewanella putrefaciens-like organisms are primarily important in spoilage of aerobically stored fresh fish (Table 3) but they also may contribute to spoilage

Table 3 Specific spoilage organisms in seafood

Seafoods	*Typical specific spoilage organism*
Fresh and chilled, stored in air	*Shewanella* putrefaciens-like [a,b]
	Pseudomonas spp.[c]
Fresh, chilled and stored in vacuum or modified-atmosphere packaging	*Photobacterium phosphoreum*[b]
	Lactic acid bacteria[c]
	Brochothrix thermosphacta[c]
Fresh and lightly preserved products stored at ambient temperature	*Aeromonas* spp.
	Vibrio spp.
	Enterobacteriaceae
	Enterococcus faecalis
Sous-vide cooked and chill stored	Gram-positive spore formers
Lightly preserved[d] and chill-stored	Lactic acid bacteria[e]
	Enterobacteriaceae[f]
	P.phosphoreum and other marine *Vibrio* spp.
Semipreserved, salt cured and chilled	*Halobacterium* spp., *Halococcus* spp. and osmotolerant molds and yeasts
Fermented and chilled	Molds and lactic acid bacteria

[a]Refer to *Shewanella putrefaciens, Shewanella baltica*, and other closely related H_2S-producing, Gram-negative bacteria.
[b]Typical of fishes from marine and temperate waters.
[c]Typical of fishes from freshwater and fishes from warmer waters.
[d]Include, for example, cold-smoked salmon, cooked and brined shrimps and brined roe products.
[e]Include, for example, *Lactobacillus curvatus* and *Lactobacillus sake*.

of vacuum-packed seafoods if present in high levels when products are packed. *P. phosphoreum* is primarily important in spoilage of packed seafood (Table 3), but it produces TMA in some aerobically stored fresh fish, and it remains unclear as to what extent this contributes to spoilage of the aerobically stored products. High levels of *Aeromonas* spp., with a substantial spoilage potential, have been detected in both chilled and temperature abused freshwater fish stored aerobically or under modified atmosphere packaging. The importance of these organisms in spoilage needs further study, as do the taxonomy and metabolism of the *Vibrio* spp. and species of Enterobacteriaceae occurring in temperature-abused seafoods (Table 3). *Psychrobacter immobilis* is frequently observed in high concentrations in seafood but is not included as a SSO in Table 3, because of a very limited spoilage potential. Recent studies suggest that lipolytic activity of these organisms contributes to the spoilage of fresh sardines, and this deserves further investigation. Finally, it should be stressed that, for numerous seafoods, the SSOs and their spoilage domain, i.e., the range of product characteristics and storage conditions within which a particular SSO causes spoilage, remain to be identified. This is particularly the case for lightly preserved products processed by various emerging preservation technologies and products containing seafood together with other ingredients.

Chemical and Biochemical Changes

Chemical, biochemical, and other changes in seafood are frequently studied with the objective of identifying indices of freshness or spoilage to be measured by instrumental methods in relation to processing or distribution. Single compound quality indices (SCQI) have been studied to find an individual substance for which the concentration increased during storage to a critical level corresponding to sensory product rejection. Owing to the complex and dynamic nature of seafood spoilage, SCQI often have a limited range of applicability with respect to product characteristics and storage conditions. Consequently, sums or ratios of concentrations of several compounds have been used as indices of freshness or spoilage. More recently, multiple compound quality indices (MCQI) have been developed using multivariate statistical methods to select a combination of instrumentally measured responses that correlate with changes in sensory attributes or remaining shelf-lives of products.

Total volatile nitrogen (TVN) and TMA are important indices of spoilage in fresh and lightly preserved seafood. TVN primarily includes ammonia, TMA, and DMA. The European Commission (Council Regulation No. 95/149/EEC) specified that TVN should be used as an index of spoilage when sensory evaluation casts doubt on fish freshness. Critical limits of 25–35 mg-N of TVN per 100 g have been indicated for different fish species. In TMAO-containing seafood, 10–40 mg-N of TMA per 100 g are typically present at the time of sensory spoilage. Nevertheless, *Pseudomonas* spp. can spoil, e.g., fresh Nile Perch without transforming its content of TMAO into TMA. Off-flavors caused by volatile amines depend on pH and possibly other product characteristics. Sugar-salted herring with a pH of <6, for example, may contain as much as ~ 75 mg-N of

TVN per 100 g and ~ 35 mg-N of TMA per 100 g without appearing sensorially spoiled. Even in TMAO-containing seafood, little TMA is produced until the SSO reaches high numbers and TMA can only be used as an index of spoilage and not as an index of freshness (Figure 1). Gadoid fishes and maybe some other species contain the enzyme TMAOase (EC 4.1.2.32) in their muscle tissue. The enzyme transforms TMAO into DMA and formaldehyde. The later causes protein denaturation and textural changes in fish muscle tissue, and the DMA content correlates with the sensory texture ratings of thawed hake. TMAOase is most active at -5 to $-10\,^{\circ}C$, but in hake, substantial amounts of DMA can be formed during frozen storage above $-20\,^{\circ}C$. In contrast with white-fleshed fish, considerable amounts of ammonia can develop in cephalopods, crustaceans, and dark-fleshed fish like herring, owing to their high content of free amino acids. Clearly, the usefulness of TVN, TMA, and DMA as indices of spoilage depends strongly on the fish species and storage conditions.

In chilled fresh and lightly preserved seafood, adenosine triphosphate (ATP) is degraded sequentially into adenosine diphosphate (ADP), adenosine monophosphate (AMP), inosine monophosphate (IMP), inosine (Ino), and hypoxanthine (Hx). IMP is formed by autolytic enzymes, whereas spoilage bacteria contribute to Ino and particularly Hx formation. The K-value $= ([Ino] + [Hx]) \times 100/([ATP] + [ADP] + [AMP] + [IMP] + [Ino] + [Hx])$ and the quantitatively similar K_i-value $= ([Ino] + [Hx]) \times 100/([IMP] + [Ino] + [Hx])$ and G-value $= ([Ino] + [Hx]) \times 100/([AMP] + [IMP] + [Ino])$ are used as measures of fish freshness. In Japan, the critical K-value limit for fish to be consumed raw is 20. These values increase linearly during the first days of chilled storage of most fishes and therefore can be used as indices of freshness. However, in some fish species, e.g., redfish, the K-value reaches maximal levels well before sensory rejection and cannot be used as a general index of spoilage (Table 2).

Production of biogenic amines in seafood varies strongly owing to large variations in the free amino acid precursors between fish species and the variability in the ability of spoilage bacteria to produce agmatine, cadaverine, histamine, putrescine, spermidine, spermine, tyramine, and tryptamine. Consequently, individual biogenic amines are rarely appropriate as SCQI. However, different ratios or sums of concentrations of biogenic amines as well as dedicated MCQI have been suggested and critical limits corresponding to the end of shelf-life determined, e.g., for fresh salmon, herring, lobster tails, mahi-mahi, plaice, rockfish, shrimps, tuna, whiting, and cold-smoked salmon. Biogenic amines are heat-stable and therefore, together with organic acids, appropriate for evaluation of raw material used in canned products. The effect of temperature, NaCl, pH, and atmosphere on microbial formation of biogenic amines in seafood needs further study.

The activity of spoilage microorganisms frequently results in the formation of volatile sulfur compounds, short-chain organic acids, aldehydes, ketones, and alcohols, and some of these metabolites are clear indices of spoilage owing to their very unpleasant odors. However, critical concentrations corresponding to the end of shelf-life remain to be determined and validated.

Degradation of lipids by enzymatic hydrolysis or chemical oxidation can result in rancid off-flavors in seafood. In chilled but particularly in temperature-abused fresh fatty fish, enzymes from tissue, intestinal content, and possibly microorganisms hydrolyze triacylglycerol into free fatty acids, causing the so-called acid rancidity. Free fatty acids are also formed by enzymatic hydrolysis during frozen storage of both lean and fatty fishes. With salmon, frozen storage of raw and cooked samples confirmed enzymatic hydrolysis as being responsible for the formation of free polyunsaturated fatty acid. Aroma-recombination studies with fresh fish showed these acids to cause the same oily, bitter, and metallic taste as observed after frozen storage of salmon. Lipid oxidation limits the shelf-life of several frozen and dried seafoods as well as of fish oil-containing products. The peroxide value (PV) and the thiobarbituric acid reactive substance (TBARS) value are classic measures of primary and secondary oxidation products, respectively. Primary oxidation products have no off-flavor and may be both formed and degraded during storage of seafoods. However, seafoods with PV of 10–20 meq of peroxide per kilogram of lipid and TBARS values of 1–2 μmol of malonaldehyde equivalents per gram of product fat often have rancid off-flavors.

It is laborious to identify microbial metabolites, oxidation products, or other compounds to be used as indices of spoilage. Chromatographic (gas chromatography and high-performance liquid chromatography) and spectroscopic techniques including near infrared and nuclear magnetic resonance can be used to determine various changes in seafoods during storage. Chromatographic and spectroscopic techniques provide large amounts of data, and in order to extract compounds or responses that correlate with sensory changes, multivariate statistical methods, particularly partial least-squares regression, can be applied. Identified combinations of compounds or responses can be used as MCQI, and the approach may facilitate development of methods for rapid detection of

relevant compounds, e.g., by using electronic noises or visual indicators. Future studies are likely to identify various MCQI for determination of spoilage cause by microbial activity, autolytic changes, or chemical reaction in seafood.

Prediction of Shelf-life

Transportation of seafood and fish raw material is increasing globally, and this has resulted in needs for methods to evaluate and predict effects of conditions of storage and distribution on shelf-life. Quality attributes can be measured in newly processed products, but unless changes in these attributes can be predicted as a function of storage conditions, measurements at the time of processing will be of little value to evaluate products as experienced by consumers/buyers. Empirical models for relative rates of spoilage, kinetic models for growth of SSO, and relations between indices of spoilage and remaining product shelf-life or time of storage have been suggested for shelf-life prediction.

Empirical Relative Rates of Spoilage Models

Temperature is the single most important factor influencing the shelf-life of fresh and lightly preserved seafood. Despite the complex and dynamic nature of seafood spoilage, it has been possible to predict the effect of temperature on the shelf-life of various seafoods. The predictions rely on relative rates of spoilage (RRS), i.e., the keeping time at a reference temperature like 0 °C divided by the keeping time at T(°C). The effect of temperature on RRS is similar for various species of fresh fish, but at the same time, RRS may differ substantially between fresh and lightly preserved products. As shown in Figure 2, the apparent activation energy (E_A), for the effect of temperature on shelf-life, can be only $\sim 20\,\text{kJ mol}^{-1}$ ($\sim 5\,\text{kcal mol}^{-1}$) for hot smoked fish and $>100\,\text{kJ mol}^{-1}$ ($>24\,\text{kcal mol}^{-1}$) for cooked and brined shrimps stored in modified-atmosphere packaging. Average RRS values of different fresh seafoods from cold and temperate waters, including superchilled and modified-atmosphere-packed products can be predicted between -3 and $+15$ °C by using eqn. 1, named the square-root spoilage model. For other seafoods, the Arrhenius model, which includes the parameter E_A to describe the apparent activation energy, or a simple exponential model, including the slope parameter, b (eqn. 2), is more appropriate for the effect of temperature on RRS (Figure 2). RRS models allow shelf-life to be predicted at different storage temperatures if only the shelf-life of a product has been determined at a single known temperature (T_{ref}) (see eqn. 2).

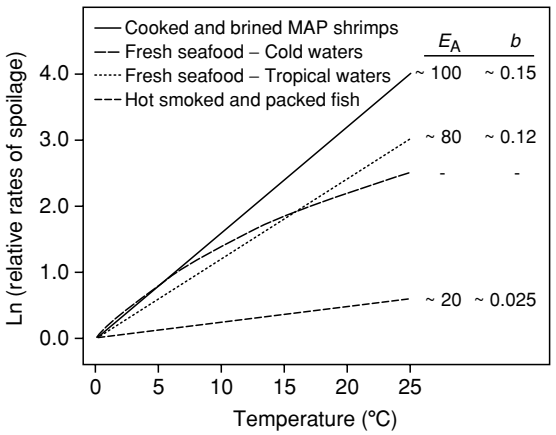

Figure 2 Relative rates of spoilage and corresponding temperature characteristics. Apparent activation energy determined by the Arrhenius equation (E_A) and slope parameter in exponential spoilage model (b). The square root model appropriate for fresh seafood from cold waters is shown in eqn (1). Modified from Dalgaard P (2000) Fresh and lightly preserved seafood. In: Man CMD and Jones AA (eds.) *Shelf Life Evaluation of Foods*, 2nd edn, pp. 110–139. Gaithersburg, MD: Aspen with permission.

$$\sqrt{\text{RRS}} = \sqrt{\frac{\text{shelf-life at } 0°C}{\text{shelf-life at } T\ °C}} = 1 + 0.1 \times T(°\text{C}) \quad (1)$$

$$\text{shelf-life at } T(°\text{C}) = \frac{\text{shelf-life at } T_{ref}(°\text{C})}{\exp\left[b \times (T - T_{ref})\right]} \quad (2)$$

Kinetic Models for Growth of SSO

Mathematical models are available to predict the effect of temperature, atmosphere, water activity, and other factors on the growth of some SSO from seafood as well as on the growth of several pathogenic microorganisms. Nevertheless, only some models have been validated and confirmed to predict shelf-life and growth of pathogenic microorganisms in seafood accurately, *i.e.*, within $\pm 25\%$.

Growth of SSO in aerobically stored seafood is often exponential until the end of the shelf-life is reached (Figure 1) or includes only a very short lag phase. This has allowed the shelf-life of different aerobically stored fishes to be predicted from growth of the SSO, *i.e.*, *Shewanella putrefaciens* and psychrotolerant *Pseudomonas* spp. The square-root model (eqn. 3) is typically used to predict the effect of temperature on maximum specific growth rates (μ_{max}) of spoilage and pathogenic microorganisms in seafood.

$$\sqrt{\mu_{max}} = \alpha(T - T_{min}). \quad (3)$$

More extensive models, including the effect of temperature and carbon dioxide concentrations, are available to predict the growth of *P. phosphoreum*

Table 4 Seafood associated hazards and their prevention

Hazard	*Safety concern*	*Preventive measures*
Histamine	Microbial production of above *c*. 500 p.p.m. in products	Reduce microbial growth and activity by storage of fresh seafood at $< 2\,^{\circ}C$ and lightly preserved products at $< 5\,^{\circ}C$
Biotoxins	Consumption of warm-water fishes with tetrodo- or ciguatoxin or filter feeding shellfish with toxins produced by marine algae	Monitoring and management of fishing areas. Biotoxins persist cooking and preservation of seafood
Viruses	Viral gastoenteritis due to consumption of raw or steamed molluscan shellfish and ready-to-eat seafoods	Monitoring of harvesting areas, depuration of molluscs, cooking seafood prior to consumption
Pathogenic bacteria indigenous in aquatic environment		
Clostridium botulinum, psychrotolerant	Growth and toxin formation in ready-to-eat (hot-smoked and fermented) products from colder regions	Salting ($> 3.5\%$ NaCl) and chilled storage ($< 5\,^{\circ}C$) prevent growth and toxin production in seafood
Vibrio parahaemolyticus, V. vulnificus, V. cholerae, V. algionlyticus and *Plesiomonas shigelloides*	Growth to high levels in raw marine seafoods from warmer waters and in cross-contaminated ready-to-eat products	Avoid consumption of improperly cooked seafood, particularly molluscan shellfish
Pathogenic bacteria from the animal/human reservoir and general environment		
Salmonnella spp. and *Shigella* spp.	Contamination by even low levels	Avoid direct or indirect faecal contamination of products. Bacteria is inactivated by cooking
Clostridium botulinum proteolytic type A and B	Growth and toxin formation in products	Inactivate bacteria and their spores by canning (> 2.4 min at $121\,^{\circ}C$) or prevent growth by chilling ($< 10\,^{\circ}C$), acidification (pH < 4.5) or curing ($> 10\%$ NaCl).
Listeria monocytogenes	Growth in ready-to-eat seafoods	Reduce growth by low storage temperature. Bacteria are inactivated by cooking
Staphylococcus aureus	Growth and toxin formation in products	Prevent growth by chilled storage of products
Campylobacter spp.	Contaminated molluscan shellfish. Bacteria die in seawater	Avoid consumption of raw molluscan shellfish
Parasites	Intake of live nematodes, or trematodes in raw and ready-to-eat seafood	Removal of infected fish or inactivation of parasites by heating ($55\,^{\circ}C$, 1 min), freezing ($-20\,^{\circ}C$, 24 h) or curing

and *B. thermosphacta* as well as the shelf-life of fresh modified-atmosphere-packed seafoods. Kinetic models predict shelf-life from the initial level of SSOs in products, and further studies are needed to determine typical distributions of spoilage organisms in seafoods.

Time–Temperature Integration

Mathematical shelf-life models can be used to evaluate product temperature profiles as recorded during distribution of seafoods. Software that includes both RRS models and kinetic models for growth of SSO is available to predict product shelf-life under constant and fluctuating storage conditions. The seafood spoilage predictor (SSP) (available from http://www.dfu.min.dk/micro/ssp/) is an example of a widely used program. Time–temperature integration (TTI) tags that change color in response to a temperature history are another type of device to evaluate product shelf-life. Storage temperature influences the shelf-life of different fresh and lightly preserved seafoods very differently (Figure 2), and selection of TTI tags with appropriate temperature kinetics is of utmost importance for successful application of this technology. TTI tags with apparent activation energies that correspond to those of most seafoods are available. However, for semi- and lightly preserved seafoods with an extended shelf-life (Table 1), existing tags relying on enzymatic, polymerization, or diffusion reactions may not always be available with appropriate response times.

Spoilage and Safety of Seafood

Growth of spoilage microorganisms in seafood reduces the risk of pathogenic microorganisms reaching high levels before products are spoiled and therefore will not be consumed. Spoilage microorganisms and reactions can be inhibited by classical processing and preservation techniques, *e.g.*, salting, drying, smoking, canning, and freezing (see appropriate articles in the present chapter). In addition, hurdle technology, minimal processing, and targeted inhibition of SSO can be used as mild preservation procedures to extend the shelf-life of seafood. Clearly, inhibition of spoilage reactions should be linked with a carefully evaluated product safety.

The major hazards responsible for seafoodborne diseases are histamine, biotoxins, viruses, bacteria and parasites (Table 4). Seafood is estimated to cause up to 10% of all outbreaks and approximately 3% of all cases of foodborne disease. The safety of seafood products varies considerable and is influenced by a number of factors, including the origin of the fish or shellfish (marine or freshwater; cold or tropical regions; clean or polluted waters), microbiological ecology of the product, handling and processing practices, and preparation before consumption (Table 4).

Histamine fish poisoning is the single most frequent seafoodborne disease ($\sim 30\%$ of all cases). Fortunately, symptoms including facial flushing, vomiting, diarrhea, and headache are relatively mild and of short duration. Molluscan shellfish is the type of seafood most frequently causing seafoodborne diseases ($> 50\%$ of all cases). These shellfish are filter-feeders and concentrate algae, bacteria, viruses, and chemicals from the surrounding water. Despite this situation, molluscan shellfish (with intestines) are often consumed raw and then may cause viral gastroenteritidis (Norwalk-like and hepatitis A), infections by *Vibrio* spp. and various shellfish toxic syndromes resulting from toxins produced by different marine algae (dinoflaggelates). In regions of Asia, raw freshwater fishes are used in various dishes, and as a result of this, a high percentage of the population can be infected with parasites (trematodes). Several other aspects of seafood safety are less closely linked to consumer behavior (Table 4). Because of the increasing international trade with fish raw material and seafoods, the safety of these products is of global importance. Continued efforts to apply hazard analysis critical control point systems in all steps of the seafood chain are essential to improve the safety record of these products at an international level.

Dietary Importance of Fish and Shellfish

A Ariño, J A Beltrán and P Roncalés, University of Zaragoza, Zaragoza, Spain

Background

During the 1990s, the world's population consumed ever larger quantities of fish. In discussing food uses of fish, the term 'fish' refers to edible species of finfish, molluscs, and crustaceans coming from the marine or freshwater bodies of the world, either by capture fisheries or by aquaculture. In 1990, direct human consumption of fish amounted to 71.7 million tonnes (live weight equivalent), rising to 93.8 million tonnes in 1997, an increase of almost a third over a period of only seven years. The average availability per capita was 15.9 kg per year during 1996, and fish provided (per day) 28 kcal, 4.4 g of protein, and 1.0 g of fat. There are wide differences among countries in fish consumption, as measured by the average yearly intake per person, ranging from countries with less than 1.0 kg per person to countries with over 100 kg. In recent years, the volume of fishery products marketed fresh has increased; in 1997, about a third of all fish was marketed fresh, compared with only a fifth in 1987.

Edible fish muscle contains 18% protein and 1–2% ash; the percentage of lipids varies from less than 1% to more than 20% in high-fat finfish. While fish has a prominent role as a source of valuable animal proteins in many communities, it seldom has a dietary significance as a source of kilocalories. Overall, fish provides about 16% of the animal proteins in the world and is a source of vitamins, minerals, and essential fatty acids. Food and nutritional professionals and consumers have known for years that fish is a high-protein food that is low in energy, total fat, and saturated fat when compared with other protein-rich animal foods. In addition, a large proportion of the fat in fish is polyunsaturated, the ω-3 (*n*-3) fatty acids.

Because of increased evidence for the cardiovascular benefits of fish (particularly fatty fish), consumption of at least two fish servings per week is recommended to maintain health. The predominant beneficial effects include a reduction in sudden death, decreased risk of arrhythmia, lower plasma triacylglycerol levels, and a reduced blood-clotting tendency.

As fish have become more popular, there have been increasing reports of foodborne diseases attributed to these foods. Foodborne diseases following exposure to fish can result from the food itself (toxic species, allergies), but also bacterial or viral contamination of the fish, naturally occurring seafood toxins, or the presence of additives and chemical residues due to environmental contamination.

General Characteristics of Food Finfish

A very large number of species of finfish are used for food by the world's population as a whole. The dressing percentage of finfish (60–70%) is similar to that of beef, pork, or poultry. The percentage of edible tissue in dressed carcasses of finfish (without head, skin, and viscera) is higher than that of other food animals, because fish contains less bone, adipose tissue, and connective tissue. There are three main categories of finfish widely used as foods. The bony fishes, the Teleosts, provide two compositional groups: white fish (or lean fish) such as cod, haddock, most flat fishes and whiting, and fatty fish, such as herring, sardines, salmon, mackerel, and tuna. The third category includes the cartilaginous Elasmobranch fish, such as dogfish, shark, and skate.

White Fish

The flesh of these fish is very low in fat and consists primarily of muscle and thin layers of connective tissue. The concentrations of most of the B vitamins are similar to those in mammalian lean meats, though fish may contain higher amounts of vitamin B_6 and B_{12}. The mineral levels are also similar, although the very fine bones that are eaten with the fish flesh can raise the calcium content; fish is also a significant source of iodine. These fish accumulate oils in their livers, which are a rich source of vitamin A (retinol), vitamin D and long-chain polyunsaturated fatty acids (PUFA) in their triacylglycerols (TAGs).

Fatty Fish

These fish have fat in their flesh, which is usually much darker than that of white fish, with similar blocks of muscle and connective tissue. The amount of fat is related to the breeding cycle of the fish, and after breeding, the fat content falls considerably. The flesh of the fatty fish is generally richer in the B vitamins than that of white fish, and there are significant amounts of vitamins A and D present. The mineral concentrations are not very different, but fatty fish is a better source of iron. The fat of these fish, or more correctly the oil, is particularly rich in very-long-chain PUFA, especially those of the ω-3 (*n*-3) series such as eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids. These fish accumulate oils in their muscles, belly flap, and skin (subdermal fat).

Cartilaginous Fish

These fish include the sharks and rays, whose flesh is rich in connective tissue and relatively low in fat, although they do accumulate oils in their livers. Compositionally, the concentrations of the vitamins and minerals are very similar to those in white fish. These fish are remarkable in that they have a high urea content, and so protein values based on total nitrogen are overestimated.

General Characteristics of Food Shellfish

The term 'shellfish' includes any aquatic invertebrate, such as a mollusc or crustacean that has a shell or shell-like exoskeleton. Owing to the presence of tough exoskeletons, the edible portion in shellfish (around 40%) is less than in finfish, with the exception of cephalopods, whose dressing percentage is 70–75%. In many communities, these foods are very highly valued gastronomically.

Molluscs

A wide range of molluscs are eaten by man, including bivalves such as mussels, oysters, and scallops, gastropods such as winkles and whelks, and cephalopods such as squids and octopuses. The flesh is muscular with low levels of fat, although the fat is more saturated and richer in cholesterol than that of finfish. The mineral levels in shelfish are usually somewhat higher than in finfish, and the vitamin concentrations are low. The bivalves and gastropods are often eaten whole after boiling and sometimes raw; usually, only the muscular mantles of cephalopods are eaten, after cooking. In some cultures, only selected parts are eaten, for example only the white adductor muscle of the scallop is eaten in North America.

Crustacea

These include a range of species both fresh water such as crayfish, and marine such as crabs, shrimps, prawns, and lobsters. These animals have a segmented body, a chitinous exoskeleton, and paired, jointed limbs. The portions eaten are the muscular parts of the abdomen and the muscles of claws of crabs and lobsters. The flesh is characteristically low in fat and high in minerals, with vitamin levels similar to those found in finfish.

Nutritional Role of Fish and Shellfish

Interest in the health benefits of fish and shellfish began decades ago when researchers noted that certain groups of people – including the Inuit and the Japanese, who rely on fish as a dietary mainstay – have a low rate of ischemic diseases (i.e., heart attack or stroke). Part of the cardiovascular health benefits of fish oils and their *n*-3 fatty acids can be explained by the ability of both EPA and DHA present in fish to reduce serum TAGs and very-low-density lipoproteins (VLDL-cholesterol). A growing body of evidence indicates that foods rich in ω-3 PUFAs confer cardioprotective effects beyond those that can be ascribed to improvements in blood lipoprotein profiles. As a result, current recommendations point out the benefits of eating fish at least twice a week, though even relatively small amounts of fish may decrease the overall risk of death from heart disease. Most experts do not advise routine use of fish oil supplements, and they favor eating fish and shellfish regularly in the context of a healthy diet and a regular pattern of physical activity.

The caloric value of fish is related to fat content and varies with species, size, diet, and season. Fish is generally considered to be a low-calorie food when compared with meats and poultry. Most lean or lower fat species of fish such as cod, hake, flounder, and sole contain less than 100 kcal per 100-g portion, and even fatty fish like mackerel, herring, and salmon contain approximately 250 kcal or less in a 100-g serving. Most crustaceans contain less than 1% fat in the tail muscle because depot fat is stored in the hepatopancreas, which is in the head region. With fish, each consumer can ingest fewer calories to meet their daily protein needs, which makes fish a good choice for diets designed to help you lose or maintain a desirable weight.

Fish Lipids, ω-3 PUFA Content, and Health

In fish, the depot fat is liquid at room temperature (oil) and is seldom even visible to the consumer; an exception is in the belly flaps of salmon steaks.

Many species of finfish and almost all shellfish contain less than 2.5% total fat, and less than 20% of the total number of calories comes from fat. Almost all fish have less than 10% total fat, and even the fattiest fish such as herring, mackerel, and salmon have no more than 20% fat (see Table 1). To obtain a good general idea of the fat content of most finfish species, the color of the flesh should be considered. The leanest species such as cod and flounder have a white or lighter color, and the fattier fish such as salmon, herring, and mackerel have a much darker color.

The triacylglycerol depot fat in edible fish muscle is subject to seasonal variations in all marine and freshwater fish from all over the world. Fat levels tend to be higher during times of the year when fish are feeding heavily (usually during the warmer months) and in older and healthier individual fish. Fat levels tend to be lower during spawning or reproduction. When comparing fat contents between farmed and wild-caught food fish, it should be considered that farmed species have a tendency to show a higher proportion of muscle fats than their wild counterparts. Also, the fatty acid composition in the lipids of farmed fish is dependent on the type of dietary fat used for raising the fish. Cholesterol is independent of fat content and similar in wild and cultivated fishes.

Most protein-rich foods including red meat and poultry as well as fish contain cholesterol. Almost all types of fish and shellfish contain well under 100 mg of cholesterol per 100 g, and many of the leaner types of fish have typically 40–60 mg for 100 g of edible muscle. It is known that most shellfish also contain less than 100 mg of cholesterol per 100-g serving. Shrimp contain somewhat higher amounts of cholesterol, over 150 mg per 100 g, and the squids are the only fish product with a significantly elevated cholesterol content, which averages from 300 mg per 100-g portion. Fish roe, caviar, the internal organs of fish (such as livers), the tomalley of lobsters and the hepatopancreas of crabs can contain high amounts of cholesterol.

ω-3 PUFA in Fish and Shellfish

The polyunsaturated fatty acids of many fish lipids are dominated by two members of the ω-3 family (*n*-3), C20:5 *n*-3 (EPA) and C22:6 *n*-3 (DHA). They are so named because the first of the several double bonds occur three carbon atoms away from the terminal end of the carbon chain.

All fish and shellfish contain some ω-3 but the amount can vary, as the relative concentrations of PUFAs are species-specific (see Table 2). Generally, the fattier fish contain more ω-3 fatty acids than the leaner fish. The amount of ω-3 fatty acids in farm-raised products can also vary greatly, depending on the diet of the fish or shellfish. Many companies now recognize this fact, and provide a source of ω-3 fatty acids in their fish diets. ω-3 fatty acids can be destroyed by heat, air, and light, so the less processing, heat, air exposure, and storage time, the better the ω-3 can be preserved in fish. Freezing and normal cooking cause minimal ω-3 losses, whereas deep frying and conditions leading to oxidation (rancidity) can destroy some ω-3 fatty acids.

The beneficial effects of eating fish for human health have been well documented. Research has shown that EPA and DHA are useful in (1) treatment or prophylaxis of thromboembolic conditions, (2) reducing cardiovascular mortalities and increased survival of patients, (3) decreasing stroke incidence, and (4) preventing fatal heart arrhythmia. DHA could also play an important role for full brain and eye tissue development and functions (learning ability and visual

Table 1 Fat levels in fish and shellfish commonly found in the marketplace

Low (<2.5% fat), less than 20% of total calories from fat	*Medium (2.5–5% fat), between 20 and 35% of total calories from fat*	*High (>5% fat) between 35 and 50% total calories from fat*

Snapper	Trout	Whitefish
Tilapia	Whiting	
Most molluscs	Clams	
Most crustaceans	Oysters	

acuity) in late pregnancy or in preterm infants. Possible relationships between ω-3 fatty acids and other disorders such as digestive tract cancers, rheumatoid arthritis, inflammatory reactions, and asthma are also currently being studied (see Table 3).

Fish proteins

Both finfish and shellfish are a highly valuable source of proteins in human nutrition. The protein content of fish flesh, in contrast to that of fat, is highly constant, independent of seasonal variations related to the feeding and reproductive cycles, and shows only small differences among species. Table 4 summarizes the approximate protein content of the various finfish and shellfish groups. Fatty finfish and crustacea have slightly higher than average protein concentrations. Bivalves have the lowest values if the whole body mass is considered, since most of them are usually eaten whole, whereas values are roughly average if specific muscular parts alone are consumed; the latter is the case with the scallop, in which mostly only the adductor muscle is eaten.

The essential amino acid composition is given in Table 5. Fish proteins, with only slight differences among groups, possess a high nutritive value, similar to that of meat proteins and slightly lower than that of egg. It is worth pointing out the elevated supply, relative to meat, of essential amino acids such as lysine, methionine, and threonine. In addition, due in part to the low collagen content, fish proteins are easily digestible, giving rise to a digestibility coefficient of nearly 100.

The recommended dietary allowances (RDA) or dietary reference intakes (DRI) of protein for human male or female adults are within the range of 45–65 g per day. In accordance with this, an intake of 100 g of fish would contribute 15–25% to the total daily protein requirement of healthy adults and some 70% to that of children. A look towards the dietary importance of Mediterranean diet is convenient; one of its characteristics is the high consumption of all kinds of fish, chiefly fat fish. In many Mediterranean countries, fish intake averages over 50 g per day (edible flesh); thus, fish protein contributes over 10% to the total daily protein requirements steadily over the whole year in those countries.

Less known is the fact that the consumption of fish protein, independently of the effect exerted by fish fat, has been related to a decrease in the risk of atherogenic vascular diseases. In fact, it has been demonstrated that diets in which fish is the only source of protein increase the blood levels of HDL in comparative studies with milk or soya proteins.

Nonprotein Nitrogen (NPN) Compounds in Fish

NPN compounds are mostly in the fiber sarcoplasm and include free amino acids, peptides, amines, amine oxides, guanidine compounds, quaternary ammonium molecules, nucleotides, and urea (Table 6). This fraction accounts for a relatively high percentage of total nitrogen in the muscle of some aquatic animals, 10–20% in teleosts, about 20% in crustacea and molluscs, 30–40% – and in special cases up to 50% – in elasmobranchs. In contrast, NPN in land animals usually represents no more than 10% of total nitrogen.

Most marine fish contain trimethylamine oxide (TMAO); this colorless, odorless, and flavorless compound is degraded to trimethylamine (TMA),

Table 3 Summary of beneficial effects of eating fish for the cardiovascular condition and other diseases

Cardiovascular disease (CVD)	*Other diseases*
Protects again heart disease	Protects against age-related maculopathy
Prolongs lives of people after a heart attack	Alleviates rheumatoid arthritis
Protects against sudden cardiac arrest caused by arrhythmia	Protects against certain types of digestive tract cancers
Protects against stroke (thrombosis)	Mitigates inflammation reactions and asthma
Lowers blood lipids such as triacylglycerols and VLDL-cholesterol	
Lowers blood pressure

which gives a 'fishy' odor and causes consumer rejection. This compound is not present in land animals and freshwater species (except Nile perch and tilapia from Lake Victoria). TMAO reductase catalyzes the reaction and is found in several fish species (red muscle of scombroid fish, white and red muscle of gadoids) and in certain microorganisms (*Enterobacteriaceae*).

Creatine is quantitatively the main component of the NPN fraction. This molecule plays an important role in fish muscle metabolism through its phosphorylated form; it is absent in crustacea and molluscs.

Endogenous and microbial proteases yield some free amino acids; taurine (Tau), alanine (Ala), glycine (Gly) and imidazole-containing amino acids seem to be the most frequent. Gly and Tau contribute to the sweet flavor of some crustaceans. Migratory marine species such as tuna, characterized by a high proportion of red muscle, have a high content (about 1%) of free histidine (His). A noticeable amount of this amino acid has also been reported in freshwater carp (*Cyprinus carpio*). The presence of free His is relevant in several fish species because it can be microbiologically decarboxylated to histamine (see Scombroid Fish (Histamine) Poisoning below).

Nucleotides and related compounds generally play an important role as coenzymes. They participate actively in muscle metabolism and supply energy to physiological processes. They have a noticeable participation in flavor; moreover, some of them may be used as freshness indices. Adenosine triphosphate (ATP) is degraded to adenosine diphosphate (ADP), adenosine monophosphate (AMP), inosine monophosphate (IMP), inosine (Ino), and hypoxantine (Hx). This pattern of degradation takes place in finfish, whereas AMP is degraded to adenosine and thereafter to Ino in shellfish. The degradation chain is very fast to IMP or AMP in finfish and shellfish, respectively. IMP degradation to Ino is generally slow, except in scombroids and flat fish. Ino degradation to Hx is slower. IMP is a flavor potentiator, whereas Hx imparts a sour taste, and high levels are toxic. ATP, ADP and AMP decompose quickly to form a build-up of Ino and Hx. As this corresponds well with a decline in freshness, the ratio of the quality of inosine and hypoxanthine to the total quantity of ATP and related substances is called the *K*-value and used as an index representing freshness of fish meat.

Guanosine is an insoluble compound that gives the characteristic brightness of fish eye and skin. It is degraded to guanine, which does not have this property; therefore, brightness decreases until it completely disappears.

The NPN fraction contains other interesting compounds, such as small peptides. Most of them contribute to flavor; besides this, they have a powerful antioxidant activity. Betaines constitute a special group of compounds that contribute to the specific flavor of different aquatic organisms: homarine in lobster, glycine-betaine and butiro-betaine in crustacea, and arsenic-betaine in crustacea. Arsenic-betaine has the property of fixing arsenic into the structure, giving a useful method for studying water contamination with this element.

Fish Vitamins

The vitamin content of fish and shellfish is rich and varied, although somewhat variable. In fact, significant differences are neatly evident among groups, especially regarding fat-soluble vitamins. Furthermore, vitamin content is highly variable within groups, also showing large differences among species as a function of feeding regimes.

The approximate vitamin concentration ranges of the various finfish and shellfish groups are

summarized in Table 7. The RDA or DRI for male or female adults is also given, as well as the percentage supplied by 100 g of fish. Regarding fat-soluble vitamins, vitamin E (tocopherol) is distributed most equally, showing relatively high concentrations in all fish groups, higher than those of meat. However, only a part of the vitamin E content is available as active tocopherol on consumption of fish, since it is oxidized as it protects fatty acids from oxidation. The presence of vitamins A (retinol) and D is closely related to the fat content, and so they are almost absent in most low-fat groups. Appreciable but low concentrations of vitamin A exist in fatty finfish and bivalve molluscs, whereas vitamin D is very abundant in fatty fish. In fact, 100 g of most fatty species supply over 100% of the RDA of this vitamin.

Water-soluble vitamins are well represented in all kinds of fish, with the sole exception of vitamin C (ascorbic acid), which is almost absent in all of them. The concentrations of the rest are highly variable; however, with few exceptions, they constitute a medium-to-good source of such vitamins, comparable with, or even better than, meat. The contents of vitamins B_2 (riboflavin), B_6 (piridoxin), niacin, biotin and B_{12} (cobalamin) are relatively high. Indeed, 100 g of fish can contribute up to 38, 60, 50, 33, and 100%, respectively, to total daily requirements of those vitamins. Fatty fish also provide a higher supply of many of the water-soluble vitamins than white fish and shellfish, namely piridoxin, niacin, pantothenic acid, and cobalamin. Crustacea also possess a relatively higher content of pantothenic acid, whereas bivalve molluscs have a much higher concentration of folate and cobalamin.

A Mediterranean diet, rich in fish – and especially in fatty finfish – contributes steadily over the year to an overall balanced vitamin supply. The last row of Table 7 illustrates this; the supply of vitamins D, B_2, B_6, B_{12}, and niacin of this particular diet is more than 15% of the daily requirements, whereas all other vitamins, except ascorbic acid, contribute to a lesser, but significant, extent.

Fish Minerals

The approximated composition of fish in selected minerals is given in Table 8. The first point to note is the fact that all kinds of finfish and shellfish present a well-balanced content of most minerals, either macro- or oligoelements, with only a few exceptions. Sodium content is low, similar to other muscle and animal origin foods. However, it must be taken into account that sodium is usually added to fish in most cooking practices in the form of common salt; also,

[a]Mediterranean diet.

surimi-based and other manufactured foods contain high amounts of added sodium. Potassium and calcium levels are relatively low, too, though the latter are higher in fish than in meat; in addition, small fish bones are frequently eaten with fish flesh, thus increasing calcium intake. Fish is a good source of magnesium and phosphorus, at least as good as meat. These elements are particularly abundant in crustacea, fatty finfish show elevated levels of phosphorus, and bivalve molluscs have high amounts of magnesium.

Fish is a highly valuable source of most oligoelements. Fatty fish provides a notable contribution to iron supply, similar to that of meat, whereas shellfish have higher concentrations of most dietary metals. In particular, crustacea and bivalve molluscs supply zinc, manganese, and copper concentrations well above those of finfish. Worth mentioning is the extraordinary dietary supply of iodine in all kinds of finfish and shellfish; however, this depends on the concentration present in feed, particularly in plankton organisms.

In summary, 100 g of fish afford low levels of sodium and medium-to-high levels of all the remaining dietary minerals. In fact, they can contribute up to 50–100% of total daily requirements of magnesium, phosphorus, iron, copper, selenium, and iodine. A Mediterranean diet, rich in fatty fish and all kinds of shellfish, can lead to an overall balanced mineral supply, which may well reach over 20% of the daily requirements of phosphorus, iron, selenium, and iodine.

Sanitary Aspects of Fish Consumption

Fish and shellfish consumption, besides its nutritional role as a nutrient source, may also cause syndromes and diseases due to infection or intoxication. Table 9 summarizes the most frequent sources of fish food diseases. Some of the etiologic agents are common to other food products (parasites, bacterial pathogens, viruses, and chemicals), either from the environment or from processing. Fish and shellfish contain other more specific toxic compounds like endogenous toxins, toxins from trophic chains, and bacterial toxins.

Table 9 Fish and shellfish toxicity

1. *Endogenous*
   - Puffer fish poisoning
   - Other less important endogenous toxic molecules: blood toxins, certain fish roe
2. *Toxins from trophic chains*
   - Biological origin
     - Ciguatera poisoning
     - Paralytic shellfish poisoning
     - Diarrhetic shellfish poisoning
     - Neurotoxic shellfish poisoning
     - Amnesic shellfish poisoning
   - Environmental contamination: chemicals, heavy metals, radioactivity, etc.
3. *Microbial activity*
   - Bacterial pathogens
   - Virus
   - Scombroid fish (histamine) poisoning
4. *Parasites*
5. *Toxic compounds from fish processing*

Endogenous Toxins

Puffer Fish Poisoning is characterized by a very potent toxin called 'tetrodotoxin' (TTX), which is produced by some members of the family *Tetraodontidae* (pufferfish). The toxin is mainly found in the liver, ovaries, and intestines, whereas muscle tissue is normally free of this. The symptoms are somewhat similar to those described for paralytic shellfish poisoning (PSP), i.e., initial tingling and numbness of lips, tongue, and fingers, leading to paralysis of the extremities and the respiratory system, which may lead to death. The origin of TTX is not clear; it has been linked to certain common marine vibrios (part of the microflora of pufferfish) that produce a form of the toxin. Low concentrations of the toxin (1–4 mg) may constitute a lethal dose for humans; it must be taken into account that internal organs of pufferfish usually contain 40 $\mu g\,g^{-1}$ in intestines to 400 $\mu g\,g^{-1}$ in ovaries.

Toxins from Trophic Chains

Ciguatera Poisoning results from the consumption of fish that have been fed with toxic dinoflagellates, *Gambierdiscus toxicus* and *Prorocentrum concavum*, being the most common. This poisoning is associated to tropical and subtropical areas and it affects specially large fishes from bottom and reef zones (grouper, barracuda, red snapper and sea basses). The symptoms are both gastrointestinal and neurological, the onset time is usually within a few hours and the prognosis for recovery is good if the patient survives the first 24 h; however, the recovery period can be rather prolonged in some cases.

PSP results from the ingestion of bivalve molluscs that have consumed toxinogenic dinoflagellates (microscopic marine plancktonic algae) of the genera *Alexandrium*, *Gymnodinium*, and *Pyrodinium*. The ultimate cause of PSP is a complex of at least 12 toxins – saxitoxins – with neurological effects. The symptoms appear within 0.5–2 h of eating toxic shellfish and can cause death by respiratory paralysis, usually within 12–24 h; patients surviving this period recover completely. The lethal dose for humans is 1–4 mg, and the Food and Drug Administration (FDA) limit is 80 µg per 100 g of shellfish tissue. A single raw mussel can contain up to 24 mg, and cooked mussel, 4 mg.

Diarrhetic Shellfish Poisoning is caused by the ingestion of shellfish containing thermostable toxins (at least seven have been identified, including okadoic acid, two dinophysitoxines and two pectenotoxins) and causes gastrointestinal disorders in many parts of the world. Dinoflagellates of the genera *Dinophysis* and *Aurocentrum* produce the toxins responsible for the illness within a time range of 30 min to a few hours; no fatalities have ever been observed, and patients recover in 3–4 days.

Neurotoxic Shellfish Poisoning is characterized by incoordination, paralysis, and convulsions caused by lipid-soluble toxins called 'brevetoxins'. *Gymnodinium breve* produces the toxins; the maximum permitted level (MPL) is 80 μg of brevetoxin per 100 g of flesh. No human deaths have been recorded.

Amnesic Shellfish Poisoning is caused by a water-soluble toxin (domoic acid) that produces nausea, headache, disorientation, and vomiting, but the most characteristic symptom is the permanent loss of short-term memory. The MPL is 20 p.p.m. domoic acid, and poisoning may cause human death.

Toxins from bacterial activity

Scombroid Fish (Histamine) Poisoning is a chemical intoxication following the ingestion of food containing high levels of histamine. Histamine is formed in some fishery products by enzymatic decarboxylation of histidine during the growth of certain spoilage bacteria that produce the enzyme histidine decarboxylase, such as certain Enterobacteriaceae, a few *Clostridia* and *Lactobacillus* spp. The possible activity of endogenous decarboxylase enzymes on free histidine leading to histamine formation in fish muscle is not well known. The most active histamine producers are *Morganella* (*Proteus*) *morganii*, *Klebsiella pneumoniae*, and *Hafnia alvei*; these microorganisms can be found in most fish, probably as a result of postharvest contamination. The fish species involved are mostly those with a natural high content of free histidine, such as *Scombrida* spp., but also *Clupeida* spp. In fact, the denomination 'scombroid fish poisoning' would be better changed to 'histamine poisoning.' Histamine concentrations of 10 mg per 100 g are considered significant; 20 mg per 100 g is the maximum allowable level in the EU, 50 mg per 100 g is a hazard in the USA Food and Drug Administration (FDA), and 100 mg per 100 g is generally considered toxic. The incubation period between ingestion and the onset of symptoms is rather short, from a few minutes to a few hours. The most common symptoms are: tingling and burning sensations in the mouth (peppery tasting), gastrointestinal complaints, and a rash with itching. The duration of the illness is also rather short, symptoms usually subsiding in a few hours.

Some evidence supports the hypothesis that certain substances in spoiled fish may potentiate the toxicity of histamine. Cadaverine and putrescine enhance the toxicity of histamine probably by inhibiting endogenous enzymes responsible for histamine detoxification.

FISH FARMING

A G J Tacon, Kaneohe, HI, USA

Background

The term 'fish farming' is synonymous with the term 'fish culture' or, more correctly, 'aquaculture.' According to the Food and Agriculture Organization of the United Nations (FAO):

> the definition of aquaculture is understood to mean the farming of aquatic animals, including fish, mollusks, crustaceans and aquatic plants. Farming implies some form of intervention in the rearing process to enhance production, such as regular stocking, feeding, protection from predators, etc. Farming also implies individual or corporate ownership of the stock being cultivated. For statistical purposes, aquatic organisms which are harvested by an individual or corporate body which has owned them throughout their rearing period contribute to aquaculture while aquatic organisms which are exploitable by the public as a common property resource, with or without appropriate licenses, are the harvest of fisheries. Aquaculture production specifically refers to output from aquaculture activities, which are designated for final harvest for consumption or other purposes such as ornamental purposes.

Fish farming is not new, with the first known monograph on the subject appearing in China in the fifth century BC with the publication of the 'Treatise on Fish Culture' by Fan Li in 473 BC. Moreover, ancient Egyptian pyramid bas-reliefs show fishing scenes and fish raised in ponds, and archeological sites attest to the fact that the Romans also reared fish in ponds or 'piscifactorias.' However, with the exception of China and the Asia and Pacific region, where fish culture has always traditionally played an important role as a provider of much needed food fish for human consumption, it was not until the twentieth century that aquaculture emerged on to the global arena as a major food-production sector and economic activity capable of rivaling the terrestrial animal-livestock farming sector.

Farmed Species

In marked contrast to terrestrial animal livestock production systems, where farming is usually restricted to the production of a handful of different animal species (i.e., pigs, cattle, poultry, sheep) under a relatively narrow range of habitats and farming systems (i.e., grazing, mixed, and industrial farming systems), *aqua*culture is more akin to *agri*culture in the wide diversity of species cultivated and farming systems employed. The 207 different animal and plant species currently cultivated on a global basis are listed in the following sections.

Fishes or Finfish (Pisces) (123 Species Reported in 1998)

Freshwater fishes (73 reported species)

- carps, barbels, and other cyprinids (24 species, including: silver carp (*Hypophthalmichthys molitrix*), grass carp (*Ctenopharyngodon idella*), common carp (*Cyprinus carpio*), bighead carp (*Aristichthys nobilis*), crucian carp (*Carassius carassius*), roho labeo (*Labeo rohita*), catla (*Catla catla*), mrigal carp (*Cirrhinus mrigala*), white amur bream (*Parabramis pekinensis*), mud carp (*Cirrhinus mulitorella*), black carp (*Mylopharyngodon piceus*) Thai silver barb (*Puntius goniono-tus*), Java barb (*Puntius javanicus*), nilem carp (*Osteochilus hasselti*), golden shiner (*Notemigonus crysoleucas*), roach (*Rutilus rutilus*), goldfish (*Carassius auratus*), tench (*Tinca tinca*), hovens carp (*Leptobarbus hoeveni*), pond loach (*Misgurnus anguillicaudatus*), rudd (*Scardinius erythrophthalmus*), bleak (*Alburnus alburnus*), freshwater bream (*Abramis brama*), rhinofishes (*Labeo* spp));
- tilapias and other cichlids (12 species, including: Nile tilapia (*Oreochromis niloticus*), Mozambique tilapia (*Oreochromis mossambica*), blue tilapia (*Oreochromis aureus*), three-spotted tilapia (*O. andersonil*), redbreast tilapia (*Tilapia rendalli*), longfin tilapia (*Oreochromis macrochir*), tilapia (*Oreochromis spilurus*), redbelly tilapia (*Tilapia zillii*), jaguar guapote (*Cichlasoma managuensis*), blackbelt cichlid (*Cichlasoma maculicauda*), yellow-belly bream (*Serranochromis robustus*), velvety cichlids (*Astronotus* spp.);
- miscellaneous freshwater species (37 species, including channel catfish (*Ictalurus punctatus*), mandarin fish (*Siniperca chuatsi*), climbing perch (*Anabas testudineus*), catfish, hybrid (*Clarias gariepinus* × *Clarias macrocephali*), snakeskin gourami (*Trichogaster pectoralis*), piaractus/cachama blanca (*piaractus brachypomus*), pangas catfish (*Pangasius pangasius*), striped snakehead (*Channa striatus*), giant gourami (*Osphronemus goramy*), cachama (*Colossoma macropomum*), kissing gourami (*Helostoma temmincki*), North African catfish (*Clarias gariepinus*), Indonesian snakehead (*Channa micropeltes*), Northern pike (*Esox lucius*),

upside-down catfishes (*Synodontis* spp.), Wels catfish (*Silurus glanis*), black bullhead (*Ictalurus melas*), Asian redtail catfish (*Mystus nemurus*), Snakehead (*Channa argus*), Philippine catfish (*Clarias batrachus*), pike-perch (*Stizostedion lucioperca*), largemouth black bass (*Micropterus salmoides*), marble goby (*Oxyeleotris marmorata*), netted prochilod (*Prochilodus reticulatus*), mudfish (*Clarias anguillaris*), European perch (*Perca fluviatilis*), bagrid catfish (*Chrysichthys nigrodigitatus*), silver perch (*Bidyanus bidyanus*), Pacific fat sleeper (*Dormitator latifrons*), dorada (*Brycon moorei*), barred sorubim (*Pseudoplatystoma fasciatum*), duckbill catfish (*Sorubim lima*), South American catfish (*Rhamdia sapo*), knife fishes (*Notopterus* spp.), African bonytongue (*Heterotis niloticus*), Murray cod (*Maccullochella peelii*), golden perch (*Macquana ambigua*)).

Diadromous fishes (18 Reported Species)

- sturgeons, paddlefishes (two species, including Siberian sturgeon (*Acipenser beeri*), beluga (*Huso huso*));
- river eels (three species, including Japanese eel (*Anguilla japonica*), European eel (*Anguilla anguilla*), Short finned eel (*Anguilla australis*));
- salmons, trouts, smelts (11 species, including Atlantic salmon (*Salmo salar*), rainbow trout (*Oncorhynchus mykiss*), coho salmon (*Oncorhynchus kisutch*), chinook salmon (*Oncorhynchus tshawytscha*), ayu sweetfish (*Plecoglossus altivelis*), sea trout (*Salmo trutta*), Arctic char (*Salvelinus alpinus*), brook trout (*Salvelinus fontinalis*), European whitefish (*Coregonus lavaretus*), chum salmon (*Oncorhynchus keta*), grayling (*Thymallus thymallus*));
- miscellaneous diadromous fishes (two species, including milkfish (*Chanos chanos*), barramundi (giant sea perch; *Lates calcarifer*));

Marine fishes (32 reported species)

- flounders, halibuts, soles (five species, including bastard halibut (*Paralichthys olivaceus*), turbot (*Psetta maxima*), other flatfishes (Pleuronectiformes), common sole (*Solea vulgaris*), Atlantic halibut (*Hippoglossus hippoglossus*));
- cods, hakes, haddocks (one species, including Atlantic cod (*Gadus morhua*));
- redfishes, basses, congers (18 species, including Japanese seabream (*Pagrus major*), gilthead seabream (*Sparus auratus*), European seabass (*Dicentrarchus labrax*), puffers (Tetraodontidae; species not given), blackhead seabream (*Acanthopagrus schlegeli*), mangrove red snapper (*Lutjanus argentimaculatus*), greasy grouper (*Epinephelus tauvina*), sharpsnout seabream (*Diplodus puntazzo*), Russells snapper (*Lutjanus russelli*), goldlined seabream (*Rhabdosargus sarba*), areolate grouper (*Epinephelus areolatus*), goldsilk seabream (*Acanthopagrus berda*), red drum (*Sciaenops ocellatus*), goatfishes (*Upeneus* spp.), white seabream (*Diplodus sargus sargus*), rabbitfish (*Siganus* spp.), meager (*Argyrosomus regius*), cabinza grunt (*Isacia conceptionis*));
- jacks, mullets, sauries (seven species, including Japanese amberjack (*Seriola quinqueradiata*), flathead gray mullet (*Mugil cephalus*), Japanese jack mackerel (*Trachurus japonicus*), cobia (*Rachycentron canadum*), silversides (Atherinidae), fourfinger threadfin (*Eleutheronema tetradactylum*), snubnose pompano (*Trachinotus blochii*));
- tunas, bonitos, billfishes (one species, southern bluefin tuna (*Thunnus maccoyii*)).

Crustaceans (Crustacea) – 26 Species Reported in 1998

Freshwater crustaceans (nine reported species, including giant river prawn (*Macrobrachium rosenbergii*), Chinese river crab (*Eriocheir sinensis*), red swamp crawfish (*Procambarus clarkii*), yabby crayfish (*Cherax destructor*), red claw crayfish (*Cherax quadricarinatus*), marron crayfish (*Cherax tenuimanus*), Signal crayfish (*Pacifastacus leniusculus*), Danube crayfish (*Astacus leptodactylus*), sawtooth caridina (*Caridina denticulata*));

Sea-spiders, crabs: (three reported species, including Indo-Pacific swamp crab (*Scylla serrata*), blue crab (*Callinectes sapidus*), swimcrabs (*Portunus* spp.));

Lobsters, spiny-rock lobsters (two reported species, including longlegged spiny lobster (*Panulirus longipes*), mud spiny lobsters (*Panulirus polyphagus*));

Shrimps, prawns (12 reported species, including giant tiger prawn (*Penaeus monodon*), whiteleg shrimp (*Penaeus vannamei*), fleshy prawn (*Penaeus chinensis*), banana prawn (*Penaeus merguiensis*), blue shrimp (*Penaeus stylirostris*), Indian white prawn (*Penaeus indicus*), kuruma prawn (*Penaeus japonicus*), akiami paste shrimp (*Acetes japonicus*), other natantian decapods (Natantia), endeavor shrimp (*Metapenaeus endeavouri*), common prawn (*Palaemon serratus*), redtail prawn (*Penaeus penicillatus*)).

Molluscs (Mollusca) (43 Species Reported in 1998)

Freshwater molluscs (one reported species, Japanese corbicula (*Corbicula japonica*));

Abalones, winkles, conchs (three reported species, including perlemoen abalone (*Haliotis midae*), periwinkles (*Littorina* spp.), stromboid conch (*Strombus* spp));

Oysters (nine reported species, including Pacific cupped oyster (*Crassostrea gigas*), American cupped oyster (*Crassostrea virginica*), slipper cupped oyster (*Crassostrea iredalei*), European flat oyster (*Ostrea edulis*), Sydney cupped oyster (*Crassostrea commercialis*), mangrove cupped oyster (*Crassostrea rhizophorae*), shell-loving oyster (*Ostrea conchaphila*), Chilean flat oyster (*Ostrea chilensis*), hooded oyster (*Saccostrea cucullata*));

Mussels (10 reported species, including blue mussel (*Mytilus edulis*), Mediterranean mussel (*Mytilus galloprovincialis*), New Zealand mussel (*Perna canaliculus*), green mussel (*Mytilus viridis*), Korean mussel (*Mytilus coruscus*), Chilean mussel (*Mytilus chilensis*), South American rock mussel (*Perna perna*), Australian mussel (*Mytilus planulatus*), choro mussel (*Choromytilus chorus*), *cholga mussel* (*Aulocomya ater*));

Scallops, pectins (five reported species, including yesso scallop (*Pecten yessoensis*), Peruvian calico scallop (*Argopecten purpuratus*), great Atlantic scallop (*Pecten maximus*), queen scallop (*Chlamys opercularis*), Pacific calico scallop (*Argopecten ventricosus*));

Clams, cockles, arkshells (13 reported species, including Japanese carpet shell (*Ruditapes philippinarum*), razor clams (*Solen* spp.), blood cockle (*Anadara granosa*), northern quahog (*Mercenaria mercenaria*), inflated ark (*Scapharca broughtonil*), pullet carpet shell (*Tapes pullastra*), groved carpet shell (*Ruditapes decussatus*), common edible cockle (*Cardium edule*), butter clam (*Saxidomus giganteus*), donax clams (*Donax* spp), Pacific littleneck clam (*Prothaca staminea*), striped venus (*Venus gallina*));

Squids, cuttlefishes, octopuses (two reported species, including octopuses (*Octopus* spp.), common cuttlefish (*Sepia officinalis*)).

Miscellaneous Aquatic Animals (Four Species Reported in 1998)

Frogs and other Amphibians (One Reported Species, frogs (*Rana* spp.));

Turtles (one reported species, soft-shell turtle (*Trionyx sinensis*));

Sea squirts and other tunicates (one reported species, red bait (*Pyura stolonifera*));

Sea urchins and other echinoderms (one reported species, sea urchin (*Strongylocentrotus* spp.)).

Aquatic Plants (classification: Plantae) (11 species reported in 1998)

Brown seaweeds (two reported species, including Japanese kelp (*Laminaria japonica*), wakame (*Undaria pinnatifida*));

Red seaweeds (seven reported seaweeds, including laver (*Porphyra tenera*), eucheuma (*Euchema cottonii*), *gracilaria seaweeds* (*Gracilaria* spp.), elkhorn sea moss (*Kappaphycus alvarezii*), spiny eucheuma (*Euceuma denticulatum*), gellidium seaweeds (*Gellidium* spp.), harpoon seaweeds (*Asparagopsis* spp.));

Green seaweeds: (two reported seaweeds, including green laver (*Monostroma nitidum*), caulerpa seaweeds (*Caulera* spp.)).

Farming Practices and Feeding Methods

As one would expect with the cultivation of over 200 different animal and plant species, farming practices vary widely from region to region, country to country, species to species, and even for the same species. To a large extent, farming practices are determined by the ease of the culture of the target species, the aim of the proposed farming activity (subsistence or cash income), the economic unit value of the cultured species (higher-value species facilitating the use of higher-cost production methods), and the availability of resources to the farmer; (the last including the availability of water, land, seed and/or brood stock, fertilizers, feed, cash, and finance).

Farming practices can be undertaken under a variety of environmental conditions, including freshwater, brackish water, or marine waters. According to the FAO, for statistical aquaculture purposes, freshwater is meant to signify waters with a consistently negligible salinity, brackish water is meant to signify waters in which the salinity is appreciable but not to a constant high level (enclosed coastal and inland water bodies in which the salinity is greater than freshwater but less than marine water are also regarded as brackish), and marine is meant to signify coastal and offshore waters in which the salinity is maximal and not subject to significant daily and seasonal variation.

Current aquaculture farm production methods depend to a large extent upon the target species and the availability of resources to the farmer, and may range from the use of low-input (and consequently low-output) extensive farming systems (equivalent to 'grazing' in terrestrial livestock production) to the use of large-scale semiintensive and intensive industrial farming systems (equivalent to 'mixed' and 'industrial' livestock production systems). In general, higher-value cash crop species such as salmon and shrimp tend to be cultivated alone as a monoculture, whereas lower-value staple food fish species such as the Chinese carps tend to be cultivated together as a polyculture of different species with complementary rearing and feeding habits.

Farm production units can be broadly divided into outdoor and indoor production systems and, in the case of outdoor farming systems, may range from the use of earthen or concrete/plastic lined ponds, artificial tanks or raceways, floating or submerged net cages or fenced pen enclosures, poles or suspended ropes and net bags, rice fields or managed large water bodies (including reservoirs), to the use of indoor tanks and raceways/ponds within closed water recirculated aquaculture production systems.

Feeding methods employed by farmers range widely from species to species and country to country, depending upon the farm production unit employed and availability of fertilizer and feed resources. In the case of extensive pond-based farming systems where animals are usually reared at low stocking densities within large volumes of water, the growth of the cultured species is usually entirely dependent upon the consumption of live food organisms naturally produced within the water body. Such *in-situ* feeding practices are typical of existing farming systems for aquatic plant and filter-feeding mollusc and finfish species. By contrast, within semiintensive and intensive farming systems, fertilizers and feeds are usually externally provided either to augment the production of natural food organisms within the culture system (in the case of fertilizers) or as an exogenous direct source of nutrients in the case of externally provided feeds. Feeds may range from the use of fresh natural food items such as agricultural byproducts and animal food items (such as insects, worms, molluscs, fish, slaughterhouse wastes within small-scale, or backyard fish farming systems) to the use of farm-made or industrially manufactured nutritionally complete aquaculture feeds, the latter usually composed of a combination of different processed plant and animal-feed ingredient sources formulated so as to approximate to the known dietary nutrient requirements of the cultured target species. Such complete diet feeding methods are typical of semiintensive and intensive finfish and crustacean production systems.

Global Aquaculture Production

Aquaculture has been the world's fastest growing agricultural food production sector for over a decade, with the sector growing at an annual percentage rate (APR) of 11% since 1984, as compared with 3.1% for terrestrial farm animal meat production and 0.8% for landings from wild harvested fisheries over the same period. According to the latest statistical information from the FAO, total global aquaculture production in 1998 was reported as 39.4 million tonnes and valued at US$52.5 billion. At a species group level, finfish contributed over half of total aquaculture production by weight in 1998 (20 million tonnes or 50.8%), followed by mollusks (9.1 million tonnes or 23.2%) and aquatic plants (8.5 million tonnes or 21.7%). The growth of the different major specific groups over the past decade has been rapid, with most groups exhibiting double digit growth rates over the period 1984–1998, including finfish (12.3% per year), mollusks (11.5% per year), aquatic plants (7.7% per year), and crustaceans (16.0% per year).

By culture environment, over half (54.1%) of global aquaculture production originated from marine or brackish coastal waters in 1998 (down from 61.3% in 1984), as compared with 45.9% for freshwater aquaculture production (up from 38.7% in 1994), the average growth rate from 1984 to 1998 being highest for freshwater aquaculture production (APR 12.5%), followed by brackishwater (APR 10.2%) and mariculture (APR 9.9%). The main species groups reared in freshwater were finfish (97.9%), crustaceans and finfish in brackish water (56.8 and 35.1%, respectively), and mollusks and aquatic plants in marine waters (46.4 and 44.2%, respectively).

By region, Asia produced over 90.8% of global aquaculture production by weight in 1998 (35.81 million tonnes), with mainland China standing above all other countries with a reported total aquaculture production of 27.1 million tonnes or 68.6% of global aquaculture production in 1998. Including mainland China, all of the world's top 10 aquaculture producing nations were found in Asia in 1998, and included India 2.03 million tonnes Japan 1.29 million tonnes, Philippines 0.95 million tonnes, Indonesia 0.81 million tonnes, South Korea 0.80 million tonnes, Bangladesh 0.58 million tonnes Thailand 0.57 million tonnes, Vietnam 0.54 million tonnes, and North Korea 0.48 million tonnes (these top 10 producing countries representing 89.1% of global aquaculture production by weight; Table 1). The next major regions in terms of production by weight were Europe (4.97% or 1.96 million tonnes: Norway 0.41 million tonnes, Spain 0.31 million tonnes, France 0.27 million tonnes, Italy 0.25 million tonnes, UK 0.14 million tonnes, Netherlands 0.12 million tonnes), followed by South America (1.70% or 0.67 million tonnes: Chile 0.36 million tonnes, Ecuador 0.15 million tonnes, Brazil 0.095 million tonnes, Colombia 0.046 million tonnes), North America (1.66% or 0.65 million tonnes: USA 0.44 million tonnes, Canada 0.090 million tonnes, Mexico 0.041 million tonnes, Cuba 0.038 million tonnes), Africa (0.48% or 0.19 million tonnes: Egypt 0.14 million tonnes, Nigeria 0.020 million tonnes, Madagascar

Table 1 Top producers in 1998: total aquaculture production

Country	Production[a] (tonnes)	Production[b]	Growth APR[c] (1984–98)	Growth[d] (1997–98)	Total value (US$1000)	Unit value (US$kg^{-1})

[a]Total aquaculture production (includes finfish, crustaceans, molluscs, miscellaneous aquatic animals/products, and aquatic plants).
[b]Accumulative total as a percentage of the total world aquaculture production.
[c]Annual percentage growth rate in production by weight between 1984 and 1998.
[d]Percentage change in production by weight between 1997 and 1998.

0.0069 million tonnes, South Africa 0.0052, Zambia 0.0042 million tonnes), and Oceania (0.36% or 0.14 million tonnes: New Zealand 0.094 million tonnes, Australia 0.028 million tonnes).

By economic country grouping, approximately 90.0 and 82.2% of global aquaculture production in 1998 was produced within developing countries (35.49 million tonnes). Moreover, whereas the developing country share of aquaculture production has increased from 72.6% (7.37 million tonnes) of total aquaculture production in 1984 to 90% (35.49 million tonnes) in 1998, the share of production from developed countries has decreased from 27.4% (2.78 million tonnes) in 1984 to 10% (3.93 million tonnes) in 1998. Aquaculture production within developing countries has grown four times faster (12.8% per year since 1984) than within developed countries (2.7% per year since 1984).

In general terms, aquaculture's contribution toward total world fishery landings has increased threefold since 1984, aquaculture production increasing from 10.15 million tonnes or 11.4% of total fishery landings in 1984 to 39.43 million tonnes or 31.1% of total fishery landings in 1998. By continent, aquaculture supplied 45.3% of total fisheries landings in Asia (up from 21.1% in 1984), 10.9% of total landings in Oceania (up from 3.7% in 1984), 10.2% in Europe (up from 6.9% in 1984), 8.0% in North America (up from 4.5% in 1984), 5.7% in South America (up from 0.5% in 1984), and 3.2% in Africa (up from 0.9% in 1984).

Major Farmed Finfish and Crustacean Species

Inland freshwater species currently form the bulk of finfish aquaculture production (17.4 million tonnes or 86.6% of total finfish production), with diadromous and marine finfish species constituting only 9.5 % (1.9 million tonnes) and 3.9% (0.78 million tonnes) of total finfish production (20.06 million tonnes) in 1998. On a species group level, the major cultivated finfish species groups in 1998 can be listed as follows:

- cyprinids (total production 14.14 million tonnes, 23 freshwater species reported in 1998; growth rate over period 1984–98: 13.3% per year);
- tilapia (total production 0.97 million tonnes, 12 freshwater species reported in 1998; growth rate over period 1984–98: 13.4% per year);
- catfish (total production 0.45 million tonnes, 12 freshwater species reported in 1998; growth rate over period 1984–98: 10.2% per year);
- salmonids (total production 1.29 million tonnes, 11 diadromous species reported in 1998; growth rate over period 1984–98: 13.6% per year);

- eels (total production 0.22 million tonnes, three diadromous species reported in 1998; growth rate over period 1984–98: 8.3% per year);
- milkfish (total production 0.37 million tonnes, one diadromous species reported in 1998; growth rate over period 1984–98: 0.3% per year);
- jacks/mullets (total production 0.20 million tonnes, seven marine species reported in 1998; growth rate over period 1984–98: 1.5% per year); and
- redfishes/basses (total production 0.20 million tonnes, 16 marine species reported in 1998; growth rate over period 1984–98: 16.1% per year).

In addition to the above finfish species group, the major crustacean groups produced in 1998 were:

- marine shrimp (total production 1.11 million tonnes, 71.2% of total crustacean production, 11 species reported in 1998, growth rate over period 1984–98: 15.4% per year); and
- freshwater crustaceans (total production 0.32 million tonnes, 20.4% of total crustacean production, nine species reported in 1998; growth rate over period 1984–98: 15.7% per year).

Table 2 summarizes the top twenty cultivated finfish and crustacean species in 1998.

Global Production by Feeding Habit and Nutrient Supply

In terms of feeding habit and nutrient supply, global aquaculture production in 1998 may be broadly divided into six basic categories, reflecting primary trophic behavior utilized by farmers, as follows:

- photosynthetic aquatic plants: 8.57 million tonnes or 21.7% of total aquaculture production, examples including all brown, red, and green seaweeds;
- filter-feeding mollusks: 9.14 million tonnes or 23.2% of total aquaculture production, major cultivated species including oysters, mussels, scallops, clams, and cockles;

Table 2 Top 25 finfish and crustacean aquaculture species in 1998

[a]Freshwater finfish.
[b]Miscellaneous freshwater fishes (species not given).
[c]Diadromous finfish.
[d]Carnivorous finfish.
[e]Crustaceans.
[f]Miscellaneous marine fishes (species not given).

- filter-feeding finfishes: 5.52 million tonnes or 14.0% of total aquaculture production, major cultivated species including silver carp, bighead carp, and catla;
- herbivorous/omnivorous finfishes: 12.0 million tonnes or 30.4% of total aquaculture production; major cultivated species including grass carp, common carp, crucian carp, Nile tilapia, rohu, mrigal carp, white amur bream, milkfish, channel catfish, and mud carp;
- benthophagic omnivorous scavenging crustaceans: 1.56 million tonnes or 3.9% of total aquaculture production; major cultivated species including giant tiger prawn, whiteleg shrimp, fleshy prawn, banana prawn, giant river prawn, Chinese river crab, marine crabs, and crayfish; and
- carnivorous finfishes: 2.53 million tonnes or 6.4% of total aquaculture production; major cultivated species including Atlantic salmon, rainbow trout, Japanese eel, Japanese amberjack (yellowtail), black carp, Japanese seabream, coho salmon, Mandarin fish, gilthead seabream, and European seabass.

In terms of nutrient supply, it can be seen from the above trophic classification that nearly half (i.e., 17.71 million tonnes or 44.9%) of global aquaculture production in 1998 was based on the production of marine plants and mollusks within extensively managed farming systems, receiving little or no supplementary nutrient inputs (i.e., in the form of inorganic and/or organic fertilizers). Similarly, over a quarter of total finfish production (i.e., 5.52 million tonnes or 27.5% total finfish production) was based on the production of filter-feeding finfish species, these species usually being reared within extensive/semi-intensively managed farming systems (i.e., within earthen ponds, pen enclosures, rice fields, or small water bodies) as a polyculture of mixed finfish species at low (extensive) to moderate (semiintensive) stocking densities, with finfish growth being dependent upon the filtration of live/suspended food organisms/nutrients from the water body (the production of the latter being augmented or not through the application of supplementary nutrient inputs in the form of fertilizers).

In marked contrast, the production of the remaining finfish (14.53 million tonnes or 72.5% total finfish production) and crustacean species (1.56 million tonnes) is almost entirely based on the provision of exogenously supplied nutrient inputs in the form of either industrially compounded nutritionally complete aquafeeds (or, to a lesser extent, natural food items of high nutrient value such as 'trash fish') or supplementary farm-made aquafeeds (often in combination with fertilization). Interestingly, carnivorous finfish species (2.53 million tonnes) represented 12.6% of total farmed finfish production in 1998, including 72.9% of total finfish production in developed countries (1.35 million tonnes from a total of 1.85 million tonnes) and 6.45% of total finfish production in developing countries (1.17 million tonnes from a total of 18.19 million tonnes).

Food Supply and Concluding Remarks

In terms of per caput availability of 'food fish' from aquaculture (i.e., the production of farmed aquatic finfish and shellfish on a whole live-weight basis, and excluding farmed aquatic plants; 30.86 million tonnes in 1998) this has increased by 261% from 1.45 kg in 1984 to 5.23 kg in 1998, with supply growing at an average rate of 10.4% per year. By contrast, the per caput availability of 'food fish' from capture fisheries (i.e., 62.45 million tonnes, excludes captured fish destined for reduction into fishmeal) has remained static, decreasing from 10.88 kg in 1984 to 10.58 kg in 1998. On the basis of the above data, over 33.1% of global 'food fish' supplies was supplied by aquaculture in 1998. In terms of total farmed meat production, aquaculture currently ranks fourth in terms of global farmed meat production (19.5 million tonnes in 1998; after gutting/shelling), with pig first (88.0 million tonnes), beef and veal second (55.3 million tonnes), and chicken third (52.1 million tonnes). In general, the main factor driving the apparent high demand for staple food fish, and in particular of low-value farmed freshwater food fish species feeding low on the aquatic food chain, within most developing countries is their greater affordability to the poorer segments of the community, including the rural poor, compared with other animal-protein sources.

With the global population now exceeding 6 billion, there is a growing trend toward increased competition between users or stakeholders, including both the agricultural and nonagricultural sectors, for available resources, including land, energy/fossil fuels, water, and nutrient sources. As a consequence of this, there is also a trend within animal husbandry (including aquaculture) toward the intensification of farming systems and increased livestock/aquaculture production per unit area/time, as well as an increasing trend toward the vertical integration of animal and feed production systems so as to reduce risks and minimize production costs. It follows, therefore, that if aquaculture is to sustain its current growth into the third millennium farming systems should become increasingly more efficient in terms of resource use and have little or no adverse impacts on society and the environment.

FISH MEAL

S M Barlow, International Association of Fishmeal and Oil Manufacturers, St Albans, Hertfordshire, UK

Introduction

Fish meal is a brown powder which normally contains a high level of protein and appreciable quantities of lipid and minerals. Of world fish meal production, about 90% is produced from oily species of fish, such as sardine, anchovy, capelin, and menhaden, and less than 10% from white fish offal (frames), such as cod and haddock. Of the annual world catch of fish, about one-third is used as raw material for fish meal production, this being sustainable catches for which there is no direct outlet for human consumption.

Nature of the Product and its Use

The nutritional values of fish meals differ, mainly depending on the species of fish from which the meals are prepared. In practice, users have classified fish meals into four broad groups, namely herring-type, anchovy/pilchard, menhaden, and white-fish. The main nutritional characteristics of these four broad groups of meals are summarized in **Table 1**.

The protein in fish meal has a high biological value in diets for animals. It is rich in essential amino acids, particularly lysine and the sulfur amino acids, and the presence of fish meal in a complete diet will supplement any deficiencies of the amino acids in vegetable proteins. The amino acid make-up of fish meal made from whole fish is similar when expressed on a protein basis. The lipid material provides a concentrated energy source and it can contribute towards essential fatty acid requirements. Fish meal is a rich source of the major elements, calcium, phosphorus, sodium chloride and magnesium, the trace elements, iron, zinc, and selenium, and the B-group vitamins, especially B_{12} and choline. Unlike vegetable sources of protein, the phosphorus in fish meal is fully available. (*See* **Essential Fatty Acids**, and refer to individual nutrients.)

Although particular proteins might on analysis be found to contain certain levels of amino acids, biological experiments have indicated that these amino acids might not be completely available to the animals ingesting the protein. The digestibilities of the nitrogen and of the critical amino acids of fish meal are approximately 89% for pigs, 85% for chicken, and 94% for the rat. Fish meal is of low degradability in the rumen, while the undegraded or bypass protein is of high digestibility in the small intestine. Meals with a low solubles content may be marketed as specially selected for ruminants. The degradability in the rumen of the protein of such meals is in the range 0.3–0.4.

The main animal species consuming fish meal in 1988 were poultry (60% of world fish meal production), pigs (20%), fish (10%), fur-bearing animals (2.5%), and ruminants (2.5%). The practical uses of fish meal in diets for these species are summarized below.

Poultry

The principal consumers are broilers, followed by turkeys, breeding birds and, to a lesser extent, laying hens. The recommended minimum level of fish meal in a broiler diet is 2%, with the maximum in a broiler finisher diet of 6–8%. The maximum level is normally dictated by the desire not to impart a fishy taint to the flavor of the broiler meat. High-fat fish

meals are more likely to do this than low-fat fish meals (e.g., white-fish meals).

The minimum levels are based on practical experience and experimental results indicating that this level of fish meal produces increases in meat or egg production and better feed utilization compared with diets not containing fish meal. It is impossible to state a typical level of fish meal incorporation in a broiler diet. This depends upon the alternative feed ingredients available and the consumer preference for different characteristics of the broiler flesh. The differences are largely geographically based.

Turkey starter/grower diets would normally have a minimum fish meal level of about 5%, with a maximum of about 8%, even of high-fat fish meals. Layer diets would have, in practice, no minimum or maximum constraints.

Recent interest in the health benefits from the long-chain ω-3 polyunsaturated fatty acids is increasing interest in their residual levels in meat resulting from fish meal feeding. (*See* **Poultry**: Chicken; Ducks and Geese; Turkey.)

Pigs

The minimum level in weaner diets for pigs typically weaned at 3–4 weeks of age through to 20 kg liveweight is about 5% of fish meal, with this level dropping to 2% in grower diets (20–50 kg). Breeding and

lactating pigs also have a minimum fish meal level of about 4% in most diets. Finisher pig diets (> 50 kg) probably have no minimum constraint. However, in circumstances of large availability of supplies of fish meal at relatively low prices compared with vegetable proteins, such as in the main fish meal-producing countries of South America, when it is economically advantageous to include fish meal, a constraint is normally placed upon the maximum level of fish meal to be used in order to ensure that no fishy taint is imparted to the pig flesh. For a high-fat fish meal containing > 10% of fat is is not unusual to see a maximum constraint of 5% in finishing diets. (*See* **Pork**.)

Fish

The principal cultivated fish species using fish meal in their diet are prawns, salmon, eels, trout, and yellow tails, i.e., mainly the marine carnivorous species. These do not use vegetable proteins efficiently, especially if they are fast-growing. Fish meal content of salmon diets is believed to average 45%, with slightly higher inclusion in diets for Atlantic salmon than for Pacific salmon. In prawns a typical fish meal content in the diet would be about 30%; the level of incorporation for trout would be 35% and for eels about 50%. (*See* **Fish Farming**.)

Fur-Bearing Animals

Fish meal is commonly used in mink feeding. The amount of fish meal used varies, but up to 60% of the protein can originate from fish meal provided that the meal is of high quality. Antioxidant-stabilized fish meal, or low-fat fish meal prepared from fresh fish, is preferred.

Ruminants

Fish meal fed at relatively low levels (0.75 kg day^{-1}) to high-yielding dairy cows (over 251 per day) has been shown to increase the milk yield significantly. The effect has been particularly pronounced with high-forage diets, especially with grass silage as the main forage source. Probably of greater economic significance is the fact that dietary fish meal increases the reproductive performance of the dairy cow. For example, conception rates have been shown to increase from 44% to 64%. This increases calving frequency and milk production.

Fish meal also has a role in the diets of sheep, improving productivity and product quality and reducing production costs. It has been found to be particularly important during the last 2–3 weeks of pregnancy for ewes given mainly roughage diets, during the first 5–6 weeks of lactation when body fat in the ewes can help to sustain a large milk production, as a feed supplement in high-energy diets for fattening of early weaned lambs, and for older lambs on high-roughage diets. Finally, it has been found to be useful in manipulating body fat stores, thus reducing excess body fat prior to going to market.

In diets for beef cattle, especially those on high-forage diets, fish meal (200–400 g day^{-1}) increases growth rate. It has been recently shown to provide a means of increasing lean growth at the expense of body fat, which decreases in over-fat finishing cattle on only poor roughage plus fish meal. (*See* **Beef**.)

Source of Raw Material

The main producing and exporting countries of fish meal are shown in Figure 1. South America, Japan, the former Soviet Union and the Scandinavian countries are the main producers. These same countries, with the exception of Japan and the former Soviet Union, are the major exporters.

The principal species of fish processed into meal and oil in these countries are listed in Table 2, together with the name commonly used (sometimes erroneously) in the fish meal trade to describe these types of fish meal.

One of the distinguishing features of the fish meal industry, compared with other sectors of the fishing industry, is the ability to process large volumes of fish in a short time. A company in South America could be processing 250 000 t of fish in a year and, because of the seasonal nature of the fishing, the storage capacity of the plant would be greater than 1000 t of fish.

Because ambient temperatures in the north of Chile and in Peru are relatively high, it is necessary to have the capacity to process the stored fish in 24 h or less. Fish stored at 30 °C will soon turn into a hydrolyzed liquid, resulting in considerable losses of raw material and reducing the yield of the meal. In addition, the quality of the meal produced by such stale fish is poorer than that produced from fresh fish, resulting in poorer performance from livestock fed on the resultant meal. Most manufacturers now monitor the freshness of raw material by measuring its volatile nitrogen content. The lower this is, the fresher the raw material. Special-product fish meals for farmed fish, early weaned pigs, and ruminants are made from fish with less than 90 mg of volatile nitrogen per 100 g of fish.

In colder climates, such as Iceland, it is possible to store the raw fish for much longer periods than in tropical or semitropical climates.

Over the years, a number of chemical agents have been added to the raw fish in order to extend its shelf-life. However, this practice is currently not

very common and physical means of preservation, such as icing or holding in refrigerated sea water, are more in favor.

Manufacture of Meal

Almost all fish meal is made by cooking, pressing, drying, and grinding fish in machinery designed for that purpose (Figure 2). On some occasions the pressing stage may be omitted since with white-fish raw material there is little oil to be removed.

When fish are cooked, the protein is coagulated, much of the water and oil separates and can be removed by pressing; raw fish, on the other hand, even when subject to very high mechanical pressure, lose very little liquor. A cooker consists of a long cylindrical plant, the outside of which has a steam jacket, and through which the fish are moved by a screw conveyor. Some cookers also inject steam into the cooked material. No drying occurs during cooking. Cooking has an important sterilizing action and assists in insuring freedom from undersirable microorganisms.

After cooking, the fish is pressed in order to remove some of the water and oil. A mixture of oil, water, and some solids is squeezed through the perforations of

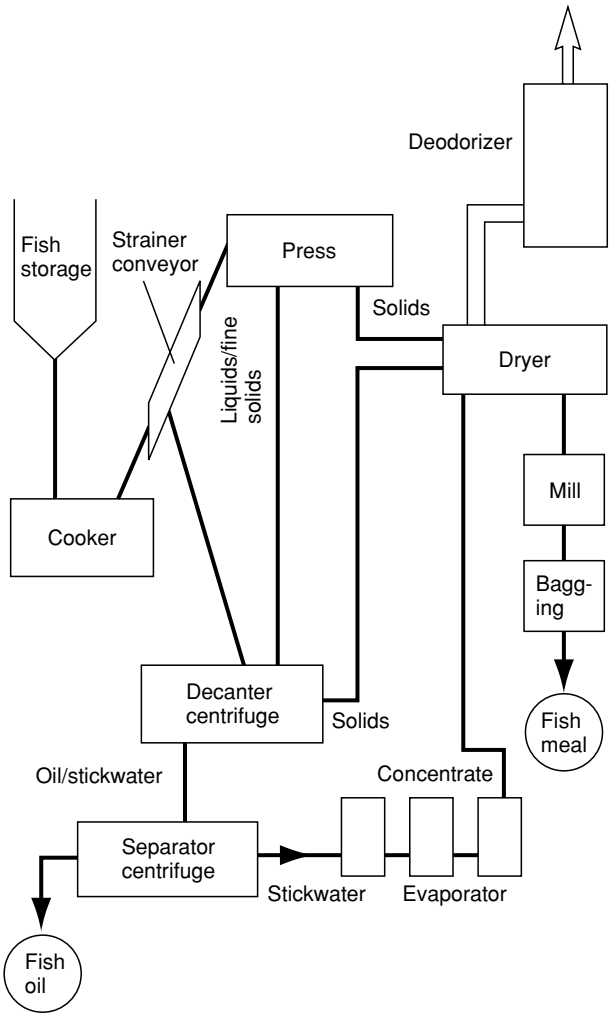

Figure 2 Fish meal processing, shown in diagrammatic form. Reproduced from Fish Meal, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

the press and later these three phases are separated; the solids and the concentrated aqueous phase (stickwater concentrate) are returned to the presscake from the end of the press and the separated oil is polished and stored as a separate product.

The presscake, together with the recovered solids and the stickwater concentrate, is then introduced into a drier to reduce the moisture level down to 10% to make the product stable.

There are two main types of drier – direct and indirect. In the direct drier, very hot air at a temperature of up to 500 °C is passed over the material as it tumbles rapidly in a cylindrical drum. The indirect type of drier consists either of a steam-jacketed cylinder or a cylinder containing steam-heated disks which also tumble the meal. Some recently developed driers operating at lower temperatures use indirectly heated hot air, or vacuum drying. The fish meal produced is sometimes referred to as a low-temperature product, particularly suitable for fish, early-weaned pigs, and mink.

Storage of the Finished Meal

Most fish meal, except white-fish meal, contains a residue of 8–12% of lipid which could not be pressed out of the product economically. This lipid reacts with oxygen and produces heat, which if not controlled properly can result in scorching or even ignition of the fish meal during storage. Thus most of the world's fish meal contains added antioxidant. This is normally ethoxyquin added at a level of about 750–1000 p.p.m. (*See* **Antioxidants**: Synthetic Antioxidants.)

The meal is then cooled through a rotary cooling drum, or, more usually, stored directly in 50-kg bags or in heaps of several hundred tonnes on the ground or in warehouses. The bags are stacked in

such a way as to allow a circulation of air in the vicinity of each bag, so that any heat produced during storage as a result of residual oxidation of the meal is easily removed to the atmosphere. Bulk heaps of meal are turned by means of payloaders from time to time. This again allows any heat produced in the meal to escape. Most large storage areas of meal are equipped with thermocouples which constantly measure the temperature of the meal to insure that there is no risk of overheating.

Provided that the meal has been treated with antioxidant and maintained in a dry condition, and not allowed to overheat, it is possible to store the product for longer than 12 months without any change in nutritional quality. If moisture levels are allowed to rise above 15%, undesirable bacteria and mold growth may occur; this is true for most types of feedstuffs and organic material.

FISH OILS

Contents

Production

G M Pigott and B W Tucker, Sea Resources Engineering, Inc., Kirkland, WA, USA

Production of Fish Oils

The importance of fish oils has increased greatly during recent years as the nutritive value of certain components is being emphasized. Prior to this time, unrefined foul-smelling oxidized fish oils known as 'cod liver oil' were spooned as a vitamin supplement for vitamins A and D. Later, partially refined and hydrogenated fish oil was used for the manufacture of margarine. However, most of the oil was, and is, used for industrial purposes such as components in paints, varnishes, and lubricants, where the quality for human acceptance as a food receives little consideration.

Highly refined fish oils are now in demand for their ω-3 fatty acids, which have been shown to have a profound effect on the cardiovascular and neurological systems. During the last few years, beginning with menhaden oil, fish oil is being approved for human consumption as food supplements and as an ingredient in foods. This creates a demand for better quality control through improved handling of oil in conventional meal plants and in other commercial processes in which fish oil is a by-product. Great improvements have been, and are being, made in maintaining the condition of raw materials and primary products so that fish oil does not have any major oxidation problems prior to extracting and/or refining oil for human and animal consumption.

The term 'fish oil' or 'marine oil' is normally used for the class of lipids that originates from the marine and freshwater bodies of the world, as opposed to those from land plants and animals. Any plant or animal raised in these aquatic environments has the high profile of ω-3 fatty acids not found in most land plants and animals. Hence, by practice, since the large majority of oils from this aquatic environment come from fish, marine oils, fish oils, and aquatic plant and animal oils are used interchangeably throughout the world and are commonly called fish oils.

Fish to be used as a source of oil must be cooled and stored at refrigerator temperatures to minimize enzymatic breakdown of certain components. Unfortunately, this is often not possible in tropical and subtropical areas, and the resulting quality of both the fishmeal and oil is significantly reduced. Not only does spoilage and oxidation occur, but also such degradation results in the formation of compounds, such as sulfur, which are catalyst poisons.

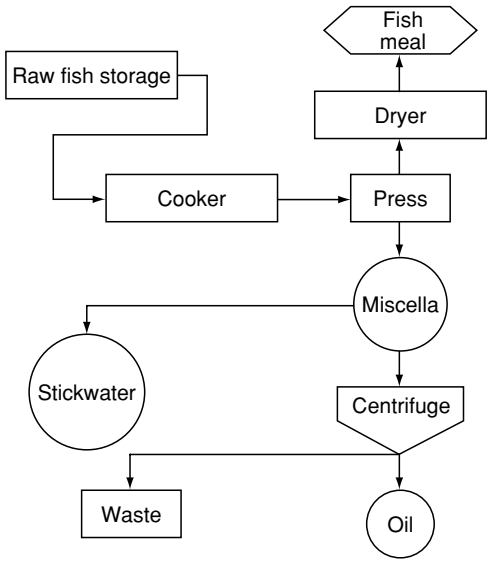

Figure 1 Conventional fish meal process.

Extraction of Fish Oils

Although both extraction and refining technology is advancing rapidly, most of the fish oil being produced in the world is as a byproduct of the conventional fish meal process, a wet rendering technique. Other processes include rendering, hydrolysis, silage production, solvent extraction, critical extraction, and ion exchange. Other new techniques are rapidly being developed to ensure a high-quality product for human and animal food. The superiority of high ω-3 fish oils is creating a demand for these oils to become a common component in engineered and formulated foods consumed by humans.

Conventional Fish Meal Process

Other than improving the machinery and equipment made possible by technical developments, the conventional fish meal process has not had any major procedural changes for the past 50 years. The process, as depicted in Figure 1, involves cooking, pressing to separate the liquid from the solids, and drying the solids. The liquid phase contains water, oil, water solubles, and suspended solids. Oil is removed from the mixture by centrifuging, after which it is pumped into large storage tanks to await bulk shipment to market. The large fish meal operations are designed for processing several hundred tonnes of industrial fish per day. Some of these plants can handle 50–60 tonnes of fish per hour and are located in areas of the world where large schools of fish such as menhaden, herring, sardines, and anchovy are located.

Until recently, a large portion of the world's fish meal products were produced from the large resource of industrial fish in Peru and Chile. However, with the growing market for high-quality fish oils and the decrease in numbers of wild fish in South America, there is a steadily increasing amount of oil being produced in other areas. Often this is related to growing government environmental regulations limiting the amount of processing waste that can be discarded into bodies of water.

Cooking Cooking the raw fish is necessary to coagulate the proteins, thus allowing the separation of oil from the solids. There are several types of cookers used in fish meal production. The most often used is a steam-jacketed cooker where the heat is supplied to the fish from steam passing through a jacket that surrounds the cooker. Many cookers also have a steam-heated augur in hollow flights that agitate the cooking fish as well as supplying additional heat.

Batch cookers are used in some processing plants, but the large volumes of fish passing through a conventional meal plant require a continuous process. This improves the economics, consistency, and quality control of the fish oil.

Pressing and drying Cooked fish solids are separated from the liquid phase by a press, normally a single screw or a multiscrew press. Wet solids emerging from the press are called 'the press cake.' The liquid phase, or press liquor, as it comes from the press contains water, oil, water solubles, and suspended solids. From the press, the press cake is passed through a continuous direct or indirect dryer to remove the moisture. The resulting fishmeal is the

primary product of this process, and oil is considered a byproduct that varies in composition and yield.

Separating oil from the press liquor Oil is separated from the other liquid components by first passing the press liquor over a vibrating screen and then centrifuging. The screen removes the solids that have been carried over during the processing operation. An oil quality-control operation, called 'polishing,' is often carried out whereby steam or hot water is used to wash or strip the oil. This final washing and then centrifuging procedure removes many of the contaminants that contribute to degradation during storage. Still quite warm from the cooking process, the oil is pumped into large holding tanks, where it is held for shipment. The solids recovered during screening of the press liquor are added to the press cake prior to drying. The remaining water phase of the press liquor is often sprayed on to the fish being dried in the dryer. This recovers the dissolved solids and reduces the environmental impact of disposing of them in the wastewater.

With the increasing importance of preventing oxidation of the ω-3 fatty acids used for human foods and health, oil should be cooled before being stored and should be introduced into the tank near the bottom and removed from the top. In fact, the quality of oil from conventional fishmeal plants can be significantly improved if it is immediately cooled after being extracted from the hot cooked fish residue and before being pumped into the storage tanks. In order to keep the free fatty acid content low during storage of oil, sludge from the bottom, which contains bacteria and other microorganisms, and water on the surface should be regularly removed. Also, an antioxidant is usually added to the oils after centrifuging, or during other phases of the processing, to further reduce oxidative degeneration during storage.

Dry Rendering

Dry rendering is carried out in a single cooker–dryer in which the fish are cooked and dried to the final product in one operation. This process is quite popular in meat plants where both bone meal and meat scrap meal is made from the low-fat continuing byproduct materials. However, since the fat or oil is not removed in the dry rendering process, the technique is used only in small fish processing plants that utilize low-fat fish. The normally utilized industrial fish containing over 5% oil would render a meal containing 20% or more oil. This would be a gummy, highly oxidized product of little commercial value.

There have been numerous efforts to modify dry rendering techniques for fishmeal, but the economics of processing have prevented viable commercial application. Certainly, in the future, as fish oil becomes a normal component of human foods, some of the processes abandoned in the past will be modified and utilized.

Hydrolysis

Fish flesh can be hydrolyzed by proteolytic enzymes, either endogenous or added, to produce a high-quality functional protein product. The general scheme for this process is shown in Figure 2. Excess oil is removed by centrifugation, or, with high-fat fish, some of the oil comes to the surface and can be decanted. Since the resulting liquefied product has good emulsion abilities, there is a certain amount of oil left in the finished product. In fact, up to 5% oil remains in the protein hydrolysate due to the formation of a water–oil emulsion. If the hydrolysate is dried to remove water, the oil remains in the dried product.

Depending on the proteolytic enzyme chosen, the process is carried out under either acid or basic conditions. The process of hydrolysis carried out by endogenous enzymes at a low pH (e.g., 2–4) has an advantage in that the resulting product is quite stable from spoilage by microorganisms. However, the reaction can be slow and uncontrollable, depending on the source and portions of fish used as substrate. The hydrolysis by endogenous enzymes varies quite widely, depending on the amount of feed in the

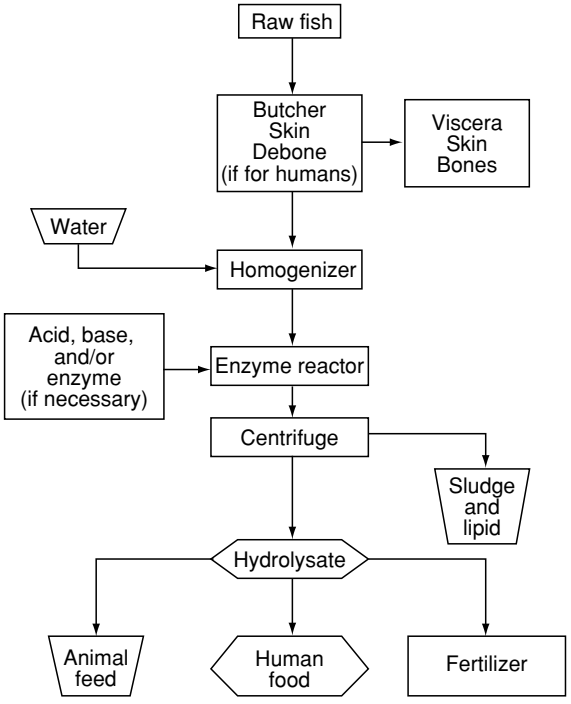

Figure 2 Fish hydrolysate process.

harvested fish stomachs. This is due to the activation of stomach enzymes by the amount and type of food being ingested.

When endogenous enzymes are used for hydrolysis, with an acid addition that maintains the pH at 4 or below, the product is known as 'fish silage.' The crude product resulting from this form of hydrolysis is used for animal feeds or fish fertilizer. As a fertilizer, the product has many advantages since it is a highly digested liquid that can be used as an efficient foliage spray. The resulting hydrolyzed fish product, when properly processed to the end point, has little fish odor and is much more efficient than petrochemical fertilizers, as well as being environmentally friendly.

Hydrolysis can be accomplished at higher pH values, particularly in the basic range, using enzymes extracted from vegetables or manufactured by microbial action. Some of these enzymes are much more efficient than endogenous enzymes in that processes can be more precisely controlled and completed in much less time. However, there is a negative factor in using processes that require near neutral or basic conditions, since the products have a short shelf-life unless stabilized after the hydrolysis is complete.

Solvent Extraction

There has been a considerable amount of work involving the extraction of fish oils by solvents. Alcohol was used in a major development program during the 1960s and 1970s backed by what is now the US National Marine Fisheries Service, National Oceanographic and Atmospheric Administration. This program, an effort to make fish protein concentrate for human consumption, was a dismal failure due to the poor economics of the process. Alcohol, a polar solvent, is not an efficient fat extractor since it preferentially removes water and results in the necessity for carrying out several extractions to ensure recovery of the oil. The cost of removing water by solvent and reclaiming the solvent from the emulsified residue of water, oil, and water solubles is economically unsound.

Extraction with nonpolar solvents is an efficient method of removing oil from animal raw material. A process using ethylene dichloride as the solvent was used commercially for animal feed. This is an efficient and safe process if properly supervised and controlled. However, the problems involving the use of a toxic solvent and the subsequent governmental restrictions prevented extensive use of this solvent for preparing human fish protein concentrate.

The recovery of high-quality oil has proven to be a problem with all solvent extraction processes. The solvents remove many pigments and other components not desired in the oil, and the economics of recovering pure oil from the solvent have not been satisfactorily solved. However, newer techniques are being developed.

Purification and Storage of Oils

Alkaline/Acid Treatment

Purification or refinement of fish oils involves a series of alkaline and acid treatments to remove unwanted products. Alkaline treatment removes the free fatty acids and products of oil decomposition, which produce the strong rancid flavor and odor. It also coagulates the protein to release the oil. The process involves agitating the oil with alkali for various times depending on the temperature and fatty acid content of the oil. Following this treatment, often involving 12 or more hours of agitation and settling, the clear oil is washed with hot water to remove the residuals and the remaining caustic compounds. Pigments must be removed by bleaching, usually by natural or activated clays.

Lipase Hydrolysis

Over the past decade, the use of microbial lipases to produce *n*-3 fatty acid concentrate has been studied. A major advantage of this technology is that there are no extremes of pH or high temperatures, which have an adverse effect on fish oil *n*-3 highly unsaturated fatty acids (eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)). This technology has tremendous potential for conserving processing energy and increasing the selectivity of specific products. Furthermore, the resulting acylglycerol/ethyl ester mixture can be distilled with much less adverse effect than when fish oil is distilled.

Resin Refinement

A cold process utilizing macroporous cation resins has been developed for improving fish oil chemical, physical, and sensory quality characteristics. Resins include both weak and strong cation and anion resins. Results have been reported indicating that a strong acid cation resin process results in many characteristics that are superior to molecular distillation and thawing fractionation.

Special Products from Fish Oils

Liver Oils

The chemical structure of fish oils gives them certain desirable properties for human consumption and other uses. Certain species of fish with low-fat flesh, such as cod, store most of their oil in their relatively

large livers. This oil was a valuable source of vitamins A and D until the development of less expensive synthetic forms of these vitamins in the late 1940s destroyed the fish liver oil market. Oil from livers is separated by gentle heating with steam. The oil is then washed and centrifuged.

Concentrating Fatty Acids

Various methods have been developed for extracting certain components from fish oils for specific medical or nutritional value. These processing techniques include distillation, crystallization, various chromatographic methods, and supercritical fluid extraction. The pharmaceutical value of fish oil components depends on maintenance of their natural form and structure. For example, it is important to retain the *n*-3 highly unsaturated (long-chain) fatty acids (HUFA) if they are to be valuable in human health. Not only are whole body oils a source of these special fatty acids, but fractionated oils are valuable as a concentrated source of specific desirable fatty acid esters such as those of EPA and DHA.

Molecular distillation Molecular stills can be used for separating oil components based on the molecular weight of the specific component and its vapor pressure. The large difference in molecular weight of vitamins A and D allows good separation of the two components in fish liver oils. Conversely, the small differences between many fatty acid components in oil make it difficult to accomplish effective separation or enrichment of a particular fatty acid.

Chromatographic techniques Fatty acids in fish oils can be fractionally crystallized at low temperatures by mixing them with solvents in which certain fatty acids are more soluble. Separation of components in fish oil can be made by chromatographic techniques in which each component will move through at a different rate in a two-phase system.

Supercritical Separation The potential for commercial scale separation of oil components (e.g., EPA and DHA) was significantly improved by the development of fractionation techniques involving supercritical fluids. Carbon dioxide is the most widely used solvent for food and pharmaceutical products since there are no residual problems involving toxicity, flammability, or environmental pollution. At a pressure of 7384 kPa (1071 psi) and a temperature of 31.1 °C, carbon dioxide becomes a supercritical fluid. As such, it acts as a solvent capable of enriching certain components in an oil. By complexing fish oil with certain chemical compounds (e.g., urea for concentrating EPA and DHA), continuous countercurrent extraction will yield highly enriched products and enriched still raffinate or bottoms. For example, EPA and DHA can be separated from urea-complexed fish oil by this method. In this case, the product is highly enriched EPA concentrated in the raffinate.

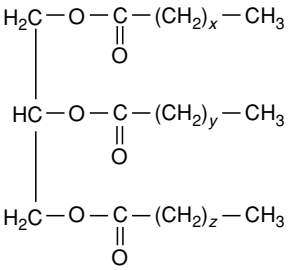
Background

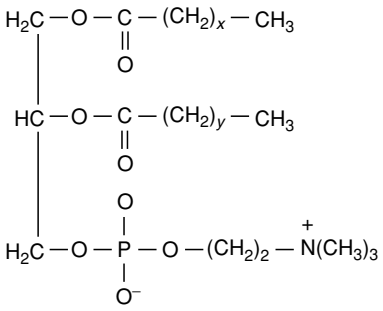
Knowledge of the chemistry of fish oils has expanded rapidly during the past few decades, beginning with the development of gas chromatography (GC). More recently, interest in the healthful effects of ω-3 highly unsaturated fatty acids (HUFAs) has spurred identification and characterization of the fatty acid constituents of triglycerides (triacylglycerols).

Composition

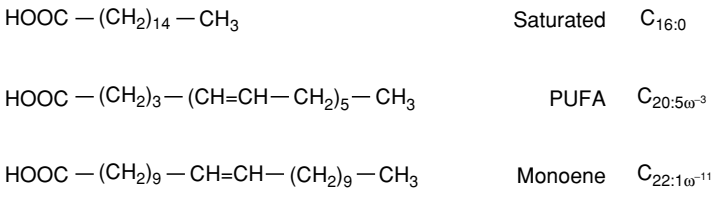
Lipids occurring in fish oils are mostly the saponifiable triacylglycerols, with far lesser amounts of di- and monoglycerides. Also present are the unsaponifiable



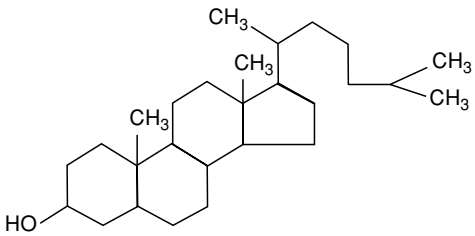
Triglyceride



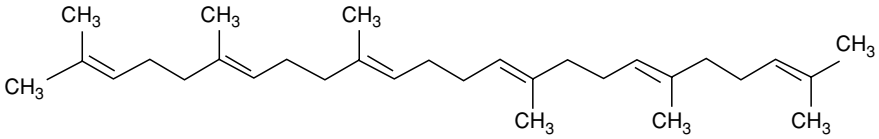
Lecithin



Fatty acids



Cholesterol



Squalene

Figure 1 Examples of component compounds found in fish oils. Three representative fatty acids (saturated, monounsaturated, and polyunsaturated) typify those found in fish oil triglycerides. Lecithin is the major phospholipid present; cholesterol is the major sterol. Squalene is a hydrocarbon often present at low levels. Reproduced from Fish Oils: Composition and Properties, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

phospholipids, sterols, wax esters, hydrocarbons, and, in certain species, diacyl glyceryl ethers, also known as alkoxydiglycerides. Additionally, minor fat-soluble components such as vitamins, pigments, and contaminants may be present as well as oxidation products. (*See* **Fats:** Classification.)

Fatty Acids

The fatty acid component of the triglycerides and other lipids are saturated, monounsaturated (monoenoic), or polyunsaturated (polyenoic) chains with lengths generally of 12–24 carbon atoms (Figure 1). More than 95% of these chains have even numbers of carbon atoms and are *cis*-oriented. Up to 5% may be odd numbered (Table 1), branched chain, and/or furanoids (F acids). Although 60–80 fatty acids have been identified from a single species, there are four pairs that comprise 80–85% of the fatty acids in fish oil: $C_{14:0}$ and $C_{16:0}$, $C_{16:1}$ and $C_{18:1}$, $C_{20:1}$ and $C_{22:1}$, and $C_{20:5}$ and $C_{22:5}$. The nomenclature specifies first

Table 1 Range of selected fatty acids in commercial fish oils

	Range of total fatty acids (%)		
Fatty acid	*Menhaden oil*	*North American herring oil*	*Mullet oil*
$C_{14:0}$	7.2–12.2	4.6–8.4	4.6–11.5

the number of carbon atoms in the chain and next the degree of unsaturation (or number of double bonds) present. (*See* **Fatty Acids**: Properties; Metabolism.)

Compared with other oils or fats, fish oils contain not only a greater variety of fatty acids, but also considerably more long-chain HUFAs. The basic pattern of fish triglycerides usually finds polyenoic fatty acids preferentially bound in the middle (2) position, with monoenes at the ends (1 and 3 positions), although not all species conform to this pattern. Saturated fatty acids comprise 20–35% of the total fatty acids in most fish oils, although herring oil may be up to 50% saturated. The $C_{16:0}$ content is between 10 and 25%, that of $C_{14:0}$ is 3–13%, and that of $C_{18:0}$ is 1–4%. Proportions of fatty acids vary considerably between and within species. Herring oil is characterized by its high percentages of long-chain monoenes, usually about 30%, but often more. Menhaden oil has more $C_{14:0}$ and less $C_{22:6}$ than other fish oils. Monoenoic fatty acids, often present in significant quantities include $C_{16:1}$, $C_{20:1}$, and $C_{22:1}$, the last two being mainly exogenous, originating as dietary components. Cetoleic acid, $C_{22:1\ \omega-11}$, is the major isomer, whereas erucic acid, $C_{22:1\ \omega-9}$, is a relatively minor component. (*See* **Triglycerides**: Structures and Properties.)

More than 90% of the polyunsaturated fatty acids (PUFAs) in fish oils are of the ω-3 configuration: an ethylene bond at the third carbon from the nonpolar or ω end of the molecule. These PUFAs make up 30–40% of the total fatty acids, whereas ω-6 fatty acids constitute less than 10%. In contrast, PUFAs in vegetable oils are almost all ω-6, with less than 5% being ω-3. (*See* **Vegetable Oils**: Dietary Importance.)

Fish oils are characterized by ω-3 HUFAs with five or six ethylenic bonds per acid, and their presence reflects the composition of the diet and other environmental factors, especially water temperature. Fish from colder waters contain larger amounts of HUFAs, which allows more cell membrane flexibility. As related to human health, the most important HUFAs are eicosapentaenoic acid (EPA), $C_{20:5\ \omega-3}$, and docosahexaenoic acid (DHA), $C_{22:6\ \omega-3}$. Although up to 50% of the total fatty acids in certain species may be made up by these fatty acids, the usual concentration found is 17.5–33% with a considerable variation between and within species. Pink salmon contains about 32% HUFAs, whereas the sablefish content is only about 7%.

The influence of environmental factors on HUFA content is illustrated by the difference in DHA levels in menhaden oil. In one study of menhaden, large samplings over 2 years at various times from the Atlantic coast of North America showed a DHA content ranging from 7.3 to 13.1%, whereas the content in menhaden from the US Gulf of Mexico coast was 4.2–8.2%. Another study of herring oil indicated that the EPA contents from Alaskan fish ranged between 11.4 and 15.2%, whereas herring from the east coast of Canada contained just 3.9–8.8%.

Farmed fish (aquaculture) have fatty acid profiles reflecting the fatty acid composition of their feed. Fish oil containing high levels of EPA and DHA is included in feeds used in production of both freshwater and marine species, not only to provide essential ω-3 fatty acids for fish health, but also to generate products nutritionally similar to wild species.

Unreliability of Data

This general discussion of fish oil composition must be qualified. Much available data on fish and fish oil composition are taken from single samplings, small numbers of fish, or samples from specific days. Unfortunately, such data have come to be considered true for all oil from a specific fish species. There exists a difference between species as well as a significant variation in a single species that is influenced mainly by season, but also by catch year, geographical location, spawning cycle, maturity or age of the fish, water temperature, and salinity. The composition of available feed that is determined by the forementioned variables contributes the most significant factor. Even analyses of commercial fish oil from many thousands or millions of fish will vary (Table 1). Statistically reliable data on fatty acid content in fish oil are lacking for nearly all species analyzed. Because of the wide fluctuation in oil content in a single species owing to these variables, data on the average oil content are not meaningful.

As much as a 10% variation in oil content among individual fish of the same species may be found. Fatty acid analyses of commercial fish oils given as ranges of values are more predictive of actual content than data from analysis of oil extracted from a small number of specimens of fish or fish tissues. Additionally, oil as a byproduct of fish meal production will have a different fatty acid content than oil from the same species that has been solvent extracted, perhaps owing to phospholipid fatty acids remaining in the fish meal. HUFAs are particularly susceptible to this phenomenon. (*See* **Fish**: Fish as Food.)

Liver Oils

Fish liver oils contain slightly different proportions of triglyceride and phospholipid fatty acids, as well as minor components, than body oils. The DHA concentration is apt to be higher than in herring or menhaden body oils. Shark liver oils may have amounts of diacylglyceryl ethers approaching those of triglycerides. These glyceryl ethers are also found, to a far lesser degree, in certain shark body oils and a few other species of fish. The fatty acids of these alkoxydiglycerides are predominantly saturated, and monoenoic in the etherlinked portion, and the esterlinked fatty acids are about 25% HUFAs.

Minor Components

Phospholipids, approximately 50% lecithin and 25% cephalin, contribute to the total fatty acid, especially HUFA, content. Phospholipids are associated with cell membranes and, therefore, are scarce in oil produced as a byproduct of meal production. Hydrocarbons are present at very low levels in most fish oils, but the liver oil of several species of shark may be up to 90% squalene (Figure 1) with small amounts of pristine and zamene. Hydrocarbons are usually found in those fish oils containing alkoxydiglycerides. (*See* **Phospholipids**: Properties and Occurrence.)

Sterols, almost all being cholesterol (Figure 1), are always present in crude fish oils, with concentrations between 5 and 8 mg per gram of oil. Processing, however, can remove much free cholesterol and some cholesterol esters.

Wax esters, while present in certain species of fish (e.g., orange roughy), are not found in liver oils or in marketed fillets as the esters occur just under the skin and are removed by deep cutting during fillet preparation. The fat-soluble vitamins A, D and E are always found as minor components, although levels present are subject to the variables previously mentioned. While body oils contain relatively low amounts of A and D, liver oils are considerably higher. Menhaden oil contains 60–150 RE/g of vitamin A and 1.25–2.50 μg/g of vitamin D. Vitamin A in halibut, shark and tuna liver oils is of high potency (up to 210 000 RE/g) while cod liver oil has a lower content (up to 1800 RE/g). Vitamin D in cod liver oil is usually less than 2.5 μg/g while some tuna liver oils reach 1250 μg/g. Vitamin A in halibut, shark and tuna liver oils is of high potency (up to 700 000 IU g^{-1}), while cod liver oil has a lower content (up to 6000 IU g^{-1}). Vitamin D in cod liver oil is usually less than 100 IU g^{-1}, while some tuna liver oils reach 250 000 IU g^{-1}. (*See* **Cholecalciferol**: Physiology; **Retinol**: Physiology; **Tocopherols**: Physiology.)

The vitamin E (tocopherol) content of fish oils is similar to that of vegetable oils. Typical published values range between 40 and 630 $\mu g\,g^{-1}$, with cod liver oil about 560 $\mu g\,g^{-1}$ and herring oil about 100 $\mu g\,g^{-1}$.

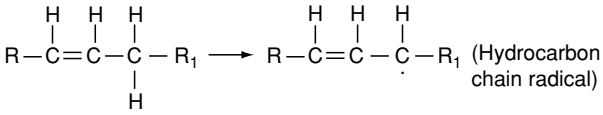
Carotenoid pigments such as astaxanthine may be present as a result of dietary components. These pigments give an orange–red tint to the oil. (*See* **Carotenoids**: Physiology.)

Oxidation and hydrolytic products, free fatty acids and amines, peroxides, carbonyls, and volatile compounds will be present to various degrees, reflecting the stability of the oil. Spoilage impurities from fish can contribute objectionable off-odors and off-flavors to their extracted oils. Insoluble matter, such as moisture, dirt, protein, and rust is removed or reduced to $< 5\%$. Soluble impurities include pigments, trace metals, oxidation and decomposition products (e.g., sulfur and phosphorus), mono- and diglycerides and unsaponifiables. Contaminants that occasionally may be found, depending on the source of crude oil, are pesticide residues and chlorinated biphenyls. The processing steps of hydrogenation and deodorization remove or reduce these compounds to nondetectable levels.

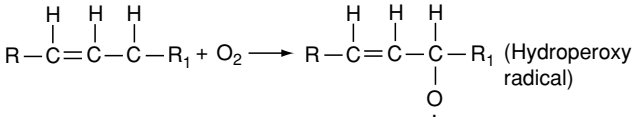
Stability

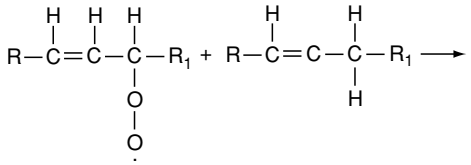
Deterioration of fish oils is associated with oxygen and/or heat. Free fatty acids are hydrolytic products of triglycerides, and levels above 3% are indicative of poor oil quality. Most changes, however, are the result of oxidation of fatty acid portions of triglycerides. The ethylene bonds of fatty acids are very reactive and combine with oxygen and peroxides. Because fish oils are highly unsaturated, they are more vulnerable to exposure to air than vegetable oils, even though the oxidative mechanisms operate in the same manner, albeit at an increased rate. An induction period during which changes are not readily detected is followed by autoxidation involving formation of free radicals and free radical chain propagation (Figure 2). During this time, free radicals react with oxygen to form hydroperoxides. Terminal

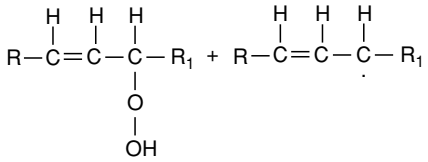
Initiation step:



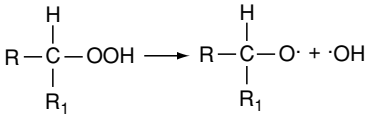
Propagation steps:





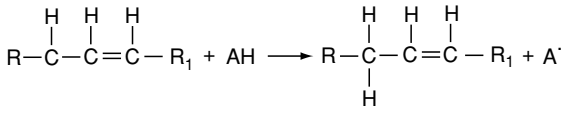


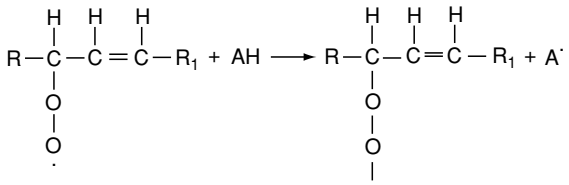
Decomposition of the hydroperoxide forms additional radicals:

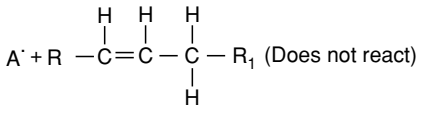


LIPID OXIDATION

AH represents the antioxidant:







ANTIOXIDANT ACTION

Figure 2 Oxidation and free radical chain propagation leading to rancidity. Antioxidants inhibit and interrupt free radical propagation. Reproduced from Fish Oils: Composition and Properties, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

oxidation products include peroxides, carbonyls such as malonaldehyde, and objectional flavor and odor compounds created by the decomposition of peroxides and oxidation of breakdown products. Plots of storage time versus degree of oxidation give a typical induction curve, indicating an accelerating oxidation rate. The increase in carbonyls and hydroperoxides is roughly equivalent to oxygen uptake. Compared with most other oils, fish oils increase in peroxide value (PV) earlier and the break in the induction curve is less sharp. (*See* **Oxidation of Food Components**.)

Flavors and Odors

'Fishy' flavors and odors occur early in oxidation and will continue if the oil is stored with limited access to air. Even when the PV is low, reversion flavors, characterized as 'beany' or 'grassy,' can be present. Reversion is characterized by a return to preprocessing flavors after storage and occurs before the onset of rancidity. The rancid odors and flavors developing later are typical of all rancid fats and oils. Capillary gas-chromatographic methods for analysis of volatile products have made possible the chemical identification of specific odours. Fish oil stability is best maintained by low-temperature storage and exclusion of oxygen. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics; **Sensory Evaluation**: Aroma.)

Sometimes fish oils are produced from fish that have not been properly refrigerated, and considerable bacterial or enzymatic spoilage may have occurred. Volatile products of spoilage will be partially transferred to the oil. Initially, spoilage products that predominate are nitrogenous, especially trimethylamine. Later, sulfur compounds may contribute to the more obnoxious odors as well as act as catalyst inhibitors.

The presence of prooxidants, such as free fatty acids and other natural impurities, hematin compounds, metal ions, peroxides, heat, air, and light as well as antioxidants and the levels of ω-3 fatty acids, determine the length of the induction period. With ω-3 fatty acids, there is a less distinct break in the induction curve, and antioxidants are less effective during this period. Since chemical tests do not give values that consistently correspond to a specific degree of rancidity, additional sensory evaluation by trained test panels is necessary for satisfactory stability determination. Different degrees of rancidity are readily detectable.

Antioxidants

Antioxidants are substances that, at relatively low concentrations, inhibit the rate of reaction of an oxidizable substrate with oxygen by reacting with a free radical early in the oxidation process. The intermediate compound formed is unable to continue the free radical chain reaction. Synthetic antioxidants – polyphenolic compounds – are added to fish oils to increase induction periods, as they are more effective than the naturally occurring antioxidants that are present in oils of both fish and plants. The tocopherols, eight or more, but mostly α-tocopherol, occur over a range of concentrations in fish oils from 40 to 630 μg per gram of oil. While the vitamin E activity is highest in α-tocopherol, antioxidant activity is less than in some of the other tocopherols. The tocopherols are readily oxidized and are destroyed by heat. Among compounds that exert synergistic antioxidant activity are lecithin, squalene, and metal sequestrants such as ascorbic, citric, and phosphoric acids. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

Determination of Fatty Acids and Triglycerides

Gas–liquid chromatography (GLC) is a commonly used method for lipid analysis. Although marine fatty acids are generally derivatized by transesterification, saponification and extraction followed by derivatization to fatty acid methyl esters (FAMEs) may be used. Separation of lipid classes and purification of FAMEs before GC, mass spectroscopy, and Fourier transform infrared spectroscopy, which enable analysis of individual fatty acid derivatives separated by GLC, is followed by computer prediction of identities. High performance liquid chromatography (HPLC) provides higher resolution and greater accuracy, but is more expensive and not universally available. HPLC can identify individual triglycerides (acylglycerides) while mono and diglycerides may be determined, after HPLC separation, with an evaporative light scattering detector. (*See* **Chromatography**: Thin-layer Chromatography; Gas Chromatography; **Fatty Acids**: Analysis; **Mass Spectrometry**: Principles and Instrumentation; **Triglycerides**: Characterization and Determination.)

Chain length can be determined by the linear relation between the logarithm of retention time and the number of carbon atoms. **Tables** of calculations of equivalent chain length (ECL) may be used to identify FAMEs separated by GC.

Further refinement of GC and related technology culminated in a collaborative study to develop an Association of Official Analytical Chemists (AOAC)-approved method to analyze fish oils and fish oil ethyl esters of PUFAs. This method, utilizing wall-coated open tubular GC (WCOT-GC) and flame ionization is especially suitable for analysis of

encapsulated fish oil and concentrated ω-3 components obtained by fractionation from triglycerides.

When such instruments are not available, GC may be used with several other AOAC, American Oil Chemist's Society or International Association of Fish Meal Manufacturers methods such as bromination, hydrogenation, argentation TLC, urea adduction, ozonolysis and/or hydrazine reduction. Bromination distinguishes between saturated and unsaturated FAMEs, as does hydrogenation with reanalysis. Argentation TLC involves separation of FAMEs on silver nitrate-impregnated silica gel-coated TLC plates followed by GC analysis of the fractions. Urea crystallization concentrates branched-chain, cyclic, and unsaturated FAMEs or nonesterified acids. Ozonolysis has long been used to determine the structure of unsaturated fatty acids and esters. The resulting ozonides are then fragmented by chemical reduction or oxidation. Partial hydrazine reduction can locate ethylene bonds.

Determination of Minor Components

Lipids that are present in relatively small amounts or are present in oil from very few species include phospholipids, cholesterol, hydrocarbons, and diacylglyceryl esters. Triglycerides are extracted with diethyl ether, whereas chloroform–methanol extracts phospholipids. Cholesterol is determined by WCOT-GC.

Commercial fish oils are routinely analyzed for free fatty acids, iodine value (IV), moisture, impurities, and color. Free fatty acids are measured by titrating with alkali. The IV measures unsaturation and, therefore, the oxidation potential of the oil. Iodine combines with fatty acids at ethylene bonds and thereby enables a measurement of unsaturation. As oxygen or peroxides react at these bonds, the IV increases. By the Wijs method, oil is combined with potassium iodide, and values are expressed as grams of iodine absorbed per 100 g of sample. Moisture is determined by distillation with an immiscible solvent. The percentage of unsaponifiable matter is gravimetrically determined after several alkali extractions of saponifiables. Color is designated by Gardner numbers after comparison with consecutively numbered standards.

Determination of stability in fish oils involves analyzing for hydrolytic and oxidative degradation products. Chemical tests most often used are to determine free fatty acid, the IV, the thiobarbituric acid (TBA) value, the anisidine value and the gain in weight of the sample during the course of oxidation. Since these tests do not give values that consistently correspond to a specific degree of rancidity, additional sensory evaluation by trained test panels is necessary for satisfactory stability determination.

The hydroperoxide decomposition product, malonaldehyde, reacts with TBA to give a pink color. PV indicates the content of hydroperoxide, an initial chemical oxidation product. The hydroperoxides oxidize potassium iodide and the liberated iodine is titrated with thiosulfate. The anisidine value is related to the level of breakdown products of hydroperoxides present and measures unsaturated aldehydes. Vitamins and contaminants may be detected by several AOAC methods. Heavy metals are best detected with cyclic instrumental neutron activation, although atomic absorption spectrometry is adequate where only a few selected (known) metals are to be determined. Chlorinated biphenyls are best indicated by WCOT-GC. Refined fish oil ready for further processing has minimal identifiable impurities and is, essentially, all triglyceride. (*See* **Contamination of Food; Heavy Metal Toxicology**.)

Dietary Importance

R Rice, The Fish Foundation, Tiverton, UK

Fish Oils

The oils from cold-water fish are unique among all of the edible oils and fats. They are the only nutritionally significant source of the long-chain omega-3 (ω-3 or *n*-3) polyunsaturates. The liver oils from fish such as cod and halibut have an added feature in that they are the major natural sources of vitamins A and D.

Changes in eating habits over the last 100 years have resulted in marked changes in fat intake, and in particular in the intake of the polyunsaturates considered essential for human health. Two families of polyunsaturates are considered essential, and they are known as ω-3 (or *n*-3) and ω-6 (or *n*-6). Average intakes of the ω-3 family have fallen considerably, while at the same time, intakes of the ω-6 family have increased dramatically. For reasons that will be explained, this change has placed more emphasis on the need to insure an adequate intake of preformed long-chain ω-3 polyunsaturates from fish. The causes and consequences of this change will be explored in what follows. In particular, attention will focus on the dietary role of the polyunsaturates, on the way in which dietary intake of polyunsaturates has changed over the years, and on the health impact of these dietary changes, in areas such as heart disease, inflammatory disease, skin, lung and kidney diseases, and mental health.

A summary of current suggestions for recommended intakes will complete this overview.

Dietary Polyunsaturates

Essential Fatty Acids

The world is now generally familiar with the concept that certain food components are vital to continued good health. Vitamins, minerals, and the essential amino acids are well studied and documented. What is less well known is that there are also certain types of fat that are essential to good health, fats which cannot be manufactured by the human body, and thus must be supplied preformed in the diet. The concept of 'essential' fats was originated by George and Mildred Burr and colleagues, working in the USA in the late 1920s. They found that rats fed on synthetic diets devoid of any fat developed scaly tails and skin problems that could be corrected by adding some corn oil. Their work started the thinking that there might be some factor or factors in fats that were essential to health. This work, and that of other pioneers such as Ralph Holman and Hugh Sinclair led to the realization that there were two distinct factors, originally termed vitamins F_1 and F_2. It was soon discovered that these factors were not vitamins as such, but nevertheless had significant health impacts if they were excluded from the diet. They were therefore called 'essential fatty acids,' and further work identified the two substances as polyunsaturated fatty acids, linoleic acid (18:2, *w*-6) and α-linolenic acid (18:3, *w*-3). Though this work was of necessity carried out on laboratory animals, such as rats, current nutrition thinking is that humans are equally in need of the essential polyunsaturates. The impact of a lack of dietary polyunsaturates is a long-term impact, with effects taking many weeks or months to become apparent. In such circumstances, it is difficult to see how ethical experiments could be designed to prove the need for the essential polyunsaturates in humans, though some data from human accident victims, and parenteral feeding studies do provide limited direct proof of their essentiality for humans.

Metabolism of Polyunsaturates

The dietary 18 carbon fatty acids linoleic and α-linolenic are converted, by a common enzyme system, into 20 and 22 carbon derivatives (see **Figure 1**). Since the conversion enzymes are the same for both ω-3 and ω-6 polyunsaturates, the phenomenon of competitive inhibition occurs. This means that if there is a predominance of one family over the other, the subordinate family gets crowded out of enzyme sites, and the conversion process favors the dominant family. The result is that an excess of the dietary ω-6 polyunsaturate linoleic acid inhibits conversion of the ω-3 polyunsaturate α-linolenic acid to the 20 and 22 carbon forms eicosapentaenoic acid and docosahexaenoic acid. Fish are the only nutritionally significant source of preformed long-chain ω-3 polyunsaturates, so consumption of fish can in principle compensate for the inhibition of the conversion process. However, in many Western countries, fish consumption is low and falling. The long-chain polyunsaturates (of both families) have most of the true biological functions of the essential polyunsaturates. These can be broadly categorized as:

1. Components of cell membranes, conferring critical properties on the membrane.
2. Precursors of short-lived, powerful biological regulators known collectively as eicosanoids.
3. Components in the regulation of gene-expression.

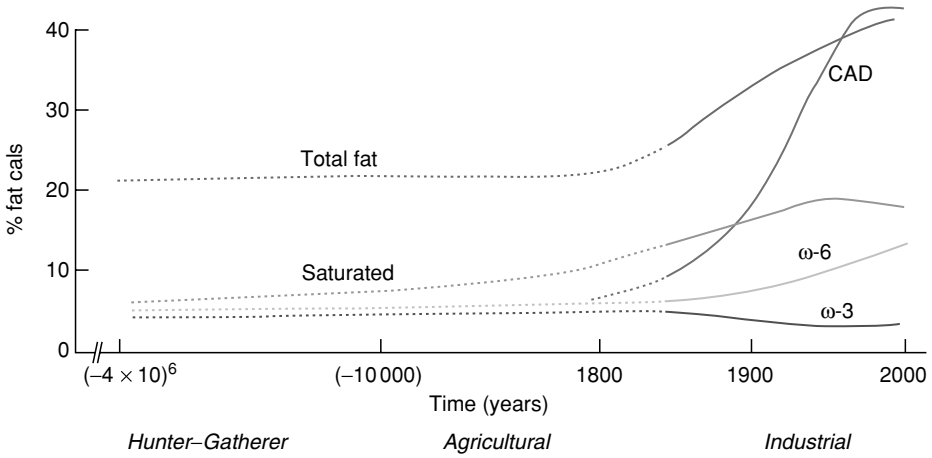

Figure 1 Dietary fat and polyunsaturate changes during man's evolution. CAD, incidence of coronary artery disease. From Leaf A and Weber PA (1987) A new era for science in nutrition. *American Journal of Clinical Nutrition* 45:1053 with permission.

Membrane Composition

All cells in the human body consist of a membrane surrounding the cell contents. These contents vary, depending on whether the cell is a skin cell, a bone cell, or indeed a nerve cell. Whatever job the cell does, the membrane surrounding it will be structurally similar, and an important feature is that it contains significant amounts of polyunsaturates. The exact structure and composition of the membrane in different cells within the body are determined by various factors including genetics, location, function, and diet. Diet affects membrane properties and function, by means of the amount and make-up of the polyunsaturates supplied in the diet and thus available for incorporation. Every cell in the human body has a need for both ω-6 and ω-3 polyunsaturates. Both are needed for optimal health, and if one or the other dominates, health can be compromised, as will be made clear in later sections.

Eicosanoid Precursors

The concept of endocrine hormones (such as insulin) is well established: these are chemical substances secreted into the bloodstream and carried by the circulatory system to any and every cell in the body, and which have specific receptors in target cells that react to the presence of the hormone, bringing about a change.

There is another system of regulators found within the body, known collectively as 'eicosanoids,' named after the 20 carbon fatty acids (Greek eicos=20) from which they are formed. These substances are much more powerful in their actions than the endocrine hormones, so much so that they cannot be centrally produced and distributed, but must be produced locally, in the cells where they are needed, and then destroyed soon afterwards. So far, two families of eicosanoids are well known and understood: the prostaglandins, and the leukotrienes. A third subgroup, known collectively as lipoxins, may also be a part of this wider group, though lipoxins are less well studied or understood at present.

The dietary 18 carbon polyunsaturates are metabolized to 20 carbon forms, which are then available for further metabolism by oxidative enzymes such as cyclooxygenase, or lipoxygenase. The oxidation products of the cyclooxygenase enzyme are available for further metabolism to prostaglandins, whereas the oxidation products of the lipoxygenases are further metabolized to form leukotrienes. Both ω-3 and ω-6 polyunsaturates are capable of being metabolized by these enzyme systems, and the resultant end products, though structurally similar, have functional properties that are slightly but significantly different. The point can be illustrated by reference to the circulatory system.

The clotting power of blood is obviously a valuable self-repair mechanism, but one that can sometimes be triggered when clotting is not needed, and this can lead to formation of a clot, or thrombus, within the intact circulatory system, resulting in a blockage of the flow of blood through a blood vessel. If this happens in an artery supplying blood to heart muscle, a heart attack can be triggered. If it happens in an artery supplying blood to the brain, a stroke can result. The circulatory system has an elaborate system of checks and balances to control this process. The cells that line the interior surfaces of blood vessels are known as endothelial cells, and they are equipped with an enzyme system that makes a substance called prostacyclin from the C20 polyunsaturates contained

within the endothelial cell membrane. Prostacyclin acts as an inhibitor of clot formation, so that if a blood clot comes into contact with endothelial cells, it is dissolved. If there is massive physical damage to the blood vessels, in circumstances where the clotting ability of blood is clearly required to prevent major blood loss, the endothelial tissue being destroyed by the trauma cannot make prostacyclin, and thus clotting is enabled. The proclotting system is based on a prostaglandin called thromboxane, and this is produced in the blood platelets circulating in the bloodstream. Enzymes within the platelet cell convert the C20 polyunsaturates in the platelet membrane to thromboxane. Both ω-3 and ω-6 polyunsaturates can be converted to prostacyclins and thromboxanes. However, and herein lies the significance, the thromboxane produced from conversion of the ω-3 20 carbon polyunsaturate eicosapentaenoic acid (EPA, 20:5, ω-3) is a weak promoter of clotting, whereas its counterpart produced from the ω-6 20 carbon polyunsaturate, arachidonic acid (AA, 20:4, ω-6) is strongly proclotting. The prostacyclin produced from the ω-3 family and the prostacyclin produced from the ω-6 family appear to have comparable levels of anticlotting power, so that the net effect of increasing the level of ω-3 polyunsaturates in cell membranes is to make clotting less likely. Of course, this can be carried to extremes, and if the ω-3 family dominates, clotting can be inhibited to such an extent that uncontrolled bleeding and subsequent blood loss can threaten life. Inuits eating their traditional diets have found themselves in this situation, and there are many reports of Inuits dying from blood loss after wounds and accidents. This imbalance is as much a problem as having too much ω-6, which predisposes to thrombotic diseases such as heart attacks and strokes.

Gene Expression

The way in which the information that is contained within the genetic code is actually put into physical form is called 'gene expression.' Though the mechanisms that are used to achieve this are known, there is still much to learn. At present, there is evidence to show that dietary polyunsaturates do have an influence over this process, but the precise way in which this influence is exercised is not understood.

Time Trends in Dietary Polyunsaturate Intake

In view of the fact that our ability to accurately measure small amounts of polyunsaturates has only existed since the mid-1950s, it is difficult to research the levels of dietary polyunsaturates much before this date. Estimates can be made, knowing the levels of polyunsaturates in certain foods (from modern-day measurements) and knowing what foods would have been available to eat at certain times. Using this approach, experts in the area have estimated that during the times prior to and during the period in which modern man evolved, the balance of the two families of dietary polyunsaturates would have been close to 1:1. Though many thousands of years may have passed since those times, evolution is such a slow process, that in evolutionary terms, the human race is still in the 'Stone Age' stage of physical development. It is therefore reasonable to assume that the biological systems that control human health today will be similar to those that evolved all those eons ago. Those systems evolved on a mix of the two families that was close to 1:1. Today, in the West, we have a diet that supplies around 10 times more of the ω-6 polyunsaturates than the ω-3s. This has come about because ω-6 intakes have increased while ω-3 intakes have declined, and much of this change has taken place within the past 50 years (see **Figure 2**).

Since the mid-1950s, data from the UK show that national intakes of the ω-6 family have more than doubled in response to advertisements promoting the cholesterol-lowering benefits of vegetable oils and margarines (such as sunflower, sesame, corn, etc.) in an attempt to increase protection against heart disease. At the same time, our national intake of ω-3 polyunsaturates has dropped, mainly as a result of reduced fish consumption and a preference for white fish like cod or haddock that have relatively low oil (and so low ω-3) content. A further complicating factor is that our ability to elongate the 18 carbon ω-3 polyunsaturate, α-linolenic acid to the 20 and 22 carbon forms is compromised by the current high intake of the ω-6 polyunsaturate linoleic acid (see **Figure 1**). Thus, not only is the dietary intake of the 20 and 22 carbon ω-3 polyunsaturates reduced, but our ability to make our own from the 18 carbon form is also reduced.

The overall consequence of these long-term dietary changes is that the cells in our bodies are increasingly being primed with the wrong mixture – too much ω-6 and not enough ω-3 – with variable effects depending on which part of the body is being considered.

Health Impact of a Change in Dietary Polyunsaturates

The exact impact of a change in the dietary balance between the two families of polyunsaturates will depend on which area of the body is under consideration. The following sections will examine the impact on the health of heart, brain, skin, lung, and kidney.

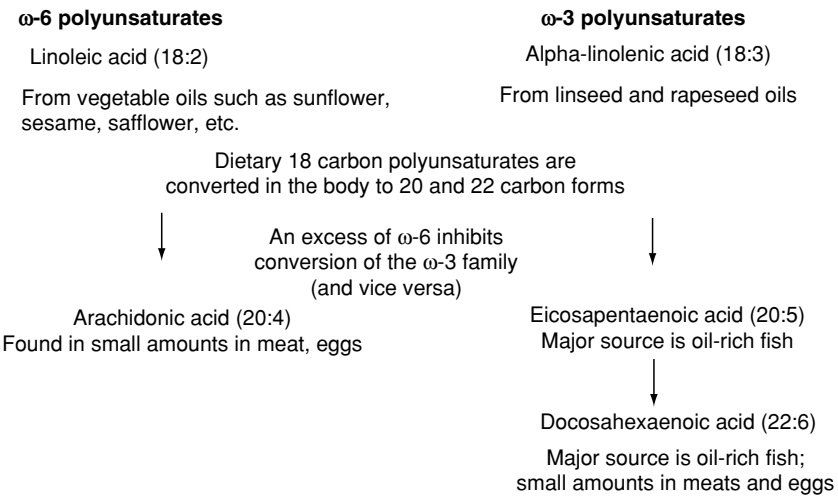

Figure 2 Importance of dietary balance with respect to the polyunsaturates. The figures after the name of a polyunsaturate denote the number of carbon atoms in the molecule, with the figure after the colon indicating the number of double bonds.

Heart Health

Since the mid-1970s, when interest in this field was sparked by observations that native-dwelling Greenland Inuits had high fat/high cholesterol diets yet no heart disease, much research has focused on the role of the ω-3 polyunsaturates in heart disease. As a result of this work, it is now widely acknowledged that the long-chain ω-3 polyunsaturates have a beneficial impact on several established risk factors for heart disease. The blood lipid profile is improved, blood pressure and viscosity are lowered somewhat, blood clotting is made less likely, and the risk of development of abnormally rapid heart rhythm is reduced.

Cholesterol The initial investigations focused on the effect of the long-chain ω-3 polyunsaturates on blood lipids. Early work suggested that the ω-3s might have a cholesterol-lowering effect. The apparent lowering of cholesterol was in fact subsequently shown to be due to a reduction in the level of very-low-density lipoprotein cholesterol (VLDL) particles in individuals with abnormally high levels of such particles. The VLDL particles were cleared from the blood of these patients, as a result of the ability of long-chain ω-3 polyunsaturates to lower serum levels of triacylglycerides (triglycerides), the major component of VLDL particles. This observation resulted in a lowering of total serum cholesterol, as a consequence of the removal of the small amount of cholesterol present in the large amounts of VLDL particles. This led to the erroneous impression that low-density lipoprotein (LDL) cholesterol was being lowered, something that was later shown to be incorrect. An elevated serum LDL level is a major risk factor for heart disease, and this mechanism was for a time thought to reflect the way in which the ω-3s offered their heart protection. The consensus of opinion now is that the long-chain ω-3 polyunsaturates do not have any marked impact on serum LDL cholesterol levels, and that the protective form of cholesterol, high-density lipoprotein (HDL) cholesterol, is elevated by around 10% in most people. The early studies on the ability of the long-chain ω-3 polyunsaturates to reduce blood levels of triacylglycerides were carried out largely in the UK. Though, at the time, an elevated serum triacylglyceride level was not considered to be an independent risk factor for heart disease, that view is now changing, particularly since the inverse relationship between serum triacylglyceride levels and high-density lipoprotein cholesterol levels has been better understood.

The long-chain ω-3s have also been shown to have a moderate but clinically significant blood pressure-lowering effect, especially in subjects with above-normal starting levels. Blood viscosity is also mildly but significantly lowered by the long-chain ω-3s. The impact of the long-chain ω-3 polyunsaturates on the balance of proclotting and anticlotting forces within the blood clotting process also contributes to protection against a heart attack, though this effect is not easy to demonstrate in a clinically meaningful way.

Though a heart attack is triggered by a blood clot formed within the circulation, the real damage occurs when the rhythm control system of the heart causes it to beat very rapidly in an attempt to pump more blood to the brain. This leads to the heart pumping so rapidly that its effectiveness as a pump is lost (ventricular arrhythmia), and death from brain oxygen

starvation follows rapidly. Myocytes are the cells within the heart tissue that generate the tiny electrical impulses that cause heart muscle cells to contract, and the heart to 'beat.' When myocytes are given extra ω-3 polyunsaturates in their make-up, they are much less prone to develop rhythm irregularities when some sort of adverse condition, such as a heart attack, occurs. Work carried out by Harvard Professor Alex Leaf has established that the type and level of polyunsaturate present in myocyte membranes have a major impact on the cell's susceptibility to the development of abnormally rapid rhythms. What this means in terms of human health is not easy to research, because of the practical and ethical problems involved. The nearest approach is the use of laboratory investigations with animals. Work by Dr John Charnock, at the CSIRO in Australia, has shown that giving more of the long-chain 20 and 22 carbon ω-3 polyunsaturates (e.g., EPA and DHA) to rats at high risk of developing cardiac rhythm disturbances completely prevented the appearance of the rhythm irregularities.

Studies with Heart Patients The key question is whether eating more long-chain ω-3 polyunsaturates (either from fish or from fish oil supplements) is useful in helping people at high risk of dying from a heart attack to live longer. Now, there are three separate, independent, controlled studies from different parts of the world demonstrating that this is indeed the case.

The first such study was carried out by a team from the Medical Research Council in the UK. One thousand heart attack survivors were advised to eat more fish, or take more long-chain ω-3 polyunsaturates in the form of fish oil. When they looked at the death rate over the following 2 years, the researchers found that, compared with a similar group of patients advised to eat more dietary fiber, or to eat less fat, the fish group had about 30% fewer deaths. A subsidiary investigation of these patients revealed that the effect was due to the ω-3 polyunsaturates in the fish, rather than some other component.

An Indian study also looked at the impact of recommending more ω-3 polyunsaturates to heart attack victims, and found a striking protective effect of the ω-3 polyunsaturates compared with patients given placebo.

The most recent, and by far the most important, study scientifically was reported from Italy in 1999. There, doctors studied more than 11 000 heart attack victims. Half were given an ω-3 supplement derived from fish oil, and the other half a placebo. After more than 3 years of follow-up, analysis revealed that the total mortality in the patients given ω-3 fatty acids was 20% lower than in those patients not so treated, and the incidence of sudden cardiac death was reduced by 45%.

Though the early studies used relatively large amounts of ω-3 (3000–6000 mg per day), more recent clinical studies have used smaller amounts (1000–2000 mg per day) and shown them to be effective at reducing death rates after a heart attack. These studies clearly show that if heart attack survivors were to be recommended to eat oil-rich fish, or take a fish oil supplement immediately after their attack, their chances of falling victim to a second attack would be greatly reduced.

Brain Health

Brain cells are different in many ways from other body cells. In contrast to most other body cells, they are formed at or around birth, and after the first year or so of life, few further brain cells are formed. The cells do, however, increase in size and form synapses, or connections, with other brain cells. There is also a high proportion of membrane in brain cells compared with content. As in heart cells, the mix of polyunsaturates in the brain cell membrane has a marked impact on how it works and, of course, on brain function.

Studies completed within the past few years have demonstrated that the level and amount of polyunsaturates in the diet can alter the composition of brain membrane polyunsaturates. Other recent studies have shown that adding ω-3 polyunsaturates to the diet can alter the way the brain functions. Increasing the dietary intake of ω-3 polyunsaturates has been shown to:

> reduce severe manic depression; ameliorate the worst effects of schizophrenia; reduce aggression under stress; improve the behavior and reading skills of children with attention deficit hyperactivity disorder (ADHD); and improve problem-solving ability in very young children.

An inadequate intake of ω-3 has also been implicated in postnatal depression and may be associated with dyspraxia in children. The 3–4 point IQ advantage found in breastfed infants compared with bottle-fed infants is also probably related to the natural ω-3 content of breast milk. Only recently have some infant formula milks been fortified with long-chain ω-3s, a trend that seems certain to continue.

Skin

The membranes of skin cells are perhaps some of the most important in the human body since they represent the ultimate barrier between our inner selves and the outside world. The part that polyunsaturates play in skin health has been extensively investigated, and

their role is relatively well understood. The moisture barrier properties of the skin are of key importance, and without a good level and balance of polyunsaturates in skin cell membranes, moisture loss would be severe. The sensitivity of skin cells to problems like psoriasis and dermatitis is related to the level of ω-3 polyunsaturates present. Recent research has suggested that there may be a link between the level and type of polyunsaturate in skin cell membranes and the recent upsurge in prevalence of asthma and allergic conditions.

One of the adverse conditions that skin cells have to face is sunlight. Studies have shown that sensitivity to ultraviolet radiation is reduced in skin cells that have a good level of ω-3, implying some protection against sunburn. The same research suggests that this could ultimately lead to a degree of protection from skin cancer.

Lungs

The cells that line the airways in the lungs are in effect modified skin cells. Lung cells containing higher levels of ω-3 are less prone to damage by cigarette smoke, and probably by other environmental pollutants. When smoke contacts the lungs, an inflammatory reaction is set up leading to congestion in the lungs and ultimately to a condition known as chronic obstructive pulmonary disease (COPD), or emphysema. Higher than average levels of ω-3 in the diet lead to a reduction in COPD, probably because the lungs are less sensitized and do not react in the same hyperresponsive way as lungs with low ω-3 levels. Cigarette smoking is none the less very damaging to health.

Kidneys

The role of the ω-3 polyunsaturates in healthy kidney function is well documented, although the research is taking a long time to penetrate renal units in hospitals. Work carried out over many years by Dr Jim Donadio at the Hormel Institute in the USA has shown consistently that ω-3 supplementation in patients with failing kidneys restores much of their kidney function and often eliminates the need for a transplant. This effect is thought to be due to a reduced inflammatory response following a greater intake of fish oil.

Associated work has also shown that the presence of ω-3 polyunsaturates when administering the immune suppressing drug, cyclosporin A, can reduce some of the drug's damaging side-effects.

Intake Recommendations

Various bodies have attempted to make recommendations on the amounts of the ω-3 polyunsaturates that should be consumed both by adults and, more recently, by infants. Table 1 summarizes the major recommendations made to date. Some of the earlier recommendations are not specific as to whether the recommendations relate to short-chain or long-chain ω-3 polyunsaturates, so have limited value. Generally, as research has led to a greater understanding of the issues involved, the recommendations have become more specific, and discussions are under way to further refine the existing recommendations. The most recent was an *ad-hoc* Expert Workshop held in the USA in April 2000. The make-up of the group, and their detailed recommendations, can be seen by visiting the ISSFAL website at www.issfal.org.uk. A summary of their recommendations can be seen in Table 2 for adults, and Table 3 for infant feeding. A consensus is emerging that intake of long-chain ω-3 polyunsaturates should be around 0.2–0.3% of energy intake, which, for a 2000-kcal intake, means a total long-chain ω-3 intake of about 400–600 mg per day, or 3–4 g per week.

Recommendations on polyunsaturated fatty acid composition of infant feeding formulae have not yet

Table 1 Summary of recommendations for intake of ω-3 polyunsaturates

Source	*Specific ω-6:ω-3 ratio recommended*	*Other specific recommendations*
National Nutrition Council (Norway) (1989)	None	ω-3 0.5%en (1–2 g per day)
Nordic Nutrition Committee (1989)	None	ω-3 0.5%en (1–2 g per day)
NATO Workshop on ω-3/ω-6 (1989)	None	0.8 g per day EPA/DHA (0.27%en)
Scientific Review Committee of Canada (1990)	5:1–6:1	ω-3 at least 0.5%en
British Nutrition Task Force (1992)	6:1	EPA 0.2–0.5%en; DHA 0.5%en
Scientific Committee for Food of the European Community (1993)	4.5:1–6:1.5	ω-3 as 0.5% of total calories
FAO/WHO Expert Committee on Fats & Oils in Human Nutrition (1994)	5:1–10:1	Consider preformed DHA in pregnancy
Committee on Medical Aspects of Food Policy (1994)	None	EPA/DHA 0.1–0.2 g per day (1.5 g per week); at least two portions of fish/week

Table 2 Recommended AI[a] for adults (by an *ad-hoc* Expert Workshop held in USA, April 2000)

Fatty acid	*g per day (2000 kcal)*	*Percentage*
LA, 18:2, ω-6	4.44	2.0
(upper limit)[b]	6.67	3.0
ALA	2.22	1.0
EPA[c] + DHA[d]	0.65	0.3
DHA[e] *minimum*	0.22	0.1
EPA *minimum*	0.22	0.1

[a]If sufficient scientific evidence is not available to calculate an estimated average requirement, a reference intake called an Adequate Intake is used instead of an RDA. The AI is a value based on experimentally derived intake levels or approximations of observed mean nutrient intakes by a group (or groups) of healthy people. The AI for children and adults is expected to meet or exceed the amount needed to maintain a defined nutritional state or criterion of adequacy in essentially all members of a specific healthy population.
[b]Although the recommendation is for AI, the Working Group felt that there is enough scientific evidence to also state an upper limit for LA of 6.67 g per day based on a 2000-kcal diet or of 3.0% of energy.
[c]Elcosapentaenoic acid, C20:5; ω-3.
[d]Docosahexaenoic acid, C22:6; ω-3.
[e]For pregnant and lactating women, ensure 300 mg per day of DHA.

Table 3 Adequate intake (AI)[a] for infant formula/diet (by an *ad-hoc* Expert Workshop held in USA, April 2000)

Fatty acid	*Percentage of fatty acids*
LA, 18:2; ω-6.[b]	10.00
ALA 18:3; ω-3.	1.50
AA, 20:4; ω-6.[c]	0.50
DHA, 22:6; ω-3.[c]	0.35
EPA, 20:5; ω-3.[d]	< 0.10

[a]If sufficient scientific evidence is not available to calculate an estimated average requirement, a reference intake called an Adequate Intake is used instead of an RDA. The AI is a value based on experimentally derived intake levels or approximations of observed mean nutrient intakes by a group (or groups) of healthy people. The AI for children and adults is expected to meet or exceed the amount needed to maintain a defined nutritional state or criterion of adequacy in essentially all members of a specific healthy population.
[b]The Working Group recognized that in countries like Japan, the breast milk content of LA is 6–10% of fatty acids, and the DHA is higher, about 0.6%. The formula/diet composition described here is patterned on infant formula studies in Western countries.
[c]The Working Group endorsed the addition of the principal long-chain polyunsaturates, AA and DHA, to all infant formulas.
[d]EPA is a natural constituent of breast milk but, in amounts more than 0.1% in infant formula, may antagonize AA and interfere with infant growth.

been widely published. The *ad hoc* Expert Group proposed that infant feeds should contain around 0.35% of the fat in the form of the long-chain ω-3 polyunsaturate DHA, together with 0.5% in the form of the long-chain ω-6 polyunsaturate arachidonic acid.

Conclusion

At first sight, the idea that a simple dietary alteration can bring about such significant changes in so many areas of the body is difficult to accept. The key to understanding this is the cell membrane, and the role of polyunsaturated fatty acids in the health and well-being of that membrane. Over the past 50–100 years, the level and amount of the two families of polyunsaturates, the ω-6 family and the ω-3 family, have changed. ω-6 intake has doubled, whereas ω-3 intake has halved. The impact of this change is not immediately obvious; the effects are subtle and take a long time to manifest themselves. During that time-scale, other things have changed also, so that pinpointing the factors responsible for certain effects is difficult. What cannot be denied is that during the past 50–100 years, the West has seen more heart disease, more depression, more aggression, more antisocial behavior, more lung disease, more skin problems, and more kidney ailments. Altering population intakes of dietary polyunsaturates so as to consume more long-chain ω-3 polyunsaturates, and perhaps less of the ω-6s would help to bring about a reversal of these trends.

FLAVOR (FLAVOUR) COMPOUNDS

Contents

Structures and Characteristics

T Cserháti and E Forgács, Chemical Research Center, Budapest, Hungary

Introduction

The quantity and composition of flavor compounds in foods and food products exert a marked influence on consumer acceptance and, consequently, on the commercial value of the products. It has been established many times that one of the main properties employed for the evaluation of product quality is flavor, that is, an adequate flavor composition considerably enhances the marketability of products. A desirable flavor is due to the complex mixture of various volatile and nonvolatile constituents mixed in proper proportions. However, flavor is not only a physical and/or chemical term; it includes the interaction of food and consumer. Flavor sensation is a dynamic process: the volatile or nonvolatile flavor compounds first have to be released from the foodstuff and then transferred to the adequate receptor organs. An exact knowledge of the stability of the flavor compounds in the face of hydrolysis, oxidation, and other environmental and technological conditions is also of paramount importance, because it may help to predict the shelf-life of products and to assess the influence of technological steps on flavor compounds, resulting in more consumer-friendly processing methods. Furthermore, the qualitative determination and identification of flavor compounds may contribute to the establishment of the provenance of the product and to its exact qualification. Unfortunately, traditional analytical methods are generally unsuitable for the separation and accurate determination of particular fractions of flavor compounds. Moreover, they do not contain any useful information on the concentration of the individual flavor compounds and are not suitable for their identification. The high separation capacity of various chromatographic techniques makes them a preferred method for the analysis of flavor compounds in foods. In addition to influencing commercial value, some flavor compounds are believed to have advantageous effect on human well-being as enhancers of appetite and promoters of digestion.

This article overviews the flavor compounds found in various foods and food products, their chemical composition, physicochemical parameters, sensorial characteristics and their separation, quantitation, and identification by various chromatographic techniques.

Chemical and Physical Characteristics of Flavor Compounds

A considerable amount of compounds have been identified in a wide variety of foods producing flavor sensation. The chemical structures of these molecules show high diversity and even flavor compounds with

highly similar chemical structures may have an entirely different sensorial effect. Therefore, the classification of flavor compounds according to their chemical structure (i.e., linear aldehydes, alcohols) is possible but from a practical point of view is irrelevant. Most flavor molecules are hydrocarbons, alcohols, aldehydes, ketones, or esters. The backbone of these compounds generally consists of a linear or branched alkane or alkene chain. Saturated and unsaturated ring structures and terpenoids also occur among the basic structures of flavor compounds. Much effort has been devoted to elucidating the quantitative relationship between organoleptic characteristics and molecular structure or physicochemical parameters of flavor compounds. Because of the complexity of molecular structures and organoleptic properties, these calculations have been of moderate success. Correlations can be observed for only a definite set of structurally similar compounds that have a very low predictive value for flavor compounds with different molecular characteristics. Most of these molecules are relatively small; they are volatile or semivolatile and especially suitable for gas chromatographic (GC) analysis. As flavor compounds generally occur in foods in very low concentrations, their enrichment before the chromatographic separation process is a prerequisite of any successful analysis. However, it has to be borne in mind that the efficacy of various preconcentration methods such as steam distillation, solvent extraction, Soxhlet method and supercritical fluid extraction (SFE) considerably depend on the flavor compound to be extracted and on the conditions of extraction. Organic solvent partition and solid-phase microextraction (SPME) can also be employed for the enrichment of flavor compounds. Furthermore, volatile flavor compounds can be purged from the accompanying matrices carried to a cold trap and then can be cryofocused.

Flavor Compounds in Foods and Food Products

Spices

Spices are important commercial commodities with diverse applications in foods and food products. The accurate measurement of the composition of flavor reveals not only the sensory value of the spice but can also be used as a marker of authenticity. Because of the marked structural diversity of flavor compounds in different spices, a large number of chromatographic methods have been developed and applied for the separation, quantitation, and/or identitification of individual components of flavor in spices. Thus, flavor compounds extracted from cinnamon (inner bark of *Cinnamon zeylanicum* Nees) by solvent-assisted SFE have been analyzed by series coupled capillary GC (cGC). The presence of the structurally similar aldehydes and alcohols as the main flavor components has been verified (Table 1). SPME, SFE followed by cGC, and mass spectrometric (MS) detection have been employed for the analysis of flavor compounds of commercial cassia. The results proved that cassia contains not only linear but also benzene-based flavor components (Table 1). A simple and easy-to-carry-out thin-layer chromatographic (TLC) method has been employed for the separation of vanilla bean extracts using automated multiple development. The occurrence of 5-(hydroxymethyl)-2-furfural, 4-hydroxybenzoic acid, 4-hydroxybenzaldehyde, vanillic acid, and vanillin has been identified. It was stated that the method is suitable for a botanical identification and authenticity test of mercantile vanilla products. High-performance liquid chromatography (HPLC) has also found application in the analysis of flavor compounds extracted from cured vanilla beans (*Vanilla fragrans*). The measurements indicated that the extract contained glucovanillin, *p*-hydroxybenzoic acid, *p*-hydroxybenzaldehyde, vanillic acid, vanillin, and ethyl vanillin. The characteristic

16	β-Pinene
17	Safrole
18	Terpinene-4-ol
19	α-Terpineol

odorants of fresh rhizomes of ginger (*Zingiber officinale* Roscoe) have also been studied by aroma extract dilution analysis and multidimensional cGC-MS. The chemical name and odor descriptors of flavor compounds identified in the fresh rhizomes of ginger are listed in Table 2.

The data prove again that compounds with similar molecular structure may have highly different organoleptic properties and the sensory effect of flavor compounds with different structures may be similar. Another study established that the pungent flavor compounds in the extract of ginger consist of 3-, 4-, 5-, 6-, 8-, 10-, 12-, and 14-gingerol, 6-, 8-, and 10-shogaol and zingerone. An online SFE-cGC-MS method was developed and employed for the separation and identification of flavor compounds in the extract of caraway fruits (*Carum carvi* L.). The presence of 23 flavor compounds has been verified, indicating the contribution of a considerable number of different molecules to the organoleptic characteristics (Table 3).

The flavor compounds in turmeric powders have been separated by both HPLC and cGC. The HPLC method quantitated bisdemethoxycurcumin (0.49–0.90 wt%), demethoxycurcumin (0.58–1.10 wt%), and curcumin 0.94–3.18 wt%). The cGC method identified 10 structurally different compounds, suggesting that the analytical method applied exerts a marked influence on the results (Table 3). A combined method (cGC-MS/sniffing port analysis) has been used for the evaluation of commercially dried

bell peppers (*Capsicum annum*) after rehydration. The chemical names of volatile components and their odour descriptors in parenthesis are compiled in Table 4.

The data prove that flavor compounds with non-typical odor may also contribute to the formation of the sensorial properties of red pepper. The effect of thermal decomposition of capsaicin on the composition of flavor compounds in the absence and in the presence of oleic acid has also been assessed by cGC-MS. It was found that 9-octadecenamide and *N*-vanillyl-9-octadecenamide are only formed in the presence of oleic acid. Characteristic flavor compounds of onion generally formed enzymatically from odorless precursors when it is cut or crushed. Various cGC-MS methods have also been applied for the identification of these onion volatiles, and the occurrence of unstable thiosulfinates such as (*E*)-ethylidene sulfoxide, (*Z*)-ethylidene sulfoxide, methanesulfenic acid methylthio ester, methanesulfenic acid *n*-proprylthio ester, methanesulfenic acid *n*-propenylthio ester, propanesulfenic acid methylthio ester, propenesulfenic acid methylthio ester, propanesulfenic acid *n*-propylthio ester, propenesulfenic acid *n*-propyl-thio ester, and isomers of zwiebelane has been demonstrated. Similar cGC-MS technique has been used for the separation and quantitative determination of volatile sulfur compounds in garlic. The compounds and their concentration in mg $100\,g^{-1}$ fresh tissue are as follows: allyl methyl sulfide (0.167 ± 0.015); dimethyldisulfide (0.204 ± 0.026); diallyl sulfide (0.122 ± 0.014); allyl methyl disulfide (1.193 ± 0.068); dimethyl trisulfide (0.075 ± 0.011); diallyl disulfide (5.297 ± 0.846); allyl methyl trisulfide (0.562 ± 0.078); 3-inyl-4(H)-1,2-dithiin (4.088 ± 2.266); diallyl trisulfide (1.288 ± 0.183), and 2-vinyl-4(H)-1, 3-dithiin (830.069 ± 1.757). (*See* **Herbs**: Herbs of the Compositae.)

Table 4 Alphabetic list of chemical names and odor descriptors (in parantheses) of volatile flavor compounds found in the dried bell peppers (*Capsicum annuum*) after rehydration. (Odor descriptors have not been determined for each component)

No. of flavor compound	*Chemical name*
1	Acetic acid
2	Benzaldehyde
3	2, 3-Butadione (caramel, butter)
4	Butanal
5	1-Butanol
6	2-Butanone
7	2-Buten-2-one
8	*β*-Cyclocitral
9	Diethoxyethane
10	Dimethyldisulfide
11	Dimethylsulfide
12	Dimethyltrisulfide (rotten, onion, leek)
13	*tert*-Dodecanethiol
14	Heptanal(lemon, orange)
15	*cis*-2-Heptenal
16	2-Heptanone
17	*trans*-3-Heptene-2 -one (mushrooms)
18	2, 3-Hexadione
19	Hexanal (grassy, green)
20	*trans*-2-Hexenal
21	1-Hexanol
22	Limonene
23	2-Methoxy-3-isobutyl-pyrazine (bell pepper)
24	Methyl acetate
25	2-Methylbutanal (chocolate)
26	3-Methylbutanal (chocolate)
27	3-Methyl-1-butanal
28	2-Methylfurane
29	6-Methyl-5-hepten-2-one
30	4-Methyl-2-hexanone
31	5-Methyl-2-hexanone
32	2-Methylpropanal (chocolate)
33	1-Methyl-1H-pyrrole
34	Nonanal
35	*β*-Ocimene (fish, rotten, sickly)
36	Octanal
37	1-Octane-3-ol
38	2, 3-Pentadione
39	Pentanal
40	1-Pentanol
41	2-Pentanone
42	1-Pentene-3-ol
43	1-Pentene-3-one (plastic/chemical)
44	3-Pentene-2-one
45	Propanal

Wine and Cider

Besides the characteristic and attractive color, the qualification of wine and cider markedly depends on the quantity and composition of flavor compounds. Because of their impact on the commercial values of these products, flavor compounds in wine and cider have been intensively investigated. Volatile molecules in wines have generally been analyzed by cGC-MS too. The flavor compounds found by this method in Galician (Spain) white wine are compiled in Table 5 illustrating again the complexity of the composition of flavor compounds. A similar cGC method found a fairly different profile of flavor compounds in the wine of Verdejo (Spain): ethyl lactate + *cis*-hexen-1-ol; acetic acid; propanoic acid; linalool; τ-butyrolactone; butanoic acid; α-terpineol; hexanoic acid; benzyl alcohol; 2-phenylethanol; octanoic acid; ethyl hexadecanoate, and decanoic acid. As volatile components also play an important role in the quality of cider they have been separated and identified by cGC-MS. The flavor compounds and their concentrations in fruity and sharp ciders in $mg\,l^{-1}$ are compiled as follows: 1-butanol (2.24;4.09), amyl alcohols (134.29;170.85), isobutanol (7.73;21.92),

Table 5 Alphabetic list of chemical names of flavor compounds found in Galician wine (Spain)

No. of flavor compound	*Chemical name*
1	Benzyl alcohol
2	Butiric acid + hotrienol
3	2-Butoxyethanol
4	Citronellol
5	Decanoic acid
6	Diendiol
7	Diethyl malate
8	Diethyl succinate
9	3-Ethoxypropanol
10	Ethyl-2-butanoate
11	Ethyl-2-butyrate
12	Ethyl decanoate
13	Ethyl hexanoate

35	Octanoic acid
36	2-Phenylethanol
37	2-Phenylethyl acetate
38	Terpineol

2-phenylethanol (185.24;57.30), benzyl alcohol (0.53;1.54), ethyl lactate (11.86;100.27); diethyl succinate (2.27;2.32), ethyl caprylate (2.22;1.92), ethyl caprate (3.39;2.15), ethyl laurate (0.68;0), ethyl palmitate (0.38;0.66), *i*-amyl acetate (0.28;0.58), 2-phenylethyl acetate (1.21;0), dihydro-2(3H)-furanone (3.50;7.90), acetoin (0;1.92), 2,3(R,R,S,S)-butenediol (37.63;90.89), 2,3-butenediol (meso form) (22.10;75.34), 3-(methylthio)-1-propanol (1.41;1.80), 4-ethylphenol (1.37;3.33), caprylic acid (1.22;3.51), capric acid (1.25;2.20), lauric acid (4.88;0.77), and myristic acid (1.91;0). The data indicate that the marked variation in the concentration of flavor compounds really reflects the difference between the two cider varieties. (*See* **Wines**: Wine Tasting.)

Beer and Hop

Similarly to wine and cider, and for the same reasons, flavor compounds in beer have also been vigorously investigated. It has been emphasized many times and empirically proved that the yeast used for fermentation and the conditions of fermentation play a decisive role in the development of flavor compounds and a considerable number of compounds contribute to the organoleptic aspects of beer quality. The presence of anethole, apiole, asaron, camphor, caryophyllene, carvone cedrol, cineol (eucaliptol), cinnamladehyde, citronellal, cuminaldehyde, cymole, eugenol, farnesol, geraniol, limonene, linalool, menthol, 2-methylbutanal, 3-methylbutanal, methyl ketone, methyl slicylate, myrcene, paradol, α-pinene, thujone, and thymol in beers has been demonstrated. It was further found that the oxidation products of humulene present in hop (five isomers of humulene diepoxy) have a typical herbal/spicy flavor and influence advantageously the organoleptic properties of beer. It has been further verified that nonvolatile compounds such as purine nucleosides and free bases may also contribute to the sensory characteristics of beer. (*See* **Beers**: Chemistry of Brewing.)

Size exclusion chromatography has been employed for the separation and quantitative determination of this class of aroma compounds and the concentration ranges ($mg\,l^{-1}$) found in 18 commercial beers were as follows: guanosine and deoxyguanosine (19–110); adenosine and deoxyadenosine (3–43); xanthin (1–41); guanine (1–11), and adenine (1–17). As the occurrence of 2-furalaldehyde (FA) and 5-hydroxymethyl-2-furaldehyde (HMFA) is considered as an indicator of the deterioration of quality, an HPLC method has been developed and employed for their determination in commercial beers. Concentrations of FA and HMFA ($mol\,l^{-1}$) varied between 1.01–8.41 and 2.62–6.80, respectively. Because of their considerable contribution to the bitter taste and typical taste of beer, the composition and amount of so-called hop bitter acids have been extensively studied. The successful HPLC separation of cohumulone, humulone, adhumulone, colupulone, lupulone, and adlupulone from the SFE extract of hop has been reported. The same aroma compounds has also been separated by microemulsion electrokinetic chromatography in 10 min analysis time.

Coffee and Tea

Flavor characteristics play a decisive role in the evaluation and commercial acceptance of coffee and tea. Because of their outstanding importance many methods have been developed and successfully applied for the separation, identification, and

quantitative determination of flavor compounds in coffee and tea. Thus, aroma components of two varieties of roasted coffee (*Coffea arabica, C. canephora* var. *robusta*) have been analyzed by cGC-olfactometry. The chemical names of flavor compounds and their organoleptic evaluation are listed in Table 6. The composition of the flavor constituents was different in the coffee varieties, suggesting that similar data sets can be employed for the identification of the origin of the product. Nonvolatile aroma precursors present in green coffee have also been separated by high-performance gel filtration chromatography. The data indicated that the concentration of total chlorogenic acid, trigonelline, and caffeine show a marked variation according to the green coffee samples. (*See* **Coffee**: Analysis of Coffee Products; **Tea**: Chemistry.)

The production of tea is a complicated biochemical and biological process. The final quality depends on the chemical composition of the original green leaves, and on the enzymatic processes. A cGC method has been used to study the effect of the concentration of sodium chloride on the efficacy of head-space analysis of volatiles present in heat-treated green tea leaves. The results indicated that NaCl markedly increase the recovery of furfural (from 7.94 to 11.59 μg ml^{-1}) and 5-methylfurfural (1.65 to 2.95 μg ml^{-1}) but did not influence the recovery of benzaldehyde (0.30 μg ml^{-1}) and ethyldimethylpyrazine (0.69 μg ml^{-1}). Another study indicated that the decomposition rate of lipids during tea processing results in the formation of the flavor compounds *n*-hexanal and *trans*-hexanal.

Table 6 Alphabetic list of chemical names and odor descriptors of flavor compounds found in two varieties of roasted coffee (*Coffea arabica, C. canephora* var. *robusta*)

No. of flavor compound	*Chemical name*	*Odor descriptor*
1	Acetaldehyde	Fruity, pungent
2	2, 3-Butanedione	Buttery
3	(*E*)-β-damascene	Honey-like, fruity
4	2, 3-Diethyl-5-methylpyrazine	Earthy
5	Dimethyl trisulphide	Cabbage-like
6	2-Ethyl-3, 5-dimethylpyrazine	Earthy, roasty
7	4-Ethylguaiacol	Phenolic, spicy
8	2-Furfurylthiol	Roasty
9	Guaiacol	Phenolic, burnt
10	2-Isobutyl-3-methoxypyrazine	Green, earthy
11	3-Mercapto-3-methylbutylformiate	Catty, roasty
12	Methanethiol	Putrid, cabbage-like, sulfurous
13	Methional	Boiled potato-like
14	2-Methylbutanal	Malty
15	3-Methylbutanal	Malty
16	2-Methyl-2-butenthiol	Foxy, skunky
17	2-Methyl-3-furanthiol	Boiled-meat-like
18	Methylpropanal	Fruity, malty
19	1-Octen-3-one	Mushroom-like
20	2, 3-Pentanedione	Buttery
21	Propanal	Fruity
22	4-Vinylguaiacol	Phenolic, spicy

Dairy Products

Sensorial properties also determine the type and marketability of dairy products. Because of their paramount importance, flavor compounds have been extensively studied, mainly in cheeses. Cheese flavor is influenced by the biodegradation of milk protein, fat, lactose due to the enzyme systems of milk, rennet, and microorganisms. The composition of volatile flavor compounds in Roncal (Spain) cheese has been investigated by preconcentrating the analytes by the 'purge-and-trap' method and then separating them by cGC-MS. The combined technique sussessfully separated hydrocarbons, alcohols, aldehydes, ketones, acids, esters, and sulfur compounds. The flavor compounds identified are shown in Table 7 and prove again the high complexity of aroma composition. (*See* **Cheeses**: Chemistry and Microbiology of Maturation.)

The flavor compounds of Swiss cheese and Gorgonzola have also been analyzed by simultaneous distillation-solvent extraction-cGC. In contrast to Roncal cheese, the main aroma components of Swiss cheese consisted of (in μg kg^{-1}) 2-heptanone (3776), 2-nonanone (1992), 3-methylbutanal (1292), 2-octanone (1188), 2-undecanone (1178), 2-pentanone (999), 2-tridecanone (873), dimethylsulfide (619), phenyl acetaldehyde (500), and heptanal (429). The aroma composition of Gorgonzola cheese was markedly different, containing 2-nonanone (3212), 2-heptanone (2916), 3-methyl-1-butanol (2534), 2-undecanone (1884), 3-methylbutanal (1120), 2-pentanone (955), 2-tridecanone (890), phenyl acetaldehyde (643), 1-octen-3-ol (601), and methyl propanoate (379).

It has been further demonstrated that the composition of flavor compounds depends not only on the variety of cheese but also on the character of starter culture. In the case of Hispánico cheese it has been demonstrated that the concentration of some flavor compounds considerably depended on the properties of starter culture. The chemical names of flavor compounds identified are listed in Table 8. The stereoselective separation of gamma and delta lactones has been achieved by enantioselective multidimensional cGC. It was found that butter, whipped cream, evaporated milk, full-cream milk, cheddar, parmesan, limburger, emmental and blue cheese contain a considerable amount of C_{10} and C_{12} lactones which

Meat, Fish, and Oils

A large amount of volatile and nonvolatile flavor compounds has been found in foodstuffs containing meat, fish, and oil as the main ingredient. The chemical character and composition of flavor compounds found in these classes of foodstuffs substantially deviated from those determined in other food varieties. A dynamic head space cGC method has been developed and used for the analysis of flavor compounds in chicken breast meat. The following compounds have been found in chicken breast meat previously heated to 70 °C: H_2S, CO_2O, methanol, propanal, and acetone, 2-propanol and thiobismethane, 2-methylpropanal, 1-propanol, 2,3-butanedione, hexane, 2-butanone, 3-methylbutanal, 2-methylbutanal,

1-penten-3-ol, pentanal, dimethyl disulfide, hexanal, 1-hexanol, 2-heptanone, heptanal, 1-heptanol, benzaldehyde, 7-octen-4-ol, octanal, *d*-limonene, undecane, nonanal, and dodecane. Olfactometry and cGC-MS have been employed for the identification of flavor compounds and their odor descriptors in boiled cod and trout. It was found that acetaldehyde (sweet), 2-methylpropanal (malty), butane-2,3-dione (buttery-like), 3-methylbutanal (malty), 1-octen-3-one (mushroom-like), and (*Z*)-1,5-octadien-3-one (geranium-like) occurred in both fishes. Moreover, boiled cod minces contained methaneethiol (sulfurous), trimethylamine, dimethyl sulfide (cabbage-like), 2-methylbutanal (malty), methional (boiled potato-like), dimethyl trisulfide (cabbage-like, putrid) and dimethyl tetrasulfide (cabbage-like, putrid). (*See* **Fish**: Fish as Food; **Meat**: Analysis.)

In contrast, boiled trout contained propionaldehyde (sweet), pentane-2,3-dione (buttery-like), hexanal (green), (*Z*)-3-hexenal (green), (*Z*)-4-heptenal (biscuit-like), (*Z, Z*)-3, 6-nonadienal (fatty, green), and (*E, Z*)-2, 6-nonadienal (cucumber-like). A similar method has been used for the study of the odor active compounds in cooked mussel (*Mytilus edulis*) and the following compounds have been identified: 2, 3-butenedione (buttery, caramel), 1-propanol (fruity, plastic), dimethyl disulfide (sulfury), hexanal (green), *m*-xylene (plastic), heptanal (citrus fruit, green), (*Z*)-4-heptenal (boiled potato), 1,2,4-trimethylbenzene (plastic), octanal (citrus fruit, orange), (*E*)-2-penten-1-ol (mushroom), (*E*)-2-heptenal (sulfury, grassy), ethylpyrazine (nutty), dimethyl trisulfide (sulfury, green, marine), methional (boiled potato), 2-nonanol (fruity, solvent), (*E, E*)-2,4-octadienal (cucumber), 1-acetylpyrazine (nutty), 2-acetylthiazole (grilled hazelnut), 4-methylthiazol (roasted, meaty), 4-ethylbenzaldehyde (fruity, anisic, minty), 2-acetyl-2-thiazoline (grilled hazelnut), and 2,6-dimethylnaphtalene (grilled, grassy).

Volatile aroma compounds have also been determined in oils using various cGC techniques. The flavor compounds found in extra virgin, regular, extra light and extra mild cooking oils are listed in Table 9. The concentration of flavor constituents of oils remarkably depended on the technological steps applied for the production of oils. The amount of aliphetic aldehydes indicating quality deterioration has also been measured by a cGC method using derivatization by thiazolidine. The presence of C_3, C_4, *i*-C_5, C_6, and C_9 aldehydes in sesame, soybean, rapeseed, cottonseed, corn, olive, and sardine oil, as well as in beef fat, lard, butter, margarine, mayonnaise, cheese, egg yolk, fresh milk, chocolate, and potato chips has been demonstrated.

Table 9 Alphabetic list of chemical names of flavor compounds found in extra virgin, regular, extra light, and extra mild cooking oils

No. of flavor compound	*Chemical name*
1	Acetic acid hexyl ester

35	Styrene
36	Toluene
37	2-Undecenal

Miscellaneous Food Products

Because of the significant impact of flavor compounds on the quality of foods and foodstuffs, they have been analyzed in a considerable amount of other food products using the well-established methods of preconcentration followed by either cGC-MS or HPLC. Thus, 46 volatile compounds have been separated and identified in fresh-squeezed unpasteurized orange juice. Ionones, decalactone, and raspberry ketone have been found in some raspberry cultivars and 17 volatile compounds have been identified in ready-made tomato sauces. The presence of 2-methylpropanal, 3-methylbutanal, and 2-methylbutanal has been verified in chocolate flakes and the enzyme activities involved in the flavor precursor formation in unfermented cocoa beans have been elucidated.

The flavor profile of corn-based snacks and peanuts has also been determined and the data have been used for the better understanding of the sensory characteristics of the products.

Production Methods

A Blake, P Cadby and F Näf, Firmenich SA, Geneva, Switzerland

Introduction

There is a large and established industry developing and manufacturing flavor systems for use in foods and beverages. Legislation and definition of flavors are complex and vary from country to country. Flavor compounds are produced by single or combined physical, chemical, biochemical, biological, and agricultural techniques (**Figures 1–6**).

A major way of producing natural flavors is by isolation from agricultural food products or waste streams of food-processing units using physical methods such as distillation, solvent extraction, and filtration. The flavors thus isolated range from complex mixtures at one extreme, to pure individual flavor chemicals at the other. Flavors produced by isolation are often designated as essential oil extracts or isolates. The raw materials used in the production of nature-identical flavors are nature-identical chemicals (i.e., identical to those found in natural foods) with the optional use of natural extracts, oils, and isolates. The manufacturing is accomplished by mixing the raw materials under tightly controlled conditions and the resulting product is termed 'compounding' or 'blending.' It is understood that chemical reactions must not take place during this process, or on subsequent storage.

The synthesis of organic compounds as flavors may involve (1) controlled chemical synthesis, (2) transformations using living biological systems, (3) enzyme-catalyzed synthesis, and (4) the reaction flavor approach which mimics established food-cooking techniques.

In addition to creating the blend of molecules necessary to provide a specific flavor effect, it is important to deliver these in a way which optimizes

their functioning. Accordingly, flavors are increasingly sold entrapped in an appropriate delivery system, either in powder or liquid form.

Legislation

Flavor production is highly regulated in order to protect both the consumer and the workers involved in their production. Since its inception in 1973, the International Organization of the Flavor Industry (IOFI) has developed a self-regulatory code of practice covering both of these aspects. Several of its recommendations have been closely modeled by international regulatory bodies. These include standards for natural flavorings and for thermal process flavors. More recently, the Joint Food and Agriculture Organization/World Health Organization Expert Committee on Food Additives (JECFA) has been evaluating the safety of chemically defined flavoring substances under their conditions of use. Since 1997, JECFA has cleared over 100 substances per year in a program that may eventually examine over 2000 flavoring substances claimed to be currently used. Work-place hazard information systems are being put in place in many countries. IOFI regularly updates recommendations on the work-place hazard classification of flavoring ingredients according to the criteria laid down by various governmental bodies.

Isolation of Natural Flavors

Isolation from natural products is the most important and simplest method for producing natural flavors. It is based on the physical properties of the flavors and exploits technologies of a wide range of sophistication. The five principal isolation techniques used

Figure 4 (see color plate 61) Road-side markets in Bangkok displaying citrus, banana, rambutan, mango, and lychee. Reproduced from Flavour Compounds, Production Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

on a production scale are, in decreasing order of importance: (1) distillation; (2) extraction; (3) pressing; (4) filtration; and (5) chromatography. An overview of today's standard technology equipment and their typical applications is presented in Table 1. In certain isolation procedures, acid and/or alkaline adjustments (pH value control) are necessary. Apart from the quality of the raw materials, the sensory properties of the flavors obtained are strongly influenced by the isolation technology (equipment and processes) used. For this reason, the isolation route to many natural flavors remains the unpatented but nevertheless confidential 'know-how' of the various flavor manufacturers (Figures 7–9). (*See* **Chromatography**: High-performance Liquid Chromatography; Gas Chromatography; **Membrane Techniques**: Principles of Ultrafiltration.)

Production of Nature-Identical Flavors

Nature-identical flavors are mixtures of synthetic nature-identical flavoring substances. These are generally made from available chemical feedstocks of plant or petrochemical origin and are, by definition, chemically identical to substances found in natural foods, herbs, spices, and essential oils. These flavors often contain natural flavoring materials as well but they must not contain flavoring substances which have no counterpart in nature. Over 7000

Table 1 Isolation techniques, equipment, and their application to the production of typical flavor types

Technique	*Equipment*	*Physical property utilized*	*Application to the production of*
Distillation			
Distillation	Still with evaporator, and condenser	Volatility of flavors	
Fractional distillation	Still with evaporator, fractionating columns (1 to several meters high), often with packing	Volatility, differences in boiling point of compounds	Folded citrus oils (concentration by removal of monoterpenes)
Distillation with high-performance condensing device	Recovery units	Low boiling point of flavor	Volatiles from concentration of tomato, apple juice, red fruits, exotic fruits, citrus (essence oils) → 'add-back' systems
Thin-film distillation	Falling-film vaporizer with or without rotating blades	Lowering of evaporation temperature of a liquid thin film as opposed to a bulky mass	Distillation of volatiles from a residue or of high-boiling materials
Molecular distillation	As above, but with extremely low vacuum (10^{-5} bar) and condenser close to vaporizer	Distillation below the boiling point in appropriate equipment and at a certain temperature/pressure (mean free path)	Distillation of volatiles from a residue or high-boiling materials under mild conditions
Steam distillation	Still with condenser and two-phase separator (+ inlet for steam)	Boiling point of a nonmiscible mixture is below the boiling point of the lowest-boiling component	Essential oils, for example, flowers, aromatic plants, and spices
Hydrodiffusion	Vessel with horizontal pallets holding material, steam entering from the top then condensed	Steam volatility of compounds	Seed oils
Extraction			
Extraction by nonpolar, organic solvents and concentration		Solubility of volatiles and certain nonvolatiles (waxes)	Flower and plant concretes (rose, jasmine, tuberose, jonquil)
Extraction of concretes by ethanol, concentration	Extractor[a], filter, evaporator	Solubility difference in ethanol between volatiles and waxes	Flower and plant absolute (rose, jasmine, tuberose, jonquil)
Extraction of plant exudates by methanol, ethanol, or toluene		Solubility	Oleoresins such as pepper, ginger, vanilla, copaiba balsam, oakmoss resin, galbanum resinoid
Extraction by supercritical carbon dioxide	High-pressure equipment	Specific solubility in supercritical carbon dioxide of compounds as a function of temperature and pressure	Various spices; hop oil
Liquid–liquid extraction	Countercurrent solvent extraction column; solvent system: pentane/ethanol–water	Different partition coefficient of terpene hydrocarbons and oxygenated compounds (flavors) in the two solvent phases	Deterpenized citrus oils
Pressing, filtration, and chromatography			
Pressing	Various types of presses	Mechanical destruction of cells and oil glands	Juices, cold-pressed (expressed) citrus peel oils
Mechanical filtration	Sieve	Mechanical separation according to particle size	Removal of solids from liquids (→ clear juices) and/or collection of crystalline compounds
Ultrafiltration	Membrane filters (pore size 1–100 nm)	Separation according to size of molecules, and/or molecular aggregates	Separation of proteins, cell material from low-molecular-weight chemicals, fruit juice clarification

volatile substances have so far been detected in common foods. Some 6510 substances are reported in a single compilation alone. However, not all have sufficiently desirable flavoring properties for use in nature-identical flavors. In countries such as the USA, only flavoring materials which are 'generally recognized as safe' (GRAS) by qualified experts may be used. Currently, there are over 2000 flavoring materials on the GRAS lists published by the US Food and Drug Administration and by the Flavor and Extract Manufacturers' Association of the USA. Of these, some 1200 are nature-identical flavoring substances, about 400 are extracts of botanicals, and 400 are artificial (never identified in nature, such as ethyl vanillin, ethyl maltol). (*See* **Essential Oils: Properties and Uses**; **Legislation: International Standards; Codex.**)

Synthesis of Organic Compounds as Flavorings

Controlled Chemical Synthesis

The merits of chemical synthesis for the production of flavor compounds were decisive for the development of today's high-quality flavors. Synthetic flavorings excel because of their constant quality, favorable price/performance ratio, unlimited supply, and toxicological integrity. Chemical synthesis is used to produce compounds in quantities from a few hundred grams up to hundreds of tons. Some examples of typical commodity flavor chemicals are listed in Table 2. They are commonly manufactured by large chemical companies, some of which do not produce and sell compounded flavors themselves. About 1000 small-scale items (with estimated consumptions of 0–500 kg $year^{-1}$) making up ~1.1% by weight of the totally consumed synthetic flavor compounds are mostly produced by the flavor industry itself, some even on laboratory and pilot plant scales. These often strong-smelling items are not profitable *per se*, but are absolutely essential for the creation of good flavors.

Common synthetic methods and reagents are used to transform either petrochemicals or plant-derived intermediates into flavorings. However, toxic reagents or intermediates are excluded. Rigorous control at all stages of manufacture insures that only chemicals of the highest quality are produced. Indeed, process and quality control is comparable to that used in the pharmaceutical industry.

Table 2 Typical commodity flavor chemicals

Chemical	*Estimated annual consumption (tons)*
Vanillin	7000
l-Menthol	9000[a]
Methyl salicylate	1800
Benzaldehyde	500–700
Maltol and ethyl maltol	400–600
Acetaldehyde	400–500
Cinnamaldehyde	400–500

[a]About 20% of this quantity is produced by synthesis.

Transformations Using Living Biological Systems

Microorganisms (bacteria, yeasts, and molds) play a very large role in the production of flavors in prepared foods. Yeasts are responsible for the production of flavor compounds in wine, beer, and bread. Cheese and yogurt flavors are produced by bacteria and molds. Such microorganisms have been exploited in the production of either complete flavors or specific flavor compounds, and the processes are generally referred to as fermentations (Table 3). (*See* **Fermented Foods: Origins and Applications.**)

Plant tissue cultures in bioreactors are being extensively investigated on a research scale as a means of obtaining a variety of flavor chemicals, e.g., citronellal from *Eucalyptus citriodora* roots or mint oil from *Mentha piperita*. However, because of low productivity and differences in the type of compounds produced (as compared to the whole plant), this technology is still far from commercial application. (*See* **Biotechnology in Food Production.**)

Synthesis Involving Isolated Enzyme Preparations

Enzymes are protein catalysts which both perform and control the chemical reactions that occur in all living systems. They are highly selective and can sometimes be used in an isolated or partially purified form to produce flavor compounds from suitable precursors. Many enzyme preparations are commercially available and are used by the food and flavor industries. Table 4 gives some examples with important applications. (*See* **Enzymes: Uses in Food Processing.**)

The Reaction Flavor Approach

Thermal processing of food, such as cooking, broiling, roasting, or baking, has been used since ancient times and is known to give rise to a variety of flavors. These flavor tonalities can also be produced as such without their food systems by the

Table 3 Microorganisms used in biotransformations/biosynthesis

Organism	*Reaction type*	*Precursors and/or carbon source*	*Flavor compound*	*Sensory description*
Bacteria				
Acetobacter spp.	Oxidation	Ethanol	Acetic acid	Vinegar
Corynebacterium spp.		Carbohydrate	Monosodium glutamate	Taste enhancer
Clostridium butyricum		Glucose	Butyric acid	Cheese, dairy
Yeasts				
Candida lipolytica or Sporobolomyces odorus	Oxidative degradation	Ricinoleic acid	γ-Decalactone	Peach
Molds				
Penicillium roquefortii	Hydrolysis, β-oxidation, and decarboxylation	Fatty acid triglycerides	Methyl alkyl ketones	Blue cheese
Ceratocystis moniliformis		Dextrose and urea	Esters	Fruity
Aspergillus niger		Sugar cane	Citric acid	Acidic

Table 4 Commercially available enzyme preparations with their areas of utilization in the flavor industry

Enzyme(s)	*Reaction type*	*Applications*
α-Amylase + glucoamylase	Hydrolysis	Corn syrup (dextrose) from corn starch
D-Glucose isomerase	Isomerization	Fructose-rich sugars (invert sugars) from corn syrup (US production in 2001: ~23.8 million pounds)
Lipases (esterases)	Hydrolysis of esters	Lipolyzed butter fat, free fatty acids from triglycerides, and synthesis of esters from alcohols and carboxylic acids
Proteases	Hydrolysis of proteins and peptides	Hydrolyzed vegetable and animal proteins
		Enzyme-modified cheeses and cheese flavors (via degradation of caseins), debittering of cheese flavors
	Autolysis of yeast	Yeast autolysates
Pectinase	Hydrolysis	Clarification of fruit juices

reaction flavor approach, which involves the carefully controlled heating of a mixture of appropriate precursors in a reactor vessel. Typical flavor tonalities are roasted and broiled beef and chicken, bread, cereal, cocoa, caramel, maple, and vegetables. Chemically speaking, carbohydrates (in particular, their reducing monomers), proteins, free amino acids, and lipids are thermally degraded and transformed into numerous oxygen-, nitrogen- and sulfur-containing five- and six-membered heterocyclic flavor compounds together with α-diketones and aldehydes. More specifically, reaction flavors produced by heating reducing sugars and amino acids (resulting from protein hydrolysis) in addition to various other ingredients such as nucleotides, phospholipids, and fats are called Maillard-type flavors, the annual commercial value of which has been estimated at some US$780 million. The type of flavor thus obtained can be controlled by the nature and ratio of amino acids and sugars which are heated together; for example, cysteine and methionine are essential for obtaining meat flavors whilst proline plays an important role in the formation of bread and cereal flavors. (*See* **Browning**: Nonenzymatic.)

Flavor Delivery Systems

Since flavors are never being consumed as such but have always to be integrated into a food, the best way of delivering flavor is of prime importance to the flavor and food industry. Therefore, various flavor delivery systems have been developed over time. They usually consist of a taste-neutral carrier which combines with a flavor, often stabilizes it, may facilitate its transport and handling, and ultimately provides a better release of the desired amount, at the right place and time. They are sold as powder or liquid flavor systems in addition to conventional flavors.

Some flavor delivery systems are concerned primarily with transport and handling issues and give little protection to the flavor ingredients. More recent encapsulation processes have been designed to extend shelf-life in addition to giving functional flavor delivery in the finished food.

Encapsulation processes to make powder flavor systems trap liquid flavors in a solid carrier matrix. The most important encapsulation technologies are spray drying, extrusion, molecular inclusion, and

coacervation. All these processes lead to products which differ from each other in particle type and size, flavor load, chemical stability, hygroscopicity, and flavor release characteristics. Furthermore, there are notable differences in the process economics. Spray drying is generally considered as the most advantageous encapsulation method, coacervation is expensive, and molecular inclusion technology using β-cyclodextrins has recently been introduced into the marketplace as a result of a cost-lowering of β-cyclodextrin, and its acceptance in the USA as a food additive. Encapsulated flavors are also made by extruding a molten (110–130 °C) low-moisture blend of carbohydrates, which contain a dispersed flavor, into a cooled (−18 °C) solvent. The melt is hardened by the rapid chilling into amorphous glass-like particulates, which provide much better oxidative stability than that obtained by spray drying. Frequently used carriers for encapsulated powder flavors are modified or hydrolyzed starches (e.g., maltodextrin), gum arabic, proteins, and alginates.

Another current way of entrapping and delivering flavor is via liquid, stable emulsions. An oily flavor/water mixture in the presence of an emulsifier is passed through a high-pressure homogenizer. Often the density of the oil phase is brought closer to that of the aqueous phase by the addition of a high-density weighting agent such as sucrose acetate iso-butyrate. (*See* **Extrusion Cooking**: Principles and Practice; **Drying**: Spray Drying.)

Storage, Packaging, and Distribution of Flavors

The storage, packaging, and distribution of flavors requires consideration of numerous issues, including flavor stability during storage, rules on acceptable food packaging materials, regulations on the storage and transport of flammable goods, rules on the avoidance of certain materials (e.g., glass) in specific industries, environmental concerns and worker safety, not to mention the special requirements of food manufactures. FLAXSEED

D H Morris, Mainstream Nutrition, Toronto, Ontario, Canada
M Vaisey-Genser, The University of Manitoba, Winnipeg, Manitoba, Canada

Background

Flaxseed was one of the first plants domesticated by humans about 8000–10 000 years ago. Ancient peoples valued flaxseed for its medicinal properties; its oil, which was used in cooking and in formulating cosmetics; and its fiber, which was used to make linen and sail cloth. The botanical name of flaxseed, *Linum usitatissimum* of the family Linaceae, reflects its versatility and importance in the economic and social development of humans: The word *usitatissimum* is Latin for 'most useful.' Flaxseed, or linseed as it is sometimes called, is valued for many of the same reasons today. This chapter describes the composition of flaxseed and its health benefits, performance properties, safety, and recommended intakes.

Composition

Flaxseed is rich in fat, dietary fiber, and protein. The composition of Canadian-grown flaxseed averages 41% fat, 28% total dietary fiber, 20% protein, 7.7% moisture, 3.5% ash, and 1% simple sugars. The amount of fat in flaxseed can range from 38 to 47%, depending on the variety and growing conditions. The proximate composition for common measures of whole and ground flaxseed and flaxseed oil is shown in Table 1.

Flaxseed has a unique fatty acid profile, being fairly low in saturated fatty acids and rich in α-linolenic acid (ALA), the essential ω-3 fatty acid (see Figure 1). Of the total fatty acids in flaxseed, saturated fatty acids constitute 9%; monounsaturated fatty acids, 18%; and polyunsaturated fatty acids, 73%. Of the polyunsaturated fatty acids, ALA constitutes the majority at 57% of total fatty acids, making flaxseed one of the richest sources of this fatty acid. Linoleic acid, the essential ω-6 fatty acid, is present in a smaller amount (16%). Because of its high ALA content, flaxseed has an ω-6/ω-3 fatty acid ratio of 0.3:1. (*See* **Fatty Acids**: Properties; Metabolism.)

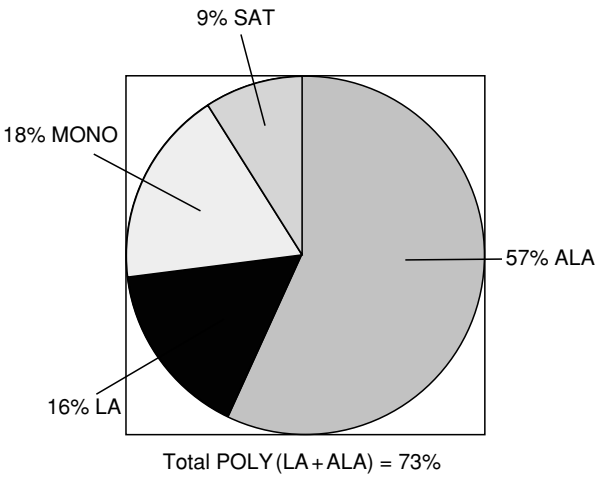

Figure 1 Fatty acid composition of flaxseed oil, based on an analysis conducted by the Canadian Grain Commission, May 2001. Abbreviations: ALA, α-linolenic acid; LA, linoleic acid; MONO, monounsaturated fatty acids; POLY, polyunsaturated fatty acids; SAT, saturated fatty acids.

[a]Used with permission of the Flax Council of Canada. Based on a proximate analysis conducted by the Canadian Grain Commission, May 2001. The fat content was determined using the American Oil Chemists' Society (AOCS) Official Method Am 2–93. The moisture content was 7.7%.
[b]Total carbohydrate includes available carbohydrate (1 g) and total dietary fiber (28 g) per 100 g of flaxseed.
[c]Total dietary fiber includes insoluble fiber (19 g) and soluble fiber (9 g) per 100 g of flaxseed.

Flaxseed provides about 28 g of total dietary fiber per 100-g dry weight. (Dietary fiber is defined as the edible parts of plants that are resistant to digestion and absorption in the human small intestine but that are completely or partially fermented in the large intestine.) About one-third of flaxseed fiber is water-soluble, consisting mainly of mucilage gum. The remaining two-thirds is water-insoluble and consists primarily of nonstarch polysaccharides such as cellulose and lignin. The flaxseed lignan, secoisolariciresinol diglycoside (SDG), is a phenolic compound related in structure to lignin.

The amino acid profile of flaxseed protein is similar to that of soybean protein. Flaxseed proteins are albumins and globulins. The predominant globulins, like linin, are less soluble and higher in molecular weight than the albumins. Flaxseed also contains minor amounts of essential vitamins like niacin, folic acid and γ-tocopherol, and minerals like potassium and phosphorus.

Health Benefits

Flaxseed has been called a functional food, because of the health effects associated with its ALA and lignan content. Functional foods have been defined as those that offer health benefits in addition to what would be expected from the food's nutrient content. Because of its wide-ranging health effects, flaxseed may help in the clinical management of chronic conditions such as cardiovascular disease (CVD), stroke, certain types of cancer, and autoimmune diseases like systemic lupus erythematosus.

Laxation

The insoluble dietary fiber in flaxseed is likely responsible for its laxative effect in young and elderly adults. For instance, in a study of 10 healthy young adults, bowel movements increased 30% during the 4-week period when they ate two 25-g flaxseed muffins daily compared with the control period, during which time they ate muffins without flaxseed.

Cardiovascular Diseases

The underlying cause of CVD is atherosclerosis. One risk factor for CVD is elevated blood total cholesterol concentrations. The results of clinical studies indicate that flaxseed has a positive effect on blood lipids. In one study of 10 healthy young men and women, plasma total cholesterol was reduced 6% and low-density-lipoprotein (LDL) cholesterol was reduced 9% following the consumption of flaxseed muffins providing 50 g of ground flaxseed daily for 4 weeks. Plasma high-density-lipoprotein (HDL) cholesterol and triacylglycerol levels were unchanged during the flaxseed supplementation period. In a study of 15 men and women with hyperlipidemia who had just completed a trial of the effect of vitamin E supplementation on serum lipids, adding 15 g of ground flaxseed to their daily diet reduced total blood cholesterol 7% and LDL cholesterol 11% without changing HDL cholesterol levels. (*See* **Cholesterol: Role of Cholesterol in Heart Disease.**)

The reductions in total cholesterol and LDL cholesterol achieved in these studies were likely due to flaxseed's dietary fiber and ALA content. Dietary fiber is widely recognized as an agent that decreases serum cholesterol levels and slows the development of atherosclerotic lesions. Populations with high intakes of dietary fiber have a lower risk of CVD and other chronic diseases than populations with low fiber intakes. ALA also affects the cardiovascular system. In dogs, pure, infused preparations of ALA and the long-chain ω-3 fatty acids, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), protected against fatal arrhythmias. Although the mechanism of action is not completely understood, ALA and the other ω-3 fatty acids are believed to regulate membrane ion channels and heart muscle fiber excitability, thus stabilizing the electrical signals of the heart and helping prevent ventricular fibrillation and arrhythmias.

Although there is no direct evidence that dietary ω-3 fatty acids are as effective in humans as pure fatty acid preparations are in dogs, indirect evidence for a dietary benefit of ALA is available from epidemiologic studies of diet and CVD risk. For example, researchers in the Lyon Diet Heart Study hypothesized that ALA may have antiarrhythmic actions that significantly reduce fatal CVD events. They recruited subjects who had survived a myocardial infarction. Those subjects who consumed a typical Mediterranean-style diet rich in ALA from many dietary sources had a nearly 70% reduction in fatal cardiac deaths compared with the group who consumed their usual Western-type diets. An extended follow-up of the study revealed that the protective effect of the Mediterranean diet was preserved – ALA, but not EPA and DHA, was associated with protection against recurrence of myocardial infarction. Data from other epidemiologic studies, including the Health Professional Follow-up Study, the Multiple Risk Factor Intervention Trial, and the Nurses' Health Study, suggest that diets high in ALA are associated with a reduced risk of fatal and nonfatal myocardial infarction, fatal CVD, and death from all causes.

ALA also affects the process of atherosclerosis by reducing inflammatory responses. Atherosclerosis is an inflammatory disease that begins in infancy and childhood when the earliest lesions, called fatty

streaks, begin developing in arteries. Flaxseed may influence the progression of atherosclerosis by inhibiting the production of major systemic components of inflammatory activity, including eicosanoids, cytokines, and platelet-activating factor.

Cancer

Flaxseed is a rich source of the lignan and phytoestrogen, SDG, which is a precursor of the mammalian lignans, enterolactone and enterodiol. Phytoestrogens are plant-derived compounds that can interfere with estrogen metabolism in animals and humans. Lignans may protect against certain types of cancer, particularly the hormone-sensitive cancers such as those of the breast, endometrium, and prostate, by interfering with the metabolism of sex hormones. Flaxseed lignans enhance the clearance of circulating estrogen, and they inhibit the binding of sex hormones to cell membranes by blocking cell-membrane receptors. In rat mammary gland tissue, flaxseed lignans decreased cell proliferation, the number of nuclear aberrations, and tumor volume. Preliminary data from one human study suggest a possible benefit of flaxseed consumption by women with breast cancer. Overall, flaxseed lignans, pure SDG, and flaxseed oil rich in ALA affect the carcinogenic process at several points, including initiation, promotion, and progression/growth of tumors. (*See* **Cancer**: Diet in Cancer Prevention.)

Diabetes and Autoimmune Diseases

Flaxseed affects the postprandial blood glucose response in healthy young adults. In a study involving nine young women, blood glucose decreased about 27% after two test meals were consumed. Studies of the hypoglycemic effects of flaxseed among patients with diabetes mellitus are under way. (*See* **Diabetes Mellitus**: Etiology.)

Flaxseed may be useful in the management of autoimmune diseases like rheumatoid arthritis and systemic lupus erythematosus through the actions of ALA on proinflammatory eicosanoids and platelet-activating factor (PAF). The one published study of flaxseed oil's effects on the clinical and subjective assessment of symptoms associated with rheumatoid arthritis found no significant differences between outcomes in patients who consumed flaxseed oil compared with safflower oil for 3 months. However, in studies of normal, healthy volunteers, flaxseed reduced significantly the production of proinflammatory eicosanoids that contribute to inflammation and other immune responses. Dietary flaxseed also inhibits PAF, a powerful mediator of the immune response. In studies involving patients with lupus nephritis, a condition marked by chronic inflammation of the kidney, flaxseed consumption reduced significantly PAF production and kidney inflammation and improved kidney function. Thus, a beneficial role for flaxseed in managing autoimmune diseases has been proposed, but more research is needed to confirm its effects.

Other Health Benefits

Reports that flaxseed aids in treating the symptoms of depression, irritable bowel syndrome, osteoporosis, and menopause are largely anecdotal. Future research will determine the effects of flaxseed's components, particularly the lignans and ALA, on the pathology and treatment of these conditions.

Performance Properties

Market Forms

Flaxseed is marketed primarily as the intact whole seed, which is reddish brown, flat, and oval with a pointed tip. The seed measures about $2.5 \times 5.0 \times 1.5$ mm, slightly larger than a sesame seed. Flaxseed is also marketed in a coarsely ground form. Whole flaxseed may be ground successfully in a home coffee grinder.

Flaxseed oil is available in health food stores either in bottles for use with foods such as salads or in capsules to be used as diet supplements. Oil for the health food market is produced by 'cold-pressing' flaxseed where the maximum allowable temperature is 35 °C. The seed is cleaned, cracked, flaked between rollers, and pressed in expellers filled with water-cooled shafts. It is normally bottled in light-proof containers to avoid photooxidation and refrigerated to limit autoxidation.

Sensory Characteristics

Appearance, texture, and taste are the sensory features that benefit from adding flaxseed to foods. The reddish brown seed provides an attractive color contrast in products like yeast breads and muffins, in cereals such as cream of wheat or corn meal/grits, and in pancakes and potato latkes. Whole flaxseed provides crunchiness and chewiness, textural features that are less pronounced in the ground form. Experienced sensory panelists have described the taste of flaxseed as nutty and cereal-like with a slightly fruity/bitter tang.

Food Uses

Flaxseed has been used in food over the centuries, particularly in the Middle East and North Africa. In Ethiopia, flaxseed is a key ingredient in porridge and, when roasted, crushed and combined with split peas and red pepper, in 'w'et,' a form of stew. There it is also enjoyed as 'ch'lk'a,' a drink made from lightly

roasted ground flaxseed, salt, water, and honey. In China, oil from cold-pressed flaxseed has long been used for stir-frying. In North America, flaxseed continues to be an ingredient of Red River Cereal®, a breakfast staple introduced in 1924.

Acceptability studies show that baked products such as yeast breads, muffins, and cookies containing flaxseed are increasingly well liked by North American consumers. This is in keeping with the growing predominance of whole wheat and multigrain breads in preference to white bread in several regions. Experienced sensory panelists give flaxseed and wholewheat breads comparable ratings in crust color, texture, tenderness, porosity, and loaf shape.

During the 1990's, a 'functional' bread, Burgen® Soy-Lin™, was developed and commercialized in Australia as one outcome from a study of the effects of phytoestrogens on the symptoms of menopause. Four slices of this 10% fiber bread daily contributed 2.5 g of ALA and contained enough soy flour and flaxseed to supply a significant amount of phytoestrogens (220 mg) as isoflavones from soy together with the lignan precursors from flaxseed. By April 1997, Burgen® Soy-Lin™ bread had captured 5.3% of the total Australian bread market and was proving successful in the UK.

Recipe Modifications

Most wheat-flour recipes including yeast breads and quick breads such as muffins, tea biscuits and cookies can comfortably accommodate a 10% replacement of wheat flour by flaxseed. However, when using flaxseed in food products, it is important to recognize two factors. First, flaxseed is an oilseed containing a generous amount of fat, and second, flaxseed is hydrophilic or water-loving.

When substituting flaxseed for wheat flour in baked goods, it is prudent to reduce the amount of fat called for in the recipe by the amount contained in the flaxseed. A useful 'rule of thumb' is the fact that 3 tbsp (1 tbsp = 15 ml) of whole flaxseed, which is 41% oil, replaces 1 tbsp of salad oil. However, 3 tbsp of ground flaxseed will replace only 2/3 tbsp (2 tsp) of salad oil. This is because flaxseed is aerated during grinding so that ground flaxseed weighs less per unit of volume, as shown in Table 1. Accordingly, it replaces a little less fat than an equal amount of whole flaxseed.

The nature of the fat being substituted by the oil in flaxseed may also influence the amount replaced. Hydrogenated shortenings, like salad oils, are 100% fat. However, because they are aerated to make them easier to cream in cake and cookie production, they contain about 10% less fat per unit volume than salad oils. The standard tablespreads butter and margarine are 80% fat with an allowable 16% water, so their fat content per unit volume is less than either hydrogenated shortening or salad oil. Thus, added flaxseed with its 74 g of oil per cup (1 cup = 240 ml) (Table 1) theoretically replaces the volume of a fat type as specified in a standard recipe such that flaxseed would replace a greater volume of butter or margarine than it would of hydrogenated shortening or salad oil. Nevertheless, the balance of ingredients in a sweetened, shortened baked product can tolerate as much as a 25% increase or decrease in an ingredient without making the product fail.

Considering the affinity of flaxseed for water, bakers recommend that whole flaxseed for yeast breads be conditioned with a water presoak for at least 30 min at 18 °C using a 2:1 ratio of water to flaxseed. The soaking water, which contains some of the soluble gums, then serves as the liquid in the recipe. When ground flaxseed is used, water should be added to approximate 75% of the flaxseed weight. Some authors suggest that the yeast used be increased by 25% if 10–15% of whole flaxseed is replaced by ground flaxseed.

Storage Stability

The usefulness of flaxseed as a staple food ingredient is reinforced by the fact that it appears remarkably stable to storage. In one study, flaxseed from a mixture of several varieties grown in Canada in 1996 was ground with a pin-mill and packed in 60-lb (27.3-kg) triple-wrapped plastic-lined paper bags. Samples were stored for 128 days at ambient temperatures under conditions similar to those used by commercial bakeries. The mixed flaxseed contained 43% oil consisting of 60% 18:3*n*-3 (ALA), 16% 18:2*n*-6, and 15% 18:1*n*-9. Table 2 shows that, despite its substantial content of unsaturated fatty acids, ground flaxseed showed little or no evidence of oxidative deterioration during 4 months of storage at room temperature. Peroxide values, free fatty acids, and conjugated double bonds did not change appreciably. These chemical results were verified by the lack of difference in odor intensity measured by a trained sensory panel that examined water/ground flaxseed slurries from all storage intervals concurrently. Furthermore, a consumer panel of 36 volunteers, using a duo–trio test, could not detect any difference between 10% flaxseed yeast breads prepared from ground seed that had been stored at either 0 or 128 days.

While volatile compounds increased during the storage of ground flaxseed, the level of total volatiles after 4 months' storage was 10–25 times less than values reported for stored vegetable oils that contained appreciably less oxidation-susceptible ALA.

Table 2 Chemical and sensory indices of the storage stability of ground mixed flaxseed[a]

Parameter	*Storage day at 23 + 2 °C*				
	0	*33*	*66*	*96*	*128*
Peroxide value (meq kg^{-1})	0.20	0.21	0.12	0.16	0.12
Free fatty acids (%)	0.34	0.48	0.31	0.35	0.31
Conjugated double bonds (absorbance at 268 nm)	0.20	0.19	0.19	0.19	0.19
Odor intensity[b]	3.1	3.6	3.2	3.2	3.5

[a]Adapted from Malcolmson LJ, Przybylski R and Daun JK (2000) Storage stability of milled flaxseed. *Journal of the American Oil Chemists' Society* 77: 235–238.
[b]1, none; 5, intense; nine-member trained panel; two replications.

Increases over time were least in the dienals, which is usually one of the major subclasses resulting from polyunsaturated fatty acid oxidation. Among individual compounds, hexanal, which is often a quality indicator, was found only at the p.p.b. level, marginally close to reported sensory thresholds.

What accounts for the oxidative stability of flaxseed remains a question. In a sequel to the above study, the fatty acid composition and the tocopherols, known antioxidants, in ground mixed flaxseed were examined after 11 and 20 months' storage at ambient temperatures. ALA levels were within the normal variability range after 20 months' storage, and the tocopherols remained essentially unchanged. The authors suggested that they were either not used or in some way regenerated.

Baking Stability

The ALA in flaxseed, whole or ground, appears to be reasonably stable to baking temperatures. For example, the proportion of ALA in a muffin mix where flaxseed made up 28.5% of the formula remained unchanged after baking for 2 h at 178 °C, despite the fact that more oxygen was consumed by flaxseed muffins during baking than those which were flaxseed-free. Biological evidence also supports the baking stability of ALA. No difference was found between the plasma fatty acid profiles of college women eating 50 g of raw, ground flaxseed added to cereal, soup, juice or yogurt daily for 4 weeks and those eating the same amount baked in bread. Both groups showed a lowering of serum total cholesterol and LDL cholesterol.

Several studies suggest that the lignan precursor SDG is stable to baking. For example, SDG levels in the center of flaxseed breads proved similar to those in the crust, even though the latter had a greater heat exposure. Lignan production, measured by *in vitro* fermentation, reflected the amounts of raw flaxseed added in both commercial and home-baked products (baked at 190 °C) and pancakes (205 °C), supporting stability to baking. Furthermore, bioavailability was confirmed in this series of studies when nine women, for periods of 1–8 days, ate 5, 15, or 25 g of flaxseed either added raw to applesauce or baked in muffins or bread. While urinary lignan excretion increased as the amounts of flaxseed eaten increased and with repeated flaxseed consumption, there was no significant difference in urinary lignan excretion due to baking conditions.

Safety

Flaxseed contains two substances that may interfere with the absorption of certain nutrients, although both substances are present in flaxseed at levels that appear to be of little consequence in the human diet. Linatine inhibits the utilization of pyridoxine (vitamin B_6). However, when 30 adults consumed 45 g of flaxseed daily in muffins for 5 weeks, serum pyridoxine levels did not change significantly from baseline. The other substance, phytic acid, is known to form insoluble complexes with calcium, copper, iron, magnesium, and zinc in the intestine, thus reducing their absorption. There is no evidence that this occurs to any appreciable extent in humans.

Flaxseed also contains cyanogenic glycosides, which are a group of natural substances found in more than 2500 plant species that can release cyanide, a poisonous compound, under certain conditions. Several agronomically important crops such as cassava, sorghum, flaxseed, and stone fruits like peaches, plums, cherries, and apricots contain the glycosides. There is no evidence that the cyanogenic glycosides pose a health problem for healthy, nourished populations in developed countries. Baking and other processing methods apparently destroy or volatize the cyanogenic glycosides. Indeed, muffins containing 25 g of ground flaxseed had no detectable levels of the glycosides after baking for 15–18 min at 230 °C.

Recommended Intakes

There is growing concern that Western populations have an unbalanced intake of ω-3 fatty acids relative to the ω-6 fatty acids. The current dietary ω-6/ω-3

Table 3 Contribution of flaxseed to ω-3 and ω-6 fatty acid intakes and the ω-6/ω-3 fatty acid ratio of the North American diet[a]

Food Item	*ω-3 content of food[b] (g)*	*ω-6 content of food (g)*	*ω-6/ω-3 ratio of the diet*
Commonly eaten foods			
Breakfast (cereal, milk, orange juice)	0.106	0.333	
Lunch (roast beef sandwich with pickle and tomato slices plus one large apple)	0.285	2.187	
Snack (4 oz (112-g) of potato chips)	0.216	13.584

Flaxseed oil, 1 tbsp	8.0	2.24	3:1

[a]Used with permission of the Flax Council of Canada.
[b]The ω-3 and ω-6 fatty acid contents of foods were calculated using the US Department of Agriculture's Nutrient Database for Standard Reference, Release 13, available on the Internet at www.nal.usda.gov/fnic/foodcomp.

ratio ranges from about 10:1 to 25:1 in typical North American diets. Health Canada recommends a ratio of 4:1 to 10:1, whereas a joint Food and Agriculture Organization/World Health Organization committee recommends a ratio of between 5:1 and 10:1. Flaxseed consumption can increase total ω-3 fatty acid intakes and reduce the ω-6/ω-3 ratio, as shown in Table 3.

The US Institute of Medicine set a daily Adequate Intake of 1.1 g of ALA for women and 1.6 g of ALA for men. These recommended intakes can be achieved by consuming as little as 8 g (1 tbsp) of ground flaxseed or 2.5 g (1/2 tsp) of flaxseed oil per day. Up to 10% of the Adequate Intake can be derived from foods containing EPA and DHA.

In most clinical trials of the health effects of flaxseed, volunteers have consumed 5–50 g of ground flaxseed or 60 ml or flaxseed oil daily. Based on the findings of these published reports, an intake of about 8–16 g (1–2 tbsp) of ground flaxseed daily is recommended. Ground flaxseed is the preferred form because it is easily added to foods and supplies the full complement of nutrients associated with flaxseed's positive health effects. Flaxseed oil is rich in ALA but does not contain dietary fiber or lignans.

Summary

Flaxseed is a functional food valued for its pleasant, nutty taste, unique nutrient profile, and health benefits. Flaxseed is a rich source of ALA, the essential ω-3 fatty acid, and the lignan, SDG. It also provides protein and dietary fiber. Newer research suggests that flaxseed may help in the prevention and management of chronic diseases such as coronary heart disease, diabetes mellitus, certain types of cancer, and autoimmune diseases. Flaxseed's high ALA content can make a significant contribution to total ω-3 fatty acid intake. The lignan precursors and ALA in flaxseed appear to be stable to common storage and baking conditions. Consumers can purchase flaxseed as whole seeds, ground flaxseed, flaxseed oil, in capsule form and in baked goods, cereal mixes, and pasta products.

FLOCCULATION

B M Baraniak, Agriculture Academy, Lublin, Poland
E Waleriańczyk, Instytut Przemyslu Cukrowniczego, Warszawaul, Poland

Background

Flocculation is a preliminary treatment of colloidal systems, employed to destabilize the sol structure by adding reagents that encourage particle growth, before separation of the solid phase is attempted by filtration or sedimentation. Particles of colloidal dimension (0.5×10^{-5} m) frequently form stable dispersions which do not settle and are not amenable to conventional filtration processes. (*See* **Filtration of Liquids.**)

Mechanism of Flocculation

Colloid Destabilization by Ions

The stability of a colloid is related to its zeta potential, which involves the charged surface of the particles and the oppositely charged layer of counter ions adjacent to it, constituting an electrical double layer. A reduction of zeta potential results in destabilization of the stable colloid structure, and may be caused either by the specific adsorption of counter ions – a nonspecific effect of neutral electrolytes – or by enmeshment of particles within a sweep floc. Since the charge of counter ions is important, it is apparent that polyvalent ions will be more effective than singly charged ions: Na(I) < Ca(II) < Al(III).

Colloid Destabilization by Polymers

A general mechanism for the destabilization of colloidal sols by high-molecular-weight synthetic polymers, termed polyelectrolytes, is described by the theory of bridging. The polyelectrolyte is adsorbed at several sites, not covering the whole area of the colloidal particles. As the polyelectrolyte molecules are relatively long, loops or chains protrude beyond the double layer. Thus, flocculation takes place through hydrophobic or hydrogen bonds, and any compression of the double layer that can be induced by increases in ionic strength should enhance bridging by allowing closer particle approach (**Figure 1**).

Polyelectrolyte adsorption may, in some cases, increase the stability of the colloid. A strongly adsorbed polymer may increase the diameter of the diffuse layer, and the larger double layer will generate repulsive

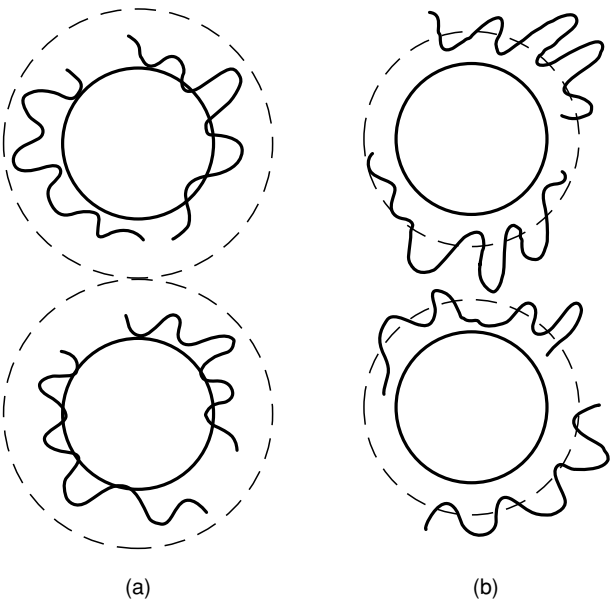

Figure 1 Bridging efficiency of polyelectrolytes: (a) low ionic strength; (b) high ionic strength. Reproduced from Flocculation, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

interreactions, leading to increased stability. The amount of polyelectrolyte applied in relation to the colloidal concentration is critical for destabilization or restabilization of colloid structure. Overdosing is a real danger, and the optimum concentration of polyelectrolyte required for flocculation should be very small (not in excess of $1\,mg\,l^{-1}$).

Aggregation Mechanism

The aggregation of the destabilized colloid structure is the second step in the final process of separation of the solid phase, and it is ultimately dependent on two factors: (1) frequency of collision between particles; (2) effectiveness of the interactions causing particle–particle adhesion. In general, there are two mechanisms by which adhesion contacts occur: (1) aggregation by thermally induced motions, termed 'perikinetic flocculation'; (2) contacts between particles in heterodisperse systems by differential settling under gravity, termed 'orthokinetic flocculation.'

In real systems, the initial stage of flocculation would be perikinetic, but with increasing floc growth the orthokinetic model becomes dominant.

Flocculants and Coagulants

Polyelectrolytes

Polyelectrolytes that are applied practically as flocculants are mainly water-soluble polyacrylamides, polyphosphates and modified natural polymers – gelatines, chitosan, and carrageenan, as well as starch and cellulose derivatives. Polyelectrolytes are classified as cationic, anionic, and nonionic according to the nature of the functional groups along the polymer chain. Predominant among these are polyacrylamide copolymers of acrylamide and acrylate, or monomers containing ammonium groups (Figure 2).

A polyelectrolyte is characterized by its molecular weight, the nature of the functional group, and the charge density. An important consideration in choosing a polyelectrolyte for a desired process is its potential as a coagulant (by destabilization of the colloid via neutralization) and as a flocculant (by interparticle bridging). The pH is also an important parameter to be considered when selecting a polyelectrolyte for a particular application. Sensitivity to pH occurs with cationic polymers in which quaternary ammonium groups are dominant, and with anionic polymers containing sulfonic acid groups. Flocculants with carboxyl or amine groups confer strong pH dependence. The toxicity of polyacrylamides is usually low,

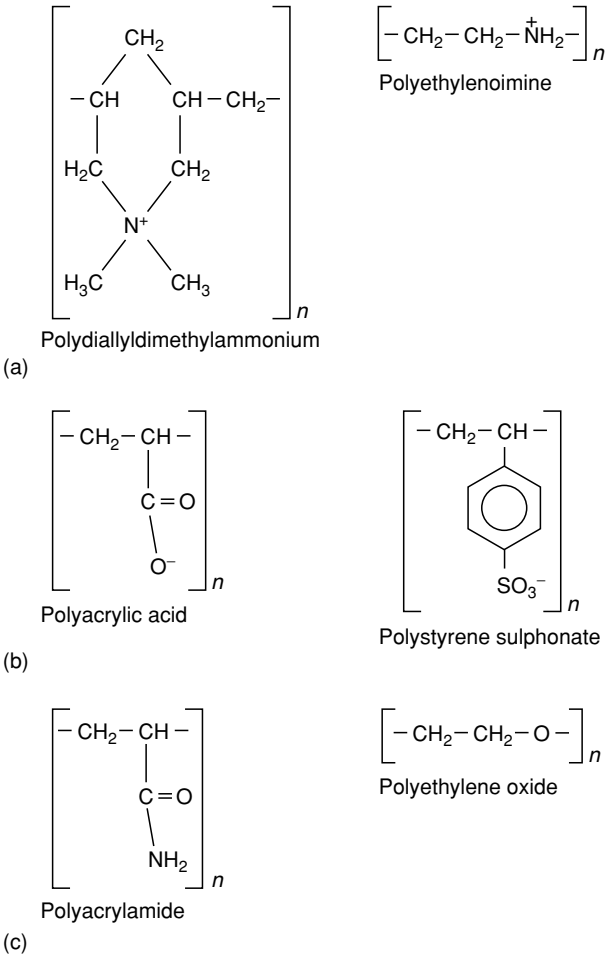

Figure 2 Characteristics of main groups of polymeric flocculants: (a) cationic polyelectrolytes; (b) anionic polyelectrolytes; (c) nonionic polymers. Reproduced from Flocculation, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

usually lower than 0.05%, and results mainly from the presence of free acrylamide.

Coagulants

The reagents most widely used in coagulation processes are polyvalent cations, such as Al(III) or Fe(III) or Fe(II), available as chlorides or sulfates in crystalline forms. Iron salts generally offer advantages over aluminum salts, and Fe(III) is also often superior to Fe(II) because it has a wider pH range of action.

Other Flocculants

Clay materials, such as bentonite or montmorillonite, activated carbon or activated silica are sometimes used to improve the filtration or sedimentation of suspended solids.

Practical Aspects

Selection of Polyelectrolyte

Factors which affect the choice of the particular flocculant or coagulant are the nature of the impurities and the particle size of suspended solids. Selection and dosage required can be determined by laboratory testing of the settling rate, clarity, and volume of sedimented mud. Laboratory testing does not exactly reproduce plant conditions and should be considered as a prelude to plant trials.

Preparation of Polyelectrolyte Solution

Most polyelectrolytes used as flocculants are available as a low dusting powder, and have to be distributed for use as a colloidal sol of concentration 0.05–0.5%. This limitation is due to the high viscosity of more concentrated dispersions (0.1–0.2 Pa s for 0.5%). The casual addition of a polyelectrolyte solid to water results in a jelly-like structure, which is useless as a flocculating agent. Efficient dispersion is achieved by use of an Educator–Venturi system, providing a homogeneous solution. Long-term storage or temperatures greater than 60 °C result in a loss of effectiveness caused by depolymerization.

Point of Addition

The point of addition of a polyelectrolyte is of utmost importance. The flocculant should be added at a point which allows for uniform mixing with the slurry, but it should not be subjected to excessive turbulence, which can disrupt the floc. It is also necessary to arrange for the introduction of the flocculant – as dilute as possible to ensure efficient distribution – at a point which allows time for particle collisions to take place prior to the solid removal stage. In practice, there are two systems which achieve the correct conditions for flocculation: gently agitated tanks, and flocculation chambers.

Removal of Flocculated Solids

The two principal techniques for removal of the solid formed – flotation or sedimentation – are employed, depending on the kind of flocs formed. A light material can be subjected to air treatment for flotation; flocs that tend to settle are generally separated by sedimentation (see Figure 3). Filtration is rarely used – mostly in water treatments, with sand or carbon filters, or rotary vacuum filters for carbonated raw beet juice.

Applications

Waste Water Treatment

Industrial waste water is frequently a complex solids–colloidal system, with soluble compounds of organic or inorganic origin.

Physicochemical treatments of industrial waste water can achieve good results where biological processes are inapplicable, e.g., with nonbiodegradable materials, toxic discharges, or removal of minerals and color. This is cheaper in terms of capital cost, more easily controlled and less space-consuming than biological treatment, but higher in terms of operational costs.

Adsorptive precipitation and flocculation are the main processes for coagulating colloidal particles to form larger aggregates. The principal reagents used are lime, ferric or aluminum sulfate, and polyelectrolytes.

The low-molecular-weight polymers have the advantage, over the inorganic coagulants, that they do not increase the salts' level, but they are often relatively uneconomical. The salts Al(III) or Fe(III) are

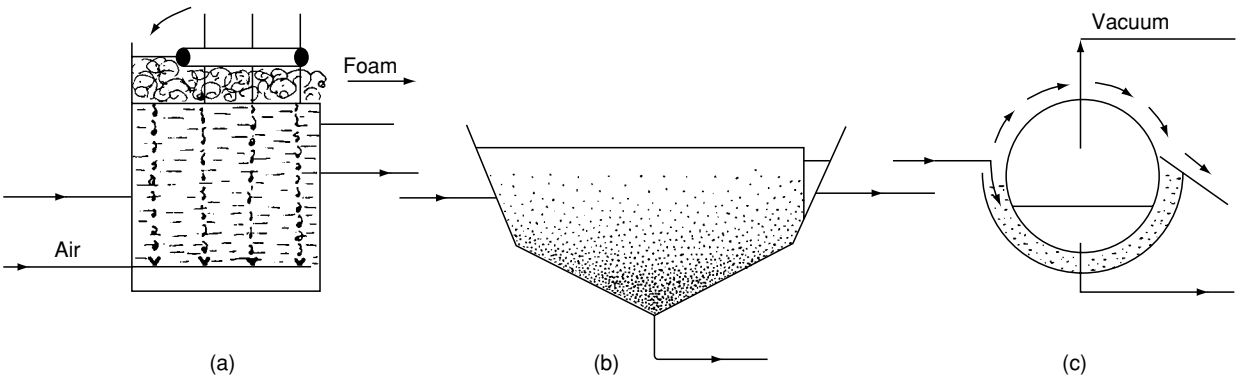

Figure 3 Equipment for removal of solids formed in flocculation: (a) flotation machine; (b) decanter; (c) vacuum rotary filter. Reproduced from Flocculation, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

commonly used first to promote coagulation; then, a high-molecular-weight polyelectrolyte is introduced to the coagulated solids. Highly dispersed solids need either polyvalent ions or low-molecular-weight polyelectrolytes. With the larger particles, high-molecular-weight polymers are more effective; for examples of applications, see Table 1. The flocculation permits the recovery of protein from waste water coming from the food industry, as well as from byproducts, e.g., agglomeration of whey proteins with carboxy-methylcellulose, or protein precipitation by amide polyelectrolytes in waste water of the potato industry. (*See* **Water Supplies**: Water Treatment.)

Raw Sugar Process

Raw sugar juices contain considerable amounts of colloidal materials which have to be removed in clarification. There are two groups of colloid: constituents of the beet cells transferred to the sol form during extraction, and those that originate as a result of condensation, e.g., melanine, melanoidine or invert or saccharose decomposition products. The process of removing colloidal substances is essential, as their presence in thin or dense juices, delays the sedimentation and filtration process, and favors foaming and the increase of coloration, and sugar loss during crystallization.

Lime acts as a primary coagulant, precipitating colloidal and colored matter. A radical improvement in the process of clarification of sugar juice was brought about by the application of flocculants. The application of sodium alginate or modified starch at dosage rates of 10–50 p.p.m. was not very satisfactory. Significant progress was made with the introduction of synthetic polyacrylamides. In general, anionic flocculants are applicable for the treatment of the raw juice from cane or beet. The flocculant dosage rates range from 0.8 to 2 p.p.m., and experience has shown that it is better to dilute the flocculant with raw juice instead of water. The favorable effect of this flocculant introduction was evident in the way the juice with sediment flowed to the filter or decanter.

A proper application is likely to increase the size of the colloidal particles by several times, which facilitates the plate and frame filter press function, and more compact filter cakes than normal are obtained. Polyelectrolytes are also recommended in sugar refining, and the addition to carbonated sugar juice improves both the clarification and filtration processes. (*See* **Sugar**: Refining of Sugarbeet and Sugarcane.)

Technology of Leaf-protein Concentrates

Leaf-protein concentrate (LPC) is one product resulting from green crop fractionation that provides the animal feed industry or food industry with a protein. Green crop fractionation offers the possibility of a greater total biological efficiency in the production of protein than can be achieved by other systems. It is possible to envisage several systems defined by the products of the process, which have as one of their products LPC in a wet or dried form. Freshly expressed juice from macerated green plants contains small amounts of fiber, minerals and proteinaceous material of leaf origin, chloroplasts or fragments thereof, and about 90% water. Removal of the protein fractions is possible through the destabilization of the colloidally suspended particles (Figure 4).

The flocculation of the chloroplastic function is carried out in chambers under light mechanical motion (100 r.p.m.) by introducing the flocculant directly to the green juice which was alkalized with sodium hydroxide to pH 7–8.5. Coagulation occurs almost instantaneously to produce macroflocs that settle down and make subsequent filtration easy.

The effectiveness of flocculation depends on the ionic character of the polyelectrolyte, as well as its

Table 1 Application of flocculation in industrial waste water treatment

Industry	*Pollution parameters*	*Flocculant*	*Benefits*	*Removal of solids*
Processing of poultry, slaughterhouse waste	Fats, grease, blood	Al(III) and polyelectrolyte	Reduction of total solids	Dissolved air flotation

charge density and concentration, on the acidity of the plant juice, and on the species of plant. Satisfactory results, in terms of both quantity and concentrates and protein content, were obtained by adding 150–300 mg of Magnafloc LT-27 (Allied Colloids, UK) or Prodefloc C/1 (Prodeco, Italy) per liter of green alfalfa juice. From 100 kg of fresh plants, the process yields 1.6 kg of dry LPC containing 56% of protein.

Cationic and anionic polyacrylamides were applied on a laboratory scale for the flocculation of green juice from the following plants: leaves of sugar beet, clover, buckwheat, vetch, sunflower, and tobacco. The chemical composition of products obtained is similar to that obtained by means of the thermal coagulation method called Pro-Xan.

The application of flocculants in the processing of LPC allows a decrease in the energy consumption and yields proteins which are not denatured thermally.

History of Flour Milling

The origins of wheat milling date back thousands of years to the dawn of civilization. Milling technology gradually advanced from the mortar and pestle, used by primitive cultures about 10 000–12 000 years ago, to the invention of the millstone in Roman times. Millstones remained in vogue until the introduction of the purifier, plansifter, and the horizontal roller mill in Europe during the latter part of the nineteenth century. The introduction of improved equipment and the concept of gradual reduction of wheat into flour allowed vast improvements in the degree of refinement of flour. Milling equipment has undergone continual improvement since then, but the basic concept of modern roller milling has remained unchanged.

Structure and Composition of the Wheat Kernel and Flour

The main constituents of the wheat kernel are bran, germ, and endosperm (Figure 1). The endosperm includes the outer aleurone layer, which is removed with the bran during flour milling, and the starchy endosperm. The germ contains the embryo, and a transport organ, the scutellum.

High-quality flour originates from the starchy endosperm. The starchy endosperm comprises about 85% of the wheat kernel. Therefore, it is theoretically possible to convert about 85% of wheat into high-quality flour, free of bran and germ contamination. In practice, the crease, which runs along the length of the grain and reaches almost to the middle of the grain, makes perfect separation of the endosperm impossible.

The constituents of the wheat kernels have very different compositions (Table 1), so that the extent of contamination of the flour by bran and germ alters flour composition and flour functionality. The starchy endosperm contains a low level of minerals compared to other kernel constituents. Accordingly, flour ash (mineral matter left behind after incineration of flour) is widely used as a flour refinement index; the low ash content is indicative of a highly refined flour containing almost pure endosperm. The endosperm contains proteins, known as gluten, which give wheat flour dough the viscoelastic properties essential for high-volume bread and firm pasta.

Wheat kernel hardness has a wide range. Durum wheat is very hard, whereas common wheat ranges from hard to soft. Endosperm structure differs for wheat of different hardness. The endosperm of

Table 1 Approximate composition of common wheat and its constituents[a]

[b]Includes the aleurone layer.

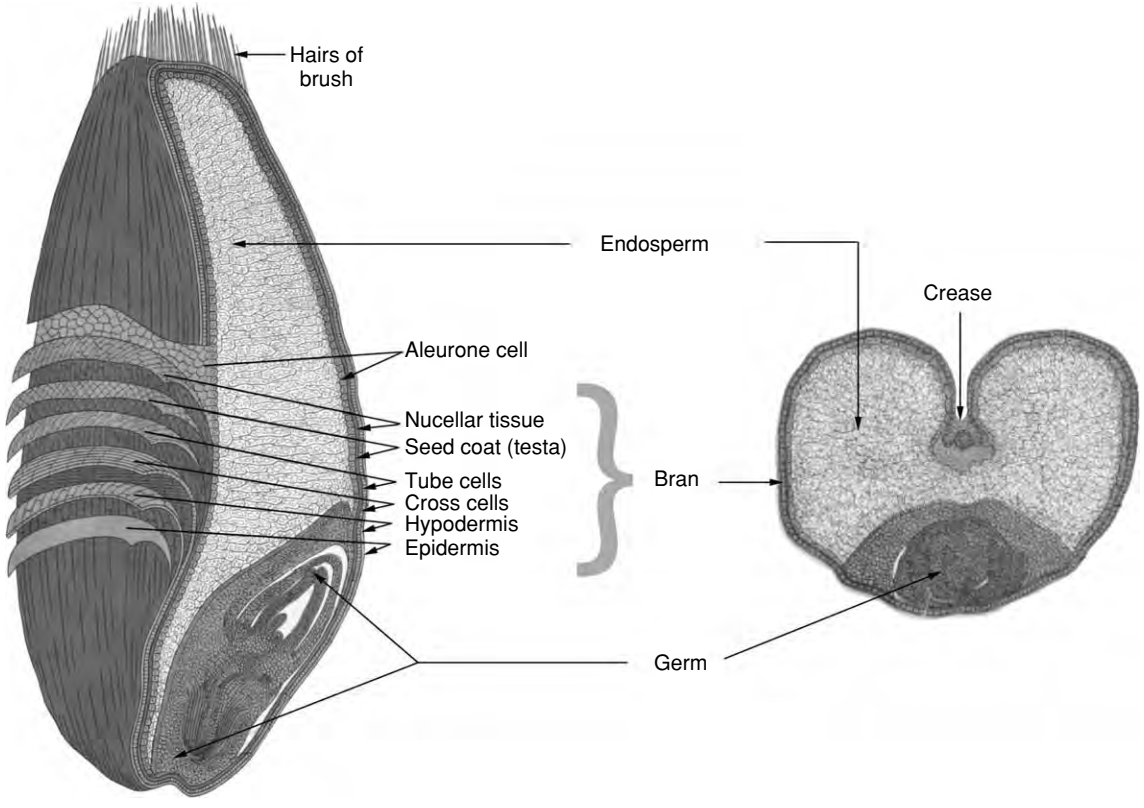

Figure 1 (see color plate 66) The structure of the wheat kernel sectioned longitudinally (left) and transversely (right). The bran layer is comprised of six layers. The aleurone layer, considered part of the endosperm, is removed with bran during roller milling. The crease, which runs the full length of the kernel, prevents fully efficient separation of bran from endosperm.

hard wheat is compact, with starch granules rigidly held within a protein network. The endosperm of soft wheat is more porous.

In general, as the proportion of wheat converted into flour (flour extraction rate or flour yield) increases, contamination by bran and germ increases. As a result the nutritional value of the flour improves as extraction rate increases, but processing quality and shelf-life diminish. The proteins in germ and bran are nongluten proteins that contribute to nutritional value, but do not contribute to processing properties. The germ contains low-molecular-weight sulfhydryl compounds that weaken dough properties by reducing disulfide cross-links, which are key elements of gluten polymer structure. The germ also contains oils and enzymes that reduce storage stability by promoting rancidity. The germ and bran are both rich in nutritionally important vitamins. The bran contains most of the fiber in the kernel, also an important nutritional consideration. However, as the level of bran in flour increases, flour dough functionality is reduced, and flour becomes darker, detracting from end-product appearance.

The Flour Milling Process

Wheat selection, preparation of wheat for milling, and milling technique all play a role in determining flour quality and milling profitability. The remainder of this article describes a modern roller milling operation, and explains how the various stages in the milling process contribute to the yield and quality of final milled products.

Wheat Selection

The milling characteristics and processing quality of wheat are dependent on physical condition and inherent quality traits. Wheat of intrinsically good quality can be rendered of poor processing quality by environmental damage or improper storage. Different classes of wheat, and wheat from different origins, have different quality traits. High-protein hard common wheat is ideal for producing bread flour. Low-protein soft common wheat is preferred for producing cake and biscuit flour. Durum wheat is preferred for pasta products.

In order to meet customer requirements, millers specify wheat type and minimum quality standards that must be met by suppliers. Differences in wheat hardness among wheat classes require alterations in conditioning and milling technique to achieve optimum results. When blends of different wheat types are milled, it is preferable to condition each type separately, but convenience, cost, and storage limitations often require blending prior to conditioning.

Wheat Reception and Storage

Wheat may be received at mills by truck, rail, or ship (Figure 2). Incoming wheat is weighed, and a sample is analyzed prior to storage. The content of foreign material and damaged grains is determined. Analyses such as weight per unit volume (test weight), protein content, and moisture content are performed. This determines whether the incoming wheat is within specification. Wheat is placed in a bin with other wheat of comparable physical condition and similar end-use potential to allow quality characteristics to be preserved, and used to the best advantage. In most cases, the wheat passes through a magnet to remove ferrous metals, and it may be given a cursory cleaning prior to elevation to storage bins.

Wheat Cleaning

Wheat must be cleaned prior to milling to remove foreign material such as stones, metal, unthreshed grain, badly damaged kernels, and foreign seeds that either adversely affect flour quality or pose a hazard to milling equipment.

Figure 2 shows a typical wheat-cleaning scheme. The wheat first passes through a magnet, and then proceeds to a grain separator which uses sieves and aspiration to remove impurities. Large impurities, such as maize, soybeans, and unthreshed wheat are removed by the top screen; small impurities, such as small and broken kernels and weed seeds, pass through the bottom sieve. As wheat falls off the end of the bottom sieve, it is aspirated to remove chaff, dust, and shriveled kernels.

Next, the wheat goes to a destoner where impurities such as mud balls and small stones comparable in size to wheat kernels, but denser, are removed. A destoner is an oscillating inclined metal screen through which an upward air current is passed. Wheat floats on an air cushion and moves down the slope. Denser materials make more contact with the screen, are propelled up the slope by the screen oscillations, and are collected separately.

The wheat now passes through disk separators to remove remaining impurities that differ in length to wheat kernels, but are of similar density and cross-section. Disk separators comprise disks revolving in a vertical plane through the wheat. The surface of the disks has numerous pockets which pick up particles that are short enough to lodge in the pockets. There are generally two units. The first is designed to pick up wheat while rejecting kernels longer than wheat, such as oats and barley. The second picks up small seeds and rejects wheat kernels.

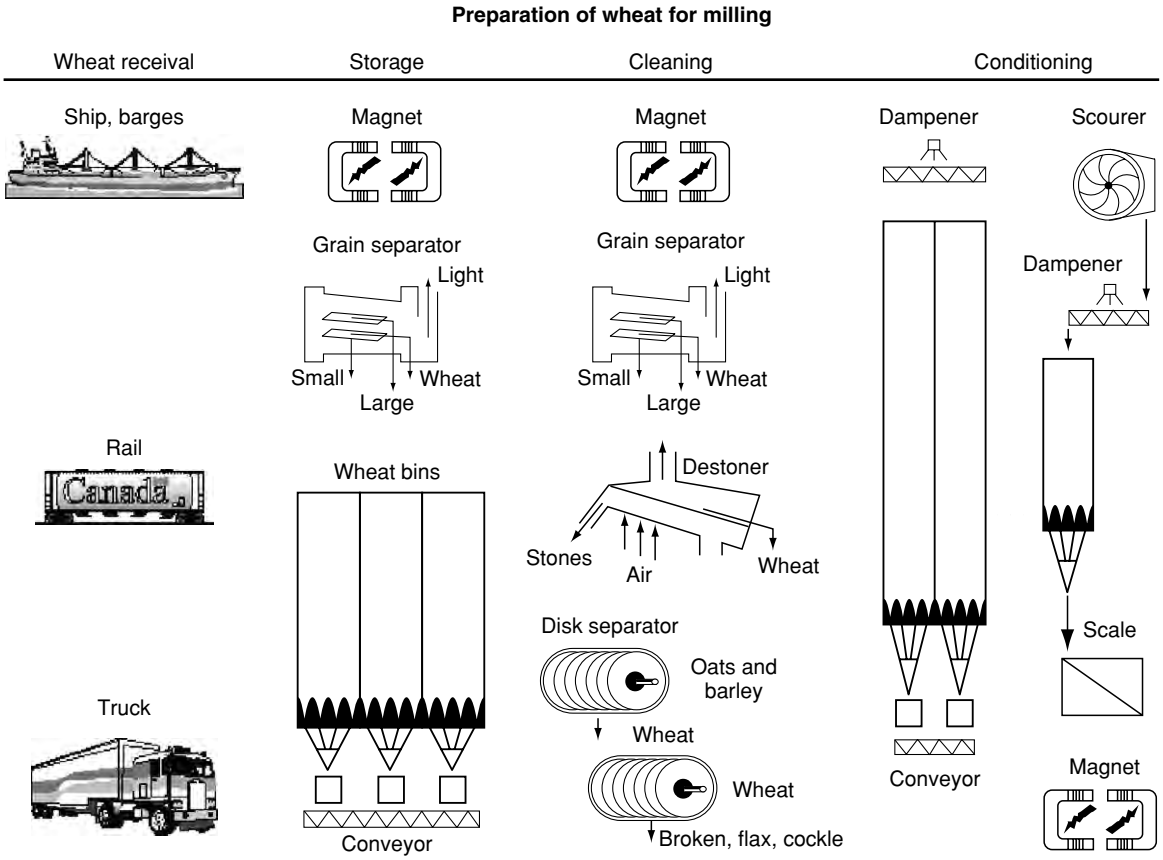

Figure 2 A simplified wheat intake, cleaning, and conditioning diagram.

Wheat Conditioning

After cleaning, the wheat is conditioned (tempered) by the addition of moisture (Figure 2). The precise addition of the correct tempering moisture is of fundamental importance to the milling process.

The primary purpose of tempering is to optimize the separation of bran from endosperm during the milling process. Tempering also reduces bran powdering, thereby reducing bran contamination in flour, and imparting optimum texture to the endosperm for efficient reduction into flour. Too much tempering moisture reduces flour yield because complete separation of bran from endosperm is difficult to achieve, and sieving efficiency is reduced. Too little tempering moisture results in bran powdering which contaminates flour.

Tempering water is added by spray nozzles to wheat in an enclosed screw conveyor. Modern tempering equipment features electronic control and vigorous mixing action to insure that precise and uniform addition of moisture is achieved. Following tempering, wheat is stored in bins for a predetermined time to allow uniform distribution of moisture within the wheat kernel.

Optimum tempering moisture varies with wheat type. Soft wheat is tempered to lower moisture than hard wheat, because soft wheat stocks are inherently more sticky and difficult to sift than hard wheat stocks, and that tendency is exacerbated as moisture content increases. Optimum tempering time may vary from several hours to a day or more depending on incoming wheat moisture content and hardness. Water penetrates into the endosperm of soft wheat more quickly than for hard wheat because soft wheat endosperm is more porous. Therefore, tempered soft wheat does not need to be rested as long before milling as hard wheat. Wheat is often tempered in two stages with a resting time between stages, particularly when a large amount of tempering moisture is added.

After tempering, wheat is scoured. Scourers use steel beaters to throw wheat against a wire screen. Dirt and loosened bran, which would contaminate the flour, pass through the screen. Commonly, as shown in Figure 2, wheat is lightly sprayed just prior to milling. This is to toughen the bran, and reduce bran powdering. Following a brief period in holding bins, the wheat is weighed, and passed

through a magnet to remove ferrous metal fragments prior to milling.

Mill Equipment

Roller milling consists of a succession of grindings, each followed by separation of the ground stock according to its size and composition. The most important pieces of equipment common to all modern flour mills are the roller mill, the plansifter, the purifier, and the bran duster.

The standard modern roller mill is a double-mounted stand consisting of two pairs of steel rollers mounted within a cast iron frame (Figure 3). The roller pairs are mounted back to back. Each roller pair is driven separately and has separate feeding and adjustment mechanisms. Recently, roller mills with four pairs of rollers, comprising two pairs stacked vertically with the upper pairs feeding the lower pairs directly, have become available. They are gaining in popularity, particularly for use early in the break system, and early in the reduction system, which allows an economical way of increasing milling capacity.

The two rollers within each pair rotate in opposite directions and at different speeds. The ratio of roller speeds is known as the differential. Having one roller rotate faster than the other imparts shear to the grinding action. The slower roll holds the stock, while the faster roll compresses and shears it.

The surface of the rollers may be smooth or corrugated, with flutes cut in a spiral pattern along the length of the roller. The spiral prevents the rollers from locking, and imparts a cutting and shearing effect. The number of flutes per centimeter and the shape of the flutes vary widely, depending on the stage of the milling process, the type of wheat being milled, and the desired flour extraction rate. Reduction rollers are usually smooth, although the surface is slightly rough (frosted) to impart some shear to the grinding action. For the most effective performance, break rollers are run at a differential of about 2.5:1, whereas reduction rollers are run at a differential of about 1.25:1.

A modern plansifter consists of as many as 30 layers of sieves, rotating in a horizontal plane. The sieves are arranged in sections, with some of the sifter units comprising up to eight sections. The aperture of the sifter clothing ranges from about 1600 μm down to less than 100 μm. Coarse clothing is composed of wire mesh, while finer clothing is composed of nylon or silk.

Stock enters the sifter at the top. The rotating motion of the sifter works the finer material through the top sieve. The coarse material is drawn away and the finer material proceeds to a series of progressively finer sieves where further size separations are made.

Bran dusters use impact to remove endosperm that remains attached to broad bran at the end of the break system. The same machine, when used to remove endosperm from shorts (fine bran from the end of the break system), is commonly referred to as a shorts duster. Bran or shorts is fed into a horizontal

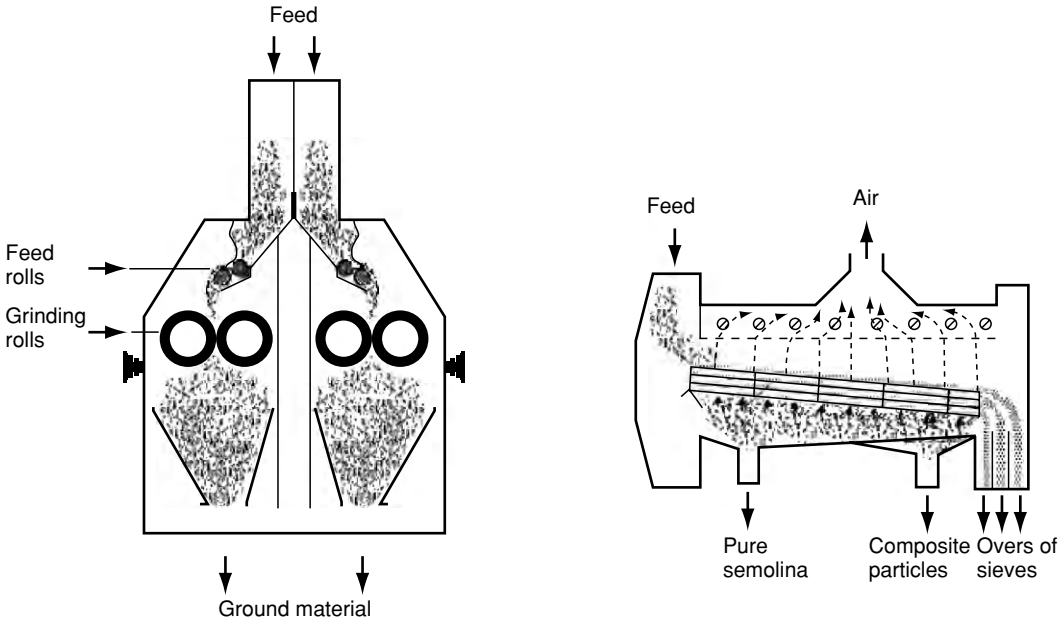

Figure 3 Schematic views of a modern roller mill (left) and a modern three-deck purifier (right).

cylinder, the lower part of which is perforated. Within the cylinder, finger beaters attached to a central shaft rotate, and scrape endosperm from bran or shorts. Endosperm is pushed through the apertures, and bran or shorts passes though the cylinder and is collected separately.

Purifiers separate pure endosperm particles from bran-rich particles of comparable size (Figure 3). This is done by taking advantage of the greater density of pure endosperm particles.

Purifiers comprise a sieve frame mounted with a slight downward slope. The frame is clothed with progressively coarser material from head to tail, and an air current passes upwards through the sieves. The frame oscillates longitudinally. The frame oscillation and the air currents cause the stock to stratify, with the lighter bran-rich particles rising to the surface. The heavier endosperm particles fall though the sieve if the aperture is large enough, whereas the bran-rich material floats over the end of the sieve frame.

The combination of the air flotation and sieving action allows the purifier to separate the incoming mixture into material that is progressively coarser and more contaminated by bran from head to tail. Modern purifiers have two or three decks of sieves to enhance efficiency of separation.

Flour Milling

Figure 4 gives a simplified version of a typical hard common wheat flour mill flow, designed to give a flour extraction rate of about 75%. The milling process comprises the break system, intermediate processing, which includes purification and sizing, and the reduction system.

The wheat kernel is opened on the first break rollers. The ground material passes to the first break sifter, where particles are separated according to size. The largest particles, which consist of wheat bran and adhering endosperm, proceed to the second break rollers. Each successive break and sifting passage separates more bran from endosperm. Immediately following the last break sifter, the bran proceeds to a shorts duster to remove some of the adhering endosperm.

The primary purpose of the break system is to separate endosperm from bran as efficiently as possible, although a small amount of break flour is

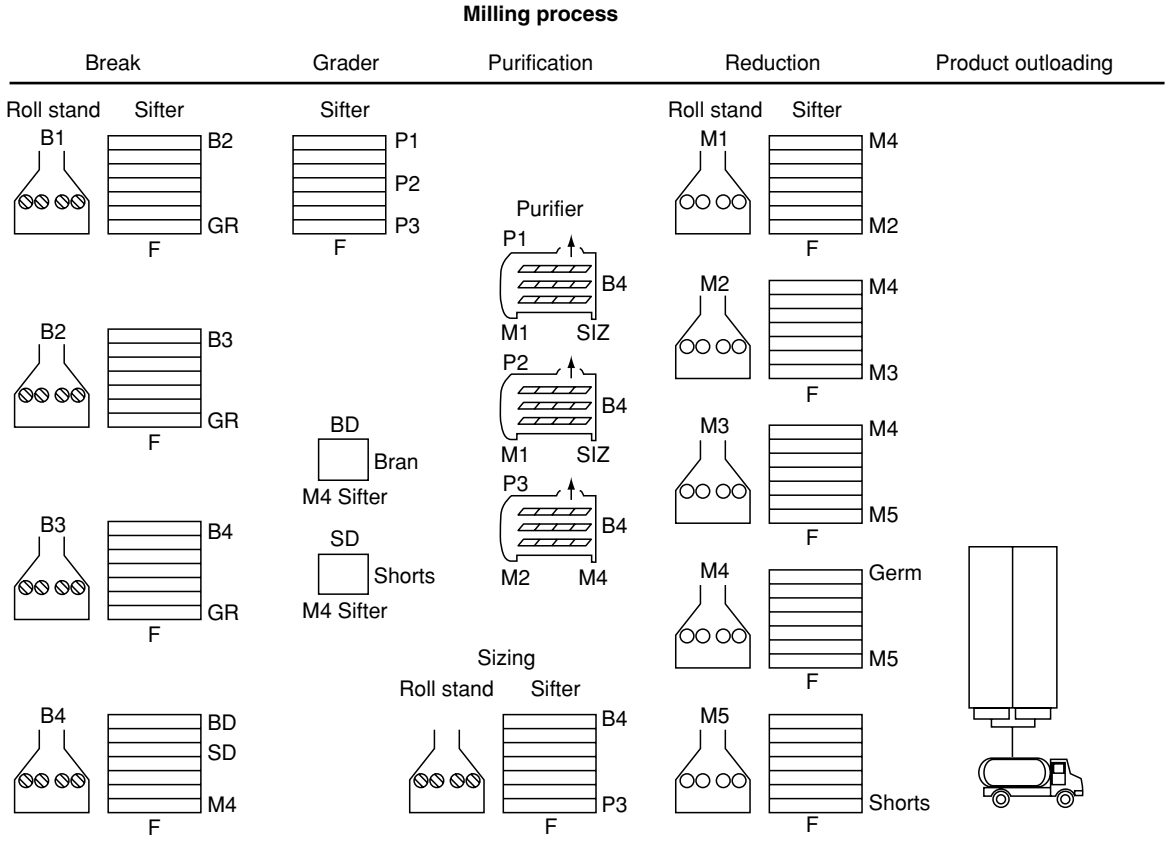

Figure 4 A simplified hard common wheat mill diagram. B, break; BD, bran duster; GR, grader; P, purifier; SD, shorts duster; SIZ, sizing; M, middling. Corrugated rollers are cross-hatched and smooth rollers are open.

produced. Most of the finer stock produced by the break system consists of particles larger than flour known as semolina (coarser particles) and middlings (finer particles). Semolina and middlings are separated by a sifter, referred to as a grader, according to particle size, before proceeding to purifiers.

Purifiers separate pure endosperm particles from brain-rich material. As a result, essentially pure endosperm is sent to the beginning of the reduction system. This allows the production of a large proportion of highly valued, highly refined white flour.

The coarse bran-rich material from purifiers proceeds to the sizing (scratch) system. The objective of the sizing system is not to make flour, but to remove bran adhering to middlings. This is accomplished by light grinding on finely corrugated rollers. The ground stock is then sifted and purified before continuing on to the reduction system.

The heart of the flour milling process is the reduction system, where most of the flour is produced. The reduction system reduces the carefully sized and purified middlings to flour particle size. This is done gradually by a series of successive grinding and siftings. Germ, which is flattened rather than reduced by smooth reduction rolls, can be recovered by sifting.

Grinding conditions must be carefully controlled to produce the maximum amount of highly valued prime-quality flour. If grinding is too severe, bran contamination is increased, reducing flour brightness. Severe grinding can also result in excessive starch damage which adversely affects flour functionality.

Flour Dividing

A flour mill may produce a single or multiple grades of finished flour from the milling of a given wheat or wheat mix. These finished flours are prepared by combining various flour streams that are produced at different stages of milling (Figure 5).

Individual flour streams, when compared with each other, exhibit variable processing quality. Flour millers may combine all flour streams to produce a single flour known as a 'straight-run' or 'straight-grade' flour. A more complex alternative is to produce several flours with different properties by judicious blending of streams. Figure 5 shows that each flour stream leaving a sifter can be directed to any one of three flour conveyors. Each continuous line represents a given flour stream flow to a designated flour conveyor. In this example, three flour streams each go to conveyors for flour #1 and flour #2, respectively, while two streams are directed to the conveyor for flour #3. This is known as 'divide' or 'split-run' milling and allows millers with demanding clients to increase return by closely targeting specific processing requirements.

Flour Additives

Mills commonly add additives to flour to improve nutritional value or to assist in achieving specific processing quality. As mentioned earlier, endosperm, the main component of flour, is poor in vitamins compared to the bran and germ. Many countries have legislation requiring the addition of vitamins and minerals to improve the nutritional properties of flours.

Bleaching agents like benzoyl peroxide may be added to give the flour a whiter appearance. Other additives impart better functionality. These include various enzymes (alpha-amylase of either fungal or grain origin) and oxidizing agents. Additives are available in powder form, and are dispensed directly into flour conveyors using powder feeders.

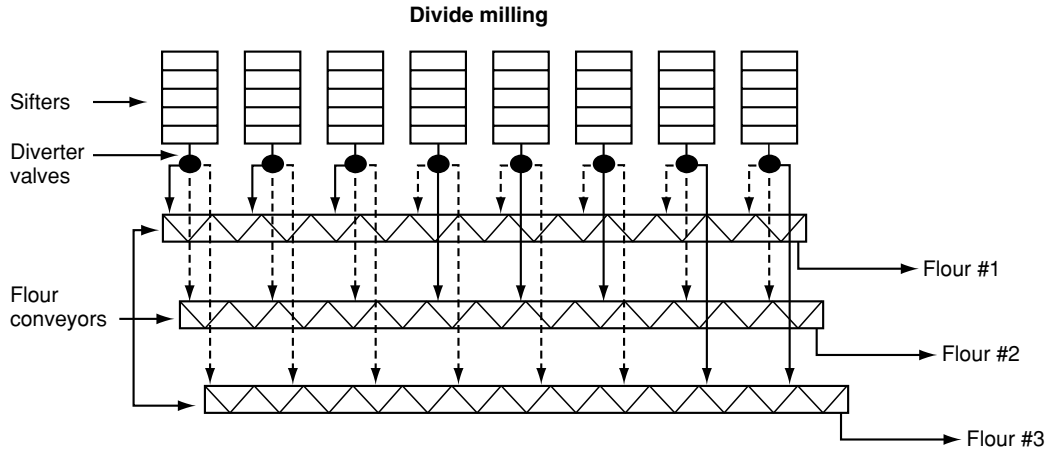

Figure 5 An example of divide milling, where three custom flours are being produced from a single wheat mix.

Soft Wheat Milling

Soft wheat milling is similar to hard wheat milling, but intrinsic differences between soft wheat and hard wheat require some modifications to the milling process. Soft wheat breaks down more quickly than hard wheat, and soft wheat stock is stickier and fluffier, which makes it more difficult to sift than hard wheat stock. In addition, the endosperm of soft wheat adheres more strongly to bran, reducing flour extraction rate expectations by up to 2% unless the break system is extended.

Soft wheat must be fed more slowly to the mill to facilitate sifting and to insure that stock flows freely through the mill. The rapid breakdown of soft wheat increases the yield of flour from the break system and reduces the yield of semolina and middlings. As a result, purifiers are of less importance and are often absent from the flow.

Durum Wheat Milling

The same milling equipment is used for durum wheat milling as for common wheat milling, but the mill flow is very different. The product preferred for premium pasta and couscous is uniformly sized semolina, free of bran. Durum wheat flour produced from semolina mills is a lower-valued byproduct.

Durum wheat is very hard, which facilitates a high yield of semolina with minimal production of flour. The break system for durum wheat is extended to allow gradual breakdown of the wheat kernel to achieve a maximum production of semolina and a minimum production of flour. Purified semolina from the break system is uniformly sized and made free from adhering bran by a succession of sizing passages, gradings, and purifications. Most of the semolina is from the sizing purifiers, making durum mills readily recognized by the large number of purifiers.

Rye Milling

Rye grain is milled into various forms of meal and flour for application in the production of a variety of baked products, particularly in northern and eastern Europe. Dark rye bread, pumpernickel, and a host of other bread products containing rye offer a unique combination of texture and flavor that is truly characteristic of rye.

A rye mill also uses grinding and sifting equipment similar to that used in wheat flour milling. Rye milling is similar to the milling of soft wheat. The endosperm is very soft and sticky, making it very difficult to grind and sift efficiently.

Because rye is so soft, a significant proportion of the total flour is produced at the beginning of the flow following each break passage. Rye endosperm is so soft and plastic that smooth rolls tend to flatten middlings rather than reduce them. As a result, all the grinding passages in a rye mill use corrugated rolls, including the reduction rolls.

Rye endosperm breaks down quickly into fine particles, and these particles lump together. Therefore, purification passages are of no value and purifiers are absent. Rye has gluten, but it imparts much less elasticity to dough than wheat gluten. Rye flour color is inherently dark. As a result, rye flour produces bread loaves that are denser, darker, and heavier in texture than wheat flour bread.

Milling Byproducts

The byproducts of milling receive little attention, but they are an important economical consideration in flour milling. These include impurities from the cleaning house (screenings), mill feed (bran and shorts), and germ.

Screenings, with the exception of metal, stones, and mud balls, are usually ground and sold as animal feed. The mill feed, which comprises large bran flakes produced from the break system and finer bran particles, or shorts, are also primarily used as animal feed. Depending on market conditions, mill feeds also find use for foods such as breakfast cereals and high-fiber specialty wheat products.

Wheat germ is a highly valued byproduct because of its excellent nutritional composition. As a result, many modern mills have sophisticated germ recovery systems.

Debranning (Preprocessing)

Wheat debranning, or preprocessing, a process in which the bran layers are removed sequentially by friction and abrasion operations in modified rice polishers prior to roller milling, has enormous potential in wheat milling. Debranning has gained considerable acceptance in durum wheat semolina milling in particular. The yield and refinement of semolina are significantly improved, allowing more efficient milling of top-quality durum wheat, or, alternatively, the use of lower-quality durum wheat to produce semolina within customer specifications. There is less conclusive evidence that debranning improves the milling performance of common wheat.

Regardless of wheat class being milled, an advantage of using debranning is lower capital investment because simplifications of the mill flow (the break

system is almost eliminated) allows more compact plants for a given capacity. In addition, the byproducts of debranning have the potential to be more valuable than byproducts from conventional roller milling. Rather than removing all bran layers together, as in conventional roller milling, during debranning the individual bran layers are stripped off in sequence. Each bran layer has distinct physicochemical and nutritional properties, giving debranning byproducts great promise as novel food ingredients.

Milling Process Monitoring and Control

All electrical motors driving various pieces of equipment are sequence-controlled and interlocked to provide ease of operation, control, and protection. This allows sequential starting and stopping of the motors and stopping of the process in a failsafe manner in case of interruptions due to a malfunction or for any other reason. Additionally, a number of process control functions are incorporated that may, depending on the extent of use of various types of sensors, switches, high-level and low-level indicators, allow the entire process to be automated. A conventional control system involves a mimic process diagram for visual display of the process, and a hard-wired electromechanical relay control system for control functions.

Since the early 1980s there has been a gradual transition to control flour mill automation with computerization. Mimic panels with small pilot lights are now being replaced by computer graphics for visual display of the process status. Hard-wired control relays are being replaced by programmable logic controllers (PLC). PLC control with PC operator interface enables performance of all the functions described above. Additionally, it offers the flexibility of changing control functions, if required, through simply making programming changes rather than changing the hard wiring. It also allows full integration of the remaining critical functions relating to process control and performance evaluation, including product yield calculations and automated roll gap adjustment.

Another important advance is online quality monitoring. Factors such as moisture content, protein content, and flour color can be monitored continuously using automated online samplers allowing flour millers to meet customer specification efficiently.

Computerized process control has greatly reduced labor requirements in flour mills. Many mills have gone to so-called lights-out operation, where the mill runs for extended periods without staff present in the mill building.

Analysis of Wheat Flours

K R Preston and P C Williams, (formerly of) Grain Research Laboratory, Winnipeg, Manitoba, Canada

Introduction

Flour, produced by the selective removal of the germ and the outer layers (bran) from the endosperm of wheat during the milling process, is used in the production of a wide variety of baked, extruded, and sheeted products throughout the world. Each of these products may require different types of flour

to produce an acceptable product, as shown in Table 1. The ability of a flour to produce a specific product is determined by the inherent characteristics of the wheat, the effects of environment during growth, harvesting, and storage on wheat properties, and the milling techniques used to produce the flour. Flour (and wheat)-testing procedures have been developed to predict or measure the effects of these factors on flour-processing quality and to insure health standards have been met.

The most common applications of flour analysis include:

1. In wheat-breeding programs where new cultivars are evaluated for selection.
2. In government and private laboratories responsible for monitoring quality and health standards, providing information for segregation of wheats and flours and providing information to buyers.
3. In flour mills for selection of wheat lots and the blending thereof and to insure that flours produced meet customer specifications and health standards.
4. In end-user facilities to verify that flour specifications have been met and that health-related standards are maintained.

This article provides an overview of quality and health-related testing procedures commonly used in flour analysis with emphasis on their use and interpretation. This review is restricted to common (hexaploid) wheat flour testing and does not include durum wheat which is normally milled to semolina for the production of pasta and couscous. Detailed information on wheat and flour test procedures are available from approved methods manuals published by the two largest associations involved in cereal chemistry – the American Association of Cereal Chemists (3340 Pilot Knob Road, St Paul, MN 55121, USA http://www.aaccnet.org) and the International Association for Cereal Science and Technology (PO Box 77, Wiener Str. 22a, A-2320 Schwechat, Austria, http://www.icc.or.at).

Table 1 Major uses of common wheat flour classified by protein content and physical dough strength

Flour type[a]	*Uses*[b]
Strong, high-protein	Pan breads, blending
Medium strong, medium-protein	Hearth breads, flat breads, steamed breads, noodles
Weak, low-protein	Cakes, cookies, dumplings Soft wheat noodles (udon)

[a]Approximate protein ranges for high-, medium-, and low-protein (14% moisture basis) flours are >12%, 10–12%, and <10% respectively.
[b]Products listed with each flour type are intended as a general guideline. Many of the products listed are often produced from the other flour types.

Flour Quality Tests

Flour quality tests are designed to predict or determine milling efficiency and end-product suitability. These tests can be subdivided into three categories including analysis of basic constituents (proximate analysis), processing-related parameters, and analysis for specific additives. The most common of these tests are summarized in Table 2.

Flours are also commonly subjected to physical dough tests which provide information involving the viscoelastic properties of flour dough and to small laboratory-scale end product processing tests which provide the most accurate estimate of product quality.

Proximate Analysis

Proximate analysis of flour normally involves the determination of moisture, protein, and ash content. Measurement of fiber components (endogenous and that added from other sources) is also becoming increasingly important in view of their nutritional importance. Determination of oil and carbohydrate composition, the latter of which is determined by difference (i.e., 100 – sum of the five constituents listed above) is not normally carried out and will not be discussed further.

Flour moisture content is fundamental information, since variance in moisture content affects the proportion of all other constituents. Analytical information for flour is normally reported on a specified moisture basis, while the amount of flour required for physical dough or for end-product testing is normally weighed to a specified moisture basis. Moisture content is also important for both economic reasons and flour storage. Selling higher-moisture flour is normally more profitable to mills. Flour will deteriorate rapidly if moisture exceeds 15% in moderate climates and 14% in tropical climates. Flour moisture can be determined by air-oven methods. For more rapid analysis, near-infrared reflectance (NIR) can be used.

The protein content of flour is an essential piece of information concerning the end-use potential of a

Table 2 Common quality flour tests

Constituents	*Parameters*	*Additives*
Moisture	Flour color	Potassium bromate
Protein	Wet gluten	Ascorbic acid
Ash	Gluten index	Riboflavin
Fiber	Starch damage	Thiamin
	Particle size	Niacin
	Amylograph peak viscosity	Iron
	Falling number	Folic acid
	Maltose value	
	Gassing power	
	Fat acidity	

sample within a flour type or class. For example, with bread-wheat flours, protein content is generally positively associated with baking quality parameters such as loaf volume and bread score, as shown in Figure 1. In contrast, with cake and cookie flours the relationship between quality and protein content is negative. However, protein quality, as well as quantity, exerts a major impact upon end-product quality and must also be considered. Protein quality can be assessed by physical dough and end-product tests, described later in this article.

For many years the Kjeldahl test and modifications thereof, involving the measurement of ammonia nitrogen released by acid hydrolysis, has been universally accepted as a method for the determination of the protein content (N × 5.7) of wheat and flour. Since the last edition of this encyclopedia, improvements in the instrumentation of the Dumas test have resulted in the introduction of a number of high-temperature combustion nitrogen analyzers (CNA). The increased accuracy and precision of these instruments (relative to the Kjeldahl method), combined with the elimination of the requirements for fume exhaust, drainage systems, and the use of highly corrosive chemicals, have led to increasing adoption of the Dumas test as the accepted reference method for protein determination in many commodities, including flour. In addition, the Dumas method offers improvements in the time per test (3 min, as compared to 2 h for the Kjeldahl test), while the method uses no offensive chemicals. The instruments are semiautomated, which enables virtually continuous analysis throughout the working day. For more rapid analysis, NIR can be used to predict protein content from whole and ground grain and flour.

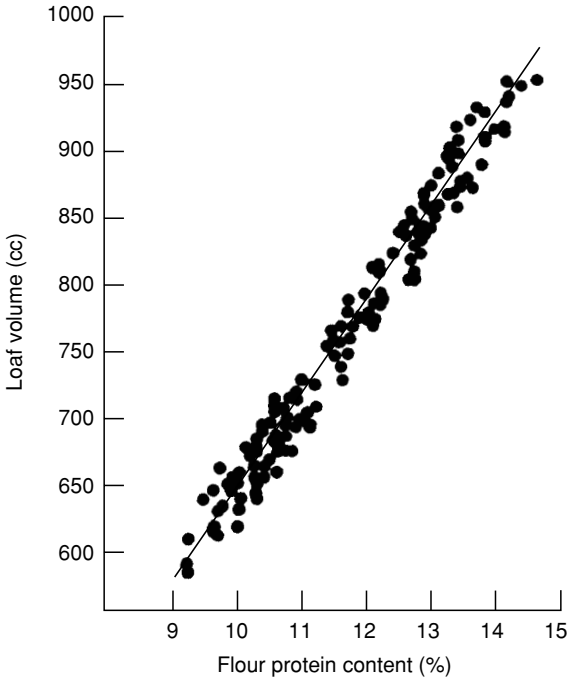

Figure 1 Relationship between loaf volume of remix-processed, straight-dough bread, and flour protein content (14% moisture basis) for Canadian red spring wheat straight-grade flours. Reproduced from Flour, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The ash test is used in the milling industry as a measure of milling efficiency and in classification of mill streams for the production of various types of flours. Ash content is primarily a measure of the efficiency of separation of the low-ash endosperm from the high-ash bran. Flours with low ash content (less than about 0.40%, 14.0% moisture basis) are termed patent flours and are derived from the inner endosperm of the wheat kernel. This flour is used where a bright white color is needed in the end product.

Straight-run, or straight-grade flours, which are most commonly produced worldwide, can have ash contents varying from approximately 0.48 to over 0.60%. They are derived from the entire endosperm with varying degrees of bran inclusion and normally represent wheat extraction rates of 74–80%. High-ash flours (> 0.60%), involving high wheat extraction rates (80–95%), are produced where a darker-colored product is preferred by the consumer (e.g., brown and wholewheat breads), for traditional high-extraction flour products such as flat breads in the Middle East and chapattis in the Indian subcontinent or where government policy requires high extraction rates for economic reasons. As with protein, ash content is a common flour measurement used by mills to meet customer specifications. In some countries, flour color is used in place of ash content as a measure of milling efficiency. Flour ash content is normally determined by weight difference after incineration of a sample for several hours in a high-temperature (550–590 °C) muffle oven.

Crude fiber and dietary fiber have not been commonly measured in flour as a routine test. However, measurement of dietary fiber is becoming increasingly important in flours to which high-fiber ingredients have been added for nutritional considerations (e.g., high-fiber breads and breakfast cereals). At present, a number of methods are used to measure dietary fiber but no single procedure has gained widespread acceptance.

NIR analysis is now in commercial use as an inline instrument in modern flour mills. The NIR instruments are calibrated to provide continual data for moisture, protein, and ash contents of flour during

the milling process. The inline instruments are used in conjunction with benchtop computers (PCs) to monitor and control flour composition. The information is used by millers to control mill-flow. As well, NIR instruments have been calibrated for the prediction of flour starch damage and wet gluten content. Table 3 summarizes typical data for proximate analysis of flour, using a scanning spectrophotometer.

Flour is an ideal medium for NIR analysis. Due to the sensitivity of NIR analysis to particle size, the technology also affords an excellent means of monitoring the consistency of the production of all products of a flour mill.

Processing Related Parameters

Several tests provide useful information concerning the functionality or end-use potential of flour. The most widely used of these processing-related parameters are listed in Table 2. They can be grouped into parameters that are influenced mainly by milling extraction (flour color), protein content (wet gluten), wheat texture (starch damage and particle size), α-amylase activity (amylograph peak viscosity and falling number), wheat texture and α-amylase activity combined (gassing power and maltose), and storage conditions (fat acidity).

In some countries (e.g., UK) flour color is regarded as being a more reliable indication of the purity of flour than the ash test and is used in place of the latter in flour specifications. Flour color is also used in conjunction with the ash test to give a better indication of potential product quality, in particular flour whiteness and brightness. Measurement of flour color is considered particularly important in many Asian mills producing flour for various types of noodles where consumer preference is strong for a bright white product (e.g., dried noodles) or a bright, light yellow product (e.g., alkali 'Chinese' noodles).

Flour color can be determined with the Satake/Kent-Jones color grader which involves measurement of the reflectance of a flour-water slurry. Other common methods include the Agtron test, and the Minolta, or tri-stimulus test. The determination of tri-stimulus color values of flour or products thereof, using reflectance spectrometers, is now being widely used. Brightness (L*), red/green chromaticity (a*), and yellow/blue chromaticity (b*) can be rapidly and simultaneously measured.

Wet gluten is formed by hand or machine washing of flour in a dilute salt solution. The resulting viscoelastic product consists mainly of insoluble proteins which are of primary importance in determining dough rheological properties. Wet gluten content is closely related to flour protein content (in the ratio of approximately 3:1). The hand-washing method is used widely in many countries in place of protein content for flour specifications due to its simplicity and low cost. The yield or the 'feel' of the resulting gluten is also useful as an overall indication of inherent quality and as an indication of damage caused by proteolytic enzymes injected into the wheat kernel by the wheat bug (Cinch bug, Suni bug, etc., *Eurygaster* sp.).

About 30 years ago Perten Instruments introduced the Glutomatic instrument, as a mechanical washing method for determination of wet gluten content. The test method has been modified to provide a gluten index value. The gluten index value is becoming widely used as an indication of gluten (flour) strength. In this procedure, wet gluten prepared by machine washing of flour or ground grain is centrifuged through a sieve. The percentage of gluten remaining on the sieve after centrifugation, relative to the total gluten content, is defined as the gluten index value. High values (90–100) indicate strong gluten characteristics while low values (up to 30) indicate weak gluten characteristics.

Damaged starch is caused by the rupture and abrasion of starch granules during the milling process. The amount of damaged starch is closely related to the texture of the wheat. Hard-textured wheat gives flour with much higher starch damage than soft-textured wheat. The degree of flour starch damage, in addition to protein content, is a primary determinant of the ability of flour dough to absorb water (damaged starch absorbs approximately three times the amount of water compared to intact starch granules). This is

Table 3 Accuracy and precision of near-infrared analysis of flour

Parameter	r^2	*SEP*	*b*	*a*	*Bias*	*RPD*	*SET*	*CV%*
Moisture	0.990	0.119	1.017	−0.232	−0.006	9.71	0.025	0.25

SEP, standard error of prediction; *b*, slope; *a*, intercept; RPD, standard deviation of reference data/SEP; SET, standard error per test; CV%, coefficient of variability.

particularly important in bread production where high water absorption is desirable and in the production of 'soft' wheat products such as cakes and cookies where low water absorption is desirable.

Damaged starch is also important in the baking of leavened products since, due to its susceptibility to α-amylase attack, it provides a source of sugar to the yeast. Damaged starch is measured by digestion with an excess of amylases (α and β) followed by measurement of the resulting released sugar. The Tripette & Renaud (Chopin) model RT instrument is also used for the determination of starch damage. The Model RT employs an iodine reaction for the prediction of starch damage.

Flour particle size (granulation) is also strongly influenced by wheat texture. Harder wheat gives larger average particle size than softer wheat. Milling conditions may also influence particle size (in particular, the choice of sieves). Finer flours generally absorb water faster than coarse flours. Flour particle size is measured by a variety of techniques including sedimentation, sieving, light refraction, and light scattering.

Enzymes present in flour can have a major impact upon processing quality. The most important enzyme in flour is α-amylase. High levels of α-amylase are usually detrimental to processing quality, particularly in the case of bread products where dough becomes difficult to handle (sticky) and shows a tendency to collapse during baking. This is mainly attributable to the formation of dextrans, which are products of starch hydrolysis. High levels of α-amylase are most commonly associated with the presence of sprouted wheat in the milling grist. Very low levels of this enzyme may also be undesirable in bread flours since insufficient sugar will be released for gas production by yeast. α-Amylase activity in flour is normally estimated by measuring the starch-pasting characteristics of flours. The most common measurements include amylograph peak viscosity Hagberg (now Perten) falling number and the Rapid Visco-analyzer. In all three methods, lower values indicate higher enzyme activity. Where activity is low, sufficient α-amylase (from fungus or malted wheat or flour) may be added to give a predetermined amylograph peak viscosity equivalent to a falling number value of about 250 Brabender units.

The ability of α-amylase to produce sugars during fermentation is also dependent on the degree of starch damage, since intact starch granules are less susceptible to attack. Gassing power and maltose or diastatic value are measurements of the effects of these two factors. These measurements are commonly used to assess the ability of flour to maintain gas production by yeast and to make adjustments in α-amylase or sugar levels if necessary.

Other enzymes also have an impact on flour quality. However, in most cases differences in activity between different flours do not have a major impact on processing quality. Exceptions include proteases and certain oxidases. Endogenous flour proteolytic enzymes do not appear to have a major impact upon flour quality but, as noted earlier, injection of these enzymes by insects into the wheat kernel can cause extensive damage (weakening) of the gluten proteins. Polyphenoloxidases can cause browning reactions while lipoxygenases can bleach flour dough due to oxidation of pigments. High levels of the former enzymes, due to sprout damage or inherent variety characteristics, can cause product discoloration, particularly in the case of wet noodles. Lipoxygenases are often added to bread flours (as bean or pea flour) as a whitening agent.

During long-term storage of wheat and flour, a gradual deterioration in quality may occur, depending upon conditions. This is indicated by increased levels of free fatty acids, acid phosphates, and amino acids. Fat acidity shows the largest changes during the early stages of deterioration and is used most commonly to diagnose this process. The most common method of measuring fat acidity in flour involves extraction of free fatty acids with toluene followed by titration with dilute alcoholic alkali.

Additives

Ingredients may be added to flour by mills as improvers and to enhance the nutritional value of the flour. The most common improvers include bleaching agents to whiten the flour and oxidants which are added to improve the baking quality of bread flours. Soft wheat flours are sometimes chlorinated (to a specified pH value) for specific products.

Bleaching agents such as benzoyl peroxide are not measured since they react rapidly on contact with flour pigments. Oxidative improvers (added in the p.p.m. range) are measured by millers to insure that correct amounts have been added. The most commonly used oxidants include ascorbic acid, potassium bromate, and azodicabonamide (ADA). The use of the latter two oxidants has been banned in many countries due to health concerns, leaving ascorbic acid as the only widely accepted chemical additive for oxidation. This has resulted in the widespread use by the baking industry of oxidative enzymes obtained primarily from fungal sources to enhance or supplement the action of ascorbic acid. Ascorbic acid is quantified by measuring the decolorization of 2,6-dichlorophenolindophenol while bromate and ADA are measured by reaction with potassium iodide at low pH.

Vitamins and minerals may be added to flours to replace those removed with the bran and germ layers

during milling. In many countries the addition of these nutrients is mandatory. Vitamins of the B complex, including niacin, riboflavin, thiamin, and folic acid are the most important additives in white flours. Niacin can be determined by absorbance at 400 nm after reaction with cyanogen bromide. Riboflavin, thiamin, and folic acid are normally determined by spectrophotometric/fluorometric or microbiological methods.

The ratio of ash in wheat bran relative to the endosperm is approximately 20:1. Consequently, removal of the bran during milling also depletes the mineral content of the flour. Efforts to replenish essential minerals include the addition of calcium in the form of creta praeparata (calcium carbonate) and iron salts. Calcium content in flour can be determined volumetrically by ethylenediaminetetraacetic acid (EDTA) titration. Iron is determined colorimetrically.

Physical Dough and End-Product Tests

Physical dough tests are commonly carried out as part of flour analysis. They provide information on the viscoelastic properties of wheat flour dough which is closely related to flour functionality. The most widely used instrumentation includes the Brabender farinograph and extensograph, the mixograph, and the Tripette & Renaud (Chopin) alveograph.

The farinograph, a torque-recording mixer, is the most commonly used instrument. It measures the mixing properties of a flour-water dough system and provides information on the mixing time required to reach peak torque prior to dough breakdown (dough development time) and on the stability of the dough to overmixing (mixing tolerance index and stability). The instrument also provides an indication of water absorption potential since addition of water is adjusted until the peak torque during mixing reaches a defined value (500 Brabender units). This information is used extensively (usually in combination with protein content and flour ash) to meet bakery specifications for pan bread flours as well as a wide variety of other products (hearth breads, flat breads, steamed breads, noodles, chapattis). Flours with long dough development times (> 4 min) and long stability times (> 12 min) are considered as strong. Flours with development times of 2–4 min and stability times of approximately 4–8 min are considered to be of medium strength and those with shorter development times and stability times are considered as weak. Examples of each are shown in Figure 2.

The mixograph is also a torque-recording mixer that provides information on dough mixing time requirements and dough tolerance to overmixing. It is used extensively in the USA for flour strength classification. The increased use of personal computers (PCs) in laboratories has resulted in development of software which assists in the interpretation of these (farinograph and mixograph) dynamometer-powered instruments.

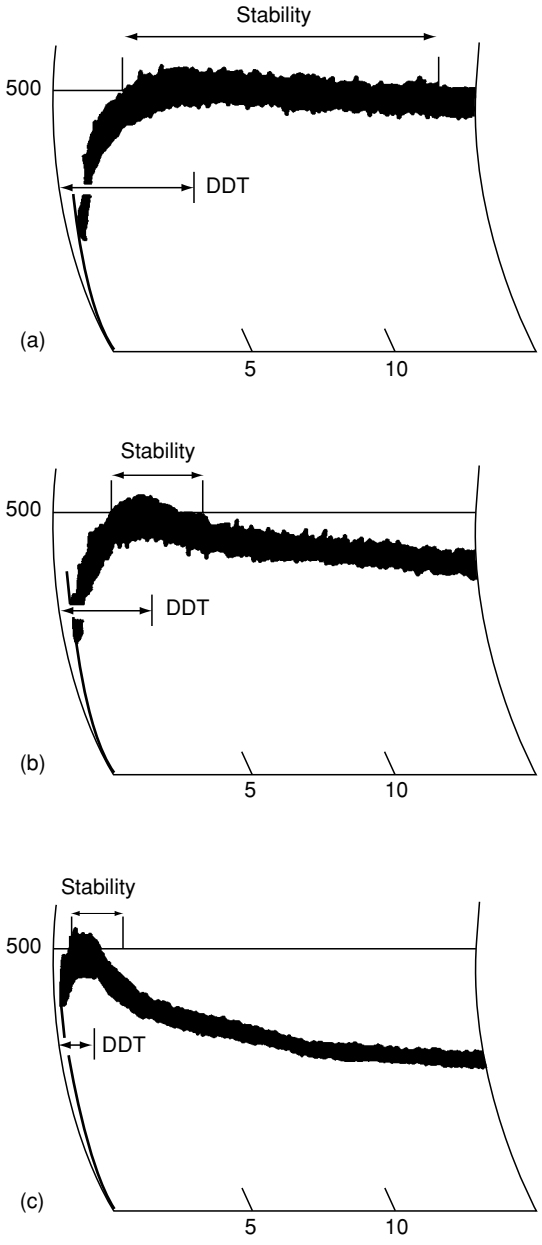

Figure 2 Farinograms of flours showing (a) strong, (b) medium, and (c) weak physical dough properties. Dough development time (DDT) and stabilities measured in minutes are shown as indicated. Reproduced from Flour, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The extensograph provides a method of measuring the stretching properties of a flour–water–salt dough which has been mixed to defined conditions in the farinograph. The load-extension curve (extensogram) provides a measure of the maximum height

(resistance of dough to stretching), extensibility (length of dough at rupture during stretching), and area of the curve (energy required to stretch dough to breaking point). This method is used to assess flour strength and viscoelastic balance for bread production. The instrument has also been used to estimate the oxidation requirements of bread flours. Due to the large sample requirement (300 g flour) and the long time required to run the test, the extensograph is not so commonly used as it was previously in quality control applications.

The alveograph, like the extensograph, is used to measure the stretching properties of a flour–water–salt dough. Ingredients are mixed in the instrument's mixing chamber, extruded and cut into rounded disks which are clamped into a chamber through which air is pumped, resulting in the stretching of a dough 'bubble' until rupture occurs. The maximum pressure required to stretch the dough and the length (time required to rupture the dough) are obtained directly, while the *W* value (related to energy required to stretch the dough to rupture) and *G* (swelling index) are calculated from the curve. These values, especially the *W* value, are commonly used in specifications for 'French-style' hearth breads in Europe, the Middle East, and South and Central America. Alveograph parameters are also being used increasingly in soft wheat flour specifications (for cakes, cookies, biscuits, etc.).

An alveograph parameter which is receiving increasing attention is the ratio of the peak height to the length of the alveogram (the *P*/*L* ratio). It is related to the *W* value, in that, while a given *W* value can arrive by different combinations of *P* or *L*, the *P*/*L* ratio gives a better picture of the shape of the alveogram. A *P*/*L* ratio of about 1.0 is preferred for the baking of raised breads. Weak, extensible doughs, suitable for cake and cookie production, have *P*/*L* ratios of about 0.2, while *P*/*L* ratios of 2 or higher indicate that the dough is inclined to be 'bucky,' and lacks the desired degree of extensibility.

Detailed information on these instruments is provided in handbooks published by the American Association of Cereal Chemists.

Small-scale end-product tests are regularly carried out in laboratories to assess flour performance. These tests vary widely depending on the product and the local, regional, or national preference of the consumer. A discussion of this topic is beyond the scope of this article.

Health-related Tests

Six categories of toxic substances may affect wheat and wheat flour. These include pesticide residues; molds and mycotoxins, (the toxic metabolites of molds); toxic trace elements; foreign substances such as filth; radionuclides and microorganisms. Of all the types of pesticides that may be used in the production and storage of grain, which include mainly insecticides, herbicides, fungicides, and plant growth regulators, compounds used just prior to harvest and postharvest chemicals such as those used for fumigation and grain protection are the major risks for residues in wheat and flour. The presence of mycotoxins in wheat is associated with high levels of fungi which in turn are usually attributed to growing and harvesting conditions favorable to mold growth and poor storage conditions. The presence of unacceptable levels of toxic elements such as mercury, lead, arsenic, and cadmium in wheat may be due to a combination of factors which include the use of agricultural chemicals containing these substances, environmental contamination of soil, inherent variety characteristics, and natural soil conditions.

The presence of filth such as insect parts and eggs, excreta from insects and rodents, and rodent hairs in wheat and flour is usually the result of poor housekeeping, failure to maintain proper sanitary conditions in grain storage areas and mills, and ineffective grain cleaning. Radionuclide contamination of grain is possible from fallout resulting from nuclear accidents such as the Chernobyl incident in 1986. The presence of undesirable microorganisms at harmful levels in wheat and flour is also a matter of poor sanitation practices and poor grain or flour storage conditions.

Quality assurance of wheat moving into food channels to insure the absence of harmful levels of toxic substances is an ongoing process. It involves screening and control measures to identify contaminated parcels so that they can be removed from food channels and monitoring measures to confirm the absence of objectionable levels of toxic substances from commercial shipments. Insuring the safety of flour with respect to toxic substances is generally the responsibility of government health agencies and is usually accomplished through ongoing monitoring of products. Flour testing by mills and end users is carried out to insure that sanitary conditions are maintained and to meet specific requirements by processors.

Tests for pesticide residues, mycotoxins (especially from *Fusarium* spp.) and toxic elements are sensitive to parts per million or parts per billion levels. The analytical technique followed for determination of pesticide residues and mycotoxins will depend greatly on the requirements for sensitivity, selectivity, rapidity, and economy. For highly accurate and sensitive work, procedures using gas chromatography, high-performance liquid chromatography and mass

spectroscopy are usually followed for determination of pesticide residues and mycotoxins, whereas for toxic elements, atomic absorption spectroscopy is most often employed. Other procedures, involving the use of thin-layer chromatography, column chromatography and enzyme-linked immunosorbent assay (ELISA) test kits are also appropriate for many applications.

Tests for microorganisms in flour normally involve the extraction of the sample with sterile buffer, adding an aliquot of the extract at several dilutions to agar containing appropriate nutrients, and counting colonies after a specified growth period under fixed conditions. Controlled growing conditions and selective media can be used to aid the detection of specific organisms. Colony appearance, biochemical activity, and staining techniques are used in the identification process. Some of the more common tests include those for nonspecific aerobic microorganisms (standard plate counts for bacteria plus molds and yeasts), coliforms, fecal coliforms, *Salmonella*, *Staphylococcus*, *Bacillus cereus* and *B. subtilis* (the cause of ropiness in bread).

Insects and filth (including insect fragments and eggs, insect and rodent excrement) present in wheat are normally removed during the cleaning process prior to milling. However, insects and eggs present in the interior of the wheat kernel may not be removed by this process. Tests for filth are therefore carried out to measure the amount of insect material derived from the wheat and, more importantly, to insure that proper sanitary conditions are maintained in the processing plant. Flour specifications from secondary users may also require verification. The first step in identifying the presence of insects and filth involves visual inspection. Flour can also be examined directly by microscopy. To obtain more accurate results, filth is analyzed by several methods, involving wetting and digestion of the flour with pancreatic enzyme solutions or boiling 5% hydrochloric acid, sieving and filtering, followed by examination of the filter paper by microscopy.

Dietary Importance

D A T Southgate, Norwich, Norfolk, UK

Background

Flour is defined in most dictionaries as a term used for the ground material from cereal grains and related materials. In the context of Western Europe and most of North America, it most often implies the ground material from wheat, although the flour from other cereals, notably rye, maize, and rice, seeds of noncereals such as buckwheat, sorghum, and millets, and legumes such as soya bean are also sources of flours widely used in human nutrition. This article will focus most attention on the flours from wheat and only comment briefly on the nutritional contribution of the other flours.

The nutritional importance of flours derives first from a source of many nutrients and, second, from the many different types of foods that can be prepared that include flours of one kind or another as ingredients. The cultivation of cereals and the recognition that, when ground, they provide the basis of a wide range of foods from breads, where they are the major ingredients, to foods such as soups and gruel's, where they can be major or minor components, formed a key stage in the development of human civilization in the Middle East.

Mature cereal grains, as harvested from the plant, are hard and rather indigestible, unless they are steamed or soaked in water. Grinding or pounding the grain breaks the hard external coat and makes them more acceptable as foods. There is good archeological evidence for the development of grinding, initially between hand-operated stones, 'querns,' and later between mechanically operated millstones, and since the late nineteenth century between steel rollers to produce flours that greatly extended the range of foods in which cereals could be used.

Structure of the Cereal Grains

While the different cereal grains differ in detail in their structure, the principal components are common across all cereals and indeed most seeds. There is a

toughened outer seed coat, which includes the wall of the ovary in the grass flower.

In the wheat grain, these bran layers amount to about 8% of the grain weight. The seed contains the embryo or germ, which accounts for 2.5% of the wheat grain. The bulk of the grain is the endosperm, which contains the food reserve for the germinating grain. The cells of the endosperm have thin walls and are packed with starch grains as the reserve carbohydrate. Legume seeds also contain lipid as the energy reserve.

In the wheat grain, the endosperm accounts for about 82% of the grain. In the wheat grain, there is distinct layer of cells with thickened walls lying between the endosperm and the bran. This aleurone layer is rich in protein and B-vitamins, and contains most of the lipid in the grain. Grinding the grain breaks the endospermal cell wall and liberates the starch, which is the major component of cereal flours. In wheat, the rotating action of the millstones and rollers has the effect of separating the branny layer as a flake, which can be separated very easily from the edospermal material. The structure of the rye grain is similar, but in barley and rice, the outer layers are fused with the seed coat, and separation requires a different method. The other major cereal, maize, has a very tough coat that separates during pounding.

Production of Flours

Once the cereal has been ground, the ground material is usually fractionated to produce a range of types of flour. The initial grinding between conventional millstones produces wholemeal flour from which the different types of flour based primarily on the proportion of the whole grain present in the flour can be produced by sieving. Wholemeal wheat flour conventionally contains 98% of the starting grain (there is an allowance for cleaning the grain) and is said to have an extraction rate of 100%. Sieving removes progressively more of the branny and germ materials from the flour leading to flours of lower extraction rates where the proportion of endosperm is higher. Low-extraction flours are very fine and white, and are used in the production of some types of cakes. Bread-making flours have typical extraction rates of around 72%.

Roller milling initially separates the branny layers as a flake, and the particle size of the remaining grain material is progressively reduced to produce different streams of flours with different proportions of endosperm. The different types of flour and nominal extraction rates are formed by combining the different streams. Rye flours can be produced in similar ways, but most flours in use tend to be of the higher extraction rates. Corn flours are produced by sieving the ground cereal and, in many parts of the world, are consumed as high-extraction pounded flours. Cornflour is a very fine endospermal fraction.

Barley and rice grains have a different structure in that the outer layers of the seed coats are fused to the grain and cannot be removed by conventional milling. These grains are usually processed by blocking or 'pearling' the grain, in which the outer coats are removed with abrasive discs that grind away the outer layers to leave a grain that is made up mainly of endosperm. This is traditionally made into flour by pounding, although both barley and rice flours form minor proportions of the total use of these cereals.

Oats have a highly silicified seed coat and are typically prepared by steaming and rolling to produce groats rather than flours similar to wheat. The composition of some important flours is given in Table 1.

Table 1 Composition of some different flours (per 100 g)

Cereal	*Water*	*Protein*	*Fat*	*Carbohydrate*	*NSP*[a]	
Wheat	14.0	12.7	2.2	63.9	9.0	Wholemeal, mixed grist

Proximate Composition

Carbohydrates

Carbohydrates form the major constituent of all flours, and starch is the major carbohydrate present. In the unprocessed endosperm, the starch is contained within starch granules, which survive into the flours, although some starch granules are broken during milling. Most cereals contain the two forms of starch, amylopectin and amylose; amylopectin is usually the major component forming 75–82% of the total starch, but waxy maize contains virtually pure amylopectin, and there are also high-amylose maizes containing around 70% amylose, which gives them special physical properties that are important for use in some types of products.

Small amounts of free sugars are present in most flours, in wheat; sucrose is the major sugar, with traces of glucose and fructose. Maltose at low levels may be present, but high maltose levels are usually evidence of grains beginning to germinate at the time of harvest, which makes them less suitable for many processes.

Nonstarch Polysaccharides (Dietary Fiber)

The outer seed coats of the cereal grains contain plant cell wall material (dietary fiber), and cereals are of major nutritional importance in the provision of dietary fiber in the diet. The amounts of the nonstarch polysaccharides (NSP), which are the major components of plant cell wall material, depend on the extraction rate of the flour. Wholegrain flours contain the highest amounts, and the amount present falls as the extraction rate decreases. Table 2 illustrates the effects of extraction on the composition of wheat flours. The nonstarch polysaccharides of wholemeal wheat and rye are rich in the noncellulosic polysaccharides; of these, arabinogalactans have water-binding properties that are important for the physical characteristic of flours. Low-extraction flours contain mainly the cell walls from the endosperm, which are rich in cellulose. The noncarbohydrate lignin is also present in many seed coats; this makes the NSP from the higher extraction flours less digestible to the intestinal microflora of the large bowel and may be nutritionally important for increasing fecal bulk. The NSP from barley and oats are rich in β-glucans, which are water-soluble, giving viscous colloidal solutions that are nutritionally important in the products of these two cereals.

Table 2 Effects of extraction on the composition of wheat flours (per 100 g)

Flour, (extraction rate)	*Water*	*Protein*	*Fat*	*Carbohydrates*[a]	*NSP*[b]	*Energy (kJ)*

Lipids

Most of the lipid in the cereal grains is located in the germ, and small amounts are transferred to the endosperm component during milling. Oats are distinctive in this respect because they contain higher levels of lipid. The cereal lipids are typically unsaturated.

Proteins

Cereal grains contain a range of proteins, the amounts and types present varying with the variety, which determines the suitability of the flours for use in products. Wheats are classified into a number of types according to the amounts of types of protein present. North American and central European wheats contain higher levels of protein and are said to be 'strong'; these provide the flours that are most suitable for bread-making. British wheats tend to have lower protein contents and are 'weak' and less suitable for bread-making, although the mechanical development of the dough in the Chorleywood Process enables high proportions to be used in the mixed grists used in bread-making. 'Hard' wheats contain higher amounts of protein and differ from 'soft' wheats in their capacity to produce high-extraction and free-flowing flours. Wheats for bread-making are preferably hard and strong. Soft wheats are used in the production of biscuits and other products.

One important group of proteins in many cereals, especially wheat and rye, are the glutens. The glutens are insoluble proteins rich in sulfur amino acids, and they have the property of producing three-dimensional networks within the dough trapping the carbon dioxide formed by fermentation with the yeast; these are responsible for the formation of the characteristic texture of breads, which is a major factor in the nutritional importance in flours, especially in wheat-producing countries. Rye flours also contain a gluten that yields a less well-developed crumb structure. Rye breads tend to be more solid than wheat breads, and wheat/rye mixtures are especially important nutritionally in northern Europe. Barley does not produce breads in this sense and are more equivalent to cake-like structures as do oat flours.

The glutens are also nutritionally significant in being responsible for the intestinal lesions in 'gluten-sensitive enteropathy' and 'celiac disease.' The amino acid composition of cereal proteins is reasonably balanced, but lysine is one of the limiting amino acids that is partially destroyed in baking. Maize proteins are low in tryptophan, and pellagra has been observed in maize-consuming populations.

Vitamins

Cereals are good sources of some B-vitamins and poor sources of vitamin C and lipid-soluble vitamins. The vitamins are concentrated in the germ and the outer layers of the grain. Milling and the separation of the endosperm from the germ and bran lead to fractionation of the vitamins so that the concentrations are much lower in low-extraction white flours (Table 3).

Inorganic Nutrients

Flours, in common with most foods derived from plants, are rich in potassium and low in sodium. The production of self-raising flours increases the amounts of sodium and calcium, depending on the type of raising agent. Cereal flours are also good sources of phosphorus and reasonable sources of magnesium. Calcium levels are modest, and significant levels of iron and zinc are present. The inorganic nutrients are concentrated in the outer branny layers and in the germ, so that milling of the grain leads to the fractionation of the nutrients, and low extraction flours have much lower levels than the wholegrain flours. Table 4 illustrates the effects of extraction on some inorganic nutrients in wheat flours. The phosphorus in cereals is mainly present in phytic acid (*m*-inositol hexaphosphate), which is nutritionally important because it forms insoluble compounds with calcium, iron, and zinc, and thus reduces their bioavailability by preventing absorption in the small intestine.

Table 3 Effects of extraction rate on the B-vitamins in flours unfortified wheat flours (per 100 g)

Grade (extraction rate)	*Thiamin (mg)*	*Riboflavin (mg)*	*Niacin (mg)*	*Vitamin B_6 (mg)*	*Folates (μg)*

Fortification increases the calcium values by about 120 mg and iron by about 0.7 mg. Modified from Southgate DAT (1999) Cereals and cereals products. In: Garrow JS, James WPT and Ralph A (eds.) *Human Nutrition and Dietetics*, 10th edn, pp. 333–347. Edinburgh: Churchill Livingstone.

Fortification with Inorganic Nutrients

At the start of World War II in 1939, the UK authorities were concerned that the supply of dairy products might be reduced by enemy action and that the proportion of cereal products in the diet would have to increase. The extraction rate of flours would also have to be increased to divert more cereal imports to human foods. These changes in the diet would accentuate the effects of phytic acid on the calcium in the diet. Regulations were introduced to implement fortification of all wheat flours, other than wholemeal, with calcium. After the war, there was a delay in returning to the low-extraction (white) flours for bread-making, but in 1953, when the regulations were relaxed, it was decided that the flour should be fortified with iron, thiamin, and niacin to maintain the concentrations of these nutrients at the levels they had been in the higher-extraction flours used in war time and the immediate postwar period. Although the primary nutritional reasons for fortification of wheat flours have largely disappeared, the fortification continues in the UK so that the calcium, iron, thiamin, and niacin levels in the UK flours are higher than those in most other countries.

Fortification with other nutrients has been considered recently in the UK. These include vitamin D in flours used primarily by immigrant communities in order to counteract the increase in the incidence of rickets in those communities. However this fortification was never introduced because of the difficulty in restricting the fortified flours to those for whom it was intended. Fortification with folic acid has been proposed as a prophylactic measure for reducing the incidence of neural-tube defects. The latter fortification is being implemented in the USA.

Losses of Nutrients on Storage of Flours

Provided the moisture content is below 15 g per 100 g, the nutrients in flours are relatively stable at cool ambient temperatures. Losses due to infestation with mites can occur on prolonged storage, especially at higher temperatures. The lipids in flours slowly oxidize at ambient temperatures, and rancidity can develop in wholemeal flours, which therefore have shelf-lives of about 3 months compared with about 9 months from brown flours and 2–3 years for white flours in paper bags.

Nutritional Contributions of Flours

The major nutritional contributions of flours to the human diet lie in the wide range of products in which flours are components. The range of products derived from flours in the UK diet, for example, is very large, ranging from breads and biscuits where flour is the primary ingredient, to its use in the preparation of pastry for meat, fish, vegetable, and fruit dishes, pizza bases, and pasta. Flours are used as thickening constituents in soups and many other dishes.

This widespread use means that flours are an important source of energy in the diet. Their contribution to protein intake is also significant because the proportion of protein to energy approaches many dietary recommendations. Although the conventional approach is to view cereals as energy sources alone, it is important to recognize that the current dietary recommendation for the proportion of energy from starchy carbohydrates in the diet could not be met without the contributions from flour. High-extraction cereal flours and the products made from them are significant sources of nonstarch polysaccharides.

FLUORIDE

A Hardisson, M I Rodríguez and A Burgos, University of La Laguna, Canary Islands, Quebec, Spain

Background

Fluorine is the most electronegative of all the known chemical elements and the most reactive. Its chemical characteristics make it one of most physiologically active ions. The interest in this element undoubtedly comes from the observations made in the 1980s of the toxic and therapeutic effects of fluorine, especially on teeth. In high doses, it can cause disorders in enamel formation, leading to *mottled teeth* or *dental fluorosis*, and in relatively small doses, it can reduce the prevalence of dental caries by over 50%. Dental caries are frequently suffered by the population, even in the most developed countries, and fluorides remain the best remedy. In fact, it has been shown that there is a correlation between communities that have consumed water containing moderate levels of fluoride (around 1.5 mg l^{-1}) and lower rates of dental caries. However, the relationship between consuming water containing high levels of fluoride ions and fluorosis has also been confirmed. Fluorosis is a disease that is characterized by 'mottled teeth,' and high intakes of fluoride are probably related to the appearance of kidney problems, leading to decalcification of the bones due to the flouride-sequestering quantities of Ca^{2+} that are essential for the correct development of the bones. Fluorine is a component of water that, according to the WHO, should be present in concentrations of around 1 mg l^{-1} to prevent dental caries, but if these levels exceed 1.5 mg l^{-1}, toxic effects start to appear, making the margin between essential and toxic levels very slim indeed.

Sources

The body's main source of fluorine is undoubtedly drinking water, as this is the cheapest and most efficient way of providing it, and fluoride plays an important role in human health. There are also traces of fluorine in almost all food products. The fluoride content in food is of great importance, as it can have both beneficial and prejudicial effects on our health when added to the quantities supplied by fluoride-treated water and toothpaste.

Man is naturally exposed to fluorides due to the increasing industrial use of these compounds, the increased use of fluoride toothpastes by the general population, and the treatment of water with fluoride as a fundamental weapon in the arsenal against caries in certain communities. Apart from water, there are other natural sources of fluorine to be found in the animal and vegetable worlds (tea is rich in fluorides); the atmosphere and even some medicines and cosmetics are occasional sources.

Dietary Intake

The level of fluorine in water is often used as a criterion to establish whether or not a population's diet is deficient in this element. However, in order to accurately determine fluoride intake, the contribution from food, both liquid and solid, the air, occasionally contaminated with fluoride either from industry or of volcanic origin, and the widely consumed products that have been treated with fluoride to fight caries should also be taken into consideration. The main tissues that are known to take up fluorine are bone and dental enamel, and uptake is proportional to total intake. Dietary recommendations are between 1.5 and 4 mg per person per day for adults, between 0.1 and 1 mg per person per day for the first year of life, between 0.5 and 1.5 mg per person per day for the next two years, and up to 2.5 mg per person per day for 12-year-old children.

Dental Caries

More than a decade passed after the discovery of the relationship between fluoride and endemic chronic dental fluorosis, before the beneficial influence of fluoride on the prevalence of caries was established. This discovery was the fruit of many years of research on dental fluorosis.

Later studies have shown that the addition of fluoride to the drinking water in areas of low natural concentrations is a practical and efficient method of reducing the incidence of dental caries. The recommendations approved by health organizations, therefore, suggest fluoride concentrations of between 0.7 and 1.2 mg l^{-1}, depending on the average local temperature. Dental health has also improved in recent years, even in areas with low concentrations of fluoride in drinking water. This is probably due to increased intakes of fluoride from other sources, such as food processed with fluoride-enriched water, external applications of fluorine by orthodontists, fluoride supplements, and even unintentional intake of fluoride-treated toothpaste.

Content in Waters and Liquid Food Products

The fact that fluoride is an element that has a beneficial effect on human health in certain dosages, but can become toxic to man in slightly higher concentrations, highlights the need for an exhaustive evaluation of the total quantity of fluoride consumed by a person in a specific community in a given geographic area. This quantity is affected both by community habits and by climate conditions, fundamentally by average temperatures (especially important in areas in which the public water supply has been treated with fluoride).

Methodology

One of the problems to be considered is the choice of the most suitable method for determining fluoride contents. The most widely used techniques include: gravimetry (precipitation as PbFCl, precipitation as calcium fluoride) and volumetry (determining the soluble fluoride and the combined fluoride), indirect colorimetry (SPADNS method, quercetin–zirconium system (III), zirconium–alizarin red system, zirconium–chromium cyanine system, zirconium–alizarin sulfonate system), direct colorimetry, potentiometric methods (based on the use of a selective fluoride ion electrode), and spectrofluorimetric methods. In some cases, especially for complex matrices, prior separation of fluorides may be necessary. The most widely used methods of separation include fluorine distillation, ion exchange, HF microdiffusion, and interference ion precipitation.

Water

Fluoride in drinking water is commonly the main source of total fluoride intake. The intake of F^- from drinking water will depend fundamentally on: (1) the concentration of F^- in the water, (2) the age of the person, (3) weather conditions (temperature), and (4) eating habits. Table 1 shows typical average fluoride concentration in drinking waters obtained in different geographic areas and at different times. Although the contents are variable in general, there are some waters in India that have a high fluoride content, similar to the levels of the north Tenerife (Spain) water supply in the health district of Icod de los Vinos. Based on the average concentration intervals and an average water consumption of 2 l per day, the fluoride intake would be between 5 and 11.1 mg of fluoride per liter per person per day, which exceeds dietary recommendations and explains the fact that this is an area with a high degree of dental fluorosis.

Table 2 shows the average concentration in the most commonly consumed domestic and foreign mineral waters in Spain, at different times in the same geographic area (the island of Tenerife). Some of these concentration values are above the recommended level of $1\,mg\,l^{-1}$, but none is above the maximum ceiling of $1.5\,mg\,l^{-1}$.

Wine

Small concentrations of fluoride can be found naturally in wine, but these quantities do not generally exceed the maximum limit of $1\,mg\,l^{-1}$ recommended by the International Vine and Wine Bureau. In fact, the fluoride contents found in most research work done in this field are between 0.1 and 0.9 mg of fluoride per liter. The natural fluoride content of wine, therefore, cannot be classified as unhealthy in normal circumstances. The fluoride gets into the wine from the fluoride contained in the irrigation water, so

when it is found in higher concentrations, one can assume that there has been some form of contamination, either natural (soil or water that is excessively rich in fluoride) or accidental, with two main sources. The first source would be the use of cement vats for making the wine and/or for storing the wine; the second source of contamination would come from the direct addition of fluoride-enriched compounds like antiseptics or antifermentation agents. Although their use is banned in many countries, they are still used, because it is known that, even when diluted to between 1:400 and 1:5000, fluoride still presents a marked antiseptic action.

Another source that must be added to the two main sources is the increasing use of kryolite (sodium fluoroaluminate) in the USA as an insecticide to control certain pests that affect the vineyards. This new source of pollution raises the fluoride content in the wine produced from these grapes to 3 mg of fluoride per liter, which, in principle, makes it necessary to review wines that were not initially considered to have a high fluoride content. On this subject, mention must be made of the *wine fluorosis* discovered in Barcelona in 1965. A joint study by the Departments of Medical Pathology, Bromatology and Toxicology of the University of Barcelona demonstrated that the etiology of some *periostitis deformans* was the consequence of consuming wine with high fluoride concentrations. Situations of this kind require not only a high intake of fluoride, but also the nutritional deficits typically exhibited by alcoholics, making it more probable that consumers of wines containing added fluorides will suffer from this kind of disease. As fluoride has a marked preference for bone, it causes alterations in the skeleton, as well as inhibiting some important enzymes (phosphoenolpiruvase, phosphotases, esterases, and even the cytochrome oxidase system).

According to several results (Table 3), the fluorine contents of wines of different vintages studied exceed neither the established limit of $1\,mg\,l^{-1}$ nor the recommended daily intake.

Beers, Soft Drinks, and Juices

Table 4 gives the fluoride contents in the most popular beers and soft drinks. These results indicate that the fluoride content found comes mainly from the water used in the manufacturing process. According to the literature, the F^- content in beers is low, around 0.3–0.8 mg l^{-1}, unlike wine, which can reach 6–$8\,mg\,l^{-1}$, due to the reasons mentioned in the section on wine; because it is stored in cement vats, and because of the use of compounds with added fluoride like antiseptics and antifermenting agents. With regard to soft drinks, the drinks made from carbonated water have the highest fluoride content ($1.05\,mg\,l^{-1}$), although they do not reach the permitted maximum of $1.5\,mg\,l^{-1}$. Bottled natural fruit juice, however, has a lower content.

Milk and Derivatives

Milk and dairy products are consumed universally. Their importance in our diet has been accepted for thousands of years. Table 4 lists literature data on the fluoride content in milks and derivatives. The values detected in dairy products are below $0.4\,mg\,kg^{-1}$, the recommended ceiling for formula for children, so

their consumption by the child population does not imply any toxicological risk for them. Furthermore, one must remember that some kinds of milk have been enriched with fluoride.

Tea

Tea leaves also have a high fluoride content. These values are above 400 mg kg^{-1} (dry weight), but tea infusions (tea-bags) have concentrations of around 0.5–1.5 mg l^{-1}. The amount of F^- present in a cup of tea will depend not only on its volume but also on the brand of tea, the amount of tea used, how long it is brewed for, whether or not it is a dilution of a previously prepared cup of tea, and whether or not it has been made with fluoride-enriched water. The F^- intake of tea drinkers can vary between 0.04 and 2.7 mg day^{-1}. Table 4 shows the fluoride contents of tea.

Fluorides in Solid Foods

Fluorides can be detected in all food. There does not seem to be a clear relation between the F^- content of most plants and the content found in the soil or the water in the area where the plants are grown. Plants grown in acid soil, however, have a higher concentration of F^-. The F^- content found in the leaves of most plants is between 2 and 120 mg of F^- per kilogram. The fruit and vegetables consumed by man have a fluoride content of around 0.1–0.4 mg kg^{-1} and, therefore, are of little interest, unless there is a prevalence of unusual dietary patterns, although F^- concentrations of up to 2.0 and 2.1 mg kg^{-1} have been found in barley and rice irrigated with nonfluoride-treated water, and concentrations of up to 4.3 and 6.4 mg of F^- per kilogram, respectively, when the water used was fluoride-enriched. Yams and cassava also make up the main diet of many tropical regions, and they contain high levels of F^-. However, fluoride contents in meat tend to be low. Fish products (tinned fish like salmon, sardines) have fairly high contents, up to 40 mg kg^{-1}. However, the consumption of fluorides from fish alone, in a combined diet, does not provide enough fluorides to exceed 0.2 mg day^{-1}.

The amount of the total fluoride intake accounted for by solid foods has been considered as low, although this can vary, depending on the composition of the daily diet and the fluoride content of the water where the food has been prepared.

These quantities of fluorides in food can be increased by the use of pesticides with added fluoride and phosphated chemical fertilizers, and because of the fluoride to be found in the irrigation and washing waters. Furthermore, one must consider the fluoride contribution made by industrially processed foods.

Table 5 Lists the most significant data collected on the fluoride contents of solid foods. It can be seen that the contents are very low, with the exception of fish products.

Table 4 Fluoride ion content in beers, soft drinks, juices, milk, and tea

Drink	*Analytical method*	*Mean concentration (mg l^{-1})*
Beers (1990)	Ion-selective electrode	0.51

FOLIC ACID

Contents

Properties and Determination

C J Bates, MRC Nutrition Research, Cambridge, UK

Introduction

In the older literature, it was customary to use the terms 'folic acid,' 'folate,' or 'folacin' interchangeably for all of the pteroylglutamic acid derivatives and their γ-polyglutamic acid conjugates. More recently, the custom has changed so that 'folic acid' is now reserved for the parent and commercially available pteroylmonoglutamic acid which is in the oxidized state, whereas 'folate' is used to describe the derivatives which typically occur in foods and tissues. The latter occur in many forms, which may be reduced; they often carry one-carbon substituents and are often poly-γ-glutamates, especially inside cells. The advantage of this new practice is that it permits a shorthand distinction between the commercial folic acid that is present in supplements and is used in food fortification, and the folate that is native in living tissues and in natural foods, and which has a different bioavailability.

Physical Properties

The fully oxidized parent substance of the folate or folacin group, pteroylglutamic acid or pteroylmonoglutamic acid (formula weight 441.4) crystallizes from hot water as yellow-orange platelets. It does not melt, but darkens and chars at about 250 °C. It is only very slightly soluble in cold water (1–10 mg l^{-1}), increasing to 1% in boiling water, and is much more soluble in aqueous alkali, acetic acid, phenol, pyridine, and other basic solvents. A solution for injection is obtained by dissolving it in aqueous sodium bicarbonate, or by using the sodium salt, which is soluble in water. The extinction coefficient ($E^{1\%}_{1\,cm}$) in 0.1 mol l^{-1} alkali is 565 at 255 nm, 350 at 282 nm, and 195 at 365 nm (absorption maxima).

5-Formyl-5,6,7,8-tetrahydropteroylglutamic acid (folinic acid: formula weight 473.4) also decomposes without melting at 250 °C; it is sparingly soluble in water, but is more soluble in aqueous alkali, and the

absorption maximum is at 282 nm in alkali. It is more stable at neutral or slightly alkaline pH than at acid pH, in solution. The 10-formyl derivative is more labile, and more sensitive to oxygen.

Tetrahydrofolic acid (formula weight 443.4) is extremely readily oxidized, and the freeze-dried solid form must be stored *in vacuo*. Solutions in 0.5% ascorbate or in 1.0 mol l^{-1} mercaptoethanol are moderately stable, and it has an absorption maximum at 298 nm in neutral solution.

5-Methyltetrahydrofolic acid (formula weight 459.4) is intermediate in stability to oxidization between pteroylglutamic acid and tetrahydrofolic acid. It can be obtained as a white powder, but in solution it requires ascorbate or another reducing substance to achieve medium-term stability. The absorption maximum at 290 nm has a molar extinction coefficient (ε) of 31.7×10^3 mol^{-1} cm^{-1}, or $E^{1\%}_{1\,cm}$ of 690, at neutral pH.

Chemical Properties

The structural formulae of three of the commonly encountered forms of folic acid are shown in Figure 1.

Pteroylglutamic acid and related pterins are readily hydrogenated in two stages to the dihydro and then the tetrahydro forms, involving firstly positions 7 and 8 of the pteridine ring, then positions 5 and 6. These hydrogenation reactions can be performed either *in vitro*, with hydrogen and a platinum oxide catalyst or by hydrosulfite, or else *in vivo*, by enzyme-catalyzed reactions involving dihydrofolate reductase. Once converted to the fully reduced form, single carbon units at various levels of oxidation can be transferred to the nitrogen atoms at positions 5 or 10, yielding methyl, methylene, methenyl, hydroxymethyl, or formyl units: the second and third of these form a bridge between the two acceptor nitrogen atoms. A combination of a carbon and nitrogen atom (formimino group, –CHNH–) can also be carried. These transfer reactions constitute the fundamental basis of the single-carbon-unit transfer operations, for which the folic acid cofactors are essential *in vivo*. (*See* **Cobalamins**: Physiology; **Coenzymes**.)

Chemical syntheses of pteroylglutamic acid have been achieved, first by condensation of guanidine with ethyl cyanoacetate to give a pyrimidine ring, then continuing either by reacting *p*-aminobenzoylglutamic acid with 2,4,5-triamino-6-hydroxypyrimi-

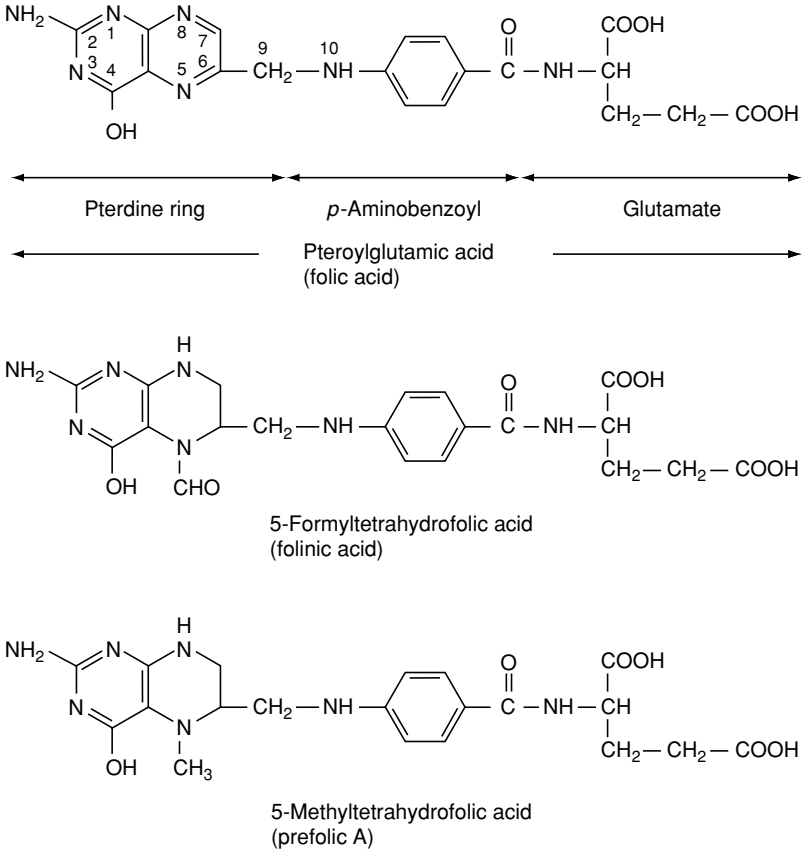

Figure 1 Structural formulae of commonly encountered forms of folic acid.

dine and α,β-dibromopropionaldehyde, or by reacting 2,4,5-triamino-6-hydroxypyrimidine with pyridine, α,β-dibromopropionaldehyde, potassium iodide, and *p*-aminobenzoylglutamic acid. For pteroylglutamic acid there is only one asymmetric center which is within the glutamic acid moiety (L form), but after reduction a second asymmetric center appears at carbon 6, and chemical synthesis produces both D and L forms, whereas the natural product has the L configuration. Degradation of folic acid *in vivo* involves an initial cleavage at the 9–10 bond.

Folate polyglutamates are the forms of folic acid (including the reduced, C_1-substituted cofactor forms *in vivo*) which have γ-linked chains of poly-L-glutamic acid. These chains can extend up to at least 10 L-glutamyl units, and different tissues differ in their spectrum of chain lengths. The glutamate residues are added by the enzyme, pteroylpolyglutamate synthetase (pteroylpolyglutamate ligase), and can be removed by pteroylpolyglutamate hydrolase (alias folate conjugase or γ-glutamyl carboxypeptidase). The latter enzyme is present, *inter alia*, in serum, in duodenal and jejunal mucosal cells and in kidney, especially within the lysosomes. The synthetase is an intracellular enzyme, responsible for building the active forms of the folate cofactors. Tetrahydrofolate and the formyl folates are preferred to methyltetrahydrofolate for the synthetase reaction, which helps to explain the poor retention of folate in vitamin B_{12} deficiency, when such nonmethylated folate species decline in concentration, leading to a change in the balance towards shorter-chain polyglutamates.

Occurrence in Food

A wide variety of forms of folate occur in food, and this complexity has resulted in major problems, both for devising accurate analytical methods to measure the folate content of foods as eaten, and in measuring the bioavailability of the different forms. As noted previously, the source of variability is threefold: (1) the oxidation state of the pteridine ring; (2) the presence and type of the one-carbon substituent carried, and (3) the presence and length of the polyglutamate side-chains. (*See* **Bioavailability of Nutrients**.)

Because monoglutamates and short-chain polyglutamates are more readily available for absorption than long-chain polyglutamates, an operational definition of 'free folate' was established, which included only the monoglutamates and short-chain polyglutamates that are most readily available to promote the growth of the test organism *Lactobacillus rhamnosus* (formerly *L. casei*). However, this category has not, in practice, proved to be very useful, because the proportion of 'free folate' can vary enormously with the history of the food sample, the assay conditions (especially the initial folate extraction, if endogenous conjugases are present), and with the duration of exposure to the assay microorganism. The original studies on this subject made use of polyglutamates derived from the oxidized form, pteroylglutamate, not those of the natural forms of folate, so that the results were not entirely applicable to the forms of folate in foods. (*See* **Lactic Acid Bacteria**.)

Table 1 shows the folate content of 'typical' (average) samples of food items as eaten. These folate values are still being revised, usually in an upward direction, as the assays are optimized. Nearly all of the existing food table folate values have been obtained by microbiological assay procedures.

It is clear that, although folate contents per 100 g vary considerably, folate is fairly widely distributed between different food types. Despite this, there are very considerable variations in folate content between diets which, on the one hand, depend heavily on unfortified cereal staples (traditionally 'poor' diets) and, on the other, include the richer plant and animal sources. Of the folates in a mixed diet, over 90% are in polyglutamates of varying chain length; 60% are methylated, and 30% have a formyl group. Foods containing substantial amounts of vitamin C also tend to be rich folate sources, partly because of the preservative effect of vitamin C on folates during storage, preparation, and cooking. (*See* **Ascorbic Acid**: Physiology; **Cereals**: Dietary Importance.)

In the UK, vegetables and cereals each provide about 30% of food folate intake; milk and milk products provide about 10%; meat, fruit, and beverages each provide about 5%; eggs, fish, and other foods each provide 1–4%.

Use in Food for Fortification

If the vitamin is added to manufactured foods, it is almost always as pteroylglutamic acid (folic acid), because this is by far the cheapest commercial form. Infant formulae usually contain added folic acid, in amounts between 3 and 15 μg 100 ml^{-1}, as fed. The practice of adding folic acid to manufactured foods is becoming much more common than it was, especially for breakfast cereals. In the USA, folic acid fortification of cereal grains for bread making has now become mandatory, at 1.4 μg g^{-1}, from the beginning of 1998. (*See* **Food Fortification**; **Infant Foods**: Milk Formulas.)

Extraction and Clean-up

Two problems dominate the procedures for extraction of folic acid from biological tissues: the prevention of

oxidation mainly by molecular oxygen, and the preservation, or alternatively the complete removal, of the polyglutamate chain. Prevention of oxidation can be achieved by a variety of reducing agents, the most common choice being ascorbic acid, usually at 1% w/v final concentration, either as the free acid or else partially neutralized, e.g., to a pH around 4.

Removal of the polyglutamate side chain can be achieved with partly purified preparations of folate conjugase (polyglutamyl hydrolase). The ones which are most commonly used for food folate release are the hog kidney enzyme and the chicken pancreas enzyme. The former hydrolyzes the polyglutamate chain and thus releases monoglutamates from the food folates more completely than the latter, which tends to produce diglutamates. Although different workers have generally taken care to optimize the assay procedures with their particular selected enzyme sources, it is important to consider carefully the implications of using an enzyme which may not liberate monoglutamates, because this can seriously affect the relative molar response of the standard (such as pteroylglutamic acid) against the more complex and variable folate species obtained from the food matrix. One study indicated that the folate content of foods as measured after deconjugation with the hog kidney enzyme can be at least 50% higher than the values achieved after deconjugation with chicken pancreas enzyme. A 'triple enzyme' mixture, comprising chicken pancreas conjugase plus α-amylase and a protease, is widely used.

The release of monoglutamyl folates from the polyglutamates in red cell extracts has generally been achieved by incubating the red cell lysates in the presence of their own plasma, because plasma contains a very active conjugase. This is why red cell folate assays in whole blood, rather than separated red cells, are preferred, since the cellular components contain little or no conjugase. Most of the published procedures for the red cell folate assay have assumed that the monoglutamates are completely released after a brief period of incubation with plasma enzyme. Another assumption, highlighted recently, that is made with the assay of folate in red cell hemolysates, is that it is unaffected by the extent of binding to hemoglobin or the extent of physical trapping, which varies with the degree of oxygenation of the sample. Although red cell folate is a preferred index, because it measures long-term status, there are still serious practical problems in achieving accurate measurements and in obtaining acceptable inter-laboratory agreement.

If the polyglutamyl folates are to be preserved, in order to measure the polyglutamyl profile that is characteristic of the undamaged tissue, then adventitious conjugase activity must be inactivated at the time of extraction. One way of achieving this is by using a boiling ascorbic acid solution during homogenization.

If extremely labile folates, such as tetrahydrofolic acid, are to be extracted and preserved intact, then special precautions such as the exclusion of oxygen during the extraction procedure, and the use of low temperatures, may be necessary.

Analytical Procedures

Once the folates have been extracted from the tissues, there are three main approaches to the problem of their estimation and characterization. The oldest general procedure depends on the extent of growth of a specific folate-dependent bacterial species. Its growth

medium contains optimum amounts of all the necessary growth factors except folate, and a small amount of the food extract is then added, to provide sufficient folate for partial suboptimum growth of the test organism. The second general approach, which has now been available for nearly three decades, depends on the specific interaction of the extracted folate with a fixed amount of a folate-binding protein plus radioactive- or fluorescence-labeled folate, after which the protein-bound folate is separated from the unbound folate and the radioactivity or fluorescence of the bound folate is measured. The amount of label bound depends on the total amount of folate present. This approach can be subdivided into those assays which depend on naturally occurring folate binders obtained from body fluids such as milk, and those which depend on binders which are artifically induced in an animal, for instance by using folate bound to a hapten as an antigen. (*See* **Immunoassays**: Radioimmunoassay and Enzyme Immunoassay.)

The third general approach is the separation of different folate species from each other and from interfering substances, using high-performance liquid chromatography. This approach has the advantage of specificity, but a disadvantage for tissue folate analyses is that the available detectors (ultraviolet absorption, fluorescence, or electrochemical) are barely sensitive enough to detect all of the folates found in tissues, and they do not always give a constant molar response with different folate species, which complicates the problem of calibration. Nevertheless, new data and further refinements continue to emerge. (*See* **Chromatography**: High-performance Liquid Chromatography.)

The microbiological assay procedures have been established for long enough to dominate the literature, for instance, on food analysis and food table compendia. Total folate has, for several decades, been measured using *L. rhamnosus* (previously *L. casei*), because this organism can respond equally well to all the common monoglutumate forms of folate. However, the use of inappropriate assay conditions, e.g., a poor choice and control of pH, has often resulted in the underestimation of total folate contents. Until this source of error has been effectively eliminated, the food table values for folate and the derived estimates of human dietary intakes of folate may be too low. Revised values are gradually being obtained to rectify this problem.

Two other microorganisms have been used, especially in the earlier studies of folate speciation. One is now called *Enterococcus hirae* (formerly *Streptococcus faecalis*). This organism grows on most forms of folate except the 5-methyl derivative. The other is called *Pediococcus pentosaceus* (formerly *P. cerevisiae*, or *Leuconostoc citrovorum*), and grows most readily on 'citrovorum factor,' i.e., N_5-formyltetrahydrofolic acid, or 'folinic acid'. Differential growth of these organisms on tissue extracts has given useful estimates of the different monoglutamate forms of folates. However, it is important to note that some tissue or food extracts contain growth inhibitors, or promoters, which may result in errors in the estimation of folate levels, and species ratios.

The binding protein methods have recently proved very popular, especially for blood status assessment, because of their ease of operation, but they too can suffer from errors. One source of error, mentioned earlier, may be the incomplete deconjugation of polyglutamate side chains; another may be the partial oxidation of folates to their degradation products. Like the microbiological assay, specific binding assays can also suffer from pH-dependent variations in response to different folate species, so that the choice of calibrant and of pH may be critical. There are many variants, using different binding proteins or antibodies; some depend on the binding of radioactive- or fluorescence-labeled folate markers; others depend on enzyme-linked immunosorbent assays. However, there is a constant need for interlaboratory methodological comparisons to achieve good comparability of results, and a careful study of the sources of error in these assays, and of procedures to insure their elimination. External quality assurance schemes are available for folate (and for vitamin B_{12}) assays in serum or plasma, and to a lesser extent for folate in red cells, because these are widely performed, especially by hospital hematology laboratories.

Those studies which have made the most use of high-performance liquid chromatography have been metabolic studies in animals, in which the intertissue distribution, turnover, and speciation of folates have been followed, using radioactively labeled precursors. The use of stable isotope-labeled folates for studies of folate economy in human subjects has recently become feasible, and a number of new studies have begun to examine the relative bioavailability of different folate congeners, with and without a food matrix, by this approach. Urinary excretion of undegraded folates and of the breakdown products derived from *para*-aminobenzoic acid has provided suitable material for isotope ratio analysis. Undoubtedly this approach will expand and be more widely used, especially to study folate bioavailability, in the future.

Physiology

C J Bates, MRC Human Nutrition Research, Cambridge, UK

Nutritional Significance of Folic Acid and Folates

Like most micronutrients, the nutritional significance of folate was recognized and explored as the result of a deficiency disease, namely megaloblastic anemia, which occurred especially among pregnant women living in India. This was characterized by enlarged (megaloblastic) red cell precursors in the bone marrow, by macrocytic erythrocytes and by abnormal polymorphonuclear leukocytes with increased numbers of nuclear lobes, in the peripheral blood. There may also be lesions of the tongue (glossitis) and of the mucocutaneous margins of the mouth (cheilosis), and malabsorption. All of these lesions are shared with other vitamin B deficiency syndromes, so none of them is unambiguously diagnostic. Normally, the total body content of folate is about 5–20 mg. (*See* **Anemia (Anaemia)**: Megaloblastic Anemias.)

As the biochemical functions of the folate coenzymes became clearer, it was recognized that folate deficiency had implications for many aspects of homeostasis, metabolism, and health beyond the limited confines of blood cell production and maturation. Folate is essential for nucleic acid synthesis at all sites, and for a wide range of biochemical pathways involving one-carbon transfers. Deficiency states are by no means confined to the developing countries, although they are commonest and most severe there. As folate deficiency progresses and becomes more severe, there is a characteristic sequence of events, in which low plasma folate levels are followed by low erythrocyte folate levels, then increased polymorphonuclear leukocyte nuclear lobe numbers, macroovalocytosis of the erythrocytes and bone marrow macrocytosis, then macrocytic anemia.

Conflicting evidence about human requirements has led to considerable fluctuations in official recommendations for folate intakes, and problems with the assay of folates in foods have created parallel difficulties in the estimation of dietary folate intakes by individuals and populations.

Physiology and Functions of Folic Acid

In order to be absorbed efficiently, the polyglutamate folates in food need to be broken down to monoglutamates, either during food preparation, or at the brush border of the jejunum, which is the main site of absorption. It is difficult to give precise figures for the efficiency of deconjugation, and of absorption, because they vary considerably with the type of folate, with other dietary constituents, and with unidentified physiological factors, especially the pH at the site of absorption, the optimum being *c*. pH 6. Many foods contain inhibitors of the intestinal brush border folate conjugase and/or folate transport system, thereby reducing the efficiency of absorption. Others, such as milk, contain folate binders which may stimulate absorption.

Absorption of food folate, which occurs mainly in the jejunum, is largely attributable to active transport against the concentration gradient at moderate intakes, and appears to involve two jejunal brush border folate-binding proteins. This process is pH-, sodium-, and glucose-dependent. Recent estimates suggest that about 50% of the complex mixture of folates that occur, in food can be absorbed and utilized. Although most individual folates, even polyglutamates, are better absorbed than this when given on their own, the effects of partial degradation and food borne inhibitors etc. reduce the overall efficiency, which can be very variable. Small amounts of folate may arise from the intestinal flora *in situ*, but in humans (unlike the rat), this is now known to be only a very minor source of absorbed folate. Although mono and short-chain polyglutamates are more readily absorbed and utilized than the long-chain polyglutamates, the difference between them is not as substantial as was once thought, and the old subdivision into 'free' and 'bound' (i.e., short-versus

long-chain polyglutamates) has largely been superseded. The nutritional status of the subject can affect the efficiency of folate utilization and its economy: deficiencies of vitamin B_{12}, iron, zinc, or vitamin C in particular can have an adverse effect. Folate absorption is also adversely affected by some drugs, including diphenylhydantoin, phenytoin, phenobarbital, primidone (anticonvulsants); cholestyramine, salicylates and nonsteroidal antiinflammatory drugs; and salicylazosulfapyridine (used to treat bowel inflammation).

Once absorbed, the monoglutamate folates in the portal plasma are carried to the liver for processing, the liver being a major repository of folate coenzymes. From there, folate is carried to the other tissues. Hepatic folate is also secreted in bile, and much of this biliary folate is reabsorbed. Absorbed folate in excess of requirements is excreted in the urine, and folate turnover results in several characteristic degradation products, such as *p*-aminobenzoylglutamates, also destined for excretion in the urine. A substantial amount of folate turnover also occurs by fecal excretion of endogenous folate. (*See* **Coenzymes**.)

Folate transport into the cells of other tissues is also mainly by carrier-mediated processes. There are two separate mechanisms: one involves a reduced folate carrier protein which is a transmembrane transporter, and the other is an anchored protein called membrane folate receptor, which has a high affinity for both reduced folates and folic acid. This is especially active in tissues like kidney, placenta, and breast, where efficient folate transport is critically important. It can be inactivated by certain mycotoxins. There are specific folate-binding proteins at various sites; some are involved in folate transport, others may have a protective function.

Within the cells of mammalian tissues, folate is converted by the enzyme, folyl polyglutamate synthetase, to γ-linked polyglutamates of the reduced folates. 5-Methyl tetrahydrofolate polyglutamate is the largest fraction of tissue folate, except in tissues with especially rapid cell division, where the formyl derivative tends to be dominant.

In most tissues, the dominant functions of the folate coenzymes are the synthesis of DNA, thus permitting cell division, growth, and tissue renewal, and the provision of active methyl groups via the methionine cycle and the methyl donor *S*-adenosylmethionine (SAM). Folates have several essential functions in the synthesis of purine and pyrimidine building blocks of DNA, but the one function that is exquisitely sensitive towards folate deficiency is the conversion of deoxyuridylic acid to thymidylic acid, catalyzed by thymidylate synthase (Figure 1). For this reaction, folate must first be converted into 5,10-methylene tetrahydrofolic acid, which undergoes a regeneration cycle each time it participates. This function of folate explains most of the pathological effects of its deficiency in humans and animals, including megaloblastic anemia, leukocytopenia and other white cell abnormalities that arise from disturbances in DNA synthesis and hence of cell division in bone marrow. Folate deficiency also reduces growth (in children), regeneration of intestinal mucosa, and cell division at other sites which have a rapid turnover. (*See* **Nucleic Acids**: Physiology.)

Certain anticancer drugs which interfere in the folate regeneration cycle (e.g., dihydrofolate reductase inhibitors such as methotrexate), and some antibiotics which are antimetabolities of folic acid, act by reducing pathological rates of cell division, thus protecting the host organism against unchecked division of parasitic cells. A major challenge for future research will be to target such antimetabolites specifically to the sites of invasion and damage, in order to reduce their side-effects on healthy tissues. Paradoxically, healthy tissues may also be protected against some carcinogenic agents by adequate folate nutrition, because removal of damaged DNA requires folate-dependent metabolic reactions. Recently, there have been several controlled studies of cancer susceptibility in human subjects, in which folic acid has been tested for possible protective effects. These have focused especially on the large bowel, uterine cervix, breast, pancreas and, to a lesser degree, lung. Although a consensus has yet to emerge, interest in this subject is rapidly expanding. (*See* **Carcinogens**: Carcinogenic Substances in Food: Mechanisms.)

Other important functions of the folate coenzymes include the turnover of histidine, the synthesis of methionine from homocysteine, interconversion of serine and glycine, and other single-carbon transfers between molecules. As noted above, the methionine-SAM pathway is of major importance for provision of methyl groups for a plethora of essential structural and functional molecules. There are complex allosteric (feedback) interactions which closely control these pathways which involve folate coenzyme/cosubstrate participation. The strong metabolic link between the functions of folate and those of vitamin B_{12} occurs at the methionine synthase reaction which transfers the carbon unit from methyltetrahydrofolate to homocysteine to form methionine (Figure 1). The requirement for B_{12} cofactor in this reaction leads to a lack of suitable active single-carbon units for DNA synthesis during B_{12} deficiency, so that either folate deficiency or B_{12} deficiency will result in megaloblastic anemia and the other sequelae of impaired cell division at sensitive tissue sites. (*See* **Amino Acids**: Metabolism; **Cobalamins**: Physiology.)

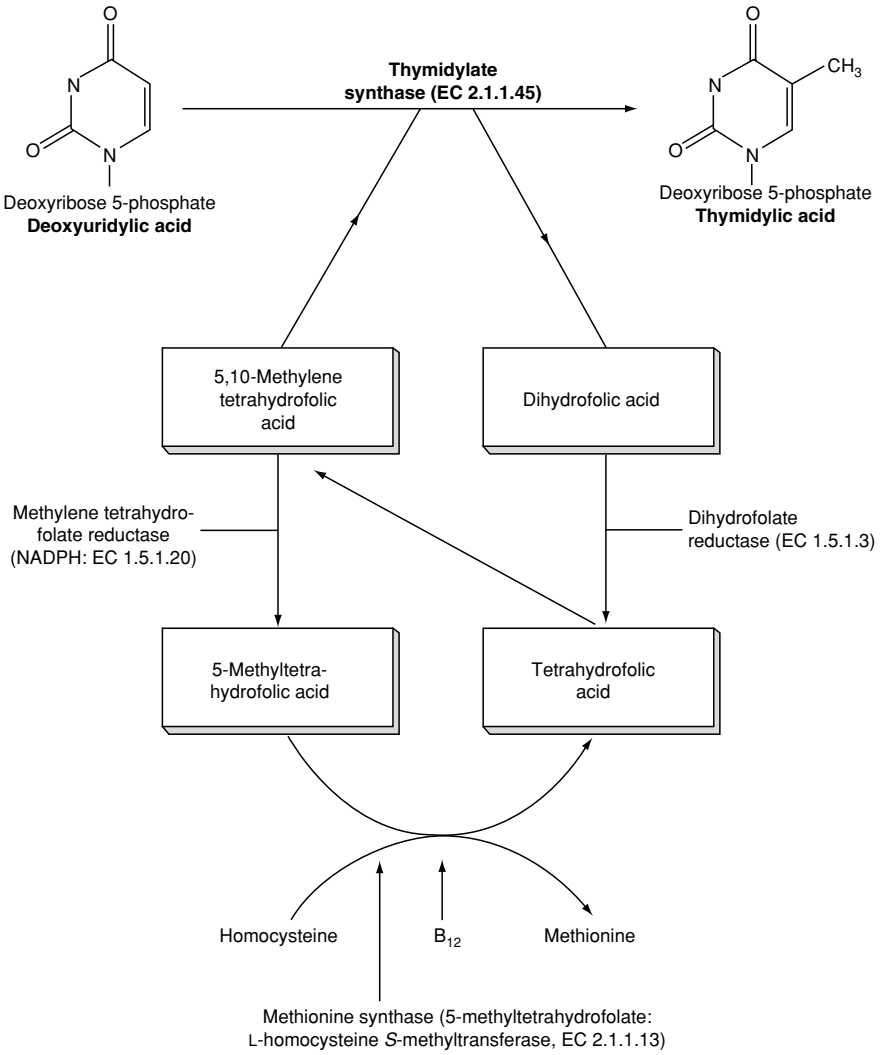

Figure 1 Biosynthesis of thymidylate, regeneration of methylene tetrahydrofolic acid, and biosynthesis of methionine.

Turnover of folate in the body results in part from its cleavage to liberate *p*-aminobenzoyl polyglutamate, which is then deconjugated and excreted as *p*-acetamidobenzoylglutamate and *p*-acetamidobenzoate. These breakdown products, plus some unchanged folate (at higher circulating levels), are excreted in the urine; however the essential body stores of folate are efficiently conserved in the kidney by reabsorption in the proximal renal tubule, and by an efficient enterohepatic circulation. Folate that is found in the feces is mainly what is formed by intestinal bacteria in the large bowel, unless folic acid intakes are very large.

Biochemical Status Measurements

Folate biochemical status is monitored most commonly by the assay of folate concentrations in plasma or in the red cells of the peripheral blood.

Plasma folate essentially reflects recent intakes and the magnitude of intertissue transfer, whereas red cell levels represent longer-term tissue stores, since intracellular (red cell) folate does not readily exchange with extracellular folate. Infants have much higher serum and red cell folate levels than those of adults, and this may be connected with the greater rate of cell division in infancy. Assays for folate which are based on competitive protein binding (radioassay or fluorescence assay), or on antibody binding, are now widely used, and several commercial kits for competitive-binding assays are now available. It is commonly accepted that serum (or plasma) levels below 3 μg l^{-1} or erythrocyte levels below 100 μg l^{-1} are indicative of biochemical deficiency, and should be further investigated or treated.

'Functional' tests, based on the efficiency of catabolism of a histidine load, or on deoxyuridine suppression of preformed thymidine utilization for DNA synthesis in tissue biopsies such as bone marrow cells,

may provide useful functional evidence of tissue folate adequacy, although they are not used for routine measurement of status. Folate deficiency, like vitamin B_{12} or B_6 deficiencies, results in raised plasma homocysteine (see below), and this functional index can provide useful information about folate status and dietary adequacy. (*See* **Immunoassays**: Radioimmunoassay and Enzyme Immunoassay.)

A useful cytological indicator of marginal folate deficiency, which is more sensitive than overt anemia or megaloblastosis, is an increase in the lobe average count of the polymorphonuclear neutrophils in the circulation. Fewer than 3.3 lobes per cell is considered normal; more than 3.65 per cell indicates a significant functional deficiency.

Human Requirements for Folic Acid and Folates

Recommended Dietary Allowances and Dietary Reference Values

Several lines of evidence have indicated that for adult men and adult nonpregnant and nonlactating women, the minimum requirement for folate (given as a supplement of pteroylglutamic acid) which is needed to prevent overt clinical deficiency is not greater than $50\,\mu g\,day^{-1}$. The problem which has faced recommended dietary allowance (RDA) committees is how much more is needed to cover the needs of nearly all individuals, when folate is obtained from food? In 1980, for instance, the US committee recommended $400\,\mu g\,day^{-1}$ and $800\,\mu g\,day^{-1}$ during pregnancy. By the end of the 1980s, the available evidence suggested that the majority of healthy adults in the USA, Canada, the UK, and elsewhere appeared to maintain acceptable folate status on intakes around 150–$200\,\mu g\,day^{-1}$. During the past decade, there has been a great deal of research activity which has once more reopened the debate and has resulted in a shift in the consensus towards a preference for higher requirement estimates once more. Metabolic ward studies of trends in status indices at different folate intakes have provided some of the evidence; studies of neural tube defect risk in very early pregnancy plus the identification of a substantial segment of the population with a genotype that implies possibly increased folate requirements is another, and the observation that plasma homocysteine concentrations are responsive to folic acid supplements even when folate intakes are as high as $300\,\mu g\,day^{-1}$ or higher, is a third.

Dietary Folate Equivalents (DFE)

The bioavailability of food folate differs from that of synthetic folic acid, mainly because the latter, being already oxidized, is not easily damaged, it is already a monoglutamate, and it is not in a tissue matrix. On average, the folic acid in supplements and fortified food is calculated to be 1.7 times as available as food folate; therefore the US National Academy of Sciences has recently introduced the concept of dietary folate equivalents (DFEs), analogous to retinol or niacin equivalents, which is equal to (μg food folate) + (1.7 μg synthetic folic acid). This has been used in calculating the new US (1998) estimated average requirements or EAR (e.g., $320\,\mu g\,day^{-1}$ for nonpregnant, nonlactating adults), and RDA (e.g., $400\,\mu g\,day^{-1}$ for nonpregnant, nonlactating adults), rising to $600\,\mu g\,day^{-1}$ during pregnancy and $500\,\mu g\,day^{-1}$ during lactation. Requirements during late pregnancy clearly must be higher than those of nonpregnant adults, because unsupplemented pregnant women, even in well-nourished societies, often develop folate-responsive bone marrow megaloblastosis during the later stages of pregnancy. Folate supplements effectively insure that this functional abnormality does not occur. (*See* **Dietary Requirements of Adults**.)

The folates that are present in breast milk ($c.50\,\mu g\,l^{-1}$) appear to be more readily available than the pteroylglutamic acid that is added to formula feeds, since breast-fed babies tend to have higher blood folate levels for a given folate intake. Folate-deficiency anemia has been encountered in premature or growth-retarded infants given inappropriate formulas, but these mistakes have now been rectified by giving folic acid-fortified feeds. Erythroblastotic infants have a particularly high folate requirement, and their growth rate can respond dramatically to folate supplements. Breast-milk folate levels are generally well protected, even when the mother's tissues and circulating pool have been partially depleted by moderate dietary folate deficiency. (*See* **Infant Foods**: Milk Formulas; **Infants**: Breast- and Bottle-feeding.)

Certain types of long-term medication, notably with anticonvulsive drugs, can interfere with folate economy, and therapeutic doses of folate may make it more difficult to control epileptic seizures in some patients. Patients with tropical sprue may, in contrast, benefit from folate supplements, at least transiently. Older people are particularly at risk, because their dietary folate intakes often fall below the safe level, and because homocysteine levels and the risk of overt vascular disease rise very steeply in old age. Chronic alcoholics, smokers, and people with chronic intestinal, renal, or hemolytic disease, or with rare inborn errors of folate economy, are at increased risk of deficiency. (*See* **Drug–Nutrient Interactions**; **Elderly**: Nutritionally Related Problems.)

Vitamin B_{12} deficiency results in impairment of folate utilization, and hence low intracellular and

tissue levels of folates. There is evidence of folate abnormalities associated with affective psychiatric disorders, and some patients may benefit markedly from folic acid supplementation. Raised homocysteine levels have recently been reported in the context of dementia, including Alzheimer's disease. A congenital disease associated with changes in the X chromosome and known as fragile X syndrome has been effectively treated with large folate supplements.

Tetrahydrobiopterin, another member of the same pteridine family to which the folates belong, is found in most mammalian tissues. It plays an important cofactor role in certain enzymes, especially those which introduce oxygen into aromatic amino acids. Unlike folic acid, tetrahydrobiopterin can be synthesized *de novo* within the body, and is therefore not classified as an essential vitamin. However, a dietary source of it may be essential in some abnormal metabolic states, particularly for some infants. A congenital lack of dihydropteridine reductase produces severe neurological defects, attributable to a tissue deficiency of tetrahydrobiopterin.

Currently Important Public Health Issues

Neural Tube Defects

During the early stages of embryonic development, failure of the normal closure of the neural tube can result in permanent abnormalities of the brain, cord, and/or spine called spina bifida, anencephaly, and encephalocele, which may be highly debilitating or fatal. This condition was relatively common in parts of the UK and Northern Ireland until the 1970s, averaging around 0.4% of human fetuses; it has now fallen to around 0.1%. Pregnancy termination has usually been advised following its detection by amniocentesis. Evidence of possible involvement of vitamins, and particularly folic acid, was suspected, and then proven by a large Medical Research Council trial, published in 1991. A 70% reduction in recurrence of neural tube defects (NTD) in a high-risk group, namely mothers with a previously affected fetus, was achieved by a 4 mg day^{-1} folic acid supplement during the critical early development period. More recently, studies in Hungary and China obtained substantial reductions in NTD incidence by smaller folate supplements, of 800 μg and 400 μg respectively. It is now recommended in the UK that women planning a pregnancy who are in this high-risk category should receive 4 or 5 mg day^{-1}, and those who are not at high risk should receive 400 μg (0.4 mg) day^{-1}, for a period which lasts from before conception until the third month of pregnancy. In the USA, there has been mandatory fortification of cereal grain products with folic acid at 1.4 μg g^{-1} from the beginning of 1998, one purpose being to reduce the incidence of NTD. In the UK, mandatory fortification has not been introduced, but a recent Commission on Medical Aspects of Food Policy (COMA) report has recommended folic acid fortification of flour at 2.4 μg g^{-1}, calculated to be the best compromise between reduction of NTD births and avoidance of intakes >1 mg day^{-1} in people >50 years.

NTD, like most pathologies, has multifactorial risks, and its etiology is not fully understood. An abnormality in vitamin B_{12} economy has been reported, and NTD occur frequently in women who are homozygous for the thermolabile form of the folate-metabolizing enzyme, methylene tetrahydrofolate reductase (MTHF). Recently, a deficiency of folate has also been linked with the occurrence of hare lip and of facial clefts.

Homocysteine

Folate, together with vitamins B_{12} and B_6, are all B vitamins whose supply and status can affect the circulating concentrations of the sulfur amino acid homocysteine. Moderately raised levels are an independent risk factor for several types of vascular disease, including cardiovascular disease, cerebrovascular disease, and deep vein thrombosis. Relatively high intakes and tissue levels of these three vitamins help to minimize plasma homocysteine levels. Homocysteine, the precursor of methionine, requires methyl tetrahydrofolate as the cosubstrate of vitamin B_{12}-dependent methionine synthase. In most normal adults, the plasma concentration of homocysteine is *c.* 5–15 μmol l^{-1}; moderate hyperhomocysteinemia is defined as 15–30 μmol l^{-1}; intermediate as 30–100 μmol l^{-1}; severe as >100 μmol l^{-1}. Folate, across its physiological range, is a particularly powerful determinant of plasma homocysteine. Although there is a widespread expectation that folate status may influence vascular disease risk, this has not yet been proven. There is the further perceived complication (see below), that high folate intakes can increase hemoglobin synthesis, without preventing neuropathy, in the early stages of vitamin B_{12} deficiency. The 'masking' of B_{12}-deficiency anemia might delay diagnosis and treatment, with irreversible consequences. Therefore, public health interventions designed to optimize the folate status of populations need to proceed with caution.

Toxicity

Folic acid is generally considered to be nontoxic, even in large amounts when taken orally, but some concern has been expressed about the danger of masking, or even possibly hastening the progress of,

the early stages of vitamin B_{12}-deficiency neuropathy, including that caused by pernicious anemia. Most workers now consider that masking is the main hazard. Very high folic acid intakes may have subtle effects on zinc economy, but this is not now considered a serious hazard. Reports of mood changes, irritability, sleeplessness, and gastrointestinal symptoms on intakes of 15 mg of pteroylglutamate per day have been reported, but other observers disagree. Occasional reports of allergic reactions to folic acid have occurred, and high doses may be epileptogenic or reduce the efficacy of anticonvulsant control of epilepsy in susceptible subjects. In general, water-soluble vitamin intakes seem to be tolerated by most people over a very wide range. However, in view of the current publicity about benefits of folic acid, it seems prudent to warn that excessive intakes of any nutrient may produce imbalances which are potentially risky.

Affective Methods

H L Meiselman and A V Cardello, US Army Soldier Centre, Natick, MA, USA

Introduction

The study of human behavior with respect to food includes food selection, food acceptance, and food consumption. Studies of food acceptability involve both sensory and affective dimensions of food. Sensory studies relate to the perception of the gustatory, olfactory, textural, visual, thermal, and other attributes of food. Affective studies concern people's evaluative reactions on a like–dislike or hedonic dimension. Over the past decade, there has been increased attention to the many variables that influence food acceptability and a growing awareness of the complexity of food acceptability. Along

with these changes have come new sensory and affective methods for assessing food acceptance, and greater appreciation for how to apply existing methods.

Sensory and Affective Judgments

While a model of food selection and consumption based solely on the sensory properties of foods is conceivable, the evaluative dimension is a primary driver of the consumer's behavioral response to food. One of the critical questions in food acceptability research is whether to ask respondents for strictly sensory judgments, or to ask for evaluative or hedonic judgments, or both. This distinction between description and evaluation is key in the selection of test subjects, methods, samples, controls, and other experimental design considerations. Both the sensory and affective aspects of food acceptability are well covered by recent volumes such as Lawless and Heymann, and Meiselman and MacFie. However, the social, cultural, physiological, and contextual aspects of the eating situation must also be considered for their influence in determining choice, acceptance, and consumption. This article will review and compare the primary methods for measuring sensory and affective responses to foods (Figure 1).

Trained, Expert, and Consumer Panels

A trained panel is a group of individuals who have been selected for training based on criteria related to their ability to perceive differences in basic sensory attributes, and then trained in specific sensory evaluation techniques and the use of a standardized lexicon. Preselection criteria commonly include sensory threshold testing. Sensory training is usually conducted in one specific technique, e.g., descriptive texture analysis, rather than in a variety of techniques. An expert panel is usually a group with extensive formal or informal experience with the product or the product category, but without formal or standardized selection and training. Expert panels are often made up of inhouse experts within an organization. Trained and expert panels members may or may not be actual users of the product or product class. Consumer panels are comprised of people without special training or experience; a consumer panel should represent the target population of the product.

Most professionals agree that affective acceptance testing should be done only with untrained, nonexpert consumers. The reason for this is that trained panelists may well have different preferences from the average consumer. A number of studies have compared trained and consumer panels for hedonic judgments. For example, Shepherd and colleagues found that ratings of eight tomato soups were different for trained and consumer panels. Only the trained panel showed significant differences in overall product ratings, and in general, the trained and consumer panels preferred different products.

On the other hand, the extent to which consumers can be used to provide sensory data is somewhat controversial. The reason for this is that the fields of psychology and psychophysics have had a long and successful history of using naive subjects (consumers) to make sensory and perceptual judgments on a wide range of both simple and complex stimuli. This paradigmatic approach has been carried over by psychologists such as Moskowitz to the study of food acceptability, and methods have been developed to apply consumer terminology to the study of the sensory dimensions of food (free-choice profiling). However, traditional food industry approaches focused on either expert or trained panels to provide such sensory data on foods. At present, it can best be said that a consumer panel should be used when affective data are being obtained or when sensory data are to be generalized to a consumer population. Trained panels should be used when there is a requirement to maximize the sensitivity to differences in the product, when detailed descriptive information is required, or when comparisons are to be made to instrumental data. Expert panels, in general, should be restricted to specific, in-plant, quality control problems or to commodity areas in which expert judgments have been shown to be a valid and reliable approach to obtaining necessary data.

Category Scales

Category scales are the most commonly used methods for assessing food likes and dislikes. They are characterized by a series of labeled points or categories, and a food item is rated by assigning it to one of several (usually 3–10) available descriptive categories. One of the earliest and still most commonly used scales of food preference and food acceptance is based on the category method. This is the nine-point hedonic scale developed by Perham and colleagues in the early 1950s at the US Army Quartermaster Food and Container Institute in Chicago which later moved to Natick, Massachusetts.

Empirical evidence indicates that the points on the nine-point hedonic scale do not represent equal subjective intervals. Jones and colleagues scaled a variety of verbal phrases for their meaning on an independent like–dislike scale. These data reveal that the intervals between phrases used as category labels for the

nine-point hedonic scale are unequal. For example, the interval between 'like extremely' and 'like very much' is larger than the interval between 'like moderately' and 'like slightly.' Earlier work on this problem has been reviewed by Schutz and Cardello, and this nonequivalence of scale intervals demonstrated using magnitude estimates of liking; this will be discussed in the next section.

Another problem with category scales is that respondents tend not to use the extreme categories, because they fear that if they use these categories to rate a food item and a more extremely liked (or disliked) item is presented subsequently, they will have no appropriate category left to assign. As such, the nine-point hedonic scale can effectively become a seven-point scale of liking/disliking. Also, many category scales (such as the nine-point hedonic scale) have a neutral point. There is some evidence that eliminating this neutral point may increase the efficiency of the scale and may discourage the complacency in judgment that is provided by this 'safe' category.

In spite of these problems, many researchers have adopted the nine-point hedonic scale for studying food acceptability because of its ease of use, its applicability to both preference and acceptance data, and its good reliability. In addition, category scales are widely used for rating other dimensions of food acceptability, such as the sensory intensity of food attributes, the situational appropriateness of foods, sensory and/or hedonic expectations toward foods, and even preference mapping.

Unstructured or Line Scales

Scales that consist of an unbroken line that is anchored on both ends are called unstructured, graphic, line, or visual analog scales. Line scales can be used to quantify both sensory dimensions and hedonic dimensions. Several different scales were tried in one study by Pangborn and colleagues: a 10-cm line marked 'dislike extremely' and 'like extremely' as the two anchors on a visual analog scale of liking, a similar line scale with the midpoint defined by 'neither like nor dislike,' and a 100-unit scale labeled at the ends and midpoint. Hedonic scores on the line scale tended to be more centrally clustered than scores of sensory intensity. Reliability of the scores from line scaling was usually good, but with some products subjects did not maintain the same order of hedonic judgment. Lawless and Malone found that line scales of sensory intensity were not as restrictive as category scales, and could be completed quickly; however, they may be somewhat more difficult to understand.

Herbert Stone and his colleagues developed the procedure known as quantitative description analysis (QDA), and recommended the use of line scales for quantifying sensory dimensions, maintaining the use of the nine-point hedonic scale for the hedonic dimension of products. In the original description of QDA, both sensory and hedonic dimensions were measured on 6-in (15-cm) line scales with anchors (0–5) located 1–3 cm from each end (labeled 'dislike moderately,' and 'like moderately') and a midpoint ('neither'). It was argued that the scales were interval scales and empirical evidence was presented to support this.

Ratio Scales

In the 1950s, SS Stevens at Harvard University developed a variety of ratio scales that permit ratio comparisons of stimuli (twice as strong, one-third as sweet, etc.). The most widely known (but not the only) ratio methods to be adopted for use in food research are magnitude estimation and its variant, magnitude matching. The latter technique has only been applied to basic sensory problems and will not be further discussed.

Magnitude estimation was originally applied to a large number of sensory modalities to establish psychophysical functions relating physical intensity to perceived (subjective) intensity. Magnitude estimation was probably first applied to foods in 1971 by Howard Moskowitz and Joel Sidel. The practical importance of magnitude estimation was argued as a 'supplement' to category scaling, and it was suggested that the category scale could be used to label the perceptual categories of acceptance, while magnitude estimation could be used to refine the degree of acceptability.

In magnitude estimation the task for the respondent is to rate the sensory intensity or liking of one product in relation to another. If one product is liked twice as much as another product, it is assigned a number twice as large. Many studies have used magnitude estimation to judge the perceived sensory intensity of laboratory food models and of real foods. Far fewer studies have used magnitude estimation to assess the hedonic dimensions of foods, primarily because affective judgments must be made by untrained consumers, and magnitude estimation is a more complex method to understanding and to use than are other methods of scaling, e.g., the nine-point hedonic scale.

Several studies comparing magnitude estimation to category and line scales for rating sensory intensity have shown equal sensitivity, reliability and precision among the scales. When used to scale affect, magnitude estimation was found by some authors to be more sensitive than the nine-point hedonic scale,

1. Category scales

(a) Peryam and Girardot (1952), Jones *et al.* (1955) – the nine-point hedonic scale

1	2	3	4	5	6	7	8	9
Dislike extremely	Dislike very much	Dislike moderately	Dislike slightly	Neither like nor dislike	Like slightly	Like moderately	Like very much	Like extremely

(b) Lawless and Malone (1986) – nine categories

1	2	3	4	5	6	7	8	9
Little								Much

2. Line scales

(a) Pangborn *et al.* (1989) – labeled 0–100

0 Dislike extremely	50 Neither like nor dislike	Like extremely 100

(b) Shepherd *et al.* (1988), Pangborn *et al.* (1989) – 100 mm

Dislike extremely	Neither like nor dislike	Like extremely

(c) Giovanni and Pangborn (1983) – 100 mm

Dislike extremely		Like extremely

(d) Stone *et al.* (1974)

Dislike moderately	Neither	Like moderately

3. Relative-to-ideal scales

(a) Shepherd *et al.* (1988) – 100 mm

Not nearly strong enough	Just right	Much too strong

4. Ratio scales

Magnitude estimation:

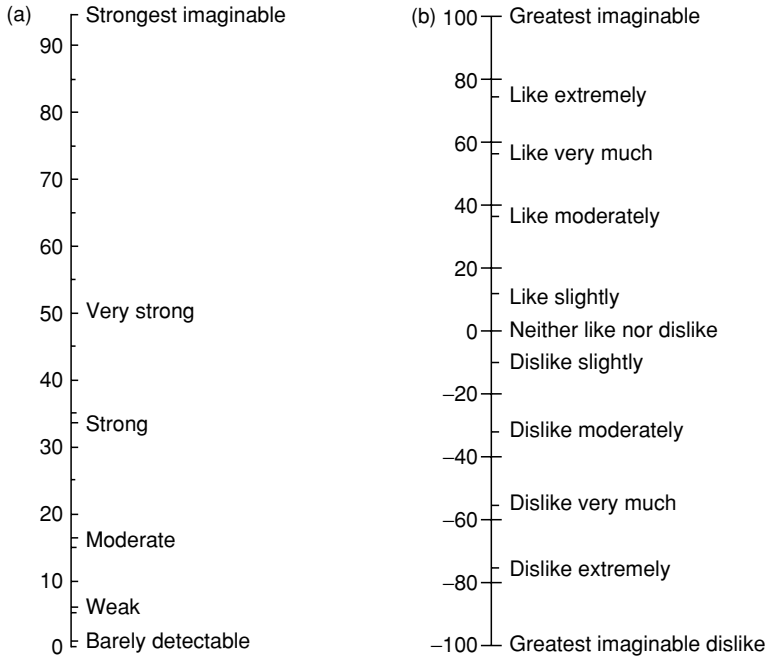
(a) Moskowitz and Sidel (1971) – first sample served as standard; no zeros or negative numbers permitted.

(b) Pearce *et al.* (1986) – unipolar scale from zero to infinity (liking).

(c) Pearce *et al.* (1986) – bipolar scale from minus infinity (disliking) through zero (neutral) to plus infinity (liking).

(d) Giovanni and Pangborn (1983) – unipolar scale; no zeros or negative numbers permitted; fixed modulus of 10.

Labeled magnitude scales



(a) Green *et al.* (1993) – equally spaced numerical labels with ratio-determined verbal labels.

(b) Schutz and Cardello (2000) – equally spaced numerical labels with ratio-determined verbal labels.

5. Frequency scales

(a) Schutz (1965)

I would eat this every opportunity I had.
I would eat this very often.
I would frequently eat this.
I like this and would eat it now and then.
I would eat this if available but would not go out of my way.
I don't like it but would eat it on occasion.
I would hardly ever eat this.
I would eat this only if there were no other food choices.
I would eat this if I were forced to.
Never tried.

(b) Meiselman (1988) – each food can be rated for preferred frequency in terms of days per week (1–7) and weeks per month (7–28 times) or rated 'never.' There are separate ratings for each meal.

	Breakfast		Mid day		Evening meal		
	days per week	weeks/ month	days per week	weeks/ month	days per week	weeks/ month	Never
Food name	1 2 3 4 5 6 7	1 2 3 4	1 2 3 4 5 6 7	1 2 3 4	1 2 3 4 5 6 7	1 2 3 4	0

Figure 1 Examples of sensory, hedonic, and frequency scales. Most of the scales can function as either sensory or hedonic scales by changing from sensory attributes (e.g., salty) to hedonic attributes (e.g., like) or vice versa.

while others found the hedonic scale to be more reliable, although both scales were linearly related. A collaborative study by Pearce was sponsored by the American Society for Testing Materials (ASTM) and compared the nine-point hedonic scale with both unipolar and bipolar (like–dislike) magnitude estimation. Eight fabric samples were rated by 20–30 panelists at 23 different sites. All three scales ranked the eight fabrics in the same order with very similar spread of ratings; they achieved very similar degrees of precision in differentiating samples, and similar discrimination. Reliability of the category scale was higher than for either form of magnitude estimation, although higher reliability would likely be obtained with larger sample sizes.

Thus, it appears that, while magnitude estimation provides valid and reliable data on the sensory and hedonic attributes of food, its practical difficulty in use has limited its broad-based application, in favor of the simplicity of category scales. However, in a recent effort to combine the practical simplicity of category scales with the quantitative sophistication of ratio scaling for rating the intensity of oral sensations, a hybrid, category-ratio scale was developed by Barry Green. This scale places verbal labels of expressed intensity along a linear numerical scale at specific locations that reflect the numerical ratios among their perceived intensities, as obtained by a magnitude estimation procedure. A critical characteristic of this scale is the presence of a phase involving the 'maximal,' 'strongest imaginable' or 'strongest possible' sensation. The use of this phase is assumed to serve as a fixed endpoint of sensation that places judgments of different subjects on a common sensory 'ruler.' Subjects can quickly look at the verbal labels and corresponding numbers and then place a slash mark (/) through the line scale to indicate the perceived strength of their sensation. The resulting data have been shown to have ratio properties. More recent studies of this scale have shown that the scale is most effective for application to chemosensory stimuli that include extremely intense (painful) sensations.

Recently, the use of such labeled magnitude scales has been extended to affective ratings by Howard Schutz and Armand Cardello. Using Barry Green's approach, the semantic meaning of various verbal phrases used to describe the liking/disliking of foods was scaled. By locating these phrases along a visual analog scale in accordance with their determined semantic meaning, it was shown that consumers could use these scales to rate the affective aspects of stimuli with equal or better sensitivity, greater reliability, and equivalent ease of use as with the nine-point hedonic scale.

Alternative Scales: Relative-to-Ideal, Food Frequency

While category, line, and ratio scales are the most commonly used instruments for assessing food acceptability, they are not the only ones. Another approach to scaling affective reactions to foods is the relative-to-ideal scale, which combines the affective or hedonic component with the sensory component. For example, rather than separately scaling sweetness and liking, the relative-to-ideal scale combines the two dimensions to yield a scale from 'much too sweet' to 'not nearly sweet enough.' The midpoint of such scales is usually defined as 'just right.' Such a scale implies that the respondent has an internal ideal of a product against which to compare a stimulus.

Hence it is appropriate for established products, but less appropriate or inappropriate for novel products or for laboratory food models (e.g., sugar water).

A number of studies have shown good agreement between relative-to-ideal scales and hedonic scales. The breakpoint in the hedonic function, at which responses shift from increasing liking to decreasing disliking, is highly correlated with the just-right point, although the latter tends to be slightly higher. Shepherd has argued that relative-to-ideal scales are 'unfolded hedonic scales,' i.e., scales which measure the amount of like or dislike from the just-right point of the scale. One advantage of the relative-to-ideal scale is that it produces a sharp fulcrum, below which are less-liked, weaker points, and above which are more-liked, stronger points. Hedonic judgments across the same range will yield a rounded breakpoint, because different respondents have different maximally preferred points.

The relative-to-ideal scale appears useful for quantifying the hedonic aspect of a product along a clear, definable intensity dimension. The scale has been used widely in the food industry because it tells product developers in which direction to make product changes along a sensory dimension (e.g., make it more sweet). It is unclear how this would be applied to complex food products with multiple physical dimensions (many tastes, smells, textures) and to combinations of food products. It is also unclear what level of training or expertise is needed for optimal use of this scale.

Another approach for quantifying food acceptability is through the use of food frequency scales. The basic concept here is that the frequency with which an individual consumes a food or expects to consume it is a valid index of the acceptability of the food to that person. Similarly, since the practical purpose of any measure of food acceptability is to predict subsequent consumer behavior toward the food, simple measures of affect may not suffice. For example, although cheesecake may receive a rating of eight on a nine-point hedonic scale, while milk may receive a rating of six, this does not mean that the individual wants to eat cheesecake more often than he/she wants to drink milk. Thus, hedonic judgments of the acceptability of foods are not as useful for menu planning or for predicting food choice as are judgments of the desired frequency of serving.

Howard Schutz developed the first form of food frequency scale was developed as a supplement to the nine-point hedonic scale. Known as the food action (FACT) scale, it consists of a series of statements concerning the frequency with which a food item is desired to be eaten, ranging from 'eat every opportunity I get' to 'eat if forced.' By combining hedonic scale data with FACT scale data, information can be obtained about both the affective aspects of a food item and the relative frequency that it is desired. The FACT scale was shown to have high group reliability coefficients of 0.97.

While the FACT scale provides only relative frequency estimates, other frequency techniques can be used to provide absolute frequency measures. A frequency scale was designed to assess food preferences of military men. Respondents indicate the number of times during a 30-day period that they would like to have an item served. Other research from Natick indicated high group reliability for such frequency scales ($r = 0.98$), moderate individual reliability coefficients ($r = 0.58$–0.60), and moderate correlation with consumption ($r = 0.59$–0.66).

Affective Judgments: The Role of Context and Expectations

The study of food acceptability and the measurement of its sensory and affective dimensions are complicated by the fact that foods are typically eaten within a context, i.e., the meal, and that the consumer typically brings to the dining situation a host of expectations that are based on previous experience, product and nutrition information, and packaging, all of which can affect liking for the food. Such influences can limit the predictive validity of laboratory-based measures of food acceptance unless adequate research methods are developed to understand and control these effects. In terms of situational context, few studies have adequately assessed the contribution of the meal context/situation to liking. Herbert Meiselman and his colleagues have studied the influence of a number of contextual variables was studied. All studies showed changes in the probability of food selection, while some studies showed changes in acceptance and some did not. For example, the effort required to obtain food showed large selection rate changes but no reliable changes in acceptance, whereas changes in food cost changed both selection rates and acceptance. Further studies identified a major difference in acceptance ratings of foods in institutional vs noninstitutional food service settings, in agreement with previous observations concerning expectations in these two different classes of environments.

In an attempt to develop a measure of food acceptability that takes into account the situational influences of the dining situation, Howard Schutz developed the concept of 'situational appropriateness' as well as a method to index the degree of appropriateness of any food in a wide range of situations. This scale has been used effectively in a variety of survey formats, and more recently has been shown

to be a valuable adjunct to laboratory affective testing of foods.

Concerning the expectations that consumers bring to the dining situation, Armand Cardello and other researchers have shown that a wide variety of extrinsic variables, such as product information, packaging, brand names, and nutrition statements, can influence the consumer's expected liking for a product. In numerous studies designed to look at the role of these expectations on actual liking and behavior toward the food, expectations were manipulated so as to lead consumers to expect a better-liked or a worse-liked product. By measuring expected liking using a simple category scale and comparing changes in actual liking relative to a baseline rating of the acceptance of the food in a blind (no information) condition, it has been shown that product acceptance assimilates the level of expectation. That is, if expectations are higher than the baseline acceptance of the product, rated acceptability increases. If expectations are lower, rated acceptability decreases. These important influences of consumer beliefs and expectations on product perception have been demonstrated for purely sensory dimensions of food and have been shown to have a direct influence on behavior, e.g., consumption.

Which Method to Use

When conducting basic research or practical product evaluations, the question arises as to which is the best scale method for measuring food acceptability. There are two parts to the answer. First, it is usually far better to select a scale that has been carefully developed and tested in a wide variety of situations, including conditions similar to those planned. Second, if any of the commonly used scales (**Figure 1**) are employed, there is probably not a great deal of difference among them. Category scaling and line scaling appear to be easier for people to use than magnitude estimation, although the use of a semantic ratio scale will provide ratio level data with equal ease of use to that of category and line scales. Relative-to-ideal scales combine a sensory and a hedonic dimension, if it is thought that people have a knowledge of what is 'just right' for the product, while frequency scales provide more meaningful data for menu planning and predicting repeat consumption of foods. Lastly, caution must always be used in generalizing the results of laboratory-based affective studies to real-life eating situations, in order to avoid the influences of both situational context and consumer expectations. In view of the increase in published methodological research on sensory and affective scaling in the past decade, the strengths and weaknesses of different scaling methods under a variety of conditions of use will be better clarified in the future.

Market Research Methods

H R Moskowitz, Moskowitz Jacobs Inc., White Plains, NY, USA

The Market Research Role in the Corporation

Market research as a profession has the job of supporting the marketing function. For the past 40 years corporations worldwide have used market research to identify consumer trends, measure the acceptance of concepts, and measure the acceptance of products.

Acceptance measurement takes on a variety of different aspects. At the one end lies small-scale taste-tests in the corporate facility. These tests are usually executed by the in-house sensory evaluation group. There are slightly larger-scale research studies run with local consumers. These are the so-called church panels. Church panels may be executed either by a market researcher or by the in-house sensory analyst. The researcher contracts with local volunteer organizations to provide a source of panelists. For the larger-scale studies, involving hundreds of consumers, marketing researchers usually play the key role, rather than sensory analysts. Marketing researchers run these types of studies, often across a country to obtain geographic dispersion, and often with a relatively limited number of products. The role of the marketing researcher in these larger-scale studies is to present a report card of the product, in terms of performance, either in an absolute sense or relative to competition.

The Market Research Role versus the Sensory Research Role in Acceptance Testing

In today's corporations market researchers and sensory analysts each have responsibility for primary research on product acceptance. Sensory analysts often run small-scale studies to identify which particular formulation among a set of formulations looks promising for further development. Sensory analysts are therefore called in to execute acceptance tests very early in the project. Sensory analysts also measure acceptance as part of a general profiling exercise wherein panelists rate the different characteristics of products. The role of the sensory analyst in acceptance testing is to support product development, and not to support marketing. Therefore, the acceptance evaluations run by sensory analysts are usually considered directional in terms of ongoing development, rather than constituting a definitive 'go/no' decision for marketing. These guidance tests, none the less, often involve consumers.

Marketing researchers interact most usually with marketers and general management rather than with research and development (R&D). By the time a product has reached the marketing researcher, the product is presumed to be optimally acceptable. The marketing researcher tests the product among many individuals, in multiple locations, and often against a market leader, or against the current in-market product. The goal is not so much to provide guidance for development (such guidance having been assumed to be already in place and implemented), but rather to measure the potential of the product in terms of market share. From time to time the acceptance testing run by market researchers may be used to identify potentially fatal flaws in the product. For the most part if the sensory analysts have done their job properly such fatal product flaws should already have been eliminated.

The Multiple Aspects of Acceptance Measurement

Market research techniques involve a number of different aspects of acceptance measurement. Each of these aspects is investigated regularly by the researcher in an attempt to help the corporation develop the best product possible. These aspects include the following:

1. basic product acceptance without the presence of a concept
2. product–concept fit (does the concept fit the product, and vice versa?)
3. frequency of use
4. purchase intent coupled with price information
5. replacement of different foods by the product
6. appropriateness measurement – when would the product be eaten (e.g., day-part)?

7. relevance of the product as part of a line of products
8. loss of acceptance due to sensory-specific satiety and/or boredom/habituation
9. branded versus blind acceptance

Basic Product Acceptance

One key corporate goal is to offer a product with a high level of liking, packaged attractively, at an affordable (and competitive) price. In order to insure final product acceptance the market researcher uses a variety of procedures. Two of the most common procedures are monadic tests and paired comparison tests.

Monadic tests These tests require the consumer to rate the product on a scale of acceptability. There are many such scales (Table 1). These tests simply ask the consumer to act as a measuring instrument, assigning a number or a verbal label to represent product acceptance. On the analytic side the researcher averages the ratings to obtain a measure of acceptance. The results are reported as a score card of the products. Statistical tests are used in order to determine whether or not the product being tested differs significantly from the competition. Whatever scale is used must be amenable to statistical analysis, such as tests of differences (viz., *t*-tests).

Table 1 Types of hedonics scales

Two-point	*Five-point*	*Nine-point hedonic scale*
Like	Very good	Like extremely
Dislike	Good	Like very much
	Moderate	Like moderately
	Tolerate	Like slightly
Three-point	Never tried	Neither like nor dislike
		Dislike slightly
Acceptable	Very good	Dislike moderately
Dislike	Good	Dislike very much
Never tried	Moderate	Dislike extremely
	Dislike	
Like a lot	Tolerate	
Dislike		*Purchase intent scale*
Do not know		
	FACT scale	Definitely would buy
Well liked	Eat every opportunity	Probably would buy
Indifferent	Eat very often	Might/might not buy
Disliked	Frequently eat	Probably not buy
	Eat now and then	Definitely not buy
	Eat if available	
	Don't like–eat on occasion	
	Hardly every eat	
	Eat if no other choice	
	Eat if forced	

Reproduced from Meiselman HL (1978) Scales for measuring food preference. In: Petersen MS and Johnson AH (eds) *Encyclopedia of Food Science*, pp. 675–678. Westport: AVI, with permission.

Paired comparison tests These tests pit one product against another. One of the products may be the current product, another may be a revised formulation or a competitor, depending upon the business objectives. The consumer selects which of the two products is preferred, either overall or on specific characteristics. Quite often commercial tests require the consumer to indicate preference on many different attributes (up to 20 or more). The researcher computes the proportion of panelists who choose one product over another, for each particular attribute being investigated. The results are reported in the form of percentages. The paired comparison tests are used for several purposes, included measurement of performance against the competition, as well as claims substantiation (viz., product X is preferred to product Y).

Results reported for many subgroups For both monadic and paired comparison tests the market researcher looks for the data analyzed by total panel, and by the different key subgroups in the population. It is not unusual for a market researcher to work with upwards of 10 or 20 different subgroups in the population. Since the researcher deals with 300+ panelists in many of these studies, and since there is a classification questionnaire accompanying the actual evaluations, the researcher can cut the data many different ways.

Product–Concept Fit

Market researchers often test products in the presence of a concept. The concept tells the consumer what to expect. The concept may stress the benefits of the product (positioning), or the features of the product (product concept), or some combination of both. The results of the product concept fit show either the degree to which the product is acceptable based upon expectations set up by the concept, or the degree to which the product delivers what the concept promises. When products are tested in the presence of a concept the researcher gets a much better idea of the actual performance of the product after the consumer better understands the reason for the product and its end uses (e.g., appropriate time of day for consumption; pricing, etc., specific health benefits). Occasionally the product may score poorly without the presence of a concept, especially when the product is a health-oriented product that by itself is not particularly acceptable, but provides other benefits, such as nutrition and energy. The basic

liking rating may remain poor in the presence of the concept, but given the information about the product benefits, the purchase intent may increase dramatically.

Frequency of Use

Another type of acceptance measurement is the estimated frequency of use. Market researchers usually do studies to estimate volume, or amount to be consumed, not just overall liking. Thus, a measure of frequency reveals whether the product is highly liked but might be consumed infrequently, highly liked and consumed frequently, etc. Frequency is measured in at least two ways. One instructs the consumer to assign a number (e.g., times per month or times per year) to show the estimated number of times that the person would eat the product. Another gives the consumer a number of eating occasions (e.g., 10), and instructs the consumer to assign the number of times out of the next set of consumption occasions when the individual would eat the product. This approach is often used with the consumer given an array of products, and instructed to assign to each product the number of eating occasions out of the next 10 (or whatever number). This is called the constant sum method, and is used to determine the impact of introducing a product on the frequency of consumption of other products with which it competes for consumption.

Of all the acceptance measures, purchase intent is probably the most popular, and the one on which many marketing decisions are based. The typical purchase intent scale comprises a limited number of points (the most common being the five-point scale; Table 1). Rather than computing an average purchase score, the market researcher most typically computes the distribution of purchase intent ratings across the population of consumers who rated the product. This generates a set of incidence statistics, treated as percentages. The term 'top-two box' refers to the proportion of consumers who, having evaluated a specific product, rate it as definitely or probably would purchase.

Purchase intent is important for a number of reasons. First, it asks the consumer to describe what action he or she would take – purchase or not purchase. Second, many researchers create a normative database from many such studies, so that when they determine the purchase intent rating for a new product they can also estimate the likelihood of success. Third, a number of proprietary research procedures, aimed at estimating volume sales, use purchase intent as part of the input information to the model.

Purchase Ratings Coupled with Price Information

Purchase intent scales are often used along with pricing information. Although in theory price information should not affect product liking, it should affect purchase intent. Thus, a product may be very well liked, but the purchase intent may increase if the product is offered at a low price, and decrease if the same product is offered at a high price. This implicit demand curve can be captured by a simple equation: Purchase intent $= k_0(\text{liking}^m) \times (\text{price}^n)$. Typically the exponent for price, n, is much higher in absolute value (and negative) than the exponent for liking, (m, which is positive). This means that small changes in price have more effect in lowering purchase intent than the same small proportional change in liking has in raising purchase intent.

Acceptance as Replacement of a Current Product

Another aspect of acceptance deals with the issue of whether the product would replace or simply be added to the consumer's choices of foods to be purchased. Although not strictly a question of degree of liking, replacement questions deal with the issue of how the food will be used. Marketers always search for products that will be added to a person's set of foods, rather than one that has to fight to oust another food. It is much easier to add to a person's list than to replace a food that already has a history of being purchased.

Appropriateness – Day-Part and Situation

Food acceptance possesses a significant cognitive component, viz., that foods have defined parts of the day when they will be eaten, and other day-parts when they are not customarily eaten. Much of this is cultural, and labile, explaining why now cola drinks are being consumed for breakfast. Consumers have no trouble identifying the appropriate day-parts for specific products, and often use implicit rules to assign a product to breakfast, lunch, dinner, and snack. Appropriateness and eating context is emerging as an important aspect of food acceptance. The same food can be highly acceptable for dinner, but not particularly acceptable for breakfast (e.g., soup for North American consumers).

Relevance of the Product as Part of a Line of Related Products

From the manufacturer's point of view a single product (e.g., a single flavor) has several aspects of acceptance. One is the acceptance of the single product by itself. Another is the degree to which the product augments a line of already existing or

planned products. For instance, a fruit-flavored cereal may be highly acceptable itself without reference to other products, but may be redundant. That is, consumers satisfied with one fruit-flavored cereal may not really be interested in purchasing another, equally liked fruit-flavored cereal featured in the same line. To the marketer this means that the product is liked but redundant. A practical outcome would be that the item is rejected as part of the line. A substantial amount of consumer research funds is devoted to line optimization, or creating the proper combination of items in such a way that the line maximizes the number of consumers who would be satisfied by at least one of the products offered in the line. Market researchers call the solution of this problem the TURF issue, or 'total unduplicated reach and frequency.' Product acceptance here is viewed as an issue that transcends the more conventional rating of liking, because it calls into account the presence of, and reaction to, other potential entries in the same product line.

Acceptance in Light of Sensory Satiety and Boredom/Habituation

Very few products enjoy continued consumer acceptance at constant level (given a constant amount of advertising and promotion support). Sooner or later consumers tire of most products, and consume the product less frequently. This reduction in consumption comes about two ways – through sensory-specific satiety, and through boredom and habituation. A food loses its acceptance very quickly after eating, so that during a meal we tire of a food and stop eating it. This is sensory-specific satiety – we may have room for dessert even though we don't want to continue eating the main course. Habituation and boredom occur when the consumer simply tires of a product, and stops selecting it and/or eating it, even if the food has not been consumed recently. To some degree the more salient the sensory characteristics of the products, the more rapidly the product becomes boring. A good example of this is the difference between steak and hamburger. Steak wins against hamburger time after time in preference tests. Yet people tire more rapidly of steak after multiple consumptions, perhaps because of the salient sensory factors. An even more dramatic example of this occurs in the case of bread versus steak. Bread almost never wins in acceptance tests against steak, but we can eat bread day after day, meal after meal. We cannot consume steak to the same degree.

Branded versus Blind Product Acceptance

Most, but not all product testing is done in a blinded environment, wherein the researcher does not identify the particular brand. Branding (the identification of the brand), however, may make a great deal of difference in the acceptance rating when the product is already on the market. For many common products the brand may add substantially to the acceptance rating. The difference between the blind and the branded product shows the impact of the brand itself. In developmental research it is easy to test products branded because the researcher has control over the product, and can instruct R&D to create products in a form that cannot be identified. It is not so easy with in-market products. When the researcher wants to test competitor products that exist in the market, attempts to 'blind' or disguise the product may require unusual precautions. These have included shaving off an imprint on the product, testing the product in a red glass in red light (to prevent visual identification), or somehow cutting the product in order to eliminate a tell-tale shape that would immediately signal the brand.

Implementing a Study of Food Acceptance – Design and Field Considerations

The importance of acceptance as a precursor for product success has led to a large number of procedural recommendations and rules of thumb. Some of these are based in science, others are simply dictated by fiat through company policy.

Choice of Panelists who Participate

The composition of the sample generally is critical for a valid acceptance study. At the early stage of evaluation the particular choice of panelists is not too critical, other than the panelists accept the product. At the later stages, usually conducted by the market researcher, sampling the proper individuals becomes more important. The financial implications of a wrong decision (so-called downside risk) grow rapidly as the product comes closer to being launched in the marketplace. That is, if the study uses the wrong consumers, then the results are immediately suspect and the business decision may be faulty, even if the study is executed perfectly. The consumers may be chosen to be current users of the product, users of the competitor products, and lapsed users (individuals who used to use the product but no longer do so). In the case of children who consume the product but do not buy it, the panelists may comprise a group of parents and children (not necessarily related), in order to determine how the 'gatekeeper' (parent) responds, and how the ultimate consumer (child) responds. The conventional market research sample comprises some or all of these individuals, in sufficiently large base sizes of individuals so that the ratings from each subgroup can be analyzed.

What Type of Questionnaire is Most Appropriate for the Acceptance Test?

Most market researchers embed the acceptance scale (whether liking or purchase) in a larger set of questions dealing with other aspects of the food, such as the sensory and image aspects. For market researchers product acceptance is only one part of the picture (albeit an important part). Other important aspects include image of the product, when the product will be used, etc. The key exception here is a claims test, whose goal is to demonstrate that one product is preferred to another. The rule of thumb for a claims test is that the researcher should *limit* the question to liking or purchase intent alone, and not deal with any other attributes that could cloud the findings, and therefore the resulting claim.

Where Should the Acceptance Test be Conducted?

There are two test venues – central location and home use. A central location venue requires that the consumer come to a central site in order to evaluate the product. The site may be a shopping mall or a specialized test facility. A central location site affords the greatest control over the evaluation, because a trained food professional and/or interviewer can ensure that the product is properly prepared and served. The other test venue is one's home, wherein the product is sent home (e.g., by mail) or given to the panelists at a shopping mall to take home. The product is prepared, eaten, and often rated at home. The panelist may then be telephoned to get the ratings, or may mail back (or e-mail back) the completed questionnaire.

Some Typical Best Practices for Choosing Consumers who Participate

Conventionally, market researchers try to use large representative consumer panels. Often (but not always) this consists of testing panelists in different markets, and of different ages. Historically, most food products have been evaluated by females, except for products specifically designed for males (which are relatively few). In more recent years it has come to be realized that geographical dispersion does not guarantee representativeness in the population, because there are more fundamental ways in which people differ that transcend geography. One newly emerging concept is the existence of sensory preference segments, where individuals in a segment show rather similar sensory preferences to product features. These members of the same segment may live in different locations, have different incomes, education, and purchase history. The jury is still out on how to improve the consumer panelist selection process in light of these overwhelming differences among sensory preference segments.

Anchoring the Scale

Some practitioners feel that every point on the acceptance rating scale should be anchored with a verbal descriptor, because they feel that it is the descriptive term, not the numerical scale, that is important. Other practitioners feel that the scale itself is relevant, and that the only anchors need be at the top and the bottom of the scale.

The Position of the Acceptance Rating in the Order of Attribute Questions

Market researchers have not adopted any hard and fast rules about the nature of the questionnaire, and the location of the acceptance measure within the questionnaire. Some researchers feel strongly that the acceptance rating should come first in order for that rating not to be influenced by other attribute ratings. Other researchers feel just as strongly that the acceptance rating should come last, because otherwise the consumers will attempt to justify their acceptance rating by having all other attribute ratings fall into line. The majority of researchers pay little attention to this issue, but the issue arises from time to time.

Appropriate Statistics for Ratings

Most market researchers come from and/or operate within a sociology-oriented system, where the emphasis is on percentage of people who exhibit certain behaviors (such as accepting a food). Thus the majority of market researchers working with purchase intent scales use percent measures (percent rating the product as probably or definitely buy), with the appropriate statistical analysis being that used for percentages. In some cases (especially with liking ratings), the researchers will use means and standard deviations, so the appropriate statistics there are the ones used in parametric analyses (e.g., analysis of variance, regression).

FOOD ADDITIVES

Safety

S A Jordan, Food Directorate, Ottawa, Ontario, Canada

Background

The relationship between humans and food additives spans thousands of years. The initial use of materials added to foods was likely for the practice of food preservation. Food preservation in ancient times took a variety of forms, from purely physical processes such as drying to the addition of substances such as smoke, salt, vinegar, or alcohol. Archeological and written evidence of food preservation reveals the use of these substances as far back as 5000 years. While the preservation of food was a critical activity for ancient populations, it was not the only reason for adding substances to food. The ancient origins of spices as flavoring agents is well known; however, it is known that naturally derived materials such as saffron and certain berry juices were used by the Egyptians and Romans to color foods. Today, however, synthetic additives have largely supplanted their natural counterparts in producing desirable technical effects.

Generally, food additives are defined as substances added to food to produce a specified and desired technical effect. In some jurisdictions, the definition is somewhat broader and may include 'indirect food additives' such as packaging materials, which may be incorporated into food unintentionally. Taking the USA as an example, at the present time, there are about 3000 food additives approved for use, while Canada, for example, regulates only about 400. While there are obviously international differences as to what is considered a food additive, this summary deals with premarket safety evaluation procedures that may apply to chemicals that can be incorporated into food either by direct or indirect addition. Examples of direct food additives are provided in **Table 1**.

Benefits of Direct Food Additives

The benefits of food additives are many. An obvious benefit of using food additives is increased safety of products. The use of antimicrobial agents to prevent proliferation of bacteria or molds that may result in food poisoning contributes significantly to providing

Table 1 Examples of food additive categories

Anticaking agents	Emulsifiers	Preservatives
Antioxidants	Enzymes	Processing aids
Antimicrobial agents	Firming agents	Propellants
Colors	Formulation aids	Stabilizers
Curing agents	Fumigants	Surface finishing agents
Drying agents	pH control agents	Nonnutritive sweeteners

a safe food supply. Other ultimate benefits of food additives include a greater choice of foods in the marketplace, the availability of lower-priced foods and enhanced organoleptic properties of food products.

The Acceptable Daily Intake

While food additives provide numerous benefits for consumers and manufacturers, there are potential risks associated with the addition of chemicals which may have widespread use. Foods generally are considered to be safe when consumed in an *ad libitum* fashion for long periods of time, and the addition of substances to food must not cause undue risk when consumed in this fashion. In order to minimize any potential adverse effects of a new food additive, a thorough safety assessment is required. This type of assessment is aimed at determining a safe level of intake of material. This level is termed an acceptable daily intake (ADI), a concept first proposed by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 1961. The ADI is the level of intake by a human of a food additive, per day, for which no adverse effects are expected when consumed over an entire lifetime. The acceptable daily intake for food additives usually is expressed as milligrams of the substance ingested per kilogram of body weight.

The concept of the ADI is based on the premise that, for most compounds, there exists a discrete threshold of exposure above which adverse effects may be produced; however, the concept of thresholds may not hold for substances that are able to produce cancer. Substances that are known or suspected of being carcinogenic to humans (especially genotoxic carcinogens) are not allowed as food additives.

Toxicity studies on specific substances, conducted as part of an industry submission of data to government agencies, or literature searches of earlier information, are geared to identify levels of these substances that produce no adverse effects (or, indeed, no effects at all). Acronyms used to identify such levels are NOEL (no observed effect level), NOAEL (no observed adverse effect level), LOEL (lowest observed effect level), and LOAEL (lowest observed adverse effect level). Any measured level of effect from experimental studies is associated with uncertainty in terms of how it can be applied to possible responses in 'real-life' situations. An ADI, applicable to humans, is calculated by dividing the NO(A)EL or LO(A)EL, usually derived from animal studies, by numerical factors in order to reduce the uncertainties associated with the available scientific data.

Types of uncertainties that typically result from the evaluation of experimental data are the extrapolation of data derived from animals studies to humans, the susceptibility of human subpopulations that may be overly sensitive to the compound under study, the use of data from which only a LOEL is available, the extrapolation of less than chronic data to chronic exposure, and any other inadequacies or deficiencies of the data. The uncertainty factor for a lack of chronic data would not normally apply to current data requirements for assessing new food additives, since chronic studies in animals would need to be submitted to the regulatory authority. The number of these 'uncertainty factors' (also sometimes termed 'safety factors') that are applied, and their numerical values, depend on the situation and the available data, and are assessed on a case-by-case basis. Table 2 outlines various uncertainty factors currently in use and their usual numerical value.

The application of uncertainty factors is somewhat subjective; however, validation exercises have provided evidence that the value of 10 is adequate for less than chronic to chronic extrapolation and LOEL to NOEL extrapolation, in most cases. Still, the use of uncertainty factors is usually tailored to suit the particular strengths and weaknesses of the database being assessed. Once an ADI has been established, it should not be considered an absolute threshold. Periodic consumption of an additive at levels above the ADI may be without appreciable risk, depending on the circumstances. As the level of exposure increases above the ADI, however, the risk of adverse effects increases as well. Owing to the subjective nature of the uncertainty factor approach in the derivation of ADIs, other mathematical approaches have been proposed.

The criticisms levelled at the uncertainty factor approach include the fact that the NOEL in scientific studies is simply one of the dose levels and may not reflect the true NOEL for the species in question. Also, the size of the study affects the size of the

Table 2 Typical uncertainty factors and their values

Uncertainty	*Uncertainty factor value*
Extrapolation from the average animal to the average human	10
Protection of sensitive populations of humans (intraspecies variation in susceptibility)	10
No NOEL, only a LO(A)EL identified from scientific studies	10
Extrapolation of data from less than chronic exposure to chronic or lifetime intakes (however, data on chronic exposure would be required for current food additive submissions)	10
Inadequacies of the data (e.g., certain types of studies missing, severity of effects associated with a LOAEL)	2–10

NOEL. Studies with large numbers of animals tend to provide a lower NOEL, and vice versa. This, in fact, penalizes the company for conducting a larger study, since a lower NOEL will be associated with a lower ADI. Another criticism is that the NOEL-uncertainty factor approach ignores any dose–response curve generated by multiple-dose studies. Included in the alternative approaches to the NOEL-uncertainty factor approach is the concept of benchmark dose, defined as the lower confidence limit on a dose producing some predetermined small increase (e.g., 1% or 10%) in response rate over the background level for a specific effect. Other variations on this method have been proposed; however, all rely to some degree on the use of uncertainty factors (e.g., for interspecies extrapolation). Advantages of alternative methods are that they take into consideration the dose–response and the variability of data, and in some cases allow the assessment of risk at exposures below the ADI. The disadvantages of these alternative methods are that they do not entirely avoid the use of arbitrary uncertainty factors and that most toxicological studies do not provide sufficient information to adequately characterize the dose–response curve. Based on these concerns, many organizations rely much more on the traditional NOEL-uncertainty factor approach in calculating appropriate ADIs for food additives.

Along with the assessment of an ADI for a food additive, another important step is the determination of how much of the additive is, or is likely to be, consumed in the general population. If the estimated daily intake is sufficiently above the ADI, concerns may be raised regarding the use of that additive in general commerce. Estimated daily intakes are calculated knowing in what foods the additive will be used and the amounts of those food products consumed by different populations of consumers. The use of proposed food additives can be limited to specific food categories to limit the consumption, if this is seen as necessary by the regulatory authority.

Toxicological Assessment of Food Additives

The toxicological assessment of proposed food additives encompasses a wide variety of tests ranging from relatively simple *in vitro* studies to complex multigeneration animal studies. The tests required for each proposed additive will vary depending on the nature of the additive itself. For proposed additives that are the same as either naturally and commonly consumed components of food or normal constituents of the human body (e.g., lecithin), the testing requirements may be much less stringent compared with additives which are novel synthetic compounds. Also, some regulatory authorities have variable minimal data requirements, depending on the expected toxicity of the additive and its anticipated consumer exposure. In this 'Level of Concern' system, increasing anticipated exposure triggers additional data requirements. As the potential toxicity of the product increases (based on structural characteristics), the exposure-based cut-off points for increased data requirements are lower. The potential toxicity is determined by comparing the structure of the proposed additive with those of known biological activity. Substances of low concern would include normal cellular constituents such as carbohydrates and fats, aliphatic hydrocarbons which are saturated and contain few functional groups, and inorganic chemicals, which are normal cellular constituents or inert gases. Those substances of high concern include aromatic hydrocarbons and halogenated and heterocyclic chemicals.

In all cases, the conduct of toxicity studies, and the interpretation of data derived from these studies, may reveal the need for further testing, which may not have been apparent at the outset. In some cases, the regulatory authority may see the need for further testing in order to address specific concerns. Since food additives generally are meant to be consumed in a long-term, *ad libitum* manner, the studies that play the most important role in assessing the safety of proposed food additives are those aimed at determining potential chronic and/or carcinogenic, along with reproductive effects. Other toxicological tests contribute to the overall understanding of the possible adverse effects of a substance on biological systems. Adequate dose levels in studies allow the definition of a dose–response and the assignment of a NOEL to the compound under study. The high dose employed in these studies should elicit some adverse effects. With any type of toxicological testing, there must be adequate methodologies employed to insure the resulting data are meaningful and to reduce any potential criticisms, which may put the results in dispute. Even so, animal methodologies do not always allow extrapolation to human exposure scenarios. For instance, the potential food additive exposure of human newborns and infants through artificial milk substitutes is not mimicked in rodent models where newborns are nourished only via maternal milk. Several regulatory authorities have issued guidelines for the appropriate conduct of toxicity tests. Both the Organisation for Economic Cooperation and Development (OECD) and the US Food and Drug Administration (FDA) have published documents in this area with the FDA's detailed Redbook II currently undergoing revision. The OECD's Guidelines for the Testing of Chemicals are comprehensive in their

coverage of a wide variety of testing methodologies and are updated as needed. The OECD guidelines have been endorsed by member countries, allowing the acceptance of data between all countries belonging to the OECD. In addition to the aforementioned guidelines, the concept of Good Laboratory Practice is important in assuring that testing laboratories are able to generate valid data. Some regulatory bodies publish principles of Good Laboratory Practice.

Types of Toxicity Tests

Short-term tests for mutagenicity/genotoxicity The potential of a test chemical to interact with or damage DNA (genotoxicity) and have carcinogenic activity can be assessed using a variety of tests, following exposure *in vitro* or *in vivo*, with cells obtained from microbial, mammalian, and human sources. Usually, a battery of short-term tests for food additives will include a test for microbial gene mutations, chromosomal aberrations in mammalian cells *in vitro*, and chromosomal aberrations in mammalian cells *in vivo*.

In vitro tests include the bacterial *Salmonella typhimurium* reverse mutation assay (Ames test) to detect base-pair substitutions and frameshift mutations. Mammalian cell lines include those from mouse lymphoma cells, various tissues from Chinese hamsters, and from human cells to measure chromosomal aberrations and gene mutations. Other *in vitro* tests sometimes conducted include DNA repair (unscheduled DNA synthesis) or sister chromatid exchanges and cell transformation. *In vivo* tests include those to detect chromosomal aberrations (including micronucleus formation) in either circulating blood cells or bone marrow cells, and DNA repair assays.

In vitro tests require an exogenous metabolic activation system that may not reflect metabolism in live animals. These tests tend to be overly sensitive and therefore may overpredict activity. However, they are generally based on well-established, easy-to-perform assays that are reproducible and can incorporate high doses of test substance. *In vivo* genotoxicity assays have the advantage of having an intact metabolic system and the ability to assess concurrently target organ distribution of the test substance and its metabolites. Also, in concert with other animal toxicity tests, the results of these types of assays are more readily applicable for extrapolation to humans. However, *in vivo* tests may be insensitive, requiring the expense of large numbers of animals and, frequently, large amounts of test material. Agents that cause cancer by nongenotoxic mechanisms will not be detected by genotoxicity tests, and these assays do not replace bioassays that are aimed at detecting cancer.

Toxicokinetics/pharmacokinetics Results from these studies are useful in the interpretation of data derived from other investigations and provide information on the absorption, distribution, metabolism, and excretion of the test substance. This information also is useful in the development of further studies. For example, if it is known that a substance passes through the gut unabsorbed, the design of other studies can be tailored accordingly.

Acute toxicity tests Generally, acute oral toxicity tests are used where no information on a particular substance is available. The data derived from these single, high-dose, studies are limited, but provide information on maximum tolerated doses and may give information on the mechanism of action of the compound and the organ systems that may be affected.

Short-term, repeated-dose, toxicity tests Usually conducted for 28 (or sometimes 14) days, these short-term, oral, multiple-dose studies are designed to gather preliminary information on the effects of the daily administration of test substances on such parameters as hematology, clinical chemistry, and pathology. Also, the data derived can be used to narrow the focus of future studies to any identified target organs and to determine appropriate doses for further, longer-term, studies. Short-term tests generally are conducted on a rodent (mouse or rat) and a nonrodent species (usually dogs).

Subchronic toxicity tests Subchronic studies are usually conducted for 90 days and generally involve parameters and testing methodologies similar to shorter-term studies. Again, both rodent and nonrodent species are employed in subchronic studies. These investigations will reveal significantly more information on physiological and pathological effects of the test chemical than will shorter-term studies. Focused studies on other parameters such as immunotoxicology and neurotoxicology are included in subchronic testing strategies.

Chronic and carcinogenicity studies These two types of studies may be conducted separately; however, if a sufficient number of animals are used, the chronic and carcinogenicity aspects may be combined in a single study. The length of the studies is to include the majority of the lifespan of the animal; however, animals in the chronic exposure arm of the study may be removed earlier. Generally, two rodent species are employed (usually rats and mice), and the study is conducted for 2 years with daily dosing of multiple dose levels. In some cases, animals are also exposed during gestation. These long-term studies are the

most comprehensive, with a considerable variety of parameters and toxic endpoints being examined and the requirement of high standards of analysis, including pathology and statistics. NOELs derived from chronic studies are important, since the exposure scenario can be extrapolated to the real-life, long-term, human situation with food additives. Important goals of all long-term studies are to develop dose–response information and to identify clear LOELs and NOELs that can be used for ADI calculations. (*See* **Carcinogens**: Carcinogenicity Tests.)

Reproduction, teratology, and developmental toxicity studies The aim of these investigations is to determine the potential effects of the test substance on the ability of animals of both sexes to produce viable and healthy offspring and on the subsequent development of these progeny. Most studies in this regard involve continuous dosing through two generations of test animals (rats or mice). Males are dosed in advance of mating to elucidate any effects of the test compound on one complete spermatogenic cycle. Females should be dosed for at least two estrous periods before attempted mating. In this way, the first-generation offspring are exposed from the moment of conception to the weaning of their own (second-generation) offspring. Reproductive parameters measured include gonadal function, mating behavior, time to conception, fetal viability, parturition, and lactation. Developmental parameters include morbidity and mortality, growth, and behavior. As part of the reproductive studies, or investigated in its own right, the potential of the test material to produce physical or functional birth defects must be determined. These teratology studies are conducted by exposing the fetuses during *in utero* development for the time that corresponds to the development of various organ systems. Just before expected parturition, the fetuses are examined for skeletal and visceral abnormalities.

Other toxicity tests The need for further studies may become apparent during other investigations. These include focused studies on the potential toxicity of the substance on the immune or nervous systems.

Human studies After significant evaluation in animals, human testing is sometimes conducted. Studies in humans usually are proposed in the case of food additives that are expected to have a wide use by a large proportion of consumers (e.g., sugar or fat substitutes). While toxicological studies obviously are not conducted in people, these human studies provide information on possible unwanted effects (such as the gastrointestinal tolerability of the additive) resulting from more realistic doses and use patterns than can be achieved with animal studies.

Interpretation of Toxicological Data

The data derived from the aforementioned studies should provide sufficient information to enable the calculation of an ADI for the particular proposed food additive. It is important, however, to keep in mind that it is not unusual for different professional opinions to exist on the significance of toxicity of a substance based on the same data. Reasons for divided opinion are varied and may include differing views on the potential severity of effects noted and on the extrapolation of animal data to the human situation. In some cases, debate has occurred as to the meaning of results from animal studies where effects noted (including tumor development) are present in biological structures that have no counterpart in humans or where the metabolism of the compound differs between animals and humans. Well-known examples of food additive substances that have produced significant debate are saccharin and butylated hydroxyanisole (BHA).

Saccharin, a sugar substitute that was generally regarded as safe in the USA until 1972, has been linked to bladder cancer in rats when exposed *in utero* or from birth, with males affected more than females. A NOAEL of 3% saccharin in the diet was established in a large two-generation study in rats, and no tumors were noted with 1% saccharin in the diet. The factors contributing to the development of bladder neoplasms by saccharin are species-specific. While saccharin is nongenotoxic, it has been suggested that its ability to cause bladder cancer results from the complexing of saccharin ions with urinary proteins with precipitation and the formation of crystals. The crystals may act to damage the walls of the bladder with increased cell proliferation. The protein suspected of being involved in the crystal formation (α-2-microglobulin) is present in higher concentrations in the urine of male rats compared with female rats, mice, and humans. This and other species differences in urine composition suggest that humans may not be susceptible to the carcinogenic action of saccharin. Epidemiologic studies in human populations using saccharin have not revealed any increase in bladder cancer.

BHA is a phenolic antioxidant used mainly in fats and oils. It has been shown to have a low acute toxicity. In chronic exposure investigations, no consistent adverse effects have been noted with up to several per cent BHA in the diet, with the exception of forestomach hyperplasia and tumor formation. Also, it has been shown to have a low potential of being genotoxic. Malignant tumors of the forestomach

have been noted in rats fed 2% BHA in the diet for 2 years, which equals almost 1 g of BHA per kilogram of body weight. No such tumors were noted when the rats were fed 0.5% BHA in their diet. In other rodent species with forestomachs, BHA has produced hyperplasia, and benign tumors have been noted in the hamster forestomach. No species other than the hamster and rat have been shown to develop carcinomas in this organ. The carcinogenic effect in certain rodent species appears to be due to indirect, rather than direct, effects of BHA on DNA. Since the forestomach is an organ that is not present in humans, the relevance of the findings in animals is questionable. In addition, the effects noted in the positive animal models were observed at very high doses, and a threshold for the formation of carcinomas in rodents was identified.

Because of new developments in the scientific literature or in the interpretation of toxicological data, it is essential that regulators keep up to date with the toxicological literature. The generation of substantial new evidence may allow a refinement or reassessment of the safety of specific food additives.

Emerging Issues

The continuing evolution of the food industry means that new types of products come into use on a continuing basis. Novel types of food additives and packaging methods and materials arise that present unique challenges to the toxicologist and regulatory authorities in terms of appropriate testing strategies.

In recent years, certain plants and microorganisms have been modified through biotechnology, including genetic modification. Food additives, such as enzymes, derived from genetically modified organisms (or the addition of the modified organisms themselves) present challenges in safety assessment. Issues to consider in the assessment of these types of food additives include the exposure to foreign DNA and proteins (and thus considerations of allergenicity), increased exposure to these types of products as the market increases, and the necessity of microbiological purity if products are derived from modified microorganisms. (*See* **Biotechnology in Food Production; Genetically Modified Foods**.)

The advent of 'functional foods' (foods containing ingredients demonstrated to have specific health benefits, in addition to providing basic nutrients and nutritional benefits) has led regulatory authorities not only to develop ways of regulating health claims associated with these products but also to consider the inherent safety of these products. Globalization of markets can result in new types of food and food ingredients being introduced. The addition of medicinal-type herbs, such as *Echinacea* species or St. John's Wort (*Hypericum perforatum*) to conventional foods, for perceived health benefits, necessitates an assessment of the safety of these new food products, since herbal ingredients may be consumed in ways that are very different from their use in traditional systems of medicine.

That young children are different from adults in many aspects of their physiology is well known, and this must be taken into account in the assessment of food additives that may be consumed by this population. In recent years, the applicability of the ADI-uncertainty factor approach to insuring the safety of food additives consumed by children has come under scrutiny, and this subject is one of ongoing discussion in many countries.

FOOD AND AGRICULTURE ORGANIZATION OF THE UNITED NATIONS

E Casadei and J Albert, Joint FAO/WHO Food Standards Programme, Rome, Italy

History and Purpose of the FAO

The Food and Agriculture Organization of the United Nations (FAO) is an autonomous agency within the United Nations (UN) system. The organization had a membership of 180 countries in 2001.

In 1943, world leaders met at Hot Springs, Virginia, USA and determined to lay a framework for peace through international cooperation in food and agriculture. The meeting, the UN Conference on Food and Agriculture, decided on the establishment of permanent organization in the field of food and agriculture and set up an interim commission to prepare a specific plan. This commission worked for 2 years and prepared the constitution of the FAO. The signing of the constitution and the opening of the first FAO Conference were arranged to take place in Quebec, Canada, on 16 October 1945. Representatives from 44 nations met at this date and established the FAO, the first of the UN agencies. As the commemorative tablet in Canada states, 'Thus for the first time nations organized to raise levels of nutrition and to improve production and distribution of food and agricultural products.' The FAO's goal is enshrined in its motto, '*Fiat Panis* – Let there be bread.'

The Conference is the FAO governing body and is composed of all member nations. It meets every 2 years and is a major forum for the discussion of food and agriculture issues. It is able to take concerted action on issues of concern to its members. Recent initiatives include the adoption of a World Food Security Compact and an International Code of Conduct on Pesticide Distribution and use.

The Conference elects a Council to which a series of committees, such as the Committees on Commodity Problems, Fisheries, Agriculture, Forestry, and World Food Security, report. Many bodies have been set up by the FAO Conference and Council to foster cooperation in particular subject areas. In adopting the International Undertaking on Plant Genetic Resources in 1983, for example, the Conference provided for the establishment of a commission on Plan Genetic Resources to guide the FAO on policy and to monitor the implementation of the undertaking. The Commission on African Animal Trypanosomiasis was established in 1979 to coordinate a large-scale FAO program to control the disease. Another example is the cooperation of the FAO with the World Health Organization (WHO) through a joint FAO/WHO Codex Alimentarius Commission, which has issued some 200 international food standards. (*See* **Legislation:** Codex.)

Along with these bodies, FAO organizes conferences and meetings on particular issues. For example, the FAO-serviced World Food Conference in 1974

resulted in a series of measures to promote world food security. In December 1992, the first International Conference on Nutrition (ICN) was held in the FAO's Headquarters in Rome. The conference was jointly sponsored by the FAO and the WHO. At this conference, a World Declaration and Plan of Action for Nutrition were unanimously adopted, committing governments to prepare their National Plans of Action for Nutrition containing attainable goals and measurable targets based on the principles and relevant strategies agreed at theICN. World leaders assembled in Rome in November 1996 for the World Food Summit aimed at renewing global commitment to the fight against hunger. The FAO called the Summit in response to widespread undernutrition and growing concern about the capacity of agriculture to meet future food needs.

Besides being a major forum for the discussion of food and agriculture matters, the FAO is an information center collecting data related to its field of work. It also acts as an adviser to governments, being a useful source of independent advice on agricultural policy and planning, on the administrative and legal structures needed for development, and on ways of ensuring that national development strategies are directed towards rural development and the alleviation of poverty and malnutrition. Its role as a development agency should be highlighted: the FAO gives direct, practical help in the developing world through technical assistance projects in all areas of food and agriculture (including fishery and forestry). These field projects strengthen local institutions, assist research and training, and develop and demonstrate new techniques.

Food Security and Nutrition

The idea of international action to achieve world food security was launched by the FAO in early 1973. The international undertaking in world food security contains a set of general principles for stockholding, special assistance to developing countries (including aid to increase production), the exchange of information, and arrangements for consultations. The concept has developed further. Today, the objective of the world food security concept is to ensure that all people at all times have both physical and economic access to the basic food they need. Its more specific aims are related to production, with special emphasis on low-income food-deficit countries, stability in the flow of supplies, and the problems of access to available supplies on the part of needy nations and social groups.

The search for policies that would cope with food shortages and surpluses has been one of the main threads in FAO history. Various activities contributed to the preparation of such a policy, including the following: expanding production, improving nutrition, stabilizing prices, obtaining a fair return for producers, and coping with famine.

Nutrition was a dominant theme at the Hot Springs Conference, with the adoption of eight resolutions dealing exclusively with various aspects of nutrition, far more than on other subjects. There is no single formula for curing malnutrition. The best approaches vary, according to local and national circumstances. The development of policies for food and nutrition is largely a question of orienting sectoral activities to have an impact on nutrition. Thus, from the mid-1970s, the FAO worked closely with a number of governments on the incorporation of nutritional objectives into development plans.

A mass of information on every aspect of food and agriculture (including production, supply, demand, prices, and technology) is needed if government planners, traders, scientists, farmers, and technologists in every country in the world are to make rational decisions on planning, investment, marketing, research, or training. The FAO provides that essential information for food policy planning. For example, the Global Information and Early Warning System for Food and Agriculture monitors production conditions and food supply prospects world-wide and issues warnings when there are indications of trouble. The role of world food surveys cannot be overemphasized in the assessment of world nutrition status. The FAO prepares these surveys for collecting essential data on the world's food problems. These data are analyzed and distributed to all member countries and concerned bodies as reference data for the elaboration of food policies at world or national levels. At the time of writing, the latest survey is the sixth one, published in 1996.

In addition to its tasks of collecting, analyzing and disseminating information, advising governments on food and agriculture (including fishery and forestry) policy and planning, and providing opportunities for governments to meet and discuss food and agriculture problems, the FAO carries out a major program of technical advice and assistance for the agricultural community on behalf of governments and development funding agencies. The FAO is involved at every stage of agricultural development, from demonstrating new cultivation techniques to subsistence farmers, to advising governments on how to achieve more stable and equitable international trade in agricultural commodities.

Food Control

In the past several decades, nations have experienced extensive changes and faced new or greater problems in assuring adequate national food security, trade, and health. This trend is continuing for the following reasons: intensification of farm production and the centralization of food manufacturing; the development of large urban markets remote from the agricultural production areas; markets and consumer demands for consistent supply of safe, uncontaminated and good-quality food and food products; the economic dependency of many countries on revenues from agricultural food exports; and the rapid growth in global food trade.

Within the overall mandate of the FAO with regard to production, distribution and marketing of food, and for nutrition improvement, the necessity of providing a safe, wholesome, and nutritious food supply, and the protection of this supply from losses, waste, deterioration, contamination, and adulteration is implicit. It is interesting that the Hot Springs Conference noted that the FAO would play a role in insuring 'protection of the public, through the medium of pure-food laws, against impurities for adulteration and against unfair competition and undesirable trade practices.' It recommended that the FAO should 'assist governments to extend and improve standards of nutrient content and purity of all important foods.' In view of this, the FAO has developed programs to assist governments to orient their country policies and programs so as to include nutrition improvement and food protection as specific objectives.

Food safety and quality start at the farm level and continue throughout the processing and distibution chain to storage and final preparation by the consumer. Good agricultural, processing, distribution, and marketing practices are essential to ensure consumer protection. Now, more than ever, food control programs are needed in order to assure that foods are safe for consumption and are sold to the consumer on fair terms; furthermore, such programs should help to reduce food losses caused by improper handling or spoilage of raw materials, prevent 'dumping' practices of shipping nonstandard (low-quality or contaminated) food products to countries that do not have the capability of food control, and increase the earnings of foreign currency necessary for the implementation of development plans. Food control, including standards, is therefore an integrated part of the programs developed by the FAO.

Issues relating to food safety and food control draw considerable public attention and represent an important concern for governments, consumers, and the industry alike. They need to be addressed at the national level by adequate legislation, which should be developed in cooperation with all interested sectors and implemented efficiently.

The Economic and Social Department of the FAO, and especially its Food and Nutrition Division (ESN) are the main bodies responsible for the programs oriented to guarantee food quality and safety and consumer protection. Within this division, the Food Quality and Standards Service focuses on activities in the field of food control. These activities are implemented through the Food Standards Group, which provides the Secretariat for the Codex Alimentarius Commission of the Joint FAO/WHO Food Standards Program, and the Food Quality and Consumer Protection Group, which assists developing countries in the formulation and development of effective food control programs and gives scientific and technical support to the Codex Alimentarius Commission. Technical assistance provided by the FAO in food control is based upon the fundamental elements that all effective programs must consider:

- a basic food law complemented by detailed regulations that provide for correct hygienic practices in food and agricultural production and processing, the establishment of food standard and codes of practice, the correct use of food additives, pesticides, etc., and the proper use of labeling to avoid consumer deception;
- an effective administration of such laws and regulations through an organization which includes technical officers, inspectors, laboratory personnel and compliance officers, together with the necessary infrastructure to carry out their tasks adequately;
- a well-informed consumer, aware of the problems related to food control, especially with respect to good handling practices and storage; and
- food producers, processors, and handlers who cooperate with government agencies in assuring food quality and safety.

In order to insure food security, facilitate trade and protect consumers, the development of the following activities receives special consideration from the FAO:

- support of developing countries in strengthening their national strategies for quality and safety, food control systems and contamination monitoring programs;
- preparation of food legislation, regulations, and standards on a national, regional, or international basis accordingly to meet changing consumer demands (e.g., food irradiation, biotechnology),

new food ingredients (e.g., vegetable proteins), and new food safety concerns (e.g., veterinary drug residues, radionuclides); and
- technical assistance in training for food control inspectorate and laboratory personnel and for food control management staff. (*See* **Legislation**: History; International Standards.)

Joint FAO/WHO Food Standards Program Codex Alimentarius Commission

The Hot Springs Conference noted the role of government services in insuring the protection of the public. It recommended that the FAO, when established, should 'consider the formulation and adoption of international standards to facilitate and protect the interchange of such products between countries, and agree upon international methods of determination.'

In 1958, work was begun by an FAO Committee of Government Experts, in collaboration with the International Dairy Federation, on the establishment of a Code of Principles concerning Milk and Milk Products and compositional standards for milk products. A further development that took place in 1958, and which was to prove to be of great importance to both the FAO and WHO in introducing an international program for the elaboration of food standards, was the creation of a body known as the Codex Alimentarius *Europaeus*. In 1961, the Council of the European Codex Alimentarius adopted a resolution proposing that the work should be taken over by the FAO and WHO. From that moment, matters moved quickly, and the Codex Alimentarius Commission was established in 1962 by the decision of the Conference of the FAO and the Executive Board of the WHO.

The basic objectives were precisely those put forward at Hot Springs: removal of nontariff trade barriers caused by differing national food legislation, insuring fair practices in international trade, and protection of the consumer against health risks and fraud. The Commission assumed the role of an international forum for elaborating standards for foods moving in international trade and for providing guidance to countries wishing to create their own national food laws and regulations.

The Uruguay Round of Multilateral Trade Negotiations concluded in Marrakesh in April 1994. It established a new World Trade Organization (WTO). Amongst the agreements were the Agreement on the Application of Sanitary and Phytosanitary Measures (the SPS Agreement) and the Agreement on Technical Barriers to Trade (the TBT Agreement). Both of these agreements are relevant in understanding the international dimensions of food. The SPS Agreement encourages the use of international standards, guidelines, or recommendations where they exist and identifies those of Codex (relating to food additives, veterinary drugs and pesticides residues, contaminants, methods of analysis and sampling, and codes and guidelines of hygienic practices), as consistent with provisions of the SPS. Thus, the Codex standards serve as a benchmark for a comparison of national sanitary and phytosanitary measures. The TBT Agreement also recognizes international standards where they exist. It requires that technical regulations on traditional quality factors, fraudulent practices, packaging labeling, etc. imposed by countries not be more restrictive on import products than they are on products produced domestically.

Membership of the Codex Alimentarius Commission is open to all Member Nations and Associate Members of the FAO and/or WHO. In 30 years, the Commission has grown from the original 30 countries that were present at its First Session in 1963 to 165 member countries in 2001. The distribution of Member Countries is as follows: Africa, 41; Near East 19; Asia, 21; Europe, 40; Latin America and the Caribbean, 31; North America, 2; Southwest Pacific, 11. The Commission has an Executive Committee and 29 subsidiary bodies. All of these bodies, like the Commission, are intergovernmental in character. The composition of the Executive Committee is such as to insure an adequate representation of the various geographical areas of the world to which the members of the Commission belong. The Executive Committee makes recommendations to the Commission regarding the general orientation of the program of the work.

The main activities of the Commission have been concerned with the development of international world-wide standards for foods as well as other texts on related matters, their publication in the Codex Alimentarius, and the registration of acceptances by member governments of standards. In addition, the Commission, through its subsidiary bodies, is concerned with the elaboration of advisory Codes of Practice, which are adopted within the Codex. The Commission determines priorities, and initiates and guides the preparation of draft standards, whether by its own subsidiary bodies or with the assistance of other appropriate organizations.

During its lifetime, the Codex Alimentarius Commission has elaborated more than 230 individual commodity standards, 37 codes of hygienic and technological practices, and maximum residue limits for pesticides covering more than 3000 potential pesticide plant and animal combinations. The Codex Alimentarius itself contains standards on the following:

processed, semiprocessed, or nonprocessed food products; raw materials used in manufacturing; labeling; nutrition information; food additives; contaminants; pesticide residues; veterinary drug and hormone residues in food; methods of analysis; sampling; codes of practice; and guidelines and other recommendations. All the above have been published in 16 volumes of the Codex Alimentarius.

Labeling

Food labeling is the primary means of communication between the producer and the consumer. One of the most vexatious problems that exporters of foodstuffs are likely to encounter is the wide disparity between different countries' requirements with regard to labeling. The work of Codex in devising and issuing a General Standard on the Labeling of Pre-Packaged Foods must be regarded as a landmark, a major achievement, in international recommendations for food legislation.

Codex has issued Guidelines for the production, processing, labeling, and marketing of organically produced foods. These guidelines set out the principles of organic production at farm, preparation, storage, transport, labeling and marketing stages, and provide an indication of accepted permitted inputs for soil fertilizing and conditioning, plant pest and disease control, and food additives and processing aids. For labeling purposes, the use of terms inferring that organic production methods have been used are restricted to products derived from operators under the supervision of a certification body or authority.

Nutrition Information

Consumer demand for nutrition information is growing, stimulated by the media, whose interpretation and presentation of the views of nutrition scientists and on national policies are not always balanced or accurate. Few consumers have any systematic training in nutritional matters or easy recourse to reliable information sources. The natural concern for the family health leads them to use the media as their information source. The problem faced by Codex was how to regulate it so that accurate and balanced information could be presented without creating a rigid system. The Guidelines on Nutrition Labelling have been issued to insure that nutrition labeling is effective:

1. providing the consumer with information about a food so that wise choices can be made;
2. providing a means for conveying information of the nutrient content of a food on the label;
3. encouraging the use of sound nutrition principles in the formulation of foods that would benefit public health; and
4. providing the opportunity to include supplementary nutrition information on the label

Nutrition labeling should not describe a product or present information that is in any way false, misleading, deceptive, or insignificant in any manner, to insure that no nutritional claims are made without nutrition labeling.

Food Additives

The use of food additives is becoming more important in the production and world-wide distribution of food. As the demand for variety increases, and with it the desire to purchase goods from distant lands, the importance of food additives will increase, rather than diminish. None the less, this is a topic of great consumer concern, and Codex has always treated it as such through the Codex Committee on Food Additives and Contaminants (CCFAC). The CCFAC considers technological needs on the one hand from information supplied by Codex Commodity Committees. On the other hand, it applies safety considerations based on the reports of the Joint Expert Committee on Food Additives. The CCFAC follows a risk-based approach to develop the General Standard for Food Additives, which includes a list of additives that can be used in accordance with Good Manufacturing Practice and specific levels of use for a number of additives for which an acceptable daily intake (ADI) has been established.

Contaminants

The term 'contaminants' is used to denote the presence in food of traces of undesirable elements of substances, e.g., traces of lead, cadmium, polychlorinated biphenyls, or even radioactive fallout. The CCFAC is responsible for establishing permitted maximum or guideline levels for individual food additives, for contaminants (including environmental contaminants), and for naturally occurring toxicants in foodstuffs and animal feeds. The establishment of maximum levels for contaminants is a complex subject, and there are specific difficulties to address in order to reach an agreement at the international level in this area. Sometimes, the complete or updated risk assessment is lacking, especially exposure assessment, and there is a need to update the scientific information. In addition, legislation in Member Countries differs widely, especially between exporter and importer countries, and it is difficult to come to a

consensus; there are also several technical problems to be addressed, especially as regards methods of analysis and sampling or inspection procedures.

Pesticide Residues

The use of pesticides is essential in agriculture and horticulture if crop yields are to be economically viable and, indeed, if crops are to be successful. The fact that residues can remain in the food is another topic of considerable consumer and even wider concern. There is well-justified concern that an unrestricted and uninformed use of these substances could damage health. The Codex Committee on Pesticide Residues, on the basis of the work of the FAO/WHO Joint Meeting (Committee of Experts) on Pesticide Residues (JMPR), has established maximum residue limits (MRLs).

Maximum Residue Limit (MRL) is the maximum concentration of a pesticide residue (expressed as milligrams per kilogram) recommended by the Codex Alimentarius Commission to be legally permitted in or on food commodities and animal feeds. MRLs are based on Good Agriculture Practice data, and foods derived from commodities that comply with the respective MRLs are intended to be toxicologically acceptable.

Codex MRLs that are primarily intended to apply in international trade are derived from estimations made by the JMPR as follows:

1. toxicological assessment of the pesticide and its residue; and
2. review of residue data from supervised trials and supervised uses including those reflecting national food and agricultural practices. Data from supervised trials conducted at the highest nationally recommended, authorized, or registered uses are included in the review. In order to accommodate variations in national pest control requirements, Codex MRLs take into account the higher levels shown to arise in such supervised trials, which are considered to represent effective pest-control practices. Consideration of the various dietary residue estimates and determinations both at the national and international level in comparison with the ADI should indicate that foods complying with Codex MRLs are safe for human consumption.

Food Hygiene

Poor food hygiene is a major cause of human illness. Most hygiene problems are caused by faulty handling of food and, in the case of processed or packaged food, often occur after manufacture and packaging. There are powerful reasons for the great attention paid by Codex to food hygiene. In matters of hygiene, it is especially true that good practices and economic benefits go hand in hand. The establishment of effective good manufacturing practice as regards hygiene is relatively simple in principle but is far from simple in practice.

Codex has issued a Code of Practice and General Principles of Food Hygiene. These General Principles lay a firm foundation for insuring food hygiene. The document follows the food chain from primary production through to final consumption, highlighting the key hygiene controls at each stage. It recommends a Hazard Analysis and Critical Control Points (HACCP)-based approach, wherever possible, to enhance food safety. The HACCP system, which is science-based and systematic, identifies specific hazards and measures for their control to insure the safety of food. HACCP is a tool to assess hazards and establish control systems that focus on prevention rather than relying mainly on end-product testing.

Principles for the establishment and application of microbiological criteria for foods have been approved by the Codex Alimentarius Commission. These principles are intended to give guidance on the establishment and application of microbiological criteria for foods at any point in the food chain from primary production to final consumption.

Current Issues

Matters related to biotechnology are at the center of considerable debate in many countries and also at the international level. In the framework of Codex, the Commission decided to establish the Task Force on Food Derived from Biotechnology, in order to insure a comprehensive approach and to consider safety, nutrition, and all relevant aspects of genetically modified organisms (GMOs) and food produced from GMOs.

Several food safety issues are related to animal feeding, especially contamination of feed with mycotoxins and other contaminants. This question drew the attention of the media owing to the recent occurrence of contamination with dioxins in feeds, but there are also several other issues, including the Bovine Spongiform Encephalopathy. The Commission decided to establish a specific Task Force on Animal Feeding to consider all aspects that can affect food safety. Another important emerging issue in relation to animal production is antimicrobial resistance in bacteria, and in view of its complexity, it should be addressed through a multidisciplinary approach. It is currently under consideration by the Committee on Food Hygiene and the Committee on

Residues of Veterinary Drugs in Foods and is also relevant to the work of the Task Force.

Future Directions

The fundamental objective of the Codex Alimentarius Commission is to establish sound internationally agreed guidelines for national food control systems based on the criteria of consumer health protection and fair practices in trade, and taking into account the needs and special concerns of all countries.

The new recognition and status that Codex standards, guidelines, and other recommendations acquired under the WTO Agreement on the Application of Sanitary and Phytosanitary Measures (the SPS Agreement) also brought new challenges and responsibilities, including the need to insure that its standards and related texts are based on scientific principles and meet the needs and mandate of the organization. The WTO Agreement on Technical Barriers to Trade is also of great relevance, given the significance of the provisions pertaining to product description, labeling, packaging, and quality descriptors for consumer information and fair practices in trade. Although quality provisions are fundamentally driven by the market, the CAC has an important role in insuring that provisions relating to quality are sound and based on the criteria of essentiality and do not constitute disguised barriers to trade.

FOOD AND DRUG ADMINISTRATION

A Miller and T Nordenberg, FDA's Center for Food Safety and Applied Nutrition, Maryland, MD, USA

Historical Introduction

The Food and Drug Administration (FDA) is an Executive Branch agency within the US Department of Health and Human Services (HHS). Its regulatory obligations include overseeing the safety of about 80% of the domestically produced and imported food in the USA – specifically, all food except meat, poultry, and processed eggs.

Long before the federal government of the USA began to regulate the country's food and drug products, individual states had made independent efforts to regulate them. But despite the threat of punishment for selling adulterated and mislabeled foods, the state laws, including the first-of-its-kind Massachusetts food and drug law passed in 1785, proved unsuccessful in preventing the marketing of violative food products.

It was not until 1906 that the first federal Pure Food and Drug Act was enacted, which made it a federal crime to sell mislabeled or adulterated food, drink, and drugs intended for interstate commerce. This cornerstone legislation of the future Food and Drug Administration was passed following the 1905 publication of Upton Sinclair's provocative novel *The Jungle*, which exposed the unsanitary conditions in American meatpacking plants, and the public crusade of Dr. Harvey Wiley, the chief chemist of the US Department of Agriculture (USDA) in the late 1800s and early 1900s, to reform the food and drug laws to protect consumers from harmful preservatives and adulterants.

Wiley, who came to be known as the 'Father of the Pure Food and Drugs Act,' was appointed as the first administrator of the landmark 1906 legislation. Under Wiley's leadership, the staff at the USDA's Bureau of Chemistry improved upon existing scientific methods

for analyzing food and refined legal procedures and inspection methods helpful in enforcing the law.

The first separate federal food and drug agency was established in 1927, and took the name 'Food and Drug Administration' in 1931. While the 1906 law laid the agency's foundation, Congress has continued to update the act over the years, ultimately assigning FDA responsibility for assuring the safety of most US food products. The Federal Food, Drug, and Cosmetic Act, signed into law by President Franklin D. Roosevelt in 1938, remains the basic food and drug law of the USA. Three amendments to the 1938 law had important implications for food regulation: the Miller Pesticide Amendment in 1954, the Food Additives Amendment in 1958 (which includes the 'Delaney Clause'), and the Color Additive Amendments in 1960.

Despite the legal amendments, the overall goal of the federal food law has remained constant: protecting US consumers from adulterated and misbranded food products, whether they are produced domestically or imported into the USA. It is the Food and Drug Administration's responsibility to implement the food and drug laws to protect and promote the health and economic interests of the American public.

Recent statistics from the Centers for Disease Control and Prevention illuminate the enormity of this challenge: foodborne illness, according to CDC, causes approximately 76 million illnesses, 325 000 hospitalizations and 5000 deaths each year in the USA. And in their quest to improve the safety of the US food supply, food scientists and regulators continue to be faced with ever-changing hurdles: for example, US consumers are eating more seafood, fresh produce (especially imported produce), and more ready-to-eat foods, as well as more foods prepared at restaurants and institutional settings such as nursing homes and hospitals. Also, up to 25% of the US population is considered 'at risk' for foodborne illness. Vulnerable populations include pregnant women, children, the elderly, and those who are immunocompromised. But perhaps the most perplexing challenge of all comes from evolving bacteria such as new strains of *Escherichia coli (E. coli)* 0157:H7.

Today's FDA: Mission and Organization

Along with setting the standards and ensuring the safety of over 75% of the food consumed in the USA, FDA is responsible for ensuring the safety of animal feed and drugs and all human medications and vaccines, blood products and tissues for transplantation, medical devices, devices that emit radiation, and cosmetics.

Of the five product-oriented centers that regulate these areas, the Center for Food Safety and Applied Nutrition (CFSAN) carries out the mission of ensuring that food products in the USA are safe, nutritious, wholesome, and properly labeled. CFSAN regulates all food products sold in interstate commerce, except meat, poultry, and processed egg products, which fall under the authority of the US Department of Agriculture. Products made and sold entirely within a single state are regulated by that state.

FDA's responsibilities cover an estimated $240 billion worth of domestic food shipments and $15 billion worth of imported foods, from the point of production or entry into the USA to the point of sale. About 46 000 food establishments are listed in the agency's 'Official Establishment Inventory' of regulated companies. These figures do not include the 600 000 or so restaurants and institutional food-service establishments, nor do they include the roughly 235 000 grocery stores and other food outlets in the USA. These are regulated by state and local authorities to whom the FDA's CFSAN provides guidance and technical assistance in the form of a Model Food Code published every other year. FDA also has regional retail specialists who provide technical assistance to state and local governments.

Since 1992, CFSAN has been organized into product-oriented offices, including the Office of Plant and Dairy Foods and Beverages, the Office of Seafood, the Office of Food Additive Safety, and the Office of Nutritional Products, Labeling and Dietary Supplements. Other offices that provide support to the product-based offices (as well as to agency stakeholders) include the Office of Field Programs, the Office of Scientific Analysis and Support, the Office of Applied Research Skills and Safety Assessment, the Office of Constituent Operations, and the Office of Management Systems. In addition to these offices involved in food regulation, CFSAN also has the agency's office of colors and cosmetics.

Two additional CFSAN component offices play crucial cross-cutting roles, including coordination of agency efforts: the Food Safety staff was formed after President Clinton's announcement in 1997 of a national initiative to enhance food safety. The FSI staff focuses on meeting the mandate of reducing foodborne disease to the greatest extent possible, and the Office of Science advises CFSAN's director and other senior managers on applying the best science available to major issues.

The nearly 900 CFSAN employees have specialized training in diverse scientific and other disciplines. Employees include chemists, microbiologists, biologists, toxicologists, food technologists, pathologists, pharmacologists, nutritionists, dietitians,

physiologists, environmental health specialists, geneticists, molecular biologists, mathematicians, sanitarians, economists, risk assessors, lawyers, and educators.

While CFSAN experts play the lead role in food safety, the premarket review of food and color additives, the chemical safety of food and dietary supplements, food labeling, and nutrition, three other FDA centers also play integral roles in food safety:

- The *Center for Veterinary Medicine* is responsible for ensuring that animal drugs and medicated feeds are safe and effective, and that people can safely consume food produced from treated animals.
- The *Office of Regulatory Affairs* (ORA) conducts food safety inspections in production plants, collects and analyzes food samples, and monitors imports for compliance with US requirements. ORA's district offices across the nation conduct 'field assignments' to assess whether imported and domestically produced food products are in compliance with FDA's regulations; remove violative products from the marketplace; provide data on food products for consideration in regulation and policy development; follow up on consumer complaints; assure that recalled or detained products are removed from distribution channels; and participate in investigations when FDA-regulated food is associated with illness.
- The National Center for Toxicological Research undertakes scientific research and testing in support of FDA's mission.

Complementing FDA's regulatory responsibilities are the food-related functions of other federal agencies – notably, the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) within HHS, the USDA's Food Safety and Inspection Service, and the US Environmental Protection Agency (EPA). FDA works closely with these and other federal agencies, such as the US Department of Commerce's National Marine Fisheries Service, the US Department of Treasury's Bureau of Alcohol, Tobacco and Firearms, the US Customs Service, the US Federal Trade Commission, the US Department of Defense, and others.

Pursuant to Presidential Order, these agencies have developed a framework to eliminate jurisdictional overlaps and fill potential gaps. A number of initiatives have integrated food-safety regulation among federal agencies and their state and local counterparts, and uniform data collection and reporting systems are being developed to enable the three levels of government in the USA to function as a national food-safety system.

While the agencies have varying approaches to food regulation under their distinct authorizing statutes, they communicate extensively with each other and abide by a series of formal agreements setting forth the agencies' respective food safety and nutrition roles.

FDA also collaborates extensively with state and local authorities, including the Association of Food and Drug Officials and state, county, and city health and agricultural departments.

Increasingly, the agency is also taking advantage of the specialized expertise that outside food-safety partners can contribute. Two academic–industry–government consortia exemplify such collaboration:

- *National Center for Food Safety and Technology.* Located near Chicago, this joint effort of FDA, the Illinois Institute of Technology, and food companies focuses on the safety of food processing and packaging technologies. Established in 1988, the center has contributed to significant improvements in the safety of sprouts and fresh juice products, for example, and to the development of alternative commercial sterilization procedures such as ultra-high-pressure processing.
- *Joint Institute for Food Safety and Applied Nutrition.* Established in 1996 with the University of Maryland, this program provides the foundation for partnerships with other academic institutions, private industry, consumer and trade groups, and international organizations. The integrated academic and regulatory science program focuses on research in the areas of food safety, risk assessment, human nutrition, and animal health and production.

FDA has also established an extramural grant program to support research in topical areas that include produce safety, egg safety, antimicrobial resistance, methods to detect foodborne viruses in foods, and research on food service, transportation and consumer practices.

By helping FDA to stay on the cutting edge in science, such collaborations ultimately support FDA in making well-founded regulatory decisions. To improve the safety of the food supply globally, FDA has undertaken cooperative research with institutions in other countries, as well.

FDA's Regulatory Role

FDA is charged with enforcing the Federal Food, Drug, and Cosmetic Act (FFDCA), which prohibits the distribution within the USA, or importation into the country, of any *adulterated* food (a food containing 'any poisonous or deleterious substance which may render it injurious to health') or *misbranded*

food (a food whose labeling 'is false or misleading in any particular').

To ensure that the food industry knows specifically what is expected of them, all of the agency's regulations are published in the US government's official daily bulletin, the *Federal Register*, pursuant to a process called 'notice and comment' rulemaking. Before finalizing certain policies, standards, and guidelines, FDA publishes a proposed approach in the *Federal Register*. The proposal contains details of the proposal and its intent, and an invitation to the public to provide written comments for agency consideration.

While 90 days is the standard period for receiving comments, the period is often extended to 180 days or longer when needed. On some issues, the agency has received as many as half a million comments. After careful analysis of all comments, appropriate suggestions are incorporated into the final version of a new regulation. The final regulation is accompanied in the *Federal Register* by a point-by-point discussion of all significant suggestions or criticisms and an explanation of the basis on which they were accepted or turned down.

This notice-and-comment rulemaking process is an essential element of FDA's fair and transparent administrative procedure, which enables the public to know how a decision was made, believe in its integrity, and have confidence that it is fair and based in science.

From the perspective of *enforcing* the FFDCA and related regulations, the agency's role can be divided into premarket and postmarket regulatory responsibilities. The premarket system focuses primarily on the safety of food additives and requires that the person or corporation requesting FDA's approval of an additive provide scientific evidence before marketing to support its safety. The requirement covers direct additives, such as a new nonnutritive sweetener, and indirect additives, such as a component of plastic bottles that can migrate into food. (Noncarcinogenic indirect food additives whose migration into food is likely to be trivial, however, are candidates for abbreviated review by FDA.)

The premarket approval requirement is waived altogether in certain cases – for example, when a substance is generally recognized by the scientific community to be safe – that is, deemed 'generally recognized as safe,' (GRAS). The procedure for a determination that a substance is GRAS has become much simpler under a recent proposed rule allowing 'voluntary notification' of GRAS status.

FDA's *postmarket* food-related activities involve primarily compliance and surveillance activities, during processing and in the marketplace. The agency's system of inspection and enforcement places priority on food at high risk of microbiological contamination (such as infant formula, ready-to-eat foods, and seafood).

Unlike in its premarket actions, in its postmarket activities, FDA bears the burden of proving that a food is adulterated (or misbranded) under the FFDCA or related regulations. The agency can collect evidence of adulteration through its inspections, laboratory analyses, and other sources of information.

If a food is determined to be violative, it can be seized or the manufacturer enjoined from producing it. Also, FDA can seek civil and criminal penalties against those who willingly introduce noncompliant foods into interstate commerce. Violative products are sometimes voluntarily recalled by the manufacturer, not by FDA, which backs the legal authority to order a product's recall.

Products imported into the USA are necessarily handled differently than domestically produced products, because it is generally not feasible for FDA inspectors to inspect the facility where an imported food was produced. In the case of imported foods, if a product appears to be adulterated or is being examined as part of a routine surveillance inspection of imported products, it can be detained or placed under bond while samples are evaluated.

If the product is determined to be adulterated under the FFDCA, it is refused entry into the country. Foreign manufacturers or importers with a history of contamination problems may be placed on 'automatic detention,' which requires the importer to provide an independent laboratory analysis showing that the product is free of any hazard. Sometimes, a product from an entire region may be considered to have an excess risk of adulteration, in which case, each lot of food seeking entry in to the USA must be tested before being admitted.

Food Regulation's Scientific Underpinnings

FDA has a longstanding commitment to supporting and participating in scientific research that can inform regulatory decision-making and contribute to a safer food supply. Agency scientists have, for example, developed a state-of-the-art polymerase chain reaction technique to allow them to detect *Cyclospora cayetanensis*, a protozan parasite on produce. The pathogen was associated with foodborne illness from imported raspberries into the USA and Canada in 1996 and 1997. Meanwhile, advances in molecular biology have also improved scientists' ability to detect foodborne viruses such as Hepatitis A and Norwalk-like viruses associated with illnesses

from produce and seafood, water, or sick food workers.

For another example, a team of scientific experts, including FDA scientists, has devised methods to reduce the microbiological hazards associated with seed sprouts, which are an increasingly popular ingredient in the American diet and, beginning in 1995, were linked with a rising incidence of foodborne disease outbreaks. Specifically, researchers evaluated a number of rapid tests that can be used to determine the safety of the irrigation water used to grow sprouts. These tests, conducted on the water after contacting the growing seeds and sprouts, can point to contaminated batches of sprouts early in the process.

Recently, another team of FDA scientists demonstrated that surface heating of fruit is an effective method to improve apple juice safety by reducing the numbers of microorganisms, including *E. coli* 0157:H7. A model was developed that showed that there is minimal penetration of heat below the surface of apples during use of the inactivation technique.

FDA's research is aimed at understanding and controlling a wide variety of potential hazards in the food supply, be they microbiological contaminants or other threats, including chemical contaminants, pesticide residues, or heavy metals. A variety of scientific tools are employed to help ensure that policy development and regulatory decisions are based on sound scientific principles.

While the agency has conducted risk and safety assessments on chemical hazards for several decades, today, FDA also conducts risk assessments to characterize the likelihood and severity of human health risks posed by microbial contaminants. Recently, FDA has undertaken quantitative microbial risk assessments to evaluate the public health impact of *Listeria monocytogenes, Vibrio parahaemolyticus*, and foodborne pathogens associated with the use of antimicrobials in food-producing animals, which can prove hazardous to people if resistant bacteria are transferred to them from the animals.

Two surveillance tools offer additional examples of how FDA takes advantage of modern scientific capabilities in fulfilling its public health mission:

- *National Antimicrobial Resistance Monitoring System*. This system, implemented by FDA, CDC, and USDA, tracks whether certain bacteria are beginning to lose susceptibility to antimicrobial drugs by acquiring antibiotic resistance genes. This objective scientific information can guide people's use of antibiotics in food animals so as to avoid potentially devastating human health consequences in the long term.
- *PulseNet*. Using high-speed internet connections and computer algorithms that can compare pulsed-field gel-electrophoresis patterns, or DNA 'fingerprints,' of foodborne bacteria, can rapidly and reliably link sporadic cases of foodborne illness to larger foodborne outbreaks. The collaborative project among FDA, CDC, and USDA was used in 1998 to support a swift response from FDA that minimized harm from a *Shigella* outbreak by quickly linking cases of infections in Minnesota, Massachusetts, California, and Canada to fresh parsley from a single farm.

Manufacturers themselves play a critical role in assuring that hazards are minimized at the site of food production. A key to achieving the safest product possible is the Hazard Analysis and Critical Control Point (HACCP) system, which identifies the critical steps in the food-production process where contamination is most likely to occur, and puts into place controls and limits to address the threat.

FDA has incorporated HACCP principles for many years in its guidance documents and regulatory programs, starting with the 1979 low-acid canned-food regulations. FDA implemented mandatory HACCP for domestic and imported seafood products in 1997 and, in January 2001, finalized the HACCP rule for fruit and vegetable juices.

FDA also has incorporated HACCP principles into its Model Food Code, a guidance document that serves as a model policy for state, territorial, and municipal and local agencies that license and inspect food service establishments, retail food stores, and food-vending operations in the USA. Recently, FDA has been working with the National Conference for Interstate Milk Shipments to develop a fluid milk HACCP pilot program.

Beyond Contaminants: Nutrition and Dietary Supplements

Besides dealing with pathogenic microorganisms and other issues of contamination or adulteration, FDA is responsible for other food and health issues such as nutrition and dietary supplements.

The system of nutritional labeling regulation dramatically changed in the USA with the passage of the Nutrition Labeling and Education Act (NLEA) of 1990, which required standardized nutrition labeling for most foods (except fresh meat and poultry) and authorized the use of nutrient content claims and FDA-approved health claims.

The FDA published final rules in 1992 and 1993, implementing the NLEA provisions. Under these regulations (and under parallel regulations from the

USDA), the food label offers complete, useful and accurate nutrition information about almost every food in the grocery store, in easy-to-read formats to help consumers make healthful food choices.

Among other features, the regulations define certain nutrient claims (such as *light* and *good source*) and list acceptable health claims about relationships between a nutrient or food and the risk of a disease or health-related condition. Some acceptable relationships are: calcium and osteoporosis, fat and cancer, saturated fat and cholesterol and coronary heart disease, sodium and hypertension, and folic acid and neural tube defects.

For dietary supplements, the framework for FDA regulation is set forth in the 1994 Dietary Supplement Health and Education Act (DSHEA). (Under DSHEA's definition, the term 'dietary supplement' includes, with some exceptions, products intended for ingestion as supplements to the diet. This includes vitamins; minerals; herbs, botanicals, and other plant-derived substances; and amino acids and concentrates, metabolites, constituents and extracts of these substances.)

Under DSHEA, FDA approval of supplement ingredients and products is not required before marketing, a feature that clearly distinguishes supplement regulation from the agency's regulation of other products such as drugs and many additives used in conventional foods. Manufacturers are responsible for ensuring that the ingredients are safe and that the ingredient list is accurate.

Dietary supplements may carry certain claims on their labels – for example, certain nutrient content claims like 'good source' or 'high' are allowed if the product meets the definition, as are FDA-approved health claims.

Under DSHEA, too, once a dietary supplement is marketed, FDA has the responsibility to prove that the supplement is unsafe before it can take action to restrict the product's use. FDA focuses its resources based on risk, so food products associated with public health emergencies are assigned the highest priority, followed by products that may have caused injury or illness. Then, products thought to be fraudulent or otherwise in violation of the law are analyzed.

Information Exchange: Stakeholder Input, Education

FDA strives to get broad input into its decisions, through public meetings, advisory committees, and other sources. By providing the opportunity for exchange of ideas and opinions between FDA and the public, including consumers, patients, health professionals, and the regulated industry, the agency is aided in reaching the best policy decisions.

Chartered advisory committees, such as the National Advisory Committee on Microbiological Criteria for Foods, the FDA Science Board, and CFSAN's Food Advisory Committee, play an important role in providing scientific advice. Internationally, FDA participates in Codex Alimentarius, in expert consultations, and on committees of the World Health Organization and Food and Agricultural Organization, to name a few.

In addition to the agency's notice-and-comment rulemaking process, supplementary outreach efforts are sometimes necessary to achieve optimal industry compliance. The following examples illustrate the types of outreach the agency engages in to inform audiences.

FDA's response to several sprout-associated foodborne illness outbreaks can serve as an example of how the agency reaches out to educate different groups on their respective food safety roles. Following the outbreaks in the late 1990s, FDA issued two guidance documents advising sprout growers and seed suppliers of steps to reduce microbial contamination: *Reducing Microbial Food Safety Hazards for Sprouted Seeds and Sampling* and *Microbial Testing of Spent Irrigation Water During Sprout Production*. In addition, FDA and the California Department of Health Services produced an educational video on good agricultural and manufacturing practices for sprout producers. Also, to educate the general public on ways to protect themselves from falling ill from sprouts, FDA issued advisories directly to consumers on the potential hazards associated with eating raw sprouts.

To disseminate food-safety messages effectively to various audiences, including consumers and food producers and preparers, FDA participates in the Partnership for Food Safety Education, which includes representatives from several government agencies as well as from industry and consumer organizations.

For several years, the Partnership has been undertaking a *Fight Bac* (Fight Bacteria) campaign to educate consumers on four simple principles of preventing food contamination while preparing food at home: clean, chill, cook, and combat cross-contamination. Major corporations have included the 'Bac' character and the food-safety messages in their national consumer-education initiatives.

To improve outbreak detection and response when outbreaks *do* occur, FDA has developed training courses. For example, FDA's satellite courses on food microbiology, foodborne disease epidemiology, and traceback in outbreak investigations have been

attended by thousands of government and industry representatives from around the country. FDA has also conducted presentations at numerous conferences in the USA, Mexico, and Latin America on how to conduct tracebacks to determine the source of an outbreak.

But these examples are a selection of food-safety efforts undertaken by FDA and its food-safety partners. Perhaps the most comprehensive information on food-safety efforts in the USA and FDA's food science and nutrition roles is available on the internet – at FDA's website, www.fda.gov, and the joint federal food-safety website, www.foodsafety.gov.

Efforts Paying Off

Educational efforts and other food-safety programs have reaped dramatic rewards in terms of improved food-safety practices, as evidenced by recent CDC and FDA data. CDC data suggest that there was a 21% decline in foodborne illness in the USA from the year 1996 to 1999. This trend continued in 2000 and 2001.

According to two recent phone-tracking surveys, the incidence of the risky practice of eating raw foods was significantly reduced in 1998 from 1993 numbers – down 33% for pink hamburger, 39% for raw oysters and clams, and 29% for raw egg-containing foods. The surveys showed similarly encouraging improvements in consumer behavior in terms of washing hands and cutting boards to prevent cross-contamination between raw and other food.

Despite the apparent effectiveness of steps to reduce foodborne illness in the USA, food-related hazards may never be eliminated altogether, and so far remain a significant threat to the public health. In an effort to extend the downward trend in foodborne illness, FDA must keep up with changes in the science and technology used in agency-regulated products, in the ways in which consumers obtain information about products, in consumer demographics and consumption habits, and in the composition of global trade and production.

By remaining on the cutting edge of science and by staying true to the tradition of science-based regulatory decision-making initiated by Wiley a century ago, FDA can ensure that its regulatory decisions are made in the best interests of the public health, while at the same time not unduly stifling industry innovation.

FOOD COMPOSITION TABLES

D A T Southgate, Norwich, Norfolk, UK

Introduction

Knowledge of the composition of foods is essential for the dietary management of patients and for most quantitative research on human nutrition. This information has traditionally been provided by tables of food composition and over the last 20 or so years, increasingly by computerized nutritional databases. The principal features of food composition tables and nutritional databases are very similar, and in this article, compilations will be used to describe both printed tables and computerized databases, and only when the comments relate to one of the types specifically will they be distinguished.

These compilations of the nutritional composition of foods are principally used for estimating the nutritional composition of diets from measurements of food consumption, constructing diets in clinical nutrition, and designing rations and menus. Data on the composition of foods from these compilations are also widely used in nutritional surveillance and in assessments of the adequacy of food supplies and as authoritative sources for nutritional labeling. Compositional data are also widely used in nutrition education and the development of nutritional guidance for public health guidance.

General Description

Food compositional tables and nutritional databases share many common features. Initially, the databases were prepared from the printed tables, but now, the compilation processes are based on computerized systems that form the starting point for preparing the printed tables, often in different formats for different types of use.

The basic format is a matrix of food items against nutrient data. The formats of printed tables are constrained by the dimensions of the printed page and the size of the tables as a whole. Two formats are used, one where the values for a number of foods and nutrients are given on a single page (or a sequence of pages) and a second, where the values for one food are given per page. Databases are most frequently presented as a food/nutrient matrix, the dimensions of which are constrained only by the database management system being used.

Introductory Text

Food composition tables have an introductory text. In databases, this forms part of the documentation of the database and may be available on line or provided as hard copy. These provide the user with the rationale adopted by the compilers in selecting the food items that are included and the range of nutrients and other constituents for which values are given. The definitions of the constituents included describe the modes of expression adopted and the analytical methods that were used to obtain the values. In most cases, the values will be derived by a combination of analytical values measured specifically for the compilation and others obtained from the literature, including other databases, and the text will document the sources.

Coverage of Foods

Most human diets include a very wide range of foods, especially cooked dishes made up from a number of ingredients. Most compilers of nutritional data work within limited budgets, and therefore, the number of food items in all compilations is restricted. The primary objective of all compilers is to present compositional values that are representative for the food items consumed by the population for which the compilation is prepared.

In a national database, priority is given to those foods that form the major part of the food intake of the population. These have been identified using national data on food consumption and a range of other information from market surveys, information on food purchasing patterns, and data from the food industry. The foods consumed by specific groups such as infant formulas, which provide all the dietary intake of young infants, are also included. The compilations often include the foods eaten by ethnic groups within the population and those with different dietary patterns. Many compilations also include food items whose composition can be seen as examples of different types of food. Most national compilations do not provide information on the composition of specific brands of foods, unless the brand name is critical for identifying the food or, more rarely, the brand is a very important brand leader.

Food Groups

The foods are usually arranged in food groups that bring together foods related to one another. Subgroups are often used within these major groupings, but this varies from compilation to compilation. Table 1 gives two widely used groupings. The groups used by the Food and Agricultural Organization (FAO) of the UN are linked to those use in classifying foods in commerce and are widely used in tables prepared for regional use.

Food Identification and Nomenclature

Most compilations assign a code number to every food item. These numbers are widely used when calculations of nutrient intakes are being made when the numbers are added to the food intake records to facilitate entry into the database calculations. Systems of numbering have been developed for assigning numbers that classify and identify the food for international use. These coding systems are used in some national compilations, but not universally.

Food names These are given in a formalized way and include descriptors as facets, which further serve to identify the foods. Unequivocal identification of a food item and relating it with its composition are very important for the users of nutritional databases. These naming facets include details of the way in which a foodstuff has been cooked or prepared for consumption. Even within one country, the naming of

Table 1 Examples of major food groups in nutritional compilations

Groups used in FAO tables	*Groups used in UK tables*
Cereals and grain products	Cereals and cereal products
Starchy roots, tubers, and fruits	(Included within vegetables)
Grain legumes and legume products	(Included within vegetables)
Nuts and seeds	Nuts
Vegetables and vegetable products	Vegetables
Fruits	Fruits
Sugars and syrups	Sugars, preserves, and confectionery
Meat, poultry, and game	Meat and meat products
Eggs	Eggs
Fish and shellfish	Fish and fish products
Milk and milk products	Milk and milk products
Oils and fats	Oils and fats
Beverages	Beverages
	Alcoholic beverages
Miscellaneous	Miscellaneous
The FAO database is most widely used for measurements of food purchases and includes mainly raw foods. The groupings are linked to classes of foods used to categorize economic aspects of food production and consumption	The UK database is widely used for studies of individual food intakes and therefore includes many cooked dishes within the food group that appears most appropriate

foods is not uniform, and the same food may be known by different names and vice versa. Most compilations include a thesaurus giving these alternative names and frequently include a list of the scientific (taxonomic) names for those foods for which this is appropriate.

Descriptions of samples analyzed These give the sources and numbers of samples on which the data are based. Most compilations give the nutrient values on the basis of the edible portion, and these descriptions include details of how the edible material was prepared and the nature of the inedible matter removed. Many compilations include a factor to convert the values on the edible portion back to a value on a raw or 'as purchased' basis. This information is used to give an indication of the reliability and quality of the nutritional compositional values.

Coverage of Constituents

Most compilations include a reasonably comprehensive range of nutrients, but the growth of nutritional research interests in the role of other biologically active constituents is increasing pressures for extending the number of constituents to include these 'nonnutrients.' The coverage is usually determined by the most demanding of the users, which tend to be nutritional epidemiologists and nutritional researchers. The typical coverage in a nutritional compilation is given in Table 2.

The inclusion of a constituent is conditional on there being a satisfactory method for analyzing the nutrient and the existence of a sufficient body of information on the amounts of the nutrient in a range of foods to assess its inherent variability. This latter factor will determine whether or not it is possible to provide representative data for the nutrient in a range of foods. Some data for nutrients (or other constituents) may only be available for a limited number of foods, and in some cases, the distribution of a nutrient is limited, and many compilations include subsidiary tables giving this more limited coverage.

Expression of Nutrient Values

The nutrient values are usually given per 100 g of edible matter, and the international preference is for the nutrient to be given in weight terms. A number of values given in the compilations are derived values.

Derived values Energy values are for metabolizable energy (energy that can be used by the body) and are calculated from the protein, fat, carbohydrates, and alcohol in foods using energy conversion factors. The most commonly used are those of Atwater, in which protein is assigned, $4\,\mathrm{kcal\,g^{-1}}$ ($16\,\mathrm{kJ\,g^{-1}}$), fat, $9\,\mathrm{kcal\,g^{-1}}$ ($37\,\mathrm{kJ\,g^{-1}}$), carbohydrates (total by difference), $4\,\mathrm{kcal\,g^{-1}}$ ($16\,\mathrm{kJ\,g^{-1}}$) and alcohol, $7\,\mathrm{kcal\,g^{-1}}$ ($29\,\mathrm{kJ\,g^{-1}}$).

In the UK and some other compilations, a modified system is used where carbohydrates (as monosaccharides) are assigned $3.75\,\mathrm{kcal\,g^{-1}}$ ($15\,\mathrm{kJ\,g^{-1}}$). Some compilations, the US for example, use 'Specific Factors' that are designed to allow for the differences in the heats of combustion of different food components and differing digestibilities.

Most compilations discount the small amounts of metabolizable energy derived from dietary fiber from the short-chain fatty acids produced by its

Table 2 Coverage of nutrients in nutritional compilations

Constituent	*Mode of expression*	*Coverage*	*Comments*
Water		Most	
Total nitrogen		Many	
Protein	Calculated from total nitrogen	All	Some use common 6.25 factor; others use specific factors for different food groups
Amino acids	mg per amino acid per gram of N or mg per 100 g of food	Usually in subsidiary tables	
Fat, total		All	
Fatty acids	Fatty acid % total fatty acids or g per 100 g of food	Usually in subsidiary tables	Compilations may include amounts of saturated, monounsaturated and polyunsaturated acids
Carbohydrates total	Often 'by difference' or by summation of sugars and starches	All	Summation is the preferred approach
Sugars	May be expressed as the monosaccharides	Total values in many	Individual sugars given in a few databases
Starches	May be expressed as glucose or as the polymer	Many	
Nonstarch polysaccharides (NSP)	Usually expressed as polymers	Limited	
Dietary fiber	NSP in UK; total dietary fiber values in US and many other compilations	Most	Data rather limited; some older compilations give 'crude fiber' values
Alcohol	g per 100 g or per 100 ml		May be restricted to relevant foods
Energy value	kcal or kJ, calculated from protein, fat, carbohydrate, and alcohol		Choice of conversion factors differs between databases
Inorganic nutrients			
Na, K, Ca, Mg, P, Cl	Usually mg per 100 g	Most	
Cu, Fe, Zn		Most	
F, I, Se, etc.	μg per 100 g of food	Limited	
Vitamins			
Fat-soluble			
A	Retinol μg per 100 g	Most	
D	Cholecalciferol μg per 100 g		
E	α-Tocopherol mg per 100 g		
Carotenes	μg per 100 g β-carotene or retinol equivalents	Most	Few give values for different carotenoids
Vitamin K	Phylloquinone	Limited	
Water-soluble			
Vitamin C	Usually as mg per 100 g	Most	
Thiamin			
Riboflavin			
Niacin			
Vitamin B_6		Limited	Few give values for vitamers
Folates	μg per 100 g	Many	Mostly total values
Vitamin B_{12}	μg per 100 g of food	Most	
Pantothenic acid	Usually mg per 100 g of food	Limited	
Biotin			
Other constituents			
Cholesterol	mg per 100 g of food	Many	
Phytic acid	mg per 100 g of food	Limited usually in supplementary tables	
Purines	mg per 100 g of food	Very few	

fermentation in the large intestine. Similarly, the energy contributed by organic acids is discounted.

Protein values are calculated from the total nitrogen values using conversion factors, which allow for the different amounts of nitrogen in proteins from different sources.

These conversion systems are described in the introductory documentation.

Modes of expression of vitamins Most vitamins are expressed on a weight basis, except where there are several vitamers with differing activities when many

compilations use a mode of expression designed to give the vitamin equivalence.

Vitamin A activity is contributed by retional (preformed vitamin A) and the provitamin A carotenoids. The values may be given as retinol equivalents (μg RE); β-carotene is usually divided by 6, and other carotenoids are usually divided by 12 to give retinol equivalents. These conversion factors are currently the subject of scientific debate at the present time, and expression of the carotenoids on a weight basis is preferred.

Some compilations give vitamin E values as milligrams of α-tocopherol equivalents calculated from the biological equivalence of the different tocopherols and tocotrienols.

Many compilations include a value for niacin equivalents, where the tryptophan content (mg) is divided by 60 and added to the niacin value.

Amino acids and fatty acids Amino acid composition may be expressed in one of two ways: either as milligrams of amino acid per gram of total nitrogen or milligrams of amino acid per 100 g of food. Fatty acids may be expressed as fatty acid percent of total fatty acids or milligrams of fatty acid per 100 g of food.

Compilation of Nutritional Data

As mention before, the compilation of food composition tables and nutritional databases follow similar principles. The compilers are faced with three major decisions: the choice of food items to include, the choice of constituents, and how to source the data.

Because the compilations are essential tools to be used, these decisions are taken in consultation with the range of users of the nutritional data. Analogously, decisions about the format of both tables and databases are based on how the data will be used and software developed to meet the users' requirements. This is usually done by forming a steering group to guide the compilers in their work. This group meets regularly during the progress of the work to monitor progress.

Choice of Food Items

Decisions in this area are the most difficult for the compiler because of the very wide range of foods eaten in the human diet. Users want as complete coverage as possible, and many would like the inclusion of branded foods. Complete coverage of the range of foods on sale in a developed country would require a database with tens of thousands of food items. Furthermore, complete coverage of all the foods consumed, which in the main consist of complex, mixed, cooked dishes, expands this number possibly by two orders of magnitude. All compilers therefore have to consider the priorities for inclusion of food items very critically. The priorities for inclusion are to give coverage of the most important foods for the population for which the compilation is intended and the inclusion of foods important in the diets of specific groups such as infants, ethnic groups, and other groups whose dietary patterns differ from that of the population as an whole.

The compilers have to develop the systems of nomenclature used and decide on the descriptions of the food items in consultation with the users.

Selection of Nutrients

This is usually a slightly easier task because the numbers of nutrients are finite. The number of biologically activity constituents in plants, where there is growing research interest, is extremely high. The compilers must be satisfied that reliable analytical methods exist, and the variation in composition of a single food is not too great to prejudice the provision of representative data.

Sources of Compositional Data

Compilers have two major sources of data. First, data that are obtained specifically for the inclusion in the compilation, which has been called the 'direct method.' This involves the development of sampling and analytical programs for obtaining the data. This approach has the advantage in that the compilers have control over the sampling protocols to insure the identity of the food and to ensure that the sample is representative. They can also control the choice of analytical methods and the quality-assurance schemes in operation in the analytical laboratory. The compilers are thus completely familiar with the provenance and quality of the data. This approach is, however, rather expensive. It can also be argued that this approach discounts the large amount of information available on the composition of foods in the scientific and other literature.

Second, the 'Indirect method.' In this, the literature on the composition of foods is searched for suitable data. This approach involves the compilers in making judgements about the applicability of the samples analyzed, their identity, and whether or not the sampling protocol ensured that a representative sample was analyzed. Judgements also need to be made about the choice of analytical methods and the control of their execution. The modes of expression of data may also need to be converted into that which will be used in the database. This approach requires the compilers to make judgements about the data they select from

the literature, and the assessment process is often demanding and time-consuming. In practice, most national compilations are based on a combination of the two approaches with literature searching typically forming the first stage in the data-compilation process. This is followed by the design of sampling and analytical protocols whenever the literature data are judged to be inappropriate for use, or the search shows that few or no data exist for a food item, which for other reasons, is required in the database.

Using Food-composition Data

The uses of databases can be considered to be of three major types: nutritional analyses, where the database is used to calculate nutrient intakes from records of food consumption; nutritional synthesis, where the database is used in calculations to generate diets with specific nutrient contents; and as a primary source of compositional information.

Nutritional Analyses

In these, the calculations may be based on food consumption measured at many different levels. These levels have important implications for the compilers because they set the requirements for compositional information appropriate to the level of measurement. These are summarized in Table 3.

Food-supplies level Governments and international agencies use measurements at this level for assessing the nutritional adequacy of food supplies. The food-balance sheets of the Food and Agricultural Organization of the United Nations are one important example of this level of use, which uses a special compilation that gives the composition of raw food at the wholesale level; e.g., the composition of bulk cereals and animal carcasses. Many national compilations also include values for this type of data.

Food-purchases level These measurements here are of two types; household budget studies, usually undertaken primarily for economic reasons where food consumption is derived from records of household purchases in monetary terms, and Food Surveys, where the amounts of food purchased by a household are measured, of which the UK National Food Survey is an example. Both these types of use require data for the composition of foods 'as purchased.' Household budgetary surveys also require information on retail prices to convert monetary expenditure into quantities of food.

Individual food-intake level These use records of food consumption by individuals either in a weighed intake study or, retrospectively, where the amounts of food consumed are obtained by dietary recall or a food-frequency questionnaire. These types of study provide the most detailed records of foods consumed and have the most demanding requirements for the inclusion of food items in a database because the records include specific branded foods and, more importantly, cooked mixed dishes, that is foods 'as consumed.'

Nutritional Synthesis

The compilations are widely used by dieticians and other health care professionals to calculate diets that will provide specific amounts of nutrients, for example, low-energy diets for the obese, controlled energy, carbohydrate and fats for the diabetic patient, and low-sodium diets in hypertension. This type of calculation requires the database to contain the range of food likely to be eaten by the patients in question, but the quantitative requirements may not be very demanding. Where, for example, in metabolic studies, diets with very precise composition are required, analyses of the foods are necessary.

At the present time, most of these diets are formulated by manual calculation from the database, but nutritional syntheses programs, which include individual food preferences, are becoming available to computerize the calculation.

Table 3 Requirements for food items and nutrients at different levels of data usage

Level of use	*Food items*	*Nutrients*	*General features of compilations*
Food supplies	Foods measured at raw, bulk or commodity level	Usually restricted to macronutrients and energy	Relatively small database is required
Food purchases			
Household budget surveys	Foods as purchased, retail raw, prices	Macronutrients, major inorganic nutrients and vitamins	Information needed on losses of food during preparation
Food-consumption surveys	Foods as purchased retail or obtained raw	Macronutrients, major micronutrients	Information needed on losses of food during preparation
Individual food intakes	Foods as consumed, cooked including mixed dishes	Comprehensive coverage of macro- and micronutrients	Requirements may extend to very detailed coverage of constituents

Sources of Compositional Information

In addition to their use in providing compositional data for guiding food choices for health reasons, nutritional databases are now widely used in nutritional labeling, where it forms part of food regulation. In most countries, where nutritional labeling is required (or permitted), the data taken from an authoritative nutritional database are permitted. The food manufacturer or distributor is thus relieved from carrying out analyses on their products. The regulations have the requirement that the item in the database must correspond to the food being labeled; generic labeling of foods such as meats, fruits, and vegetables is often permitted.

In the USA, the nutritional labeling regulations require manufacturers to carry out their own analyses, using specified methods defined by the Association of Official Analytical Chemists, and also specifies that the sample shall be representative of production within certain limits. This has provided the US National Database with a great deal of manufacturers' data on branded foods. The UK database also uses some manufacturers' data where the requirements about choice of analytical method and that the sampling was representative can be met.

Accuracy in Use

Judgements in this area depend on the use that is being made of the compilation.

Many users of nutritional databases require a semiquantitative guide in order to give general dietetic advice, but some dietetic uses are more critical, for example, in formulating diets for diabetics and low-sodium diets in hypertension; even so, the accuracy required is not as demanding as for those who conduct nutritional analyses with the database in which nutrient intakes are calculated from records of food intakes.

Relatively few large formal studies have been undertaken, but these show that the calculated values for energy, protein, fat, and available carbohydrates (sugars and starch), are usually within a few percent of the analyzed values. The calculated values for potassium, calcium, phosphorus, and magnesium show a similar agreement. Analytical values for sodium are often in excess of calculated estimates because of the addition of salt in cooking, and analytical values for iron are similarly slightly higher, possibly because of iron contamination. Those nutrients for which natural variability is high tend to be the more difficult to predict with accuracy. Thus, the micronutrients are usually predicted with a lower accuracy, say around 10%, except for vitamin C and folates, where the calculated values may be substantial overestimates.

It is important in comparisons of calculated values with analyzed values that the amounts of foods making up the analyzed diets be precisely the same amounts as those used in the calculations; where collections are not supervised closely, the tendency is to undercollect.

Where a compilation is being used as a source of compositional data on a specific food, the accuracy depends on two major factors, first, how closely the food item in the compilation corresponds to the food in question, and second, the natural variability of the food. All users of nutritional data on foods must take into account that foods are biological materials and show natural variations in composition. This is true, even for processed foods that are produced under closely controlled conditions.

Limitations

Many of the limitations have been mentioned briefly in the earlier sections. They can be considered under three headings.

Coverage of Foods

As is clear from the section on Compilation of Nutritional Data, no existing databases are truly comprehensive in the sense of covering all the foods likely to form part of the human diet. The analytical resources required to construct such a comprehensive database are very great indeed, and coverage of all cooked mixed dishes is virtually impossible. Additionally, the production of new food products and the reformulating of existing products are a continuous activity of the food industry. This means that complete coverage of all food items is a practically impossible aim. Users of nutritional compilations therefore have to evolve strategies for dealing with missing foods.

In most cases, choosing a food that is biologically related or similar to the missing food is satisfactory. In the case of cooked dishes, calculation from the recipe using data on the loss of weight on cooking provides an acceptable strategy, but the estimation of vitamin losses in cooking means that the calculated values must be regarded as estimates.

Coverage of Nutrients

Most compilations provide coverage of all the macronutrients and most of the vitamins and major inorganic nutrients. The principal gaps at present are the trace elements for which, despite their nutritional desirability, it is difficult for the compilers to provide representative values for the reasons discussed earlier.

The coverage of the carotenoids in most databases is limited at present, but in the future, one should expect better coverage. The same will be possible for the different folate vitamins, although the analytical methods are possibly less well developed. Many databases give limited coverage of the carbohydrates in foods. Coverage of the nonnutrient biologically active components represents a greater problem because of the great number of potential constituents coupled with the variety of methods, but nutritional research interests in these components should eventually identify the most important constituents to include.

Data Quality

Quality implies fitness for its purpose, so the uses made of databases need to be considered in any discussion of the limitations on the quality of the data in databases.

Most databases give only mean values, and only a few include limited estimates of variation. The accuracy of databases will always be limited by the natural variability in the composition of foods, and this places a limit on the predictive accuracy of any database both for predicting the composition of any one sample of a food and in the calculations made from the database. These limitations decline as the number of food records used in the calculations increases so that, in effect, the foods eaten approach a representative sample size.

The major limitation in producing databases is the documentation of sampling and the analytical methods used, and particularly the use of quality-assurance schemes in analytical laboratories. In many countries, the need for quality assurance schemes in analytical laboratories producing data on food composition, particularly for use in databases, is becoming accepted. Research is needed to develop objective quality-assurance schemes for sampling protocols to ensure that this important aspect of data quality is covered.

However, the quality of the data in most nutritional databases at present is considerably superior to the quality of food-intake data, and this is the major limitation in using nutritional databases to assess nutrient intakes.

Compatibility of Databases

The growth in the study of nutritional epidemiology at the international level has focused special attention on the compatibility of national databases, and in this, data quality is an essential aspect. A number of international initiatives have been undertaken to address these issues of these INFOODS (International Network of Food Data Systems) and FAO have been very prominent, and a number of European activities have been undertaken, including Eurofoods and Cost 99.

FOOD ETHICS

R Early, Harper Adams University College, Newport, UK

Background

Food is necessary to the life of humans, and all human-beings must either work to provide the food they require to live or obtain their food from another person (or organization) who may specialize in the provision of food. When a man[1] works to provide food for himself and his family, independently of others, few ethical issues are found in the way in which he produces food. The way in which animals are kept and slaughtered for food, and the way in which the land and other natural resources are utilized for food production, and maintained for the benefit of future generations, may be the only sources of moral and ethical concern. The situation changes when a man has to obtain food from another person, or an organization established to provide food. In this circumstance, he places himself at risk of exploitation, abuse, and inadvertent and intentional unethical treatment. Examples of food producers intentionally acting against the interests of consumers are found in historical references. Accum and Hassall recorded a variety of unethical food industry practices occuring in nineteenth century Britain, such as the adulteration of tea and coffee with charcoal and the use of red lead to color cheese, and Sinclair chronicled the sorry practices of Chicago's meat-processing industry at the end of the nineteenth century. Both Hassall and Sinclair catalyzed the development of food laws in their respective countries.

Consumers today may believe that the practices of unethical food producers of over a century ago are features of a distant past, but this is not so. The motivation of profit can tempt food businesses to place their interests above those of consumers, with the risk of causing them various forms of harm through immoral and unethical conduct. For instance, false declarations made by food manufacturers or retailers about food products, or the withholding of facts, concern the moral issue of truth-telling. Any intention to mislead consumers amounts to the intention to harm them, and, in this instance, harm may amount to the purposeful erosion of consumers' autonomy. A consumer's consent to enter into a form of contract with a food manufacturer or retailer – as signified by the consumer purchasing a product offered for sale – can be valid only when the consent is competent, informed, and freely given. False declarations and the withholding of facts constitute lying and reduce the consumer's ability to make purchasing decisions that are both competent and informed and, therefore, freely given. Although such conduct on the part of food businesses does not cause physical harm, instances do occur of food businesses knowingly placing consumers at risk of physical harm. During 1999 and 2000 in the UK, cases came to light of food processors 'cleaning up' chicken meat condemned as unfit for human consumption and selling it into food processing and the retail food marketplace. Not surprisingly, this practice contravened the UK's food safety law. Food laws establish boundaries for the conduct of food businesses, and crossing the boundaries entails the risks of social proscription, prosecution and, penalty. In some ways, laws may be considered to define what is ethically acceptable and, certainly, laws may express requirements that relate directly to moral principles. But though laws state requirements for, and set limits on, certain kinds of conduct, what is considered to be morally and ethically defensible ought not to be defined entirely by the law. The process of legislation is subject to bad judgement, political bias, and lobbying by parties intent on protecting their own interests. Laws can be wrong and fail to protect those who ought to be protected. The moral values exercised by food businesses ought to ensure that their conduct reflects what is right, and not just what the law requires.

Generally, consumers can feel secure in the protection afforded by food law, but such are the pressures of the commercial world that the temptation exists constantly for food businesses to engage in behavior that, though within the boundaries set by law, contests the tenets of common morality. The moral character and the conduct of those who challenge moral values and norms, and who may work to stretch the limits of the law without breaking them, will, inevitably, attract moral scrutiny. Those who determinedly break the law and whose conduct is clearly morally indefensible choose to step outside what is acceptable to society, and they are readily recognized as a threat to society. In comparison, those who maintain a sense of moral respectability in order to remain part of society, but whose conduct erodes generally accepted moral values, might be considered a greater threat to the stability of society. Such agents ought to

[1]Use of the term 'man' indicates no gender bias. It is used purely for convenience.

attract greater moral scrutiny than those who are purely dishonest, because their actions may have more far-reaching effects. The modern food industry has created much that is good, and Western consumers today routinely have access to food of a variety, quantity, quality, and safety, unparalleled at any time in the past. By its very nature, the food industry is an agent of social change. It takes and creates opportunities to influence people, and by its conduct, it risks, and may intend, catalyzing social change: consequently, it exists within society as a kind of moral agent. As part of society, the food industry works to maintain respectability within society, but those businesses that constitute the industry may, at times, be tempted by forms of conduct that challenge moral acceptability. Because consumers are becoming increasingly dependent on the industry for their food, and because the industry exercises increasing levels of influence over society, the justification exists to scrutinize the moral values by which the industry operates and the ethical nature of its conduct.

The expression of moral and ethical concern over matters relating to food is not new. Though the term 'food ethics' may have been formally established relatively recently, Zwart suggested that food ethics has a long history. He argues that, while modern food ethics is concerned with food production, historically, it was centered on consumption. Certainly, this resonates with ancient religious moral conventions that prohibit the consumption of certain types of food materials as well as the practices of vegetarians and vegans, whose food choices are often defined by their particular moral values. Today, food ethics is a branch of moral philosophy that encompasses the relationship of people, and society, with food and the food supply system. In wealthy, Western societies, food ethics is concerned mainly with the conduct of the food businesses that make up the food supply system and the methods by which food is produced for, and marketed to, consumers. With the development of the consumer society, *people* have been transformed into *consumers*, whose function is to consume, in accordance with the policies of governments and the strategic plans of businesses. The degree to which people in Western societies have come to rely on food businesses for their food – and survival – has caused, and legitimizes, the development of food ethics as a field of intellectual inquiry. Modern food ethics is a response to the industrialization and commercialization of the food-supply system. Factors such as the increasing utilization of science and technology in food manufacturing and supply, the methods used in food marketing and advertising, and the evolving dynamics a global food marketplace create and energize the food ethics debate. But food ethics does not respond solely to food issues in the developed, Western world. The problems of global food security, and food shortage and malnutrition in developing countries, are primary issues of food ethics, as recognized by the Food and Agriculture Organization (FAO) of the United Nations. The FAO also recognizes the use of biotechnology and genetically modified organisms in the food-supply system as issues of food and agricultural ethics. Food ethics has emerged to guide and inform those who work within the food-supply system, and those with a professional interest in the activities and conduct of the system and the organizations that constitute it.

Morality and Ethics

As human beings, we generally recognize certain moral values and understand that moral principles derived from moral values can act to guide and stabilize the society within which we live, and inform both social and cultural development. The word 'moral' originates from the Latin, *moralis*, while 'ethics' is derived from the Greek, *ethos*. Both words equate to 'custom' and are sometimes used interchangeably, though different meanings can be assigned in relation to the way in which we think about morality and ethical behavior. Often, we consider morality in terms of values, or standards of conduct, that prescribe concepts of what is right and wrong. In contrast, we judge what is ethical in terms of the analysis and assessment of morally acceptable behavior. For instance, an evaluation of the ethical nature of a food business' conduct would lead to a review of the business' moral values as the justification for the conduct. Similarly, though rich nations may recognize their moral duty to help feed poor nations, translation into practice of the moral values that give rise to the notion of duty relies on ethical conduct that ensures the poor are fed. The ethical assessment of conduct enables us to see that moral values and principles exist and have been upheld. Ethics is concerned with the application of moral values and principles and, specifically, with concepts of right and wrong, good and bad, duty, obligation, virtue, freedom, and choice.

People interact with each other at a personal level, and their moral values influence the ethical nature of their conduct. Of particular interest to moral philosophers, since the time of Socrates (*c.* 470–399 BC), has been the question 'How ought we to live?' The question embodies the concern that, for each of us, our lives should be lived as good lives and that the influence we have on other people's lives will then only be good. At its most basic level, ethics is

concerned with our conduct as individuals in relation to other people and, increasingly, in relation to other species and the environment generally. However, the infrastructure of modern society is complex, and though, as private individuals, we may exert some influence on society, the greatest source of influence is often the organizations that operate within society. Yet, organizations are made up by people, but when the conduct of an organization is assessed in terms of its ethical nature, paradoxically, the moral values from which the conduct is derived are judged to belong to the organization, and not the individuals who make up the organization. Any examination of the moral values and ethical conduct of the food industry must concern the businesses that constitute the industry and the executives who lead the businesses. Conduct that is perceived to reflect the moral values of a food business is most likely to be based on the moral values of the executives in charge of the business and, specifically, the chief executive officer.

Ethics is delineated as *metaethics, descriptive ethics*, and *applied ethics*. Metaethics is a form of philosophical inquiry concerned with concepts, beliefs, and meaning. Metaethics seeks to explain what is meant by concepts such as good, bad, right, and wrong in relation to the character or conduct of the moral agent. It is a process of rational inquiry separate from the 'real-world' domain of applied ethics, but has significant bearing on the practice of applied ethics. Descriptive ethics, as the name suggests, is concerned with the study of the belief systems, moral values, and ethical behavior of social groups and organizations. It is observational in method and somewhat disconnected from its subject matter, and so it compares with sociology and anthropology. Applied ethics contrasts with both metaethics and descriptive ethics in that it is concerned with the translation of moral values into ethical practices and the application of ethics to practical problem-solving and decision-making. Food ethics falls within the realm of applied ethics, because it is concerned with the 'real-world' ethics in relation to the operation of the food supply system and the conduct of the food industry.

Many ethical issues exist in relation to the food-supply system and the activities of the food industry. Food businesses must deal with ethical issues in the way in which they operate, e.g., in the sourcing of raw materials from developing countries, in the methods used to gain and hold market share, and in the way in which products are promoted to consumers. Consumers face ethical issues in the way in which the food industry relates to them and, for instance, maintains respect for them. Problem-solving in applied ethics relies on judgements made in relation to facts, and the quality of facts is critical to decision-making that is ethically defensible. Ethical judgements cannot be made in isolation from ethical theory, and an appeal to accepted concepts in moral theory and systems of ethical thinking is usual. Five ethical theories are commonly accepted as approaches to ethical problem-solving and decision-making: the common-good theory; deontological theory; utilitarian theory; the theory of justice; and virtue theory.

The Common-good

Though we exist as individuals with our own desires and goals, we generally recognize that our own good is linked to the good of the community of which we are a part. If we value the community and what it stands for, we must allow that while we may expect others to respect our interests, and in return we may respect theirs, the interests of individuals must not be placed above those of the community as a whole. As individuals, we may strive to achieve our own goals, but collectively, we must also recognize the importance of achieving goals that are shared by, and benefit, the community as a whole. In complex societies, individuals exert only a small influence over the common good compared with governments, institutions, and the organizations that bear upon the social and economic structures of society. Society must place reliance on those in government, for instance, to recognize the common-good as it relates to all people, and to maintain conditions and achieve objectives that are similarly to everyone's advantage. Social and economic policies must be aimed at benefiting all of society equally. Social institutions such as education and public health provision, the legal system, and the police and fire services are all common-goods. Food businesses contribute to the common-good through the provision of food and employment. Sometimes, they become involved with society in ways that appear altruistic and intended to further the common-good, but, we must question the degree to which they are able to place the interests of society above their own interests. A supermarket chain providing computers to schools might appear intent on benefitting the common-good, but such action may, in reality, be self-interested and designed expressly to gain access to children to influence the household food purchasers of the future.

Deontological Theory

The term 'deontological' is derived from the Greek, *deontos*, meaning duty. Deontological theory is concerned with notions of duty, rights, and justice. It proposes that we have a duty to tell the truth, not to harm others, to keep promises and to respect the privacy of others. Consequently, it recognizes the right of others to: know the truth and be informed

of issues that affect them; be protected from any harms that may arise from our actions; receive what has been promised to them in agreements and contracts entered into freely; and be allowed privacy in their personal lives provided their actions do not violate the rights of others. The German philosopher, Immanuel Kant (1724–1804), has had a profound influence on the development of this class of ethical theory. Significantly, his concept of the *Categorical Imperative*, is proposed as a guide to right action. He states that in matters of morality, we should act only in ways that we would want to be universalized, i.e., ways that would be acceptable as the norm, and that we should treat other people as ends-in-themselves and not the means to our ends. In the marketing of 'reduced fat' foods, we often see truth sidelined and weight-conscious consumers made the means to the end of increased sales. Foods marketed with the suggestion that they are healthy, because they have reduced fat levels, often contain substantial amounts of energy from the carbohydrate content: a fact not honestly revealed to consumers.

Utilitarianism

As a *consequentialist* ethical theory, utilitarianism is concerned with the outcomes of actions. Consequentialism takes the position that the value of an action is dependent on the 'good' of the consequences, but the definition of 'good' is dependent on the moral agent and may not be what is commonly agreed to be good. To resolve this difficulty, Jeremy Bentham (1748–1832) defined the 'good' as whatever yields the greatest pleasure and the least pain, and proposed a calculus of utility – hence the name utilitarianism – by which to measure the balance between pleasure and pain. The practical limitations of Bentham's utilitarian calculus led John Stuart Mill (1806–1873) to define the 'good' as happiness. In utilitarian theory, an action is morally right if it results in "*the greatest happiness for the greatest number.*" The conduct of the food industry as a whole appears, on the surface, to accord with notions of utilitarianism. Through the work of the industry, Western consumers are generally able to obtain nutrition of a very high standard, and it would seem that the industry is well disposed to provide for the greatest happiness of the greatest number in matters of food.

Justice

The desires, ambitions, and goals of human beings as individuals can conflict with the good of others and the common-good. Egoism is a form of consequentialism that considers people to be self-interested moral agents who will judge an act to be right if it furthers their own interests, even to the exclusion of others. If it is in their interests, egoists will act with favoritism and discrimination, both of which, by general moral agreement, are regarded to be unfair and unjust. Ideas of justice are central to moral philosophy. Aristotle (384–322 BC) proposed a system of justice and considered that people should be treated equally, unless there is some morally defensible reason to treat them differently. John Rawls has recognized that the stability of a society, or social grouping, depends on the members of the society, or group, feeling they are treated justly. In his book, *A Theory of Justice*, he proposes a *contractarian theory*, whereby social justice can be delivered only by rational agents who have dispensed with particular allegiances and interests, but who retain human needs and dependencies. To enable rational agents to make decisions for the benefit of society without the conflict of self-interest, he creates the metaphor of the 'veil of ignorance,' which shields agents from knowing their role in society. Rawls' ideas on justice, thought of as justice-as-fairness, recognize the difficulty that those in authority have in stepping outside the circle of their own interests to act for the good of others. Accepting that society generates benefits and burdens, he puts forward the 'difference principle' as a moral requirement to ensure that the situation of the least well-off is made as good as it can be, thereby working towards justice-as-fairness. Ensuring that the poor have access to an adequate diet is an issue of justice.

Virtue

A person who is virtuous in the way he lives will be an ethical person. Aristotle's theory of ethics is virtue theory. He considered there are two kinds of virtue: moral virtues or qualities of one's character, and intellectual virtues or qualities of one's mind. Of the moral virtues, he proposed 12, sitting in each case midway between representatives of the vices of excess and deficiency. So, the virtue of courage sits between rashness and cowardice, and the virtue of patience between irascibility and lack of spirit. Of the intellectual virtues, he identified five primary virtues (technical skill, scientific knowledge, prudence, intuition, and wisdom) and four secondary virtues (resourcefulness, understanding, judgement, and cleverness). Today, people who exhibit the virtues of courage, honesty, integrity, fairness, compassion, generosity, fidelity, and self-control are most generally admired, for they are recognized as possessing qualities to which we should all aspire. Though we might believe that virtue is important to society, some food businesses celebrate vices to further their own interests, e.g., wickedness and sin made synonymous with pleasure in chocolate, snack-food, and alcoholic beverage advertisements.

Ethical Decision-making

The resolution of ethical problems will benefit from reference to ethical theories, as well as the ethical principles of respect for autonomy, nonmaleficence, beneficence, and justice. Ethically defensible decision-making must be based on:

- identifying the benefits and harms likely to result from alternative courses of action;
- selecting the course of action likely to yield the best consequences and least harm for those affected;
- maintaining respect for the moral rights of those affected;
- treating everyone equally and justly;
- valuing moral virtues and promoting the common good.

Issues in Food Ethics

A wide variety of food ethics issues exist. Those of growing concern to consumers in the UK have been identified by the Co-operative Wholesale Society, as listed in Table 1. A detailed discussion of issues would be beyond the scope of this article, and the following examples have been selected for illustrative purposes.

Feeding the World's Poor

The United Nations' Universal Declaration of Human Rights states that everyone has the right to a standard of living adequate for the health and well-being of themselves and their family, including food, clothing, housing, etc. The imbalance in the quality and supply of food between the rich and the poor people of the world marks one of the central injustices of our time and a critical issue of food ethics. The lack of food necessary to the health and well-being of the poor is significantly a matter of economics as well as politics, but the degree to which remedies to the problem may be sought depends on the sense of moral duty felt by the rich for the poor. In Western societies, supermarkets exhibit a remarkable array of food products, many of which are unnecessary to either the health or happiness of consumers. With the march of globalization, Western food businesses are increasingly sourcing cheap food products in developing countries to maintain the array of products available in supermarkets and to enhance profitability. The extent to which farmers and growers in developing countries are able to benefit from this global trade is questionable. The growth in 'fair-trade' organizations in response to the development of the global food chain would indicate that justice is not distributed equally throughout the chain. Questions therefore arise about the food industry's recognition of its moral duty to suppliers in developing countries and the ethical nature of the industry's relationships with them.

Table 1 Cooperative wholesale society's 'food crimes'

1. *Blackmail* – ''the insidious targeting of the public by global big business putting huge marketing muscle behind products that fail to fit with healthy eating advice''
2. *Contamination* – ''the unnecessary use of chemicals on land and in livestock – interference with nature's way''
3. *Grievous bodily harm* – ''the disregard of animal rights to keep costs down or, even worse, to pamper our taste buds with so called 'luxuries' ''
4. *Vandalism* – ''the destruction of the planet by the intensification of food production systems''
5. *Cannibalism* – ''the practice of permitting animals to be fed with the remains of their own species, or herbivores with animal by-products, or giving animals feed made from the blood of other animals''
6. *Pillage* – ''the careless exploitation of countries, cultures and creeds by multinational concerns milking the so-called global economy''
7. *Fraud* – ''the deliberate assault on the taste and appearance of our food''

Source: CWS (2000) *The Food Crimes Report*. Manchester, UK: The Co-operative Wholesale Society.

Marketing Food to Children

Given the inequalities of the world's food supply, it is ironic that the public health institutions of many Western societies report increasing levels of disease associated with the overconsumption of food. Fast-foods, convenience foods, snack-foods, and confectionery, as well as carbonated beverages, are placed at the center of concerns over the quality of diets in Western societies. Examination of advertising associated with these product groups shows how much manufacturers and retailers depend on children and young people for their markets. The value of children to some kinds of food businesses is seen in the way in which fast-food organizations operate synergistically with movie companies, such as linking cartoon characters with food products, when conditioning young minds has been set as a marketing priority. Food habits formed during childhood are extremely resistant to modification and change. The 'branding' of children's minds with images of certain kinds of food products to sustain the desire for products throughout life may seem an effective strategy for some food businesses. The practice raises many questions about the moral duty of society to protect children, and about the ethical conduct of the industry in making children the means to its end of profitability.

Consumer Dependency

With the development of the food industry during the last quarter of a century, food and cooking have been

taken out of the kitchen and into factories. Many people today do not learn the skills associated with cooking in the home that were commonly held in the past. Processed and prepared foods are attractive to consumers. Such foods allow consumers to buy time for activities other than cooking. Questions arise about the ability of 'food-ignorant' consumers to manage a balanced diet and any moral responsibility the food industry has for the health and well-being of consumers encouraged into dependence on the industry for their food.

Limits to Added-value Products

Of the problems faced by the food industry, perhaps the greatest is the physical limit on the amount of food a consumer can eat in a day and the consequences this has for the industry's goal of continuous economic growth. The innovation of 'added-value' food products that command higher prices and the creation of a now vast range of such products has generated new areas of profitability. The industry maintains that it only responds to consumer demands. Whether consumers actually demand so many new products that making food choices becomes problematic or whether the industry manipulates consumers using sophisticated marketing techniques to create markets for new products is debatable. In this, there is a possible conflict with the idea that the industry is utilitarian in nature; perhaps, alternatively, it is egoistic, according to the moral values of food-business leaders. This is something of which food ethics may bring a greater understanding.

Conclusion

Numerous questions can be asked about the moral values of the food industry and the ethical nature of its conduct. Food ethics provides a reasoned and structured approach to answering questions and to guiding the conduct of the industry such that it maintains respect for people and a common-good relationship with society. In Western societies, people exist in a state of mutual interdependence with the food industry. People as consumers rely on the industry for their food, and the industry needs people to consume its products to remain in business. The food industry regards people not as individuals but as consumer groups, categorized according to various socio-economic criteria. For society to flourish, people as the individuals who constitute society must also flourish. The food industry has a critical part to play in this, as the products of its endeavors are essential to the life of people. Critically, they are consumed and become part of people, affecting both their health and well-being. The food industry has a moral duty to act at all times for the good of people as individuals, not merely as units of consumption. In this, food ethics is of instrumental value to the industry's decision-making and strategic development, helping to ensure that the basis of its existence is morally sound and its conduct is ethically defensible, for the good of people, society, and the industry itself.

Glossary

Autonomy a person's capacity for self-determination.
Beneficence acting to benefit others.
Consumers people as purchasers and/or users of the products and services provided by industry and commerce.
Food supply system the organization of business entities and their activities operating to bring food and food products to the food marketplace.
Non-maleficence acting so as to cause no harm.
Utility The basic unit of desirability as judged by the agent who desires it.

FOOD FORTIFICATION

M G Venkatesh Mannar, The Micronutrient Initiative, Ottawa, Canada

Synopsis

Vitamins and minerals (commonly termed 'micronutrients') are essential for efficient energy metabolism and other functions of the human body. Food fortification is increasingly recognized as an effective means of delivering micronutrients through commonly consumed foods. Fortification of foods can provide meaningful amounts of the nutrient at normal consumption of the food vehicle. The level of fortification should take into account variations in food consumption to ensure safety for those at the higher end of the scale and impact for those at the lower end. Fortification needs to be supported by adequate food regulations and labeling, quality assurance, and monitoring to ensure compliance and desired impact.

Prevalence and Impact of Micronutrient Deficiencies

Many vitamins and minerals cannot be synthesized by the human body. They must be provided by the diet. They are necessary for the regulatory systems in the body for efficient energy metabolism and for other functions such as cognition, immune system, and reproduction. The amounts needed are small – micrograms or milligrams a day – so they are called 'micro' nutrients (Table 1). When intake of these nutrients is inadequate, individuals and communities suffer serious consequences, including learning disabilities, impaired work capacity, illness, and death. During rapid growth, micronutrient intake must increase or else growth failure or deficiency diseases develop. It is during these periods that deficiency symptoms are most prevalent. For this reason, preschool-aged children, adolescents, and reproductive age women are high-priority groups.

Nearly one in three people living especially in the developing world are affected by one or more micronutrient deficiency. Iron and iodine deficiencies are the most common and widespread nutritional problems. About half the reproductive age women in most of the developing countries suffer from iron-deficiency anemia (IDA). Other high-risk groups include preschool and school-age children and adolescents. Iodine-deficiency disorders affect 20–60% of people in different areas. Vitamin A deficiency (VAD) has been widely recognized, though at a lower clinical prevalence (around 1% in preschool children). However, VAD at a subclinical level (based on serum retinol assays) is thought to be around 10–25%. This is associated with increased mortality and morbidity risk in children and pregnant women. There are other deficiencies that are certainly widespread but far less well recognized, e.g., rickets in young children, associated with calcium and vitamin D deficiency. Dietary intake surveys and limited biochemical indicators show that zinc deficiency is likely as widespread as that of IDA. Selenium and other micronutrients such as folate and vitamin E may have major role in reducing risks of chronic disease (e.g., cancers, heart diseases).

The major cause of micronutrient deficiencies is a lack of adequate intake of bioavailable minerals and vitamins from the diet. This is exacerbated by the fact that commonly consumed foods and beverages (such as rice, wheat, corn, legumes, tea, and coffee) are high in inhibitors and low in enhancers of micronutrient absorption.

Role of Food Fortification

Micronutrient deficiencies can be prevented and even eliminated if populations consume adequate quantities of the required micronutrients on a continuous and ongoing basis. In addressing micronutrient malnutrition in a country, a combination of interventions involving promotion of a well-balanced diet, improving food availability and micronutrient bioavailability, and increasing food consumption, food fortification, and pharmaceutical supplementation need to be emphasized and implemented in a complementary manner. Among these options, food fortification could play an important role to meet a demonstrable need for a nutrient in the population apparent from dietary, biochemical, or clinical evidence.

Fortification is therefore one part of a range of measures that influence the quality of food that include improved agricultural practices, improved food processing, and storage and consumer education to adopt good food-preparation practices. The role of foods and specific nutrients and nonnutrients in providing beneficial nutritional and physiological effects is also gaining attention. As consumer interest in the link between diet and health increases, there are many

opportunities for developing foods that can have positive effects on health and performance.

Food fortification involves the identification of commonly eaten foods that can act as vehicles for one or more micronutrients and lend themselves to centralized processing on an economical scale.

The Codex Alimentarius provides definitions for terminology relating to the addition of nutrients to foods. Fortification or enrichment means the addition of one or more essential nutrients to a food, whether or not it is normally contained in the food for the purpose of preventing or correcting a demonstrated deficiency of one or more nutrients in the population or specific population groups. Restoration refers to compensation for unavoidable nutrient losses during the course of good manufacturing practice in the preparation and preservation of food or during normal storage and handling procedures. In many countries, there are requirements for the compulsory addition of micronutrients such as iron, niacin, and thiamine to bread and flour.

Fortification, when imposed on existing food patterns, does not necessitate changes in the customary diet of the population and does not call for individual compliance. Often, it can be dovetailed into existing food production and distribution systems. For these reasons, fortification can often be implemented and yield results within 2–3 years and be sustained over a long period of time. It can thus be the most cost-effective means of overcoming micronutrient malnutrition.

Effectiveness of Fortification

The concept of nutrient fortification of staple foods was developed in the early part of this century as a means of dealing with micronutrient and vitamin deficiency diseases that were prevalent in Europe and North America. Salt was iodized in Switzerland in the early part of the century. Margarine fortified with vitamin A was introduced in Denmark in 1918. During the 1930s and 1940s, milk was fortified with vitamin A, and flour was fortified with iron and B vitamins in a number of European countries and in North America. In developed countries, where there is a high dependence on processed foods, and industries are streamlined and automated, food fortification has played a major role in the health of the populations at large over the last 40 years, and several nutritional deficiencies have been eliminated. In addition to the virtual elimination of VAD and iodine deficiency disorders (IDD) and the substantial reduction of IDA, diseases as varied as xerophthalmia, pellagra, beriberi, rickets, goiter, and ariboflavinosis have essentially disappeared. Several studies have demonstrated the effectiveness of food fortification in eliminating micronutrient deficiencies. The current low levels of iron deficiency in the USA are attributable to fortified sources. Almost a quarter of iron intake in the US diet comes from fortified sources, much of that from flour products. In Canada, flour fortification with B vitamins began in Newfoundland in 1944. Within four years, deficiencies that were earlier found in nearly 20% of the population had dropped to negligible levels.

In the developing world, there has been a rapid growth in fortifying a wide range of foods. The most successful global fortification experience is the fortification of salt with iodine. Fortification of other staple foods such as flour, oils, sugar, condiments, dairy products, and a range of processed foods with other micronutrients and vitamins are also increasing. In Latin America, flour fortification is reaching significant numbers of people, and sugar fortification has taken hold in Central America. In Asia, the overall reach of fortified foods and its impact in eliminating micronutrient malnutrition is still small, but growing.

In the last decade, the contribution of salt fortification towards the virtual elimination of IDD in developing countries has been substantial. In most nations where IDD was recognized as a public health problem at the beginning of this decade, an average of 60–70% of all salt for human and animal use is now iodized. The stage is set for the global elimination of iodine deficiency disorders globally by 2005.

Food fortification has also played a major role in substantially reducing vitamin A and iron deficiencies. A national sugar fortification program in Guatemala has virtually eliminated VAD as a public health problem. Flour fortification in Chile and Venezuela are substantially improving iron status across all sectors of the population. Today, in Latin America, Asia, and Africa, consumers of fortified products as varied as margarine, milk, noodles, and cornstarch are substantially protected from a range of micronutrient deficiencies.

Food fortification has to be an integral component of the overall strategy to eliminate micronutrient malnutrition. It involves opening new communication channels among the public health community, research institutions, government regulators, food companies, and a variety of civic and consumer organizations. The inputs from these groups could result in a new alliance focused on accomplishing national development through elimination of micronutrient malnutrition. Food fortification should also be the preferred option to reach preschoolers and primary graders.

Considerations for Planning a Food Fortification Intervention

Food fortification involves the identification of commonly eaten foods in a country or region that can act as vehicles for one or more micronutrients and lend themselves to centralized processing on an economical scale. In developed countries, a range of cereals and cereal products, dairy products, processed foods and beverages are fortified. In most developing countries, staple foods and condiments are the obvious choice for fortification, given their consistent consumption by large sections of the population. In such situations, the choice of vehicles at the present time is limited to a handful of foods and condiments: cereals, oils and fats, sugar, salt, and sauces.

Fortification of foods is aimed to provide meaningful levels of the nutrient at normal consumption of the food vehicle. Variations in food consumption may affect the safety of those at the higher end of the scale and the level of impact for those at the lower end. They should also consider prorated intakes by young children to ensure efficacious and safe dosages. Food fortification also requires careful attention to food regulations and labeling, and a careful assessment of the technical and analytical limitations for compliance with label declarations. The Codex Alimentarius has adopted a number of basic principles set out in Table 2 for the addition of nutrients to foods.

Infants and children under the age of 24 months consume a different dietary pattern than do older individuals. There are no major differences in consumption among children aged 2 years and older. Where there are few centrally processed complementary foods, and consumption of such foods is infrequent and rare, careful research is needed on the best ways to address micronutrient problems of infants.

Key considerations for planning and implementing food fortification programs in countries are discussed below.

Selection of Food Vehicles

The selection of a suitable vehicle and a fortificant that deliver the micronutrient in the right amounts consistent to an entire population is extremely rare. Salt iodization is one example of successful large-scale fortification in the developing world – the primary reason being the simple and low-cost technology and the narrow variation in salt consumption within a given region or population. There exist other opportunities for single and multiple fortification of several commonly eaten foods such as wheat and wheat products, corn, rice, milk and milk products, cooking oils, sugar, and condiments. As processed foods gain popularity in the developing world, with an increasing market outreach, they offer new channels for micronutrient delivery. The decision to use a particular food or beverage must be based on scientific data. Well-designed market research, which includes dietary surveys and habits and practices, should be used as a tool in identifying the commonly consumed foods and beverages.

Potential food vehicles could be visualized as a three-tiered pyramid (Figure 1). Staple foods such as sugar, cereals, grains, fats, and oils form the base; basic foods such as breads and biscuits, packaged cereals and flours, and dairy products are in the middle; and value-added foods such as condiments, snacks, candies, convenience and ready-to-eat foods are at the top. Fortifying less expensive staple foods at the base of the pyramid results in broader dissemination of micronutrients throughout the population. Also, since basic and value-added foods are processed

Table 2 General principles for the addition of nutrients to foods

1. The essential nutrient should be present at a level that will not result in either an excessive or an insignificant intake of the added essential nutrient considering amounts from other sources in the diet
2. The addition of an essential nutrient to a food should not result in an adverse effect on the metabolism of any other nutrient.
3. The essential nutrient should be sufficiently stable in the food under customary conditions of packaging, storage, distribution, and use.
4. The essential nutrient should be biologically available from the food.
5. The essential nutrient should not impart undesirable characteristics to the food (e.g., color, taste, flavor, texture, cooking properties) and should not unduly shorten the shelf-life.
6. Technology and processing facilities should be available to permit the addition of the essential nutrient in a satisfactory manner.
7. Addition of essential nutrients to foods should not be used to mislead or deceive the consumer as to the nutritional merit of the food.
8. The additional cost should be reasonable for the intended consumer.
9. Methods of measuring, controlling and/or enforcing the levels of added essential nutrients in foods should be available.
10. When provision is made in food standards, regulations, or guidelines for the addition of essential nutrients to foods, specific provisions should include identifying the essential nutrients to be considered or to be required and the levels at which they should be present in the food to achieve their intended purpose

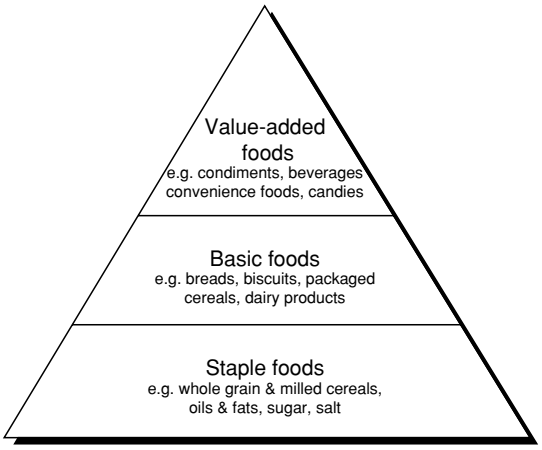

Figure 1 Food-product pyramid.

from staple commodities, fortifying foods at the base of the pyramid results in fortifying products throughout the food chain.

In many countries, a flexible approach using a variety of vehicles each fortified to a specified proportion of recommended dietary intake (RDI) may offer an effective option. If consumption of a particular vehicle is consistent in some groups but only sporadic in others, fortifying several vehicles will likely provide complementary coverage. When considering a multifaceted approach, each food vehicle offers specific opportunities and constraints:

Cereals Cereal grain products such as rice, corn, and wheat flour constitute an important calorie and protein source for many populations. They have proven to be good vehicles in several developed and developing countries, but their application may be limited where cereals foods are often eaten where they are grown and processed at the community level.

Fat and oils Cooking fats and oils may offer an option to deliver a portion of the recommended dietary allowance (RDA), particularly the fat-soluble vitamins such as vitamin A. They have an advantage in that they are often centrally refined and packed.

Dairy products Milk may offer an option where centralized dairy processing exists.

Condiments Sugar, spices, starches and sauces are attractive carriers. Some are processed centrally and consumed in regular quantities.

Value-added products In developed countries such as the USA, fortification of snack foods has been recommended as an appropriate public health measure, given the increasing percentage of dietary energy that the population derives from snack foods. In developing countries, the most vulnerable populations consume these higher-priced products only sporadically. However, consumer awareness, technical breakthroughs, and marketing innovations often emerge from the development of fortified value-added products.

When no universally consumed vehicle is available in a country, the fortification of a number of foods offers several key strategic advantages. When a variety of food sectors are engaged, no single industry can claim unfair treatment. When a variety of foods are fortified, each with a lesser proportion of RDI, the theoretical possibility of consuming dangerous levels of a micronutrient through excess consumption of a single food becomes more remote.

Technologies

Depending on the manner in which foods are processed, different methods for addition of micronutrients have been developed:

- *Dry mixing* for cereal flours and their products, powder milk, powder beverages.
- *Dissolution in water* for liquid milk, drinks, fruit juices and in the water to be used for making bread pastas cookies.
- *Spraying* as in iodization of salt and cornflakes, where the vitamins do not support the cooking or extrusion step.
- *Dissolution in oil* for the lipo-soluble vitamins for enrichment of oily products like margarine.
- *Adhesion* for sugar fortification where the vitamin A in powder form is adhered to the crystals surface by a vegetable oil.
- *Coating* as in rice where the vitamins sprayed over the grain must be coated in order to avoid the losses when washing the grains before cooking.
- *Extrusion* of a blend of rice flour with micronutrients and stabilizers to provide a premix grains that can be blended with rice after milling.

Research and development efforts have enhanced effectiveness of fortification technology. Better refining procedures and packaging have significantly improved the stability of iodine compounds in salt. In the case of iron, stabilizers and absorption enhancers are added along with the fortificant to retain it in an absorbable form or improve absorption. The structure of the iron or iron compounds has been modified to improve absorption. In the case of vitamin A, work is ongoing to retard the loss of potency on storage through addition of antioxidants and other stabilizers. In all these cases, there is scope for further improvement and refinement for better

product stability, absorption, and lower cost, and development efforts need to continue.

Regulations, Guidelines, and Standards for Fortification

The objective of the regulations and guidelines should be (1) to protect the population who buy and consume the product and (2) establish standards and guidelines to which all producers of the fortified products should conform.

The regulation and guidelines should include the following:

A rationale for fortification The decision to fortify a product with particular nutrient has to be based on scientific data obtained through dietary surveys and biochemical and/or clinical studies.

Recommended minimum and maximum level(s) of nutrient added per serving The level of the fortificant added should not be too low to have little or no impact on the nutrition status of the population. At the same time, the level added should not be in excess to cause toxicity.

Establishing RDA This is essential as a reference for fortification and in communicating the amount of the nutrients per serving to the population that consume the fortified product.

Establishing labeling standards The goal is to detail only relevant information.

Establishing guidelines for making nutritional and health claims Claims made on the nutritional and health benefits of the product should be supported by scientific data.

Establishing a monitoring and surveillance system For the regulations and guidelines to be effective, there should be a monitoring and surveillance system established.

Quality Assurance

The success of producing and distributing a micronutrient-fortified product is dependent on the placement of a quality assurance program that includes the following:

Finished product specification and description In order to build quality into the fortified product, the specification and description of the finished product must be established prior to its manufacture. The manufacturing process should be detailed in written operating procedures. Based on the claim to be made, the type and dosage of the micronutrients and the form and source of fortificants are specified.

Raw materials The quality of the raw materials for both the product and packaging play an important role in the quality of the final micronutrient fortified product. The micronutrient fortificants should meet established specifications. In addition, premix purchases are made from approved suppliers that follow good manufacturing practices (GMP). Once received, the fortificants are recorded and stored as specified in an appropriate condition.

Production and Packaging A quality product is ensured by following GMP. The micronutrient sources are added into the product formulation by using already-specified procedure and equipment. The amount of each fortificant added is recorded. Finally, the amount in the finished product is verified by using a validated analytical method.

Release of finished product The product released for distribution should meet all final product specifications. This includes the safety of the product and the level of the micronutrients claimed. There should be a system for (1) monitoring and correcting deviations from specification and (2) identifying the product in case there is a complaint from the consumer.

Documentation Accurate recording is essential for (1) identifying and correcting deviations, (2) recalling a product with serious problems, and (3) making an improvement on the quality of the product.

Training All personnel involved in the development, manufacturing, packing, and storage of the fortified product should be trained in quality assurance.

Advocacy and Social Communications

An effective communications campaign supported by the government should necessarily accompany any major fortification effort in order to gain the understanding and support of key sectors from policymakers and legislators to medical professionals, health workers and consumer groups.

Monitoring and Evaluation

As micronutrient fortification programs expand in countries around the world, the need to monitor the quality of the fortified food (in terms of its micronutrient content) and evaluate its contribution to the alleviation of micronutrient deficiencies will increase. Monitoring activities should ensure that a fortified product contains a sufficient amount of the micronutrient and that it reaches the target population. The

indicators used to monitor fortification efforts reflect the need to determine the quality and safety of the products and their availability to the populations at greatest risk. Monitoring is carried out at various levels – production or importation, wholesale and retail and household. The production and importation levels are the most important point for monitoring the fortification activity.

Monitoring is vitally important to the success of a fortification program for the following reasons:

To improve program effectiveness A fortification program can be effective only if a high-quality fortified is produced, delivered, accepted, and consumed by the target population on a continuous and self-sustaining basis.

To ensure compliance with government standards Monitoring systems will provide information on the extent to which the product conforms to national standards at points of production and consumption. This information is needed to enforce compliance through regulation and encourage voluntary corrective action by the producer.

To identify problem points in the fortification process As food moves from the factory to the household, it generally goes first to distributors, then to retail outlets. In some cases, foods are fortified outside the country and imported for eventual consumption. Monitoring must occur at various critical points starting at the production level and ending at the household level, where the fortified food is stored, prepared, and consumed.

To ensure safety Effective monitoring will ensure that the micronutrient content of the fortified food is within the desired range.

As a final indication of effectiveness, an impact evaluation conducted after 2 or 3 years will determine whether the micronutrients are absorbed well and are preventing recurrences of micronutrient deficiencies in the population.

Progress in Food Fortification

Key global developments to address specific micronutrient deficiencies through food fortification are summarized below.

Iodine Over the past 60 years, a variety of vehicles including bread, flour, sugar, and salt have been proposed as carriers for iodine. Among these, salt iodization has witnessed a remarkable growth in application globally over the past decade. A significant proportion of the populations in over 110 countries have access to iodized salt. Once established in a country, salt iodization is a permanent and long-term solution to the problem of iodine deficiency. Depending upon per-capita salt consumption and anticipated iodine losses between production and consumption, iodine dosage ranges from 20 to 100 mg per kilogram of salt. These losses are dependent upon the quality of salt and packaging. Toxicity issues are negligible, and cost considerations fairly small. Although there is considerable progress in streamlining control programs through salt iodization in several countries, producer compliance, quality assurance, logistic problems, and bottlenecks do remain. The challenge is to systematically identify and tackle these constraints through effective advocacy, social communications, monitoring of salt iodine levels, regulation, and enforcement. In many developing countries, salt iodization is the first large-scale experience in national fortification of a commodity. It has provided valuable lessons in collaboration between government, industry, nongovernmental organizations, the media, and other sectors. It has also given insights into building and sustaining an intervention politically, technically, financially, and culturally.

Iron Although iron has potential for use in more food vehicles than iodine or Vitamin A, fortification with iron is technically more difficult than with other nutrients, since iron reacts with several food ingredients. There are a number of iron compounds that are approved for food fortification. The greatest challenge with iron is to identify a form that is adequately absorbed and yet does not alter the appearance or taste of the food vehicle. The buff-colored, insoluble iron phosphate compounds are stable under a variety of storage conditions but are poorly absorbed. The soluble iron salts like ferrous sulfate are well absorbed but easily discolor by reacting with food ingredients. In addition to the general fortification criteria, iron fortification needs to take into account certain specific considerations:

1. The vehicle should be a component of all meals, because absorption varies inversely with the iron content of the meal.
2. It should not require prolonged storage particularly under hot and humid climatic conditions, since this could cause organoleptic problems.
3. Vehicles that are dark in color or have a strong taste or odor permit the use of more reactive iron compounds.
4. Segregation of iron should not occur during mixing or storage.

Reducing the global prevalence of iron deficiency anemia will require the use of several alternative

fortification compounds and food vehicles, depending upon the local dietary patterns. Some promising possibilities are:

Wheat/corn flour and bakery products In developed countries like the USA, Sweden, and Canada, these foods have had significant success as vehicles for iron. Flour fortification ensures an even meal distribution of the added iron and provides a reasonably constant iron supply to each individual. More recently, all corn and wheat flour in Venezuela was fortified with iron (mixture of ferrous fumarate and reduced iron), vitamin A, and B vitamins.

Condiments In Thailand, fish sauce, which is consumed in many parts of the country, has been tested as a vehicle for iron [in the form of sodium iron ethylenediaminetetraacetic acid (EDTA)] and has shown a good hemoglobin response. Fish sauce and fish pastes have also been tried as vehicles in the Philippines and Vietnam. Curry powder used by an Indian population in South Africa has been fortified with sodium iron EDTA with successful results. In China, the feasibility of using soy sauce as a carrier for iron is being examined.

Processed foods There is a growing trend in several developing countries increasingly to use processed foods such as noodles, cereals, and soup cubes. Weaning foods for children are also becoming popular. Elemental iron of small particle size is being used for the fortification of processed cereals in several developed countries. In Mexico, a chocolate milk powder is fortified with iron. In Tanzania, a fortified orange beverage drink has proved effective in improving the iron and vitamin A status among school children and pregnant mothers.

Salt Recent work has focused on developing a formulation that would permit the addition of both iodine and iron. (The acidic medium in which the iron compound is stable causes the rapid oxidation of iodide/iodate to free iodine, which vaporizes and is lost). A promising approach uses dextrin-encapsulated potassium iodide/iodate mixed with encapsulated ferrous fumarate to provide a barrier between the iron and iodine and improving stability. The successful testing and large-scale application of available technology for the double fortification of salt could represent a major breakthrough for combined iron and iodine delivery.

Zinc Several zinc compounds are available for food fortification ranging in solubility from very soluble (sulfate and chloride), freely soluble (acetate), to almost insoluble (carbonate and oxide). The soluble compounds, especially sulfate and chloride, are most preferred as fortificants. Unlike iron, zinc does not undergo oxidation–reduction. As a result, it does not cause the development of undesirable color and/or flavor when added to foods and beverages. However, like iron, it does cause metallic aftertaste and astringency. Currently, only infant formulas, cereal products (especially infant cereals), and dietetic products (e.g., products used for enteral feeding) are fortified with zinc.

Calcium Foods normally fortified with calcium include cereals and beverages, foods sold as a replacement to milk/yogurt, e.g., soy milk/yogurt, infant formula, weaning foods, enteral foods, slimming foods, and meal replacements. Flour is one of the best examples of fortification of cereal products. A range of breakfast cereals, rice, and corn products are also fortified with calcium in a few countries. More recently, orange juice and concentrates have been fortified with calcium. The compounds commonly used for fortification include carbonate, phosphate/lactate, citrate malate, or gluconate.

Vitamins A and D Vitamin A has been successfully added to foods such as milk (various forms of liquid and dry milk), butter, cheese, flour, bread and cereal product, snacks, and beverages. The most widespread application is in oils or fats that are dietary ingredients of most populations. It is essential that foods fortified with vitamin A are sealed in opaque or dark-colored glass containers with closures to eliminate the effect of light, a stimulant to oxidative processes. Edible antioxidants may also be added to protect both the oil and the added vitamin A from oxidation. Fortification of margarine is widely practiced (at levels of 20 000–50 000 IU kg^{-1}) to equal or exceed the average levels of this nutrient in butter. Often, vitamins D and E are also added. If synthetic β-carotene is also to be used, both color and vitamin A can be added simultaneously. When fat is removed from whole fluid milk, all fat-soluble vitamins, including vitamin A, are removed. All skim milk or low-fat liquid or dry milk products should have vitamin A added and, if given to infants, should probably have vitamins D, E, and possibly C as well. Sugar is another vehicle for vitamin A in Central American countries like Costa Rica, Guatemala, Panama, and Honduras.

B vitamins and folate Thiamine, riboflavin and niacin have been traditionally added to wheat flour in many countries for several decades. As a result, several vitamin B deficiency conditions like beriberi

and pellagra have been eliminated. Most recently, the addition of folate to grain products was made mandatory to reduce the prevalence of neural-tube defects and other congenital abnormalities in children caused by folate deficiency in the mothers during pregnancy.

FOOD INTOLERANCE

Contents

Types

J Gray, Guildford, Surrey, UK
W Chan, London, UK

Introduction

The umbrella term 'adverse reactions to food' has been adopted to describe a range of different types of responses to food, in particular food intolerance, food aversion, and food poisoning (**Table 1**). One way of distinguishing food intolerance and food poisoning is to consider the former as a defect in the individual and the latter as that of the food. The mechanisms underlying food intolerance are numerous, complex, and incompletely understood. It is certain that far fewer reactions are due to true allergy (involving the immune system) than is commonly believed. This article discusses the definitions and

Table 1 Adverse reactions to food

Food aversion	*Food intolerance*	*Food poisoning*
Food avoidance	Allergic reactions	Bacteria and viruses
Psychological intolerance	Enzyme deficiencies	Molds
	Pharmacological reactions	Chemicals
	Toxic and irritant effects	Toxins

mechanisms of the various types of food intolerance, as well as the clinical symptoms, diagnosis, treatment, and prevalence of food intolerances and their predisposing factors.

Much of the confusion surrounding this topic has arisen from the lack of universal agreement about definitions of the terms used to describe food intolerance. There is also a difference in terminology used in the UK and in the USA. For the purposes of this review, the definitions based on those developed by the British Nutrition Foundation Task Force (2001) will be used (Table 1).

Food Intolerance

Food intolerance is the term used to describe a range of responses to food, including allergic reactions, adverse reactions resulting from enzyme deficiencies, pharmacological reactions, and responses to toxic or irritant components of food (Table 1). All the adverse reactions categorized under this heading share one specific characteristic: they are reproducible adverse reactions to specific foods or food ingredients.

Allergic Reactions

These are abnormal reactions of a person's immune system to foreign but normally harmless substances, such as pollen grains or food constituents. These reactions may often be mediated by immunoglobulin E (IgE), but there are some reactions which are delayed and which do not involve IgE.

IgE-mediated reactions

Allergic reactions with IgE involvement are immediate, can be severe, and are mediated by IgE antibodies which trigger mast cells (and other cells). The mast cells are present below the surface of the skin and in the membranes lining the nose, respiratory tract, eyes, intestine, and other mucosal sites. During an IgE-mediated reaction, histamine and other proinflammatory substances which are present in these cells are released, causing symptoms such as rhinitis, asthma, dilation of blood vessels and flushing, swelling (e.g., of the lips), and difficulty in breathing. These allergic reactions are usually localized to one or two organs of the body.

Genetic factors are considered to be of particular importance in the development of IgE-mediated reactions. Atopy is the term used to describe a situation where there is a predisposition to the production of IgE antibodies and development of allergic disease.

Children with IgE-mediated reactions often react to more than one food and high levels of IgE antibodies to common food proteins, such as those present in eggs and cows' milk, are often predictive of later allergy to inhalants such as house dust and pollen. Food allergy does not commonly develop for the first time in adults. However, oral allergy syndrome is sometimes seen in adults who have previously suffered hayfever. Oral allergy syndrome is an IgE-mediated reaction, characterized by an initial irritation to the lips, oral mucosa and palate, followed by edema within minutes of ingestion of the trigger food, which is frequently a raw fruit or vegetable, although the syndrome is also associated with the consumption of tree nuts, peanuts, egg, fish, or milk.

Allergic reactions to food vary considerably in their severity and the discomfort they cause, but the majority are not life-threatening. However, anaphylactic reactions can be very severe and even fatal. The term anaphylaxis is now mainly applied to severe reactions of rapid onset, often accompanied by a fall in blood pressure and severe shock. Peanuts are well known for causing this type of extreme reaction. Other foods that are known occasionally to cause a severe (IgE-mediated) reaction are tree nuts, seeds, eggs, milk, and shellfish. Although most children with sensitization to eggs or milk usually spontaneously recover in 12–24 months, sensitization to peanut protein typically is more persistent.

Non-IgE-mediated reactions

These reactions are delayed and complex. Celiac disease is the best-defined example of this form of response. It is a disease that involves a sensitivity to gluten and appears to be mediated by the cells of the immune system. Most experts agree that celiac disease is a non-IgE-mediated reaction occurring in genetically susceptible individuals and triggered by exposure to the gluten fraction of wheat and other related cereal grains, such as rye and barley.

Delayed reactions to food may take several hours or days to develop. Reactions to cows' milk are often delayed and the majority are not accompanied by detectable IgE antibodies.

Enzyme Deficiencies

The most common intolerance linked to an insufficiency of an enzyme is lactose intolerance (also known as lactose maldigestion). Before it can be

absorbed and utilized by the body as fuel, lactose (the sugar in milk) has to be broken down to its two component sugars, glucose and galactose. This requires the enzyme lactase. If lactase is produced in insufficient quantities, some of the lactose can pass undigested into the large intestine, causing symptoms such as diarrhea and flatulence. The symptoms result from bacterial fermentation of lactose in the colon and the associated osmotic effects.

In most populations, especially where the consumption of milk beyond infancy is culturally uncommon, lactase levels decline in childhood. The deficiency is present in about 70% of the world population, particularly among those of African, Asian, and Jewish descent. In South-east Asia, India, the Middle East and parts of Africa, maldigestion of lactose in adults may affect about one-third of the population. However, in the UK, only 1–2% of adults are affected.

On occasions other enzyme deficiencies can result in an inability to handle specific dietary carbohydrates such as galactose and sucrose. These conditions are very rare. (*See* **Inborn Errors of Metabolism**: Overview.)

Pharmacological Reactions

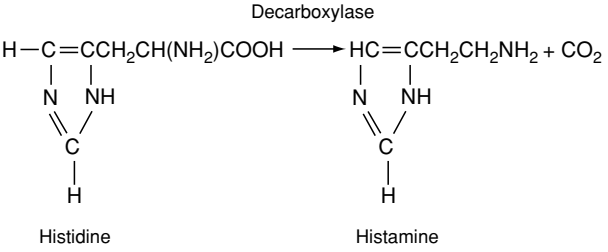
There are many food components that can produce a pharmacological effect. These effects are usually insignificant in clinical terms, unless the substance is consumed in very large quantities, e.g., the methyl xanthine caffeine. (*See* **Caffeine**.)

Also sometimes responsible for this type of reaction is the group of substances known as vasoactive amines, including histamine and tyramine (Table 2). These are normal constituents of a variety of foods such as cheese, pickled fish, yeast extract, chocolate, bananas, avocados, citrus fruits, and wine. It is often stated that some foods have a histamine-releasing action, e.g., egg whites, shellfish, strawberries, tomatoes, and chocolate.

Histamine may also accumulate in several foods as a result of microbial action during spoilage. During this process, histidine in the food is converted to histamine and it is believed that bacterial decarboxylase enzymes are responsible. (*See* **Histamine**.)

Table 2 Examples of vasoactive amines in foods

Vasoactive amine	*Food*
Tyramine	Cheese
	Pickled fish
Phenylethylamine	Chocolate
Serotonin	Bananas
Octopamine	Citrus fruit
Histamine	Fermented foods, e.g., blue cheeses, pickled fish



High levels of histamine are responsible for scombrotoxin illness which can occur following the ingestion of scombroid fish, such as mackerel, which has been stored inappropriately and has undergone spoilage. This type of problem can be prevented by insuring that fish are properly refrigerated throughout the processing and distribution chain. (*See* **Fish**: Spoilage of Seafood.)

Histamine-induced symptoms are similar to those found with IgE-mediated food allergy, which also involves the release of histamine and other chemical mediators from mast cells. The two conditions can be distinguished by the relatively large amount of the substance needed to trigger histamine-induced symptoms, in contrast to the minute quantity needed to trigger an allergic reaction.

There is some evidence that reactions to certain food additives, including some coloring agents, such as tartrazine, and some preservatives, such as the benzoates and sulfites, are also pharmacological in origin, and may result from the release of histamine or other chemical mediators. Although these reactions may emulate allergic reactions, convincing evidence to support an immunological basis for them is lacking. Nevertheless, the expression of such reactions is so variable that the possibility of an interaction between biochemically and immunologically mediated mechanisms cannot be excluded until further research is carried out. (*See* **Food Additives**: Safety.)

Toxic and Irritant Effects

Some foods contain natural toxins or substances that can irritate the lining of the intestine. Examples of natural toxins include protease inhibitors in legumes, cyclopeptides, and muscarine in mushrooms, and oxalates in spinach and rhubarb. Spices and chilli may irritate the gut mucosa and cause rapid intestinal transit times. This may be confused with other types of food intolerance. Some people are more susceptible to these effects than others and irritation is more likely if the mucosa is diseased.

Food Aversion

Food aversion is the alteration of eating behavior for psychological reasons. It may manifest as

psychological food intolerance, where there is an adverse physical reaction associated with the ingestion of a particular food, or food avoidance.

Psychological Food Intolerance

This response may be associated with symptoms that may be similar to those associated with true food intolerance. Such reactions are psychosomatic and do not occur when the food or food ingredient is administered in disguised form. Anecdotally, in some cases the bodily reaction can even be reproduced by the mere suggestion that a particular food may have been consumed. Development of an aversion to specific foods is recognized to occur occasionally following vomiting associated with medical treatments, where the food has been eaten at about the same time.

In some individuals food aversion can manifest itself as hyperventilation syndrome in response to food. In such cases, when faced with the food, individuals may hyperventilate to the extent that they suffer severe symptoms and may even lose consciousness. A variant of this form of aversion has been dubbed 'food intolerance by proxy.' This has become increasingly recognized in children. It occurs when an individual's family is unable to accept the symptoms and behavior of the person, except in terms of a physical illness. The belief that the problem is due to an 'allergy' is continuously reinforced within the family, but there is no evidence of a physical intolerance on double-blind challenge.

Food Avoidance

Food avoidance is quite common in the population as a whole, especially in preschool children and adolescents. It may manifest as the avoidance of all food, or of particular foods or food types. It is most prevalent in teenage girls who are frequently obsessed with losing weight and maintaining a particular body image. The extremes of this type of behavior manifest as the eating disorders anorexia nervosa and bulimia nervosa. (*See* **Anorexia Nervosa; Bulimia Nervosa.**)

Clinical Manifestations

The symptoms which can occur as a result of reactions to food fall into three main groups: immediate (within 1 h of ingestion); delayed or late (more than 1 h after ingestion); and remote.

Examples of these symptoms are as follows:

1. immediate gastrointestinal symptoms, e.g., lip and tongue swelling, mouth tingling, vomiting, abdominal pain
2. late gastrointestinal symptoms, e.g., diarrhea, bloating, constipation
3. remote symptoms, e.g., anaphylaxis, angiedema, rhinitis, urticaria, eczema, asthma, joint pains, headaches, depression, irritability

Diagnosis

The diagnosis of food intolerance and specifically of food allergy is not straightforward in most cases because of the nonspecific nature of many of the symptoms. The first stage is to take a careful medical and family history. A positive family history of atopy increases the likelihood of the diagnosis of allergy in an individual.

The timing of development of reactions to foods is also an important part of the diagnosis. The time course of some common symptoms of food intolerance is shown in Figure 1.

A reaction that may involve swelling of the lips and tongue, vomiting, rhinorrhea, urticaria, and asthma within minutes of ingesting a food is evidence of an immunological mechanism. When the symptoms occur more than an hour after the food is consumed, or only after repeated exposure to the food, an immune basis for the reaction is less frequently found.

Laboratory investigations may be used to confirm the diagnosis, especially when food allergy is suspected. The immediate type of allergic response is frequently associated with increased blood levels of IgE and the presence of IgE antibodies to food proteins. Skin prick tests and the radioallergosorbent test (RAST) are used to identify the presence of IgE. The procedure for RAST is as follows: a sample of blood is placed on paper impregnated with purified antigen; the amount of antibody that interacts is estimated by

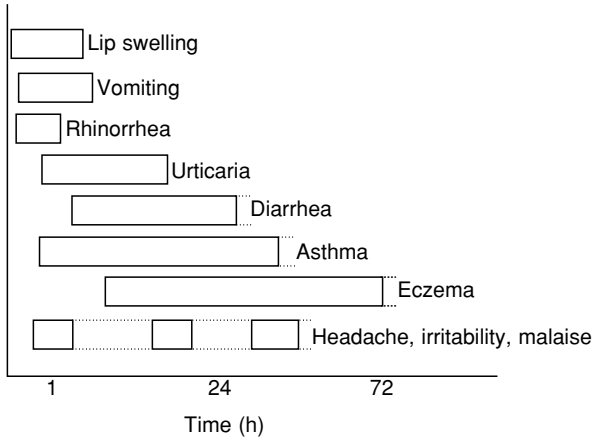


Figure 1 Symptoms and time course of food intolerance. From Lessof MH (1983) Reactions to food in adults. In: Lessof MH (ed.) *Clinical Reactions to Food*, p 112. Chichester: John Wiley.

the use of radioactive markers. These tests are widely used in the diagnosis of allergic disease which is not related to food. The results are likely to be positive in cases of immediate reactions to food, but general use of these tests in the diagnosis of food allergy is controversial because of difficulties in obtaining pure food proteins for testing and frequent false-positive responses.

The measurement of blood levels of histamine, of histamine release, and of other mediators from white blood cells has been investigated as another diagnostic technique. As yet, the results have been too variable for these tests to become part of routine diagnoses.

The only sure diagnostic approach in food intolerance is the use of some form of elimination diet. The nature of the diet will depend on the clinical symptoms and provisional diagnosis. This may simply involve the elimination of individual suspect foods, or the exclusion of all foods commonly associated with adverse reactions. These include milk products, eggs, wheat products, fish, nuts, pork, chocolate, coffee, tea, citrus fruits, and foods containing preservatives and coloring agents. In some cases an extremely restricted or 'oligoantigenic' (few foods) diet of lamb, rice, and pears is used.

If the symptoms disappear over the course of the diet, the patient is 'challenged' with the suspect food or ingredient. If there are many foods involved, these must be reintroduced slowly, one at a time and over a period of weeks or months, to see if the symptoms recur. In some cases it is necessary to confirm the diagnosis by a double-blind challenge, in which the suspect food is given in disguised form so that both the patient and doctor or dietitian are unaware of what has been ingested.

There are also numerous unorthodox diagnostic tests for which extravagant claims are made. In general these have been shown to be of little value in diagnosis and in some cases to be misleading and potentially dangerous because the false diagnoses resulting from their use can lead to inappropriate treatments. These include the pulse test, the sublingual test, the interdermal skin test, cytotoxic tests, and hair sample tests.

Treatment

Once the food or range of foods or ingredients has been identified as the cause of intolerance, a diet which avoids these foods must be followed. If this only involves the removal of a few foods which are 'nonessential', e.g., strawberries or shellfish, then this is straightforward. Where important groups of foods must be excluded, such as cereals or milk products, the advice of an experienced dietitian is essential and supplements may be necessary to insure nutritional adequacy of the diet, particularly in children.

Various drug treatments such as antihistamines and antiinflammatory drugs may be used as an adjunct to the diet, depending on the severity of the condition.

Predisposing Factors to Food Intolerance

There is still much to be learnt about the predisposing factors to food intolerance. It is established that enzyme defects are inherited and that the predisposition to the true food allergy is also inherited. Food allergies are certainly more common in the offspring of atopic parents. In some individuals, more than one type of intolerance may coexist. For example, a person might display an allergic (IgE-mediated) reaction to certain foods and a pharmacological sensitivity to other foods. Much more research is needed to explain the causes of food intolerance and to establish what factors, both genetic and environmental, determine an individual's susceptibility.

Prevalence

Assessment of the prevalence of food intolerance is also difficult, and wide ranges of incidence have been reported in the scientific literature. This is not surprising as many of the estimates are based on selected populations and the diagnostic criteria and testing procedures used in different studies vary considerably.

When adverse reactions to food occur, intolerance rather than true allergy is usually the problem. With the exception of the very rare inborn errors of metabolism, which are usually diagnosed in the neonatal period, there are few reliable estimates of the prevalence of nonallergic reactions.

Food additive intolerance has been studied more carefully and it is estimated that between 0.01% and 0.23% of the general population in the UK may have adverse reactions to some food additives. The incidence of such reactions rises dramatically in sensitive populations, such as those suffering from chronic urticaria. Reports in the scientific literature suggest that as many as 30–50% of such populations may display sensitivity to certain additives.

Estimates of the prevalence of food intolerance in the general population are no more than 5–6% and an estimated 2% of the population may have IgE-mediated food allergies, whereas as many as 20–30% of the UK population perceive themselves to be food-intolerant, or in common parlance, 'allergic' to food. However, as yet there are no systematic data which enable the accurate calculation of the incidence

and prevalence of adverse reactions to food, either in the UK or elsewhere.

Adverse reactions to food are more frequently reported in infants and young children, with varying prevalence estimates from 0.3% to 20% of children. However, the majority of such reactions resolve themselves in childhood and certainly by adolescence. The prevalence of IgE-mediated reactions is higher in young children than adults, with an estimate of about 5%.

It has been suggested that inhalant and possibly food allergies have increased in prevalence, but the swiftness with which apparent change has come about precludes a change in the gene pool being responsible. There has been an increase in the numbers of people suffering from food-induced anaphylaxis; the reason for this is uncertain.

Food Allergies

J Gray, Guildford, Surrey, UK
W Chan, London, UK

Introduction

Allergic disorders such as asthma, hayfever, and eczema are common. Adverse reactions to food are also common, particularly in children, but it is recognized that many such reactions are not true allergy, i.e., they are not caused by an adverse response of the body's immune system.

This article examines the specific problem of food allergic disease, including the types of immune reactions and the mechanisms believed to be responsible for them, clinical manifestations of food allergy, genetic and immunological predisposition, prevalence, and the vulnerability of newborn infants to the problem.

The Immune System

The immune system is capable of distinguishing between proteins and other molecules that are part of the body and those that are foreign to it. It is able to protect against harmful foreign particles such as bacteria, viruses, and parasites by generating a response to eliminate them. One of the ways it does so is by producing antibodies against the foreign particle. An antibody is a protein (immunoglobulin) that specifically combines with a foreign substance, referred to as an antigen or allergen. The immune system is also able to ignore harmless foreign matter; otherwise it would be in a constant state of overactivity. (*See* **Allergens**.)

However, in some people there is an abnormality of the immune system so that it produces antibodies in response to harmless and sometimes beneficial molecules, usually proteins, glycoproteins, or polysaccharides. When the antigen is encountered subsequently, an adverse reaction with unpleasant and occasionally dangerous symptoms occurs. Someone whose immune system reacts in this way is said to be allergic. Almost any food, food constituent, food additive, drug, or other substance which is swallowed, such as dust and microorganisms, can act as an antigen within the gut.

The cells which are involved in the immune response are organized into tissues and organs which are collectively referred to as the lymphoid system. This comprises lymphocytes, accessory cells (macrophages and antigen-presenting cells) and, in some tissues, epithelial cells. The lymphoid tissues and organs are described as primary (central) and secondary (peripheral). The primary lymphoid organs, which are the major sites of lymphocyte production, comprise the thymus and bone marrow. The secondary lymphoid organs, which provide an environment for lymphocyte and accessory cell interaction with antigens, comprise the spleen, lymph nodes, and the mucosa-associated lymphoid tissues (MALT). The MALT include the tonsils, and all the tissues associated with the mucosal surfaces of the respiratory tract, of the intestinal tract, referred to as the gut-associated lymphoid tissue (GALT), and including the Peyer's patches of the ileum, and of the genitourinary tract. More than 50% of the body's lymphoid tissues is associated with the mucosal system, especially the GALT, as this is the point of entry for external antigens. The GALT is particularly important in the

context of food allergy because food antigens exert their main immunological effects locally in the gut, although they may also enter the body through the nasal and oral mucosal surfaces, or through the lower respiratory tract and skin.

An immune response can involve various cell types: the lymphocytes, which recognize pathogens or antigens, and the phagocytes, which engulf foreign material and degrade it. The lymphocytes can be divided into two main categories: the B lymphocytes (bursa- or bone marrow-dependent cells), which release antibodies; and the T lymphocytes (thymus-derived cells), which have a wide range of activities. Some T cells interact with the B cells, helping them to make antibody, and another group interacts with phagocytes; these are termed T helper cells (TH). A third group of T cells is responsible for killing infected host cells: they are known as T-cytotoxic cells (TC). The T cells produce soluble proteins (cytokines) which also have regulatory effects in the immune response, acting as signals between lymphocytes, phagocytes, and other cells of the body. The cytokines include the interferons (IFNs) and interleukins (ILs) and tumor necrosis factors (TNFs). The immune response can also involve other soluble mediators, including the complement system, which is a group of about 20 serum proteins that interact and control inflammatory reactions.

Mechanisms of Allergic Reactions

Immune response are frequently classified into four main types, referred to as types I–IV. Types I–III are antibody-mediated, with type I effected by immunoglobulin E (IgE) antibodies; type IV is mainly mediated by T cells and macrophages. In practice, more than one of these types of reactions may occur in an individual at the same time.

Food allergic reactions may be IgE (type I) or non-IgE-dependent, but most common food allergies are mediated by IgE antibodies. IgE-mediated reactions are immediate. This immunoglobulin is normally present in very small quantities, but it is produced in large amounts in some people who are described as 'atopic.' Such people are more prone to allergic reactions such as hayfever, asthma, eczema, urticaria, and food allergy. On the first encounter with an antigen, there is a complex series of events leading to the release of IgE antibodies from the B cells, with assistance from T cells.

The structure of an antibody is shown in Figure 1. It contains a fragment antigen-binding portion (Fab) which is shaped to bind to a specific antigen and a fragment crystallizable portion (Fc) which binds to white blood cells and may also activate complement.

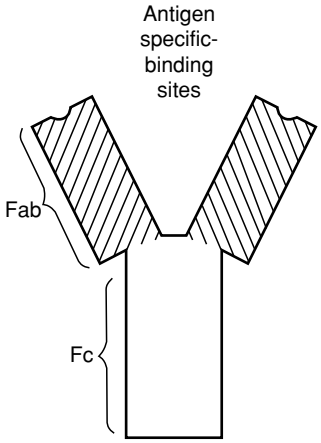

Figure 1 The antibody consists of two portions: the fragment antigen-binding (Fab) portion, shaped to bind a specific antigen, and the fragment crystallizable (Fc) portion, which binds to white blood cells and complement proteins. Reproduced from Food Intolerance: Food Allergies. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The antigen-specific IgE molecules bind to mast cells, which are granular connective tissue cells containing histamine and other chemical mediators. These cells are present in large numbers in mucosal surfaces of the skin, nose, mouth, eye, respiratory tract, and gut. IgE binds to the mast cells via Fc receptors and the individual is then said to be sensitized. On the next encounter, the antigen interacts with the specific IgE antibodies on the sensitized mast cells, causing an explosive degranulation of the mast cells, with the release of histamine and other mediators, such as serotonin and various cytokines, including IL-3 and IL-4. These mediators act on blood vessels, mucous glands, and smooth muscle, causing the symptoms of allergy. The sequence of events is shown in Figure 2. (*See* **Prostaglandins and Leukotrienes**.)

Delayed reactions to food may take several hours or days to develop and are complex. They are usually not accompanied by an increase in IgE antibodies. Celiac disease is the best defined example of this type of response. (*See* **Celiac (Coeliac) Disease**.)

Clinical Features of Food Allergy

The clinical manifestations of food allergy are variable in location, timing, and severity. Symptoms range from mild and tolerable, e.g., slight abdominal pain, to anaphylaxis – a rapid and extreme generalized allergic response which can result in physical collapse and death. The main organ systems affected are the gastrointestinal tract, skin, and respiratory tract. The clinical features may be influenced by

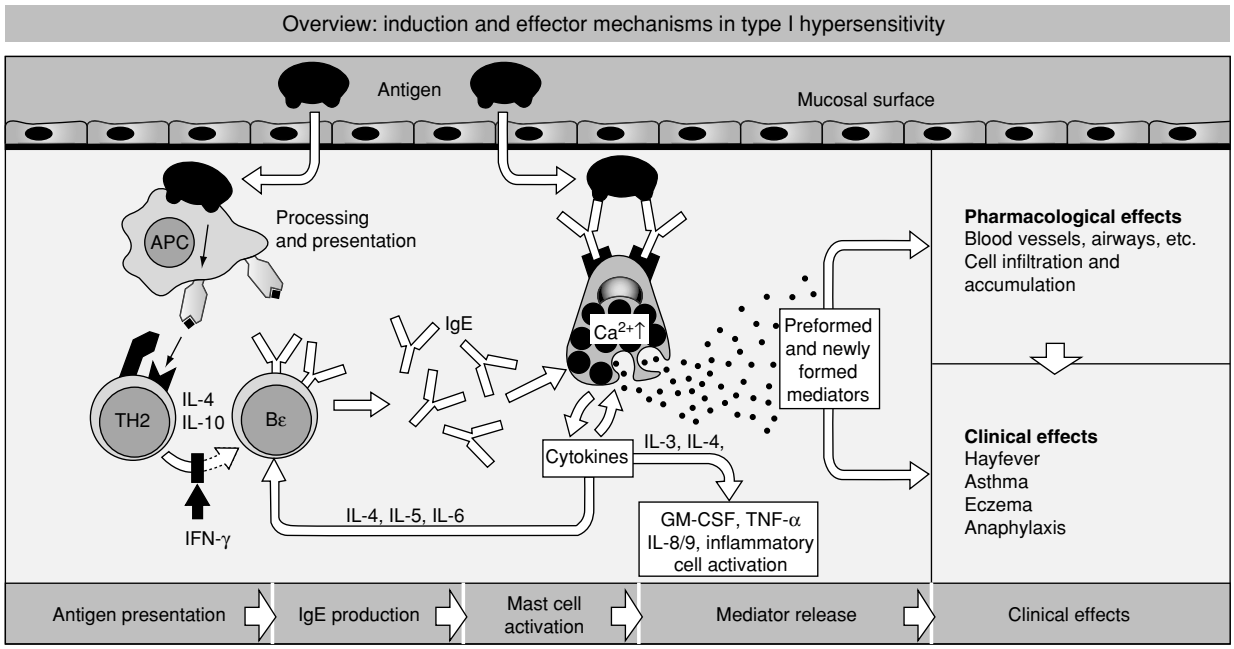

Figure 2 Innocuous environmental antigens (allergens) enter via mucosal surfaces and are taken up by local antigen-presenting cells (APCs), which process and present them to TH cells. TH2 cells secrete cytokines that induce B-cell proliferation and favor the production of an allergen-specific immunoglobulin E (IgE) response. The IgE binds, via Fcε receptors (FcεRI), to mast cells, thus sensitizing them. When allergen subsequently reaches the sensitized mast cell, it cross-links surface-bound IgE, causing an increase in intracellular calcium (Ca^{2+}) that triggers the release of preformed mediators, such as histamine and proteases, and newly synthesized, lipid-derived mediators such as leukotrienes and prostaglandins. These autocolds produce the clinical symptoms of allergy. Cytokines are also released from degranulating mast cells and may augment the inflammatory and IgE responses. IL-4, interleukin-4; IFN-γ, interferor-γ; GM-CSF, granulocyte – macrophage colony-stimulating factor. Adapted, with permission, from Roitt I, Brostoff J and Male D (1998) *Immunology*, 5th edn. Sidcup: Mosby.

other factors such as age, physical exercise, stress, and coexisting medical problems.

Gastrointestinal Tract

Swelling and tingling of the lips, tongue, and throat can present as initial symptoms of food allergy occurring as the antigen comes into contact with these organs. Nausea and vomiting are common acute symptoms, and abdominal pain and diarrhea also occur frequently.

The pathological changes in the small intestine which occur in food allergy have been characterized from biopsy specimens. It is well documented that mucosal damage can occur in cows' milk protein allergy and there is evidence that reactions to soya, egg, fish, and chicken may also result in mucosal damage.

More extensive intestinal mucosal damage is seen in celiac disease in response to the ingestion of gluten. Although abnormal immunological mechanisms are believed to be partially responsible for this condition, the exact mechanism remains uncertain. (*See* **Celiac (Coeliac) Disease**.)

Food allergy can also lead to inflammatory changes in the large bowel and bloody diarrhea (proctocolitis) in infants. However, in adults there is a lack of evidence to suggest an immunological basis for large-bowel disorders. (*See* **Colon: Diseases and Disorders.**)

Skin

Urticaria (an itchy raised skin rash also known as nettle rash) and angiedema (swelling of the skin, mucous membranes, and underlying tissues) are frequently seen as manifestations of food allergy. There is increasing evidence that food intolerance may be a cause of eczema but the basic mechanism of the reaction is still unclear. Infantile eczema is certainly more common in children from atopic families. Such reactions frequently occur in response to cows' milk protein and may be ameliorated by dietary manipulation.

Respiratory Tract

Sneezing and rhinorrhea (running of the nose) can be manifestations of food allergy, either in association with gut or skin symptoms or alone. More rarely, bronchoconstriction occurs when a food is ingested, but food allergy is not a common cause of asthma.

Anaphylactic Shock

Although the majority of food-allergic reactions are not life-threatening, a small proportion of reactions

can lead to anaphylactic shock (anaphylaxis), which is severe and may be fatal. Anaphylaxis is an acute allergic (IgE-mediated) reaction of rapid onset and affecting many organ systems, including the cardiovascular system, the respiratory tract, the mouth, the pharynx, and the skin, either individually or in combination. It is characterized by swelling of the lips and throat, shortness of breath, a rapid fall in blood pressure, progressing to cardiovascular collapse and severe shock. Treatment consists of intramuscular injection of epinephrine (adrenaline), and without this anaphylaxis may cause death. Anaphylactic reactions are relatively rare, but there is evidence that deaths from food-induced anaphylaxis are increasing. In the UK and Europe, peanut is the most common food reported to cause anaphylaxis, but other foods that are known sometimes to cause the condition are tree nuts, seeds, eggs, milk, and shellfish. Inadvertent exposure to potential allergens in foods containing, or contaminated with, minute amounts of the allergen poses a major risk to the small number of people at risk of anaphylaxis.

Predisposition to Food Allergies

It is believed that genetic predisposition and immunological predisposition, notably elevated serum IgE levels, are the most important determinants of allergic disease. Environmental factors are secondary but may still play an important role; they include nondietary factors such as the level of allergen exposure, which may be influenced by season of birth, maternal smoking habit, exposure to pollutants, viral illness, and the nutritional status of the individual.

The importance of genetic factors in the etiology of allergic disease and IgE production is evident from the simple observation that allergic disease is more common in the children of atopic parents. Children from families where both parents are atopic have more than a 50% chance of developing an allergic disorder; where one parent is atopic, the chance is about 30%. However, twin studies have shown that concordance is far less than 100% in monozygotic (identical) twins, indicating that environmental factors are also important in the expression of atopic disease.

Research in atopic families and twins suggests that total IgE levels are influenced by genetic factors. The major control of antigen-specific IgE responses is believed to be linked to the human leukocyte antigen (HLA) immune response genes. However, HLA-linked genes do not appear to be responsible for high IgE levels. There is evidence that general levels of IgE may be determined by other genes, including those responsible for cytokine production.

Inherited immune deficiency disorders, e.g., deficiencies of complement or IgA, can also predispose towards allergy. The presence of a specific type of IgA, secretory IgA, in the gut is believed to reduce antigen absorption. It might be deduced that IgA deficiency could lead to increased antigen absorption and IgE antibody stimulation. However, again the explanation must be more complex, as not all such people develop allergy.

As ingested food travels through the gut, it presents the immune system with a vast array of foreign particles to distinguish. The intestinal mucosa itself is a barrier which can protect against dietary antigens and the secretion of mucus from intestinal goblet cells and the production of secretory IgA are protective mechanisms which help to reduce antigen absorption. Disruption of the intestinal barrier, as occurs after intestinal infection, and increased permeability of the barrier, as in premature infants, the newborn, in malnutrition, and in immune deficiency, may increase the penetration of antigens.

The significance of increased gut permeability in the etiology of food allergic disease is nevertheless uncertain. It has been demonstrated that antigens can cross the gut wall in both allergic and nonallergic individuals, and that immune complexes may circulate in the blood of nonallergic individuals without ill effect. This underlines the complexity, as well as the gaps in our understanding, of the ways in which genetic and environmental factors may interact to cause allergic disorders.

Vulnerability of the Newborn to Food Allergy

It is evident from clinical experience that the newborn is vulnerable to food allergens. For example, there is clear evidence that infants exposed to unmodified cows' milk within the first few weeks of life are particularly susceptible to the development of symptoms of allergy to cows' milk such as eczema. However, our knowledge of the pathogenesis of food allergic disease and the relative importance of the various contributory factors in the neonatal period is still limited.

The immunological response to feeding a 'foreign protein' may result from the immaturity of neonatal digestive and absorptive functions and early penetration of the antigens. It has also been suggested that because newborn infants are temporarily deficient in IgA – secretory IgA does not appear until the age of 2–4 weeks – the gut mucosa is particularly vulnerable to antigen penetration.

The influence of maternal diet during pregnancy and lactation, the protective role of breast-feeding,

and the timing and introduction of solids at weaning may all play their part in the pathogenesis of food allergic disease. The coincident occurrence of infection with the introduction of a specific antigen may also be a crucial factor. (*See* **Pregnancy**: Safe Diet.)

The idea that breast-feeding might protect against allergic disease has existed for some 50 years. Although there are many studies that support this idea, there are many that do not. Such conflict appears to result from the difficulty in controlling studies on infants and differences in methodology. (*See* **Infants**: Breast- and Bottle-feeding.)

On balance, it appears that breast-feeding decreases the likelihood of allergic disease in children who are 'at risk' because of family history. To some extent this is due to the late introduction of foreign protein but it is also attributable to the presence of protective immunological factors, such as IgA, in colostrum and breast milk. Breast milk protects against infection, and breast-feeding should help to maintain the integrity of the gastrointestinal mucosa in the neonatal period.

The level of total IgE in umbilical cord blood is believed to be predictive of allergic disease. The influence of maternal diet on cord blood immunoglobulin levels and the placental transfer of antibodies to specific food proteins in atopic and nonatopic mothers are subjects of active research at the present time. As yet the influence of maternal diet on allergic outcome in the offspring remains uncertain.

The current view is that sensitization *in utero* does occur. However, the influence of dietary manipulation of the mother in pregnancy in preventing food allergy in the infant is contentious and in need of further research before it can be recommended.

Food antigens pass into breast milk in small amounts and these are significant in immunological terms. It is believed that this may lead to sensitization in susceptible infants. Therefore the exclusion of specific foods from the mother's diet during lactation may be beneficial for at-risk infants. Again, this is the subject of research.

The potential severity of the reactions associated with peanut allergy has led to the recommendation, in the UK, that pregnant and breast-feeding women from atopic families (whether they are themselves atopic or if the father or any other sibling has atopic disease) should avoid peanuts and peanut products in order to reduce the risk of peanut allergy developing in their offspring. However, the scientific basis for this recommendation is still open to debate and other countries have not made similar recommendations. (*See* **Food Intolerance**: Types.)

Particularly important for at-risk infants is the timing of weaning and the nature of the foods introduced early on. Exclusive breast-feeding, for at least 4 and preferably 6 months, and avoidance of the early introduction of foods commonly known to cause allergies, e.g., cows' milk and its products, eggs, wheat, fish, nuts, and citrus fruits, would seem to be the best preventive approach. However, more research is needed on the links between weaning and subsequent development of food allergic disorders. (*See* **Infants**: Weaning.)

Prevalence of Food Allergies

It is difficult to arrive at a precise estimate of the prevalence of food allergic disease because of the different testing procedures and diagnostic criteria used in research studies. Figures ranging from 1% to 20% have been cited, but the true prevalence is currently estimated to be towards the lower end of this range, at about 2%. Our present state of knowledge suggests that food allergy is far less common than food intolerances (with a nonimmunological basis), and less common than allergic reactions to pollen and house dust. However, as yet there are no systematic data to permit the accurate calculation of the incidence and prevalence of food allergic reactions, either in the UK or elsewhere.

Milk Allergy

S L Taylor and J Kabourek, University of Nebraska, Lincoln, NE, USA

Introduction

Cows' milk is one of the most common causes of adverse reactions in foods and can occur through several mechanisms. True cows' milk allergy (CMA) occurs through an immunoglobulin E (IgE) mediated mechanism. The prevalence of allergy to cows' milk is reported to be about 2% of the general pediatric population in developed countries. Treatment of CMA involves the strict avoidance of cows' milk and products containing cows'-milk proteins. Education of both the affected child and parents is also vital to successful management of CMA.

Milk Allergy

Cows' milk is one of the most common causes of adverse reactions in foods and can occur through several mechanisms. True CMA or hypersensitivity is indicative of an adverse reaction to bovine milk proteins that produces symptoms and where an immunologic mechanism may be implicated. CMA is mainly an IgE-mediated, type I immediate hypersensitivity reaction, although type III and IV reactions have also been implicated. CMA is considered the most severe form of intolerance because the threshold dose for elicitation of a reaction is low, and symptoms can be severe in some affected individuals.

Classified by Coombs and Gell, hypersensitivity reaction mechanisms are divided into four types: I–IV. The first three types are antibody-mediated, whereas the fourth type is mediated by T cells and macrophages.

Type I (anaphylactic) reaction is immediate and is due to interaction of antigen (allergen) with IgE-sensitized mast cells and basophils, resulting in histamine and mediator release from these cells.

Type II (cytotoxic) reaction involves both IgG and IgM antibodies. A specific cell or tissue is targeted, activating the complement cascade and causing cytotoxic cells to damage membranes.

Type III hypersensitivity (immune complex) involves an antigen–antibody complex, causing an inflammatory response with fixation of complement.

Type IV (cell-mediated) hypersensitivity involves T cells producing cytokines that recruit phagocytes and other inflammatory cells. Continued stimulation of these cells causes tissue damage.

In true IgE-mediated CMA, exposure of susceptible individuals to one or more of several cows'-milk allergens (naturally occurring proteins) elicits the production of allergen-specific IgE antibodies. These IgE antibodies become fixed to the membranes of mast cells in the tissues and basophils in the blood. This symptomless process is called allergic sensitization. Upon subsequent exposure to cows' milk, the specific cows'-milk allergen cross-links two IgE antibodies on the membrane surface of the sensitized mast cells and basophils. This interaction triggers the release of a host of bioactive mediators from the mast cells and basophils, including histamine, leukotrienes, and prostaglandins. These mediators are responsible for the range of symptoms experienced in an allergic reaction.

Cows'-milk protein intolerance (CMPI), not to be confused with IgE-mediated CMA, is generally a nonimmune-mediated reaction against cows'-milk proteins. CMPI is probably a cell-mediated inflammatory reaction that damages the absorptive function of the intestinal tract. Symptoms are primarily gastrointestinal (nausea, abdominal cramps, and diarrhea) and delayed, appearing several days after milk ingestion. Generally, CMPI is a disorder occurring in infancy that is frequently outgrown.

Lactose intolerance refers to inadequate digestion of lactose, the major carbohydrate found in milk, usually from a deficiency or low levels of β-galactosidase (lactase) enzyme. Lactose intolerance produces gastrointestinal symptoms, including cramps, bloating, gas, diarrhea, and/or nausea. In contrast to CMPI and CMA, lactose intolerance primarily affects adults.

Composition

Cows' milk is a nutrient-dense food consisting of varying amounts of carbohydrate, fat, and protein. The major constituents of cows' milk are water (87.4%) and milk solids (12.6%), which includes vitamins, minerals, carbohydrate, fat, and protein. Cows' milk is known to contain many nutrients, including varying concentrations of fat and water-soluble vitamins, minerals, trace elements, and salts. The principal carbohydrate in milk is lactose. The lactose content of milk varies by species. Cows' milk contains about 4.8% lactose (12–12.5 g lactose per cup), whereas human milk has 7% lactose. In addition to lactose, minor quantities of glucose, galactose, and oligosaccharides are present. Milk fat is a complex lipid existing as an oil-in-water emulsion. Milk lipids are mainly triacylglycerols or fatty acid esters with glycerol, of which more than 400 have been identified. Phospholipids,

sterols, waxes, and free fatty acids have also been identified.

Cows' milk is a heterogeneous mixture of at least 20 proteins. Eighty percent of the total protein is casein proteins and 20% is whey proteins. Caseins are relatively heat-stable, whereas whey proteins are more labile. Casein can be fractionated into four major components: alpha, beta, kappa, and gamma casein. The whey proteins consist of α-lactalbumin, β-lactoglobulin, bovine serum albumin, and several minor proteins, including lactoferrin and lactoperoxidase.

Great variability of the human IgE response to cows' milk exists. Many patients are allergic to more than one milk protein. The major allergens of cows' milk are α-$_{s1}$ casein and β-lactoglobulin. α-Lactalbumin is also involved in some patients. IgE antibodies directed to minor cows'-milk proteins, such as bovine serum albumin and lactoferrin, have been identified in a few patients but their role in CMA is not firmly established.

Prevalence

CMA and CMPI are primarily diseases of infancy. CMA has become one of the most common food allergies in early childhood since cows' milk is usually one of the first foreign antigens encountered in large quantities in infancy. Most infants develop symptoms before 1 month of age, often within 1 week of introduction. Onset of CMA after 1 year of age is extremely rare. Major risk factors for CMA are a positive family history of CMA or other atopic disease and early cows'-milk protein exposure. The onset of disease in most cases is closely related to the time of introduction of cows'-milk products. The prevalence of allergy to cows' milk is reported to be about 2% of the general pediatric population in developed countries. CMA occasionally occurs in adults, affecting less than 1% of the adult population; however, good prevalence estimates for CMA in adults are not available.

Prevention

Because cows' milk is usually one of the first foreign antigens encountered in infancy, preventive measures are ideally employed during this time period, particularly in children of atopic parents. Although conflicting data exist and no single prevention method is completely effective, protective effects have been seen with breast-feeding and delaying introduction of cows' milk.

Prolonged breast-feeding in all infants is the ideal source of nutrition, providing immunological factors, developing intestinal maturation, and enhancing infant–mother bonding. The protective effect of breast-feeding may be due, in part, to avoidance of high doses of cows'-milk proteins or an inherent protective effect of human milk. Support for the benefits of breast-feeding in preventing or delaying the development of CMA has been seen in prolonged breast-feeding practice of at least 6 months. In addition to breast-feeding, delaying the introduction of cows' milk until 6 months of age also has a preventive effect. If breast-feeding is not possible or during weaning, an extensively hydrolyzed formula in combination with delayed milk introduction may be protective. Partially hydrolyzed infant formulas (PHF) are also available. These formulas appear beneficial in the prevention of sensitization to cows' milk and are more palatable than extensively hydrolyzed formula (EHF). But the partial hydrolysates can provoke allergic reactions in previously sensitized infants. There may be a preventive effect of maternal avoidance of common allergenic foods during lactation but there has been no protective effect shown for an altered diet during pregnancy. Occasionally, CMA seems to develop in exclusively breast-fed infants, ostensibly from exposure to small amounts of cows'-milk proteins secreted into the breast milk and arising from the mother's diet. However, cows' milk is so important in the nutrition of lactating women that avoidance of cow's milk during the lactation period is not often recommended. Similarly, the practice of cows' milk avoidance during pregnancy should not be suggested because it may put the health of the mother as well as the fetus in jeopardy of nutritional complications or deficiencies.

Symptoms/Manifestation

Clinical manifestations and severity of symptoms of CMA vary widely from one individual to another. Symptoms arise involving the skin, gastrointestinal or respiratory tracts. The majority of patients have greater than two symptoms affecting greater than two organs/systems. CMA in individuals exhibiting gastrointestinal symptoms and/or dermatitis usually resolves early in life, whereas individuals with urticaria, angioedema, respiratory symptoms, or anaphylaxis may persist with CMA into adult life.

Individuals with immediate reactions often exhibit systemic anaphylaxis and/or dermatological symptoms. Anaphylaxis is a systemic, multiorgan reaction associated with IgE-mediated hypersensitivity. It may progress slowly or rapidly and can involve hypotension, bronchospasm, edema, and cutaneous symptoms. Treatment for anaphylaxis involves the use of

epinephrine (adrenaline) given intramuscularly, antihistamines, and steroids. Although severe reactions to cows' milk are rare, deaths have been documented. Dermatological features may include urticaria, angioedema, and eczema (dermatitis).

Intermediate reactions occurring from 1 to 24 h after ingestion may involve gastrointestinal symptoms, including vomiting, diarrhea, reflux, colic, and bleeding.

Symptoms appearing more than 24 h after cows'-milk ingestion often affect the respiratory tract and skin. Respiratory symptoms may involve nasal stuffiness, coughing, wheezing, tachypnea, and rhinitis. Atopic dermatitis is a rather common manifestation of CMA involving the skin; it can be a chronic condition.

Diagnosis

Differentiation between CMA and CMPI cannot be based on clinical symptoms alone, nor is there a lone clinical test. The first step in evaluation of someone with a history of possible adverse reactions is to take a detailed food history. Along with identifying the suspected food, the quantity of food needed to produce symptoms and the frequency with which reactions occur need to be reported. Physical exams may be helpful in revealing a chronic skin condition such as atopic dermatitis. However, other physical signs, such as respiratory symptoms, may be present but are not necessarily a result of food hypersensitivity and may be attributed to other conditions. Gastrointestinal complaints, in particular, can have numerous causes.

Diagnosis is usually based on cows'-milk protein elimination and challenge tests. Open, controlled cows'-milk challenges are recommended for infants 0–1 year. In children older than 1 year and adults, double-blind placebo-controlled challenges (DBPCFC) are performed. These tests determine if cows' milk is the cause of symptoms but do not identify the mechanism.

Several methods, including skinprick test and radioallergosorbent test (RAST), are available as diagnostic tools in identifying immunological-mediated CMA. Recent advances in RAST have improved the diagnostic value of these tests and lessened the need to perform DBPCFCs. Milk-specific IgE is seen in some milk-hypersensitive individuals but not all. CMPI may be suspected if symptoms are restricted to the gastrointestinal tract and have delayed onset, especially in cases where specific IgE antibodies are absent.

Presently, allergic sensitization to cows'-milk proteins usually occurs during the first few years of life, often disappearing thereafter. The majority of children outgrow CMA and CMPI and will acquire tolerance, with an estimated remission rate of 85–90% before 3 years of age. However, an early increased IgE response to cows' milk proteins is associated with an increased risk of persisting allergy to cows'-milk proteins, development of asthma or rhinoconjuctivitis, or development of atopic disorders later in life.

Treatment/Management

Treatment of CMA and CMPI involves the strict avoidance of cows' milk and products containing cows'-milk proteins. Because even a minute amount of allergen has the potential to trigger sensitization and/or symptoms, awareness is key in treatment. Breast milk is the ideal source of nutrition. If breastfeeding is not possible, numerous formulas are available as cows'-milk substitutes.

Soy protein formulas can be well tolerated by some individuals. However, soy is also a commonly allergenic food and has been reported to cause symptoms in some CMA individuals due to the development of soy allergy.

Meat-based formulas from sources such as chicken or lamb may be used but have also been shown to cause symptoms on rare occasions. Also, a formula based on goats' milk contains β-lactoglobulin and often causes symptoms in CMA individuals.

More commonly, modified-protein formulas are the treatment of choice. Protein hydrolysates are classified as PHF or EHF and may be derived from casein or whey. For the most part, however, these EHFs are generally tolerated and are a good alternative for CMA management. A few CMA infants will respond adversely to trace amounts of milk proteins or peptides present in EHF.

PHF were developed for the purpose of dietary prevention of CMA and are not recommended for individuals who already have CMA. EHF have been in use for over 50 years as a therapeutic diet in CMA management and are the recommended treatment. However, palatability of EHF is an issue, and EHF can be quite costly. In severely sensitive individuals, hypoallergenic, nutritionally complete infant formula composed of individual amino acids (elemental formula) may be the only effective substitute.

Hypoallergenic formula or breast-feeding should be the recommended dietary options for infants with CMA for the first 6 months of life. From 6 months of age, solid foods may be introduced. Generally, highly allergenic foods such as egg, soy, peanut, fish, and wheat are also avoided until the age of 1 year.

Reintroduction of cows'-milk protein may be performed in 3–6-month intervals after the age of 1 year; with infants having severe CMA, pediatric advice should be sought before attempting reintroduction.

Education of both the affected child and parents is vital to successful management of CMA. Both the physician and dietitian can provide guidance and recommend ways for introducing foods in childhood. This helps guarantee a cows'-milk protein-free diet as well as a nutritionally complete diet. Dietitians are also very useful in teaching how to read labels on food packages and identifying milk-derived products.

Lactose Intolerance

F Suarez, Abbott Laboratories, Columbus, OH, USA
C Shannon, The Toledo Hospital, Toledo, OH, USA
S Hertzler, The Ohio State University, Columbus, OH, USA
D Savaiano, Purdue University, West Lafayette, IN, USA

Introduction

Lactose intolerance is best defined as the development of gastrointestinal symptoms after the consumption of the 'milk sugar' lactose. Symptoms of intolerance can occur in most humans and all mammals if the amount of lactose consumed exceeds the ability of the gastrointestinal tract to digest this lactose. Thus, lactose intolerance is intermittent since it depends on both the dose of lactose and the response of the gastrointestinal tract. Lactose, a carbohydrate unique to milks and dairy foods, is a disaccharide composed of glucose and galactose, synthesized in the mammary glands of almost all mammals. Young mammals have a large capacity to digest lactose due to a very high activity of a digestive enzyme (a lactase) found on the lining of the small intestine. Most humans and all mammals exhibit a reduced level of this lactase enzyme (and thus a reduced capacity to digest lactose) as they mature past infancy. Interestingly, approximately 25% of the human population maintains a high level of lactase activity and therefore a large capacity to digest lactose throughout life. These individuals are called lactose-tolerant or lactose digesters. A more scientific name for this group is lactase-persistent since the enzyme activity is maintained or persists. The majority of lactose digesters come from northern European, central African and Middle Eastern backgrounds. The remaining 75% of the world's population, including almost all Asians, Native Americans, and many Africans and Latinos, are thus described as lactose-intolerant or lactase-nonpersistent. The regulation of intestinal lactase activity is under genetic control.

The belief that lactase-nonpersistent individuals will always have abdominal symptoms, such as flatulence, abdominal pain, and diarrhea, following dairy food consumption has resulted in many individuals eliminating dairy products from their diet in an effort to prevent symptoms. However, dairy products provide key nutrients and the majority of calcium found in the food supply. The elimination of milk and milk products from the diet makes it very difficult to obtain the recommended dietary allowance of calcium from natural dietary sources. The average American

woman consumes only 50–60% of the 1000–1500 mg recommended for maximum retention of body calcium. Inadequate calcium intake compromises bone structure and may eventually result in osteoporosis. Thus, it is important to provide clear dietary management that allows lactase-nonpersistent individuals to consume adequate amounts of essential nutrients, including calcium, while avoiding symptoms of intolerance.

Lactose intolerance must not be confused with milk allergy. Milk allergy is caused when the immune system reacts against one or more of the proteins found in milk. Milk allergy usually develops in early infancy, before 1 year of age. In developed countries, the incidence in infancy is estimated at $\leq 5\%$ and the remission rate is about 90% before 3 years of age. Gastrointestinal symptoms are reported in approximately 50% of infants with milk allergy while cutaneous symptoms are more common and respiratory symptoms less so. In contrast, lactose intolerance has no immunological bases, only follows the loss of intestinal lactase activity, which occurs around 3–5 years of age, and is limited to gastrointestinal symptoms.

To understand the dietary management of lactose intolerance, it is important to recognize that multiple factors affect the body's ability to digest and tolerate lactose. These factors include: (1) the amount of lactose ingested; (2) the level of the residual lactase activity that remains after maturation; (3) gastrointestinal transit time; and (4) the capacity of the colonic microflora to ferment (digest) lactose. This article will review these factors in order to describe a dietary approach to eliminate symptoms of intolerance while consuming adequate calcium, as well as to correct the perception that lactose intolerance is a frequent and severe problem.

Lactose Digestion and Lactase Activity

Lactose is present in varying degrees in all mammalian milk, with the exception of the milk of the sea lion. Mammary glands have a unique capability to synthesize lactose via the enzyme lactose synthetase. Lactose sythetase links the two monosaccharides (simple sugars) glucose and galactose by a beta 1–4 bond, forming the disaccharide lactose. Cows' milk contains about $50\,g\,l^{-1}$ of lactose, whereas human milk contains one of the highest concentrations, up to $75\,g\,l^{-1}$. Table 1 lists the lactose content of common dairy foods. Fluid milk products have the highest concentration of lactose. When cheese is manufactured, lactose remains with the whey. Thus, hard cheeses contain very small amounts of lactose since the whey is removed in the elaboration process. Lactose may also be found in medications in biologically insignificant amounts (milligrams) due to its excellent tablet-forming properties.

Dietary lactose cannot be absorbed intact directly across the small intestinal mucosa; it must first be hydrolyzed. The enzyme lactase-phlorizin hydrolase (commonly called lactase), a disaccharidase located on the brush border of the intestinal epithelium, breaks the chemical bond between glucose and galactose. These monosaccharides are absorbed across the intestine and transported to the liver for utilization. The lactase enzyme is found must abundantly in the proximal ileum and specifically only hydrolyzes lactose. Human infant lactase is the last of the disaccharidases to appear during fetal production. The gene responsible for the synthesis of lactase has been located in humans on chromosome 2. Lactase activity can be detected as early as 8 weeks after conception and increases to that of only one-third of a full-term infant by 34 weeks' gestation. During late gestation (35–38 weeks), lactase activity reaches approximately three-quarters of that of a full-term infant. Lactase synthesis and activity are high in nearly all full-term infants and remain high throughout the first 4 years of life.

At some point after weaning, a genetically programmed reduction of lactase synthesis occurs, in approximately three-fourths of the world's population, to a residual level of 5–10% that of infancy. This loss of intestinal lactase activity is not a disease, but rather a normal pattern in human physiology and is transmitted by a recessive gene. The decline in lactase activity is known as lactase-nonpersistence (LNP) or primary acquired hypolactasia and cannot be modified by continued exposure to milk or lactose.

In humans there appears to be a mosaic pattern of lactase activity in the jejunal enterocytes. In LNP individuals, some jejunal enterocytes produce high amounts of lactase while others, even those sharing the same villus, do not produce lactase. Thus, rather than a uniform reduction in lactase production among all enterocytes, a hypolactasic individual may have a patchy distribution of lactose-producing enterocytes that are low in number relative to the nonlactase-producing enterocytes. Current evidence suggests that the regulation of lactase is accomplished primarily at the level of transcription, although post-transcriptional factors may still be elucidated.

Congenital lactose intolerance is an extremely rare inborn error in metabolism in which detectable levels of lactase are absent at birth ($0–10\,IU\,g^{-1}$ protein) and remain abnormal throughout life. An infant with congenital lactase deficiency will have severe diarrheal illness beginning a few days after birth.

Table 1 Lactose and calcium content of selected milks, milk products, and substitutes

Product	*Serving size*	*Lactose (g per serving)*	*Calcium (mg)*
Milk	1 c (237 g)	11	291

Treatment with a lactose-free diet eliminates symptoms and promotes normal growth and development.

Because lactase enzyme protrudes from the membrane of the epithelial cell and the greatest activity is found at the tip of the intestinal villi, lactase is extremely vulnerable to intestinal disease or insult. Secondary hypolactasia is a temporary condition caused by damage to the enterocytes via disease, poisons such as alcohol, medications, surgery, or radiation to the gastrointestinal tract (Table 2). This condition is relatively common in developing countries, but most common in Third-World countries where chronic intestinal infections are prevalent. Once the causative disease is resolved and the epithelium heals, lactase activity returns to normal. Total resolution of the insufficiency may require up to 6 months or more of diet therapy.

Assessment of Lactase Levels and Lactose Maldigestion

Lactase level can be ascertained with a modest degree of accuracy simply from the determination of the subject's heritage, because prevalence varies among ethnic and racial groups (Table 3). Individuals of African, Asian, middle Eastern, Mediterranean (Jews, southern Italians, Greeks, Arabs), and Native American origin have a greater than 70% chance of being LNP. Subjects of Scandinavian and middle European origin have about a 5% and 15% chance of being LNP, respectively.

The geographical and racial distribution of lactase persistence has led to the hypothesis that three separate gene mutations occurred several thousands of years ago in places where dairy foods had become

an important component of the adult diet. Darwinian theory suggests that mutation yielded a survival advantage to subjects provided they were drinking milk. Herding animals and the use of mammalian milk as a human food originated in northern Europe, the Middle East, and central Africa several thousand years ago. Interestingly, it is in these populations that lactase persistence also appeared. Thus, the current view is that selective advantage in these populations led to the maintenance of a genetic mutation in each of these three populations. Inheritance has spread the persistence trait to other populations. Table 4 shows that approximately 200 million individuals in the USA are lactase-persistent.

Lactase levels can be measured directly or indirectly. Directly assaying the lactase activity requires a mucosal biopsy from the jejunum, since the enzyme is attached to the brush border of the small intestinal mucosa. Such biopsies can be obtained at endoscopies or via the use of a variety of tubes equipped with biopsy capsules. While this test can accurately measure lactase activity, it is an expensive, invasive, and time-consuming test and is therefore rarely used clinically. Thus, lactase activity is usually assessed indirectly from measurements of lactose absorption via blood or breath tests. Digested lactose results in free glucose, which is absorbed rapidly, and ultimately

increases blood glucose levels. The blood glucose test involves feeding a standard 50-g lactose dose and measurement of plasma glucose every 30 min over a period of 2 h. In the presence of lactose maldigestion, blood glucose increases less than 25 mg dl^{-1} above the fasting level. Unfortunately, this test is mildly invasive and with a relatively low reliability.

Because of its ease, low cost, and noninvasiveness, the breath hydrogen test is most widely used to diagnose lactose maldigestion. Undigested lactose remains in the intestine and is fermented by colonic bacteria, producing hydrogen gas, carbon dioxide, and methane in some individuals. Bacterial fermentation is the only source of molecular hydrogen in the body. A portion of the hydrogen produced in the colon diffuses into the blood and is excreted via the lungs. The breath test measures the excretion of this hydrogen. Typically, a subject is given an oral dose of lactose following an overnight ($\geq$ 12 h) fast. Breath samples are collected at regular intervals for a period of 5–8 h and analyzed by gas chromatography. The historical test used 50 g of lactose as a challenge dose, and an increase of 20 parts per million (p.p.m.) or greater above the fasting level as an indicator of lactose maldigestion. More recently, it has been shown that using a sum of hydrogen from hours 5, 6, and 7 and a $\geq$ 15 p.p.m. above-fasting criterion for maldigestion resulted in 100% sensitivity and specificity for carbohydrate maldigestion.

Pathophysiology of Lactose Maldigestion

A positive breath hydrogen test measures undigested carbohydrate in the colon and is indicative of lactose maldigestion. However, the correlation between lactose maldigestion and intolerance symptoms, such as flatulence, abdominal pain, and diarrhea, is unclear. The lactose may or may not result in perceptible symptoms depending on a number of factors, including the amount of lactose entering the colon, the metabolic activity of the colonic flora, the absorptive capacity of the colonic mucosa for the end products of lactose fermentation, and the 'irritability' of the colon.

Colonic bacteria metabolize lactose, thereby reducing osmotic pressure in the colon. If the colonic bacteria did not ferment undigested lactose, the osmotic activity of even relatively small doses of lactose could result in diarrhea. However, diarrhea is virtually never encountered when LNP subjects ingest a cup of milk (12 g of lactose). Colonic bacteria ferment lactose to short-chain fatty acids that are readily absorbed by the colon. However, when massive quantities of carbohydrate are maldigested, colonic absorption of fatty acids may not keep up with production. In this situation the bacteria may actually enhance the osmotic activity and hence aggravate the ensuing diarrhea.

In the fermentation process of lactose, appreciable quantities of gas (carbon dioxide, hydrogen, and sometimes methane) are also produced. The removal of these gases is accomplished by bacterial utilization, excretion in flatus, or by absorption through the colon. With small doses of lactose, gas may be removed as rapidly as it is produced and there will be no symptoms. However, with large lactose loads these removal mechanisms may not keep up with production, and bloating, distention, and flatulence result.

A final important factor that plays a role in the development of gastrointestinal symptoms is the response of the colon to the presence of gas and organic acids. Subjects with an 'irritable' colon might perceive symptoms whereas subject with a 'nonirritable' colon might tolerate the same degree of distention without symptoms. The intensity of symptoms may also vary with the amount of lactose consumed, the degree of colonic adaptation, and the physical form of the lactose-containing food.

The Relationship Between Lactose Maldigestion and Lactose Intolerance

The larger the dose of lactose, the greater the risk that the LNP subject will perceive symptoms of lactose intolerance. Early unblinded studies in which subjects were fed milk or lactose and then asked if they had symptoms suggested that over 45% had symptoms following a glass of milk or its lactose equivalent (12 g). The results of such studies have provided the basis for claims that many subjects require a diet severely restricted in milk and milk products or the use of a variety of commercially available lactose-digestive aids. However, tolerance to milk can be affected by factors unrelated to its lactose content and may be due to psychological factors or cultural attitudes toward milk. There is a psychogenic component to abdominal symptomatology, particularly relating to the minor and nonspecific type of symptoms (bloating, distension), that may result from ingested food. The true symptomatic potential of milk (or other foods) can only be obtained with rigidly controlled double-blind studies. Under these controlled conditions, researchers have found that lactose intolerance is less prevalent than commonly believed. For example, in a well-controlled trial, 50 g of lactose (the quantity in a quart (approx. 1l) of milk), taken as a single dose caused symptoms in most of LNP subjects. On the other hand, several blinded studies indicated that LNP subjects tolerated

up to one cup (237 ml) of milk without experiencing significant symptoms. However, the results of these studies did not gain general acceptance, in part because of failure to utilize subjects with 'severe' lactose intolerance. Some LNP individuals believe that small amounts of lactose, such as the amount used with coffee or cereal, cause gastrointestinal distress.

In 1995, our group conducted a study in 30 self-described 'severely lactose-intolerant individuals.' Initial breath hydrogen test measurements indicated that approximately 30% (9 of 30) of the subjects claiming severe lactose intolerance were digesters, and thus, had no physiological basis for intolerance symptoms. Among the true lactose maldigesters there were no significant differences in symptoms of bloating, flatulence, or number of flatus passages during the period when conventional milk (lactose-containing) versus lactose-hydrolyzed milk was ingested. During both treatment periods, symptoms were extremely mild. The triviality of these symptoms with conventional (or lactose-hydrolyzed) milk was particularly impressive given the subjects' prestudy perception that symptoms would be so bad that they would be compelled to withdraw from the study. These findings further demonstrate how strongly behavioral and psychological factors influence symptom reporting. Additional research is necessary to evaluate the psychological component of symptom reporting in lactose maldigesters.

Lactose Digestion and Calcium

Lactose maldigestion could potentially increase risk of osteoporosis either by decreased milk, and therefore calcium, intake or by decreased calcium absorption. Lactose maldigestion has been associated with lower calcium intakes and consequently a higher prevalence of osteoporosis. A sizable fraction of lactose maldigesters may unnecessarily restrict their intake of lactose-containing, calcium-rich dairy foods. Milk and milk products contribute 73% of the calcium to the US food. A second potential relationship between lactose maldigestion and osteoporosis is that maldigestion of lactose decreases absorption of calcium. Human and animal studies suggest that lactose stimulates the intestinal absorption of calcium. However, there is considerable disagreement regarding the influence of lactose and lactose maldigestion on calcium absorption in adults. Differences in study methodology (milk versus water, dose of lactose, and the choice of method for determining calcium absorption) may explain contrasting results. Physiologic doses of lactose (up to two cups (474 ml) of milk) do not appear to have a significant impact on calcium absorption. Therefore, increased prevalence of osteoporosis in lactose maldigesters is most likely related to avoidance of dairy foods and subsequently inadequate calcium intake rather than impaired intestinal calcium absorption.

Dietary Management for Lactose Maldigestion

There are several dietary strategies that effectively reduce or eliminate intolerance symptoms without compromising nutritional status (Table 5).

Dose–Response to Lactose

There is a strong positive correlation between the dose of lactose consumed and the symptomatic response. In general, increasing the amount of lactose consumed increases the number and severity of symptoms. In lactose maldigesters, 2 g of lactose is almost completely absorbed, whereas 6 g of lactose results in a minimal degree of maldigestion as measured by breath hydrogen. On average, maldigesters absorbed about half of a 12.5-g lactose load, whereas the other half passes to the terminal ileum. Interestingly, unblinded studies have frequently reported intolerance symptoms after consuming only 12 g lactose. In 1995 a double-blind protocol demonstrated that feeding 12 g of lactose (approximately one cup of milk) with a meal resulted in minimal to no symptoms in maldigesters who believed themselves to be extremely intolerant to lactose. Further evidence indicated that lactose-intolerant individuals could consume two cups (474 ml) of milk daily with divided doses at breakfast and dinner, without experiencing appreciable symptoms. Overall, a dose containing 18–25 g of lactose has the potential to produce symptoms (mostly flatulence) in approximately half of a population. However, the frequency of symptoms varies from less than 40% to greater than 90% of a subgroup. Thus, a first important dietary strategy is to limit milk consumption to one eight-ounce glass (12.5 g lactose) per meal. Doing so will dramatically reduce the likelihood of intolerance symptoms.

Factors Affecting Gastrointestinal Transit of Lactose

A key explanation of the large variability in dose–response studies is whether or not the lactose is fed with a meal. Consuming milk with other foods slows the intestinal transit of lactose. Slowing the intestinal transit permits longer contact between residual lactase in the small intestine and lactose, thus improving digestion and reducing the potential for symptoms. It is also possible that additional food in the intestine may slow the rate at which lactose is delivery

Table 5 Dietary strategies for lactose intolerance

Factors affecting lactose digestion	*Dietary strategy*	*References*
Dose of lactose	Consume a cup (237 ml) of milk or less at a time, containing up to 12 g lactose	Suarez *et al*. 1995 Hertzler *et al*. 1996 Suarez and Savaiano 1997
Intestinal transit	Consume milk with other foods, rather than alone, to slow the intestinal transit of lactose	Solomons *et al*. 1985 Martini and Savaiano 1988 Dehkordi *et al*. 1995
Yogurts	Consume yogurts containing active bacteria cultures. A serving, or even more, should be well tolerated. Lactose in yogurts is better digested than the lactose in milks	Kolars *et al.* 1984 Gilliland and Kim 1984 Savaiano *et al*. 1984 Shermak *et al*. 1995
	Pasteurized yogurts do not improve lactose digestion. However, these products, when consumed, produce little to no symptoms	Savaiano *et al*. 1984 Kolars *et al*. 1984 Gilliland and Kim 1984
Digestive aids	Over-the-counter lactase supplement pills, capsules, and drops may be used when large doses of lactose (> 12 g) are consumed at once	Moskovitz *et al*. 1987 Lin *et al*. 1993 Ramirez *et al*. 1994
	Lactose-hydrolyzed milks are also well tolerated	Nielsen *et al*. 1984 Biller *et al*. 1987 Rosado *et al*. 1988 Brand *et al*. 1991
Colon adaptation	Consume lactose-containing foods daily to increase the colon bacteria's ability to metabolize undigested lactose	Perman *et al*. 1981 Florent *et al*. 1985 Hertzler *et al*. 1996

in the colon. A slower entry of lactose into the colon might also improve the fermentation and reduce the potential for symptoms.

Individual foods also affect lactose digestion and tolerance. Whole milk, due to its greater fat and energy content, may slightly decrease breath hydrogen relative to skim milk. Whether this effect is large enough to improve tolerance is unclear. Likewise, the addition of chocolate to milk may improve lactose digestion and symptoms, possibly due to its higher osmolality or energy content and/or the effect of cocoa on intestinal transit. Thus, a second key dietary recommendation is to consume milk and other lactose-containing dairy foods with meals. This strategy will also insure that adequate calcium intake can be achieved without symptoms of intolerance.

Yogurts

Lactose that is found in yogurt with live active cultures (*Lactobacillus delbrueckii* subsp. *bulgaricus* and *Streptococcus salivarius* subsp. *thermophilus*) is digested better than lactose in milk. As a result, yogurt is well tolerated by lactose-intolerant individuals. During the manufacture of yogurts, milk solids are typically added to fluid milk to enhance the product. During yogurt production, the bacteria reduce the lactose level from around 6% to approximately 4%. Lactic acid bacteria in yogurt exhibit a very high activity of β-galactosidase. This activity functions during the manufacturing process, and most importantly also during gastrointestinal digestion of lactose *in vivo* in the stomach and/or small intestine. Clinical studies have showed that consumption of up to 18 g lactose as yogurt (two cups of yogurt) is well tolerated, and results in few symptoms of intolerance.

Pasteurization of yogurt increases the shelf-life but decreases the number of active cultures that are partly responsible for improved lactose digestion. However, pasteurized yogurt is moderately well tolerated, producing minimal symptoms. It is believed that the physical form of the yogurt and the caloric density are additional factors that improve tolerance to lactose found in yogurt. Thus, a third dietary strategy is to include yogurts as a part of a calcium-rich and well-tolerated diet.

Lactase Supplements and Lactose-Reduced Milks

Pills, capsules, and drops that contain lactase derived from yeast (*Kluyveromyces lactis*) or fungal (*Aspergillus niger, A. oryzae*) sources have proved effective for lactose digestion. Since 1984, these over-the-counter preparations have been given the status of generally recognized as safe (GRAS) by the US Food and Drug Administration. Additionally, milk that has been treated with lactase, resulting in a 70–100% reduction in lactose, is commercially available. Lactose-hydrolyzed milk typically has increased

sweetness, due to the presence of free glucose. Lactose hydrolysis can be carried out by the consumer at home, or products can be purchased already in low-lactose form. A number of studies have evaluated the effectiveness of these products. Doses of 3000–6000 FCC (Food Chemical Codex) units of lactase administered just prior to milk consumption decrease both breath hydrogen and symptom responses to lactose loads ranging from 17 to 20 g. Thus, a fourth strategy is to include lactose-reduced products and/or utilize enzyme preparations if symptoms of intolerance are present, despite adherence to simpler and more cost-effective approaches.

Unfermented Acidophilus Milk

Various strains of *Lactobacillus acidophilus* exist; however strain NCFM (North Carolina Food Microbiology) has been most extensively studied and used in commercial products. Unfermented acidophilus milk tastes identical to unaltered milk since the NCFM strain does not multiply in the product, provided that the storage temperature is below 40 °F (5 °C). *L. acidophilus* strain NCFM is derived from human fecal samples and contains β-galactosidase (lactase). However unfermented acidophilus milk does not enhance lactose digestion or reduce intolerance symptoms in doses present in commercially available products. It appears that the ingested bacteria are not disrupted by the bile acids, thus microbial lactase is not released. However, when acidophilus milk is sonicated, which destroys the bacteria membrane, lactose digestion improves.

Colonic Fermentation and Bacterial Adaptation of Lactose

The colonic bacteria ferment undigested lactose and produce short-chain fatty acids and gases. Historically, this fermentation process was viewed as a cause of lactose-intolerance symptoms. However, it is now recognized that the fermentation of lactose, as well as other nonabsorbed carbohydrates plays an important role in the health of the colon, and impacts the nutritional status of the individual. The most compelling evidence for colonic bacterial adaptation to lactose comes from studies where the amount of lactose is carefully controlled and gradually increased over time. Increasing the daily lactose dose from 0.3 g kg^{-1} body weight up to 1.0 g kg^{-1} body weight over a period of several days to 3 weeks results in a several-fold increase in fecal β-galactosidase activity. This elevated enzyme activity returns to baseline levels with in a few days after the lactose-feeding period. Furthermore, lactose feeding dramatically decreases the breath hydrogen response to a lactose challenge dose (Figure 1). In fact, after lactose adaptation, the subjects may no longer appear to be lactose maldigesters according to the breath hydrogen test. The large doses of lactose fed during these adaptation periods (up to 70 g day^{-1}) result in only minor symptoms. Additionally, the severity and frequency of flatus symptoms in response to the lactose challenge dose are significantly reduced.

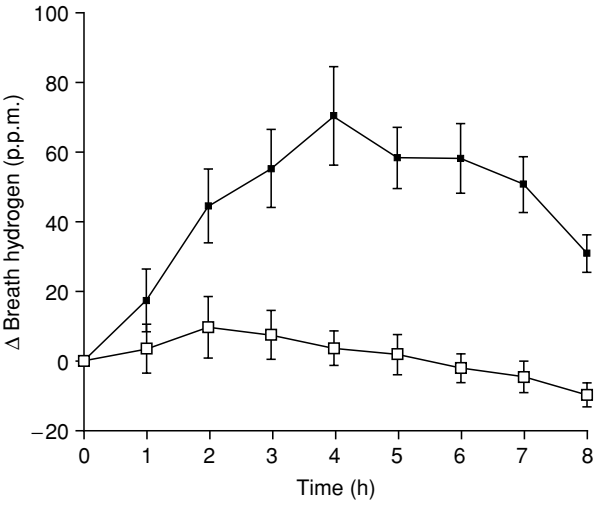

Figure 1 Breath hydrogen response to a lactose challenge after lactose (open squares) or dextrose (filled squares) feeding periods. Data are the means ± SEM, $n = 20$. Reproduced from Hertzler SR and Savaiano DA. Colonic adaptation to daily lactose feeding in lactose maldigesters reduces lactose intolerance. *American Journal of Clinical Nutrition* 64: 232–236, with permission.

Thus it appears that colonic bacterial adaptation to lactose does occur. Although the mechanisms that cause colonic adaptation need further investigation, it is clear that many lactose-intolerant individuals will develop a tolerance to milk if they consume it regularly. This may represent a simpler and less expensive solution than the use of lactose digestive aids. Thus, a final dietary recommendation to lactose-intolerant individuals is not to avoid dairy foods, but rather to include them in the diet on a daily basis. Daily consumption of milk and dairy foods will enhance colon bacterial adaptation and reduce the likelihood for symptoms of intolerance.

Conclusion

Milk and milk products are important sources of many nutrients, including calcium. The avoidance of dairy products to prevent intolerance symptoms jeopardizes bone density, thus increasing the risk for osteoporosis. The inescapable conclusion to be drawn from blinded studies is that virtually all LNP subjects, including even those with severe self-perceived intolerance, can drink milk or milk

products with minimal symptoms if taken in single serving doses with meals. Thus, the role of the health care provider is to convince the patient with self-diagnosed or, less commonly, physician-diagnosed lactose intolerance that various dietary strategies effectively manage lactose intolerance by reducing or eliminating gastrointestinal symptoms. However, beliefs concerning lactose intolerance are not easily reversed, and it may be very difficult to convince patients that their abdominal symptoms are not appreciably aggravated by ingestion of moderate doses of lactose.

Elimination Diets

C M Carter, Great Ormond Street Hospital for Children, London, UK

Definitions and Aims

An elimination diet is one which excludes one or more foods or food additives. The aim of an elimination diet is to diagnose and/or treat food-allergic disease. Food-allergic disease is an intolerance to food(s) resulting from an abnormal immunological response. The title 'food allergy and intolerance' is often used because an immunological basis cannot always be demonstrated. This article discusses the indications for the use of an elimination diet and the dietary manipulations involved.

Indications and Contraindications

The symptoms of food allergy or intolerance may come on quickly or slowly (**Table 1**). Symptoms may

Table 1 Symptoms of food allergy and intolerance

Part of body involved	Usually IgE-mediated	Probably non-IgE-mediated
	Immediate onset	Delayed onset
	Within 2 h	Within a few hours to 3 days
	After small amount of food	After larger amount of food
Gut	Swelling of lips, mouth	Reflux vomiting
	Oral allergy syndrome	Abdominal pain, bloating
	Vomiting	Small-bowel enteropathy
	Colic	Failure to thrive
		Allergic colitis, rectal bleeding
		Diarrhea
		Constipation
Skin	Urticaria	Eczema
	Angiedema	Urticaria (rarely)
	Skin rashes	
Lung	Cough/wheeze/sneeze	Asthma
	Laryngeal edema	
	Bronchospasm	
Systemic	Cardiac arrhythmia	
	Hypotension	
	Anaphylaxis	
Controversial		Migraine
		Migraine with epilepsy
		Attention deficit hyperactivity disorder
		Rheumatoid arthritis

IgE, immunoglobulin E.

appear immediately after a very small amount of food has been consumed and are usually associated with immunoglobulins of the immunoglobulin E (IgE) class. The gut, skin, and/or respiratory tract may be involved and symptoms are listed in Table 1. Skin symptoms include urticaria (also known as nettle rash or hives, an itchy reaction characterized by the appearance of raised red patches or wheals) and angiedema (localized swelling of parts of the face, mainly lips, eyes, and throat) The most serious reaction is known as anaphylaxis, which is a state of shock induced by antigen–antibody (mainly IgE) reaction. It can be life-threatening unless epinephrine (adrenaline) is administered rapidly. People who have these very severe reactions to foods tend to be asthmatic. First signs may be tingling of the lips, tongue, and throat, sneezing, pallor, and feeling unwell and light-headed. Skin rashes, angiedema, and urticaria may or may not occur. First signs are quickly followed by upper or lower airway obstruction, low blood pressure, and cardiac arrhythmia.

On the other hand, symptoms may come on slowly after hours or days and only when a considerable amount of the food has been consumed. Gut, skin, and respiratory reactions are well documented and are likely to be T-cell-mediated without IgE being involved (Table 1). However there is some evidence for a 'late-phase' IgE response. Less well-documented reactions to food include migraine, epilepsy with migraine, attention deficit hyperactivity disorder (ADHD), and rheumatoid arthritis. There is much difference of opinion as to the role of diet, although the small amount of research carried out indicates that the idea that food is involved should be taken seriously, but etiology is not known.

Immediate IgE-mediated Food Allergy

The presence of specific IgE antibodies can be demonstrated quantatively with skinprick tests (SPT) or in the serum with radioallergosorbent tests (RAST). Although the negative predictive accuracy of SPTs is 95%, the positive predictive accuracy is only about 50%. This means that a negative result virtually precludes the possibility of an IgE-mediated allergic reaction, while a positive result indicates an allergic person, but an elimination diet cannot be based on the results of these tests. RAST tests are no more accurate.

However, people (or parents of children) who have immediate reactions to foods usually have no doubt as to the problem food and will need to avoid it. Those who have severe or anaphylactic reactions to food will need to avoid even the smallest trace and this is difficult to do in practice. Any food may be a trigger but the most common provoking foods are peanut, tree nut, milk, egg, wheat, soya, fish, and shellfish. Such elimination diets are hard to achieve for the following reasons:

1. Problems with manufactured food labeling. In Europe and other parts of the world (except the USA and Canada) there is a '25% rule' which means that if a product has a compound ingredient which forms less than 25% of the finished product, its ingredients do not have to be declared. For example, the ingredients of salami on a pizza would not have to be declared. Many food manufacturers are disregarding this rule for peanuts and tree nuts and it is to be hoped that this will happen for milk and wheat also. Another aspect of food labeling involves the use of many terms for one food item. Table 2 shows the many different terms which denote the presence of milk.
2. Factory contamination. Many manufactured foods are not produced on designated lines so there is the possibility of food being contaminated from a previous run or other factory contamination. For this reason most chocolate in the UK and many other manufactured foods carry a 'may contain nuts' label. This precludes a large array of manufactured food for peanut- and tree nut-allergic people.
3. Eating out. Although attempts are being made to educate the catering industry, there are reports of people eating in restaurants or purchasing takeaways being told food was free of the requested items when it was not. There is the possibility of contamination when eating out (or at home) when, for example, a sandwich for a nut-allergic person may be made with an unwashed knife which was previously used for a peanut-butter sandwich. Alternatively a serving spoon could be contaminated with food dished up previously. Cross-contact may also occur through shared grilling surfaces, food containers, and frying oil.

Table 2 Words denoting milk used in ingredient lists on manufactured food labels

Hydrolyzed milk protein
Rennet casein
Sour cream
Whey protein concentrate

Children often grow out of allergies to milk, egg, soya, and wheat but this is much less likely for allergies to peanuts, tree nuts, and fish. Although SPTs may give an indication, the only way to know if an allergy has been outgrown is to perform a food challenge. For people who are at risk of severe reactions challenges are performed in hospital where graded doses of food are given over several hours and resuscitation equipment is available.

Delayed-onset Food Allergy or Intolerance

In the case of delayed reactions to foods, it is much less likely that people know which foods are upsetting them. Indeed, problems with foods which are eaten at nearly every meal such as wheat and milk tend to go completely unnoticed. SPTs and RAST tests are not helpful. Claims of alternative diagnostic tests have not been validated. Although the small-bowel biopsy can be a useful tool in the diagnosis of gastrointestinal disease, it does not indicate which foods are the problem.

The elimination diet is therefore the only available 'diagnostic' tool for suspected delayed-onset food allergy or intolerance. The severity of symptoms should be taken into account before deciding whether or not to embark on an elimination diet. For example, it is inappropriate to use such a diet for eczema unless the child has failed to respond to the optimum skin treatment and the eczema is severe enough to warrant diet intervention. Diets can be socially disruptive and nutritionally inadequate unless supervised properly and may cause more problems than the disease it is intended to treat. However, if symptoms are severe and foods are suspected as being implicated (although this is not a prerequisite), a 'diagnostic' elimination diet is indicated. In the case of severe symptoms, it is important that other more serious disease has been ruled out before embarking on the diet approach.

Elimination Diet Strategy

Diagnosis of food allergy/intolerance by elimination diet involves several phases. The first is an appropriate elimination diet which, if successful, results in relief of some or all the symptoms. The second phase involves sequential reintroduction of foods to identify those foods that cause problems, and a third phase is the final maintenance diet excluding all foods that were demonstrated to have caused problems on open introduction.

Phase 1: elimination diet This may be a diet excluding only one or two foods, a diet omitting a large

number of foods, or even a diet consisting of a hypoallergenic formula only.

The empirical exclusion diet An empirical diet is used where food allergy/intolerance is suspected, causative agents are not known, and one or several of the most commonly provoking foods are avoided. Studies with children who have delayed reactions to food indicate anecdotally that the most common provoking foods are similar to those listed for immediate reactions to foods, except that intolerance to some food additives and chocolate appears more common and intolerance to fish and nuts less common.

In under 1-year-olds the most frequent offender is cows' milk-based infant formula, so a cows' milk-free diet is often used. Diet avoiding egg and milk together with any known problem foods is sometimes used for eczema. It is not unusual for pediatric gastroenterologists to use a diet free of milk, egg, wheat, rye, and possibly soya for children with gastrointestinal symptoms. Several adult centers use a diet free of all grains (some include rice), egg, milk, chocolate, and additives. This is sometimes known as a 'hunter gatherer' diet.

The empirical diet may be followed for up to 6 weeks before a decision is made as to whether it has helped or not. Unhelpful diets must be abandoned.

Problems occur with empirical diets when excluded foods are inadvertently replaced by others which are equally capable of causing adverse reactions. For example, a child on a milk-free diet may drink soya milk or orange juice instead and it is possible to be equally intolerant to these foods. Failure to respond to an empirical diet does not rule out the possibility of food intolerance. More restricted diets therefore have a role to play.

Few-foods diet There are considerable difficulties in teaching people how to avoid a large number of foods. For very restricted diets it is easier to decide on which foods the child can eat and teach the diet in terms of which foods are allowed rather than concentrating on those that are forbidden. This is the basis for the few-foods diet and 3–4 weeks is the longest time one should consider using a very restricted diet, although improvement may occur in a shorter time.

The few-foods diet may consist of no more than 5–10 foods, all of which are least likely to cause problems. Different people working in this field have achieved this in several ways. The simplest few-foods diet consists of lamb, pears, and spring water only. Although an adult may manage this, a child would have great difficulty. Diets using one meat, one carbohydrate source, one fruit, and one vegetable have been used. If no improvement occurs, a second diet containing a different set of foods can be used. This is an ideal diet in theory but, because of compliance problems, especially in children, it is not uncommon to double up and allow two meats, two carbohydrate sources, etc. (Table 3). The diet should be individualized to some extent in that it cannot

Table 3 Few-foods diet and modifications

	Few-foods diet	*Possible variations and/or additions*
Meats	Turkey, lamb	Pork, chicken, rabbit
Starches	Rice, potato	Sweet potato, corn/maize
Vegetables	Two from:1. Brassica	All vegetables except tomato
	2. Carrot, parsnip	Include pulses
	3. Cucumber, marrow, courgette	
	4. Onion, leek, asparagus	
	5. Swede, turnip	
Fruit	Two from:1. Peaches and apricots	Allow all fruits listed on the left
	2. Pears	
	3. Pineapple	
	4. Melon	
	5. Grapes	
Drinks	Tap/bottled water	Hypoallergenic formula for under 2s
	Juice from allowed fruits	
Miscellaneous	Sunflower or olive oil	Spices
	Whey-free margarine	
	Small amount of sugar	
	Jam from allowed fruits	
	Salt, herbs	
Vitamin/mineral supplements	Not essential in short term	
	May be needed in the long term	

Rice can be given as Thai rice noodles, puffed rice cakes, homemade rice cookies, rice 'drink,' boiled and fried rice, and risotto. Potatoes can be prepared in many ways, including plain crisps/chips.

include known problem foods, disliked foods, or foods which are craved and usually eaten in large amounts. Table 3 gives ideas for variations or slightly enlarging the diet to make it more practical. Allergy/intolerance can occur with any food and the few-foods diet is really a 'guesswork' diet using those foods least likely to be implicated.

The few-foods diet can be difficult to follow and should only be adopted if symptoms are frequent and severe. The diet should be carefully taught and the patient given ideas for menus and packed lunches and provided with recipes for cooking with the foods allowed. Close professional support is essential.

Hypoallergenic formula only For such a diet, the only food allowed is a nutritionally complete formula which has no intact protein, the protein source being supplied by either peptides derived from hydrolyzed protein or synthetic amino acids. Such formulas are available for infants and children and adults.

This may be the first choice of diet for the infant but it is very much a last resort for children and adults and it probably means tube feeding (these products do not have a good taste).

Phase 2: reintroduction of foods If the elimination diet has resulted in a worthwhile improvement, foods are reintroduced sequentially in an effort to identify provoking foods. If the effect of the diet is unclear or if there is no improvement it should be abandoned or another type of elimination diet tried. New foods should be given in normal amounts for a week before they are incorporated into the diet. During the period of reintroduction, which may take months, the nutritional adequacy of the diet must be monitored. Vitamin and/or mineral supplements may be required. If staple foods must be avoided, e.g., milk and wheat, alternatives should be found.

If there is a risk of a severe immediate reaction to a food, it should either be avoided or reintroduced in hospital as described. Some children with multiple symptoms and multiple food intolerances have immediate reactions to some foods and delayed reactions to others.

Some people's symptoms are triggered by inhaled substances, e.g., house dust mite, or by contact with substances, e.g., grass as well as food. It can sometimes be difficult during the reintroduction phase to know whether an adverse reaction is due to a food or other allergens in the environment.

Phase 3: maintenance diet Once all foods (and additives) have been introduced and those foods causing problems avoided, the patient has arrived at a maintenance diet which will need to be adhered to.

Children have a tendency to grow out of their problems so the possibility of reintroducing avoided foods should be discussed every 6 months to a year. This may happen in an unsupervised way as a result of an accidental or a deliberate break in the diet.

If the maintenance diet excludes many foods it may be necessary to compromise. During the introduction phase some foods have an adverse effect after normal amounts are consumed regularly over several days. It may be possible to allow these foods from time to time with no adverse effect.

Outcome Assessment

It is extremely helpful for patients (or parents) to keep a daily symptom score diary beginning at least 1 week before the diet starts and continuing during the open reintroduction of foods. It can report on severity of symptoms, dietary indiscretions, and other factors that may be relevant. Diet manipulation is a very crude form of diagnosis and a diary may make it more objective.

Formulas for Infants with Cows' Milk Allergy

The infant who is not breast-fed and who is allergic to the usual infant formulas which are based on cows' milk protein will require an alternative.

Formulas based on whole soya protein isolate have been available for many years. Infants with immediate IgE-mediated allergies often do well on these formulas, although about 15% will be allergic to soya also. Infants with gastoenteropathic symptoms are much more likely to be intolerant of soya and these formulas should not be used.

As previously mentioned, there are several infant formulas available where the protein has been extensively hydrolyzed to form small peptides. These formulas are usually tolerated by cows' milk-allergic infants but a few highly allergic ones cannot manage these either. A formula where the protein consists of pure synthetic amino acids is most useful in these circumstances.

Proof by Blind Food Challenge

Since diet treatment may have a powerful placebo effect, the only way to prove that there is a physical rather than purely psychological basis for the improvement on diet is to administer the foods 'blind', i.e., when the subject is unaware that he or she is consuming it. This is achieved by offering the challenge food hidden in other food known to be tolerated. On a second occasion, in random order with the

first, material is given which looks and tastes like the challenge but does not contain challenge material. When the observer is also blind to the order of administration the procedure is known as a double-blind placebo-controlled food challenge (DBPCFC). This is regarded as the 'gold standard' for proof of food allergy or intolerance.

The DBPCFC has been used in many research studies. Over the last 25 years or so, American workers have used the DBPCFC as an integral part of investigations into immediate allergic reactions to food. Researchers used incremental doses of food over 2–5 h so that placebo and challenge could be completed in one day. They have been recommended as a diagnostic tool outside the research area but are very little used in the UK.

The DBPCFC has also been used to investigate more controversial slow-onset reactions to foods such as ADHD. However, open reintroductions of foods into an apparently successful elimination diet tend to reveal that many people relapse after several days of eating normal amounts of food. This makes a DBPCFC much more difficult to design. One would need to provide challenge and placebo material for a week each with a 2-week washout period in between. This has to be organized on an individual basis and the following crititeria must be fulfilled:

1. Enough of the provoking food must be given for a sufficient length of time. The amount will have been established during open reintroduction.
2. The challenge food must be disguised in food known to be tolerated in the amount to be given.
3. The two must be indistinguishable from one another.
4. For children in particular, the material must be acceptable in taste and quantity.
5. The challenge food should be provided in the same form as that which caused symptoms on open reintroduction. For example, dried powdered milk may not have the same effect on a subject as fresh pasteurized milk.

Although DBPCFCs may be an essential part of research, they are rarely performed in clinical practice. For the more controversial areas of food allergy or intolerance they are time-consuming and difficult to design. They are perhaps best reserved for those cases in which there are serious doubts about the diagnosis.

Elimination Diets for Prevention of Food Allergy

There is much interest in the possibility of preventing the onset of allergies in babies born into allergic families (sibling or parent with allergic disease). Results of research studies are not clear-cut but some tentative guidelines may be drawn.

Diet During Pregnancy

Although research is ongoing in this field there is not enough evidence to suggest that women who are expecting 'at-risk' infants should alter their diets during pregnancy.

Diet of the Mother During Lactation

There is little evidence to suggest that the diet of the mother during lactation has any effect in the long term on her child. However, there is some evidence that in the short term this may be helpful. Indeed, some highly allergic breast-fed children develop allergic symptoms which can be controlled if their mother avoids certain foods. For mothers who wish to do so, a milk- and egg-free diet could be followed, provided the mother has professional support and will need at least a calcium supplement.

Careful Weaning of the Potentially Allergic Child

Breast-feeding should be encouraged for all children. The 'at-risk' infant should have nothing but breast milk for at least the first 4–6 months. If breast milk is not available the best alternative is probably an infant formula where the protein has been highly hydrolyzed. It is not known whether soya formula has a protective effect. It would seem prudent to begin the weaning process with pure baby rice, vegetables, fruits, and meats, and wait until nearer 1 year old to introduce milk, egg, and wheat. There are no specific guidelines on this. Introduction of nuts should be delayed until at least 3 years.

Conclusion

Elimination diets can be expensive, are socially disruptive, and run the risk of being nutritionally inadequate. They should be reserved for individuals with troublesome symptoms who have not responded to symptomatic treatment. The ideal place for this type of treatment is in specialized clinics with interested doctors and dietitians who have the necessary expertise. Immediate reactions to foods can occasionally be very severe or even life-threatening so very careful advice must be given. Despite all these problems, elimination diets can be of great benefit to many people.

FOOD LABELING (LABELLING)

Applications

P Berry Ottaway, Berry Ottaway & Associates Ltd, Hereford, UK

Background

Accurate labeling of food has an important role in the marketing and distribution of food, both in providing information to the consumer and in helping to sell the product. Over the past 150 years, labels have developed from being on-pack advertisements for the food to providing information on the composition, nutritional value, usage instructions, and appropriate storage conditions for the food. The increase in consumer awareness of food composition, processing and nutritional content, together with the need for national and international distribution of food products has inevitably led to increased legislation on labeling.

Essential Labeling Requirements

Irrespective of the country, the legislative requirements for labeling contain most, if not all, of a number of essential requirements in common. These requirements are laid down in the Codex Alimentarius General Standard for the Labeling of Prepackaged Foods (CODEX STAN 1-1985, Rev 1-1991) and are:

- an appropriate product name and/or description;
- a list or description of ingredients;
- a net quantity declaration;
- usage or preparation instructions where appropriate;
- address of the manufacturer or marketer;
- batch or lot coding to allow traceability;
- date marking and storage instructions;
- country of origin.

As 165 countries were members of Codex Alimentarius (Codex) in 2000, adherence to the essential requirements for labeling is becoming universal. For example, in the European Union, the directive on food labeling (2000/13/EC) is, in general, consistent with the Codex Standard.

Name of the Food

According to Codex, the name of the food must indicate the true nature of the food and should normally be specific and not generic. Where a name has been established in a Codex Standard or is prescribed in national legislation, the prescribed name should be used. Where a name for the food has not been prescribed, either a common or usual name based on common usage or an appropriate descriptive term for the food that is not misleading or confusing to the consumer can be used. Where a brand name, trade mark, or 'fancy' name is given to the food for marketing purposes, it must be accompanied by a specific name, as defined above.

The Codex Standard also requires that any additional words and phrases necessary to describe the food to avoid misleading or confusing the consumer with regard to the true nature and physical condition of the food should appear on the label in conjunction with, or in close proximity to, the name of the food. This description should include, but is not limited to, the type of treatment the food has undergone (e.g., dried, concentrated, reconstituted, smoked).

List of Ingredients

The Codex Standard requires that a list of ingredients be declared on the label except in the case of single ingredient foods. This list should be headed or preceded by an appropriate title that should consist of, or include, the word 'ingredients.' The list should consist of all ingredients listed in descending order of weight (m/m) at the time of manufacture of the food, often referred to as the 'mixing bowl' stage.

Added water should be declared in the list of ingredients, except when it forms part of an ingredient such as brine, syrup, or broth used in a compound food and which is declared as such in the list of ingredients. If the water, or other volatile ingredients, are evaporated in the course of the manufacture of the food, there is no need for a declaration.

Codex provides that where a compound ingredient for which a name has been established in a Codex Standard or in national legislation constitutes less than 5% of the food, the ingredients that make up the compound ingredient, other than food additives serving a technological function (e.g., antioxidants or preservatives), need not be declared. A compound ingredient at higher levels in the food can be declared as such, provided that its ingredients are listed in descending order by weight in brackets after the name.

The Codex requirement for compound ingredients is not followed in the European Union (EU) where, since 1979, the directive permits that where a compound ingredient constitutes less than 25% of the finished product, the subcomponents of that ingredient do not have to be declared. It is likely that this exemption will eventually be repealed.

In the USA, there are two options for compounded ingredients. The first is to list the ingredient by its established common or usual name with the components given in descending order by weight in brackets. The second is to theoretically break down the compounded ingredient and incorporate each component in the ingredients list in their weight order.

The declaration of permitted food additives is required by Codex to include the class of additive in accordance with the list of additive classes given in the Standard (Table 1). The equivalent list in the European Union labeling directive differs from Codex in that the categories of color retention agent and foaming agent are not included, but modified starch(es) is included in the EU list.

The increasing awareness and concern over allergens in foods are addressed by Codex, which specifies that foods or food ingredients known to cause hypersensitivity should always be declared. These foods and ingredients are given in a list (Table 2). Very few countries have included this requirement into their legislation. The Food and Drugs Administration (FDA) in the USA has not formally defined allergens but has provided examples of foods that are commonly associated with allergic responses. Further to concerns that certain allergenic foods might have been inadvertently excluded from specific declarations, the FDA issued a warning letter to manufacturers on the topic in 1996, which clearly laid out the need to label potentially allergenic ingredients. The letter also acknowledged that potentially allergenic substances (e.g., collective labeling for spices, flavorings, and colorings) may be exempt from specific declaration under the current regulations.

Table 1 Additive classes for labeling (Codex Standard 1–1985 (Rev: 1–1991))

Acidity regulator	Flour treatment agent
Acids	Flavor enhancer
Anticaking agent	Gelling agent
Antifoaming agent	Glazing agent
Antioxidant	Humectant
Bulking agent	Preservative
Color	Propellant
Color retention agent	Raising agent
Emulsifier	Stabilizer
Emulsifying salt	Sweetener
Foaming agent	Thickener
Firming agent	
The following class titles may also be used for food additives falling into the respective classes:	
Flavor(s) and flavoring(s)	Modified starch(es)

Table 2 Foods and ingredients that are known to cause hypersensitivity and must always be declared (Codex Standard 1–1985 (Rev: 1–1991))

Cereals containing gluten, i.e., wheat, rye, barley, oats, spelt, or their hybridized strains and products of these
Crustacea and products of these
Eggs and egg products
Fish and fish products
Peanuts, soybeans, and products of these
Milk and milk products (lactose included)
Tree nuts and nut products
Sulfite in concentrations of 10 mg kg^{-1} or more

EU legislation to require the labeling of a number of allergens has been proposed, but was still not adopted by mid-2001.

One aspect of the ingredient list that tends to be inconsistent is the declaration of processing aids and the carryover of food additives. Codex defines a processing aid as a 'substance or material, not including apparatus or utensils, and not consumed as a food ingredient by itself, intentionally used in the processing of raw materials, foods or its ingredients, to fulfill a certain technological purpose during treatment or processing and which may result in the non-intentional but unavoidable presence of residues or derivatives in the final product.'

In general, processing aids and additives carried over into the food at a level less than that required to achieve a technological function do not have to be declared. However, if a food additive such as an antioxidant or preservative is carried over into the food from an ingredient in an amount sufficient for it to act in that function in the final food, it must be declared in the list of ingredients.

Net Contents

All prepackaged food should carry a declaration of net quantity. Whilst Codex requires that net content declarations are given in the metric system, this still does not apply in some countries. For example, the law in the USA requires the weight to be given in terms of avoirdupois pounds and ounces, and liquid in US gallons, quarts, pints, fluid ounces, and subdivisions thereof. The American gallon is not the same volume as the Imperial gallon originally in use in the UK and many British Commonwealth countries. Declarations for net contents should be:

- by volume for liquid foods;
- by weight for solid foods;
- by either weight or volume for semisolid or viscous foods.

Codex also requires that food packed in a liquid medium should carry a declaration, in the metric system, of the drained weight of the food. A liquid medium refers to the water, syrup, or salt solutions used, for example, in canned fruits and vegetables. Depending on the legislation of the country, the net contents declaration can be based on the 'average weight' system or 'minimum weight' system, or in some cases both.

Instructions for Use

The labels of foods should contain instructions for use, as applicable, to allow the correct or best utilization of the food. Where necessary, details of reconstitution or other ingredients needed to prepare the food should be given.

Name and Address

There is a general requirement that the name and address of a person or company responsible for the food should be included on the label. This can be the name and address of the manufacturer, packer, distributor, importer, or exporter, and should be the most appropriate contact. European food labeling legislation requires that the name and address must be of a person or company established within the EU. The name and address are required to allow the authorities or consumers to contact those responsible for the food in case of complaint or recall.

Batch or Lot Marking

In order to ensure traceability and identification of the food in terms of production, a batch or lot identification must be indelibly printed or embossed on each container. The identification can be in code or in clear and must identify the producing factory, the batch (lot) number, and/or the date and time of production. In some cases, national legislation dictates the method by which the batch or lot number must be declared.

Date Marking

Many countries, including those in the EU, require an easily understood indication of the minimum durability or shelf-life of the food. The Codex Standard on Food Labeling gives the criteria for the date marking of food in cases where there are no special requirements in individual Codex Standards on foods over commodities.

Codex requires that a 'date of minimum durability' must be declared. The form in which this date is given depends on the estimated life of the food and should consist of the day and the month for products with a minimum durability of not more than 3 months, and the month and the year for products with a minimum durability of more than 3 months. If the month is December, under Codex requirements, it is sufficient to indicate the year. For the first case where the day and month are given, the date should be preceded by the words 'Best before . . . ,' and where the month and year is given, by the words 'Best before end . . . ' These statements should be clearly visible on the package or label. Where it is impractical to print the date in conjunction with the statement, there should be a reference to where the date can be found, for example: 'Best before end: see bottom of can.'

Table 3 Products for which an indication of the date of minimum durability shall not be required

Fresh fruits and vegetables, including potatoes that have not been peeled, cut or similarly treated
Wines, liqueur wines, sparkling wines, aromatized wines, fruit wines, and sparkling fruit wines
Beverages containing 10% or more by volume of alcohol
Bakers' or pastry-cooks' wares, which, given the nature of their content, are normally consumed with 24 h of their manufacture
Vinegar
Food-grade salt
Solid sugars
Confectionery products consisting of flavored and/or colored sugars
Chewing gum

According to Codex, the declaration of the day, month, and year should be declared in an uncoded numerical sequence. The month, however, may also be indicated by letters in those countries where such use will not confuse the consumer. The use of letters for the month can be particularly important in the case of trade between the USA and Europe. In the USA, when defining the date in numerical terms, it is common to place the month before the day (i.e., 04/12 for 12 April), whereas in most European countries, the day comes before the month.

The Codex Standards exempt a number of foods and drinks from the date marking requirements (Table 3). An important declaration that should accompany the date of minimum durability on the label is that giving any special storage conditions required if the validity of the date (i.e., the shelf-life) is dependent on the conditions under which the product is kept.

Nutrition Labeling

An increasing awareness of healthy eating and the impact of the diet on heart disease has led to a consumer demand for information relating to the nutritional composition of foods. This demand has led to many food labels containing information on the nutrient content, and to ensure consistency in the manner in which this information is given, most countries have included detailed requirements for nutrition labeling in their legislation.

As with the general labeling of food, Codex also has produced guidelines on nutrition labeling (CAC/GL 2-1985. Rev 1-1993). According to Codex, the information supplied in a nutrient declaration should be for the purpose of providing consumers with a suitable profile of the nutrients contained in the food and which are considered to be of nutritional importance. This information should not lead consumers to believe that there is exact quantitative knowledge of what individuals should eat in order to maintain health, but rather to convey an understanding of the quantities of the nutrients contained in the food. Nutrition labeling should not be used to deliberately imply that a food that carries such labeling necessarily has any nutritional advantage over a similar food that is not so labeled.

The Codex guidelines lay down both the nutrients that should be declared, and the form in which the information should be given. It lists those declarations that should be mandatory as:

- the energy value of the food;
- the amounts of protein, available carbohydrate (i.e., excluding dietary fiber), and fat;
- the amount of any other nutrient for which a nutrient claim is made;
- the amount of any other nutrient considered to be relevant for maintaining a good nutritional status, as required by national legislation.

Where a claim is made for the type and/or quantity of a carbohydrate, the amount of total sugars should be listed, and the amounts of starch or other forms of carbohydrate may also be listed. In the context of this requirement, sugars are defined as mono- and disaccharides present in the food. Similarly, where a claim is made for the quantity and/or type of fatty acids, the amounts of the saturated and polyunsaturated fatty acids should be declared.

If a claim is made for a dietary fiber content, the amount of dietary fiber should also be declared. The Codex guidelines define dietary fiber as 'edible plant and animal material not hydrolyzed by the endogenous enzymes of the human digestive tract as determined by the agreed upon method.' As this definition may differ in detail from that used in some countries, national legislation needs to be considered to ensure that the calculation of dietary fiber is carried out appropriately.

The vitamins and minerals that can be declared, and the method of their declaration, can vary from country to country. The Codex guidelines are general in that they state that, in addition to the information described above, vitamins and minerals may be listed but only for those micronutrients for which recommended intakes have been established and/or which are of national importance in the country concerned.

Where vitamins and minerals are declared, only those present in significant amounts should be listed. As yet, there is no international agreement on what constitutes a significant amount of a micronutrient in a food. Codex states that, as a rule, 5% of the recommended intake of the population concerned, supplied by a serving as quantified on the label, should be taken into consideration in deciding what constitutes

a significant amount. European law, however, states that, as a rule, 15% of the recommended allowance for the vitamin and mineral supplied by 100 g or 100 ml or per serving, if the package contains only a single portion, should be taken into consideration in deciding what constitutes a significant amount.

When the nutrient content of a food is declared, it is essential that the calculations are in accordance with national legislation, as there are differences between countries in the way in which energy and the quantities of nutrients are to be calculated.

Codex and European nutrition labeling law require that protein is calculated as the Total Kjeldahl nitrogen × 6.25. However, in Codex, there is the rider that this factor is to be used unless a different factor is given in a Codex Standard or a specific Codex method of analysis for a food.

The Codex guidelines give the conversion factors to be used for the calculation of energy (Table 4). These factors are not consistently used across the world. For example, European law introduces a further category of polyols contributing 2.4 kcal/10 kJ g^{-1}.

The format for the presentation of nutrition information can vary from country to country, although the 15 EU member states and many non-EU countries closely follow the Codex guidelines. Codex requires that the declarations of nutrient content should be numerical, but additional presentation in other forms (e.g., pie chart) is not excluded. The energy statement should be given in kilojoules and kilocalories per 100 g or 100 ml or per package if the pack only contains a single portion. The energy may also be given per serving or per portion, provided the serving size is given on the label, or the number of portions in the package are given on the label.

The information on the quantities of protein, carbohydrate, and fat should be given in grams and in the same manner as the energy statement. The information on vitamin and mineral content should be given in the metric system (milligrams or micrograms as appropriate) and/or as a percentage of the nutrient reference value per 100 g or per 100 ml or per package, if the product only contains a single portion. The nutrient reference values for nine vitamins and five minerals are given in the Codex guidelines. The EU nutrition labeling directive 90/496/EEC gives reference values (as recommended daily allowances) for 12 vitamins and six minerals, and requires that the micronutrients also be given as a percentage of these values.

In the USA, there is also a requirement for micronutrients to be labeled as a percentage of reference daily intakes. In both European and US law, the order in which vitamins and minerals are to be declared is laid down. However, these requirements differ in detail. There is also some confusion between the EU and USA in the way in which the activity of certain vitamins is calculated. For example, in Europe, the activity of thiamin (vitamin B_1) is measured as the cation, whereas in the USA, it is often measured as the salt. US law also has specific labeling requirements for micronutrients in products that fall into the category of a dietary supplement under the Dietary Supplement and Health Education Act 1994.

Table 4 Conversion factors that should be used for the calculation of energy from food

Protein	4 kcal/17 kJ g^{-1}
Carbohydrate	4 kcal/17 kJ g^{-1}
Fat	9 kcal/37 kJ g^{-1}
Organic acid	3 kcal/13 kJ g^{-1}
Alcohol (ethanol)	7 kcal/29 kJ g^{-1}

Claims

The use of claims on food labels is the most controversial aspect of food labeling with a lack of agreement between countries as to what is permitted.

In most countries, food law prohibits the making of claims that a food can prevent, cure, or treat a human condition or disease. In most cases, this prohibition has been in the law for decades. More recently, there has been increasing awareness that certain diets, and possibly certain foods, may play a significant part in the reduction of risk of a disease such as heart disease or cancer.

Since the mid-1990s, the interest in functional foods has increased the debate as to what claims could be permitted. Claims have been classified into two categories, both with further subdivisions. These are:

- nutrition claims and
- health claims.

Nutrition Claims

A nutrition claim is any representation that states or implies that a food has particular nutritional properties. These include, but are not limited to, the energy value and the contents of protein, carbohydrate, fat, vitamins, and minerals. It is generally accepted that the mention of nutrients in an ingredient list or in a nutritional declaration does not represent a claim.

Nutritional claims can be categorized as:

1. Nutrient claims that describe the amount of a nutrient in a food, such claims can be either for enhanced levels of a nutrient in a food or for reduced levels of certain nutrients, such as fat, or

2. Comparative claims that compare the nutritional components of a food with different versions of the same food or with similar foods, an example would be the comparison of a low fat or low energy food with the normal version, or
3. Nutrient function claims that relate to the function of a nutrient in the body, such claims relate to the biological functions of the nutrient in the body, for example 'calcium aids in the development of strong bones and teeth' or 'protein helps build and repair body tissues.' A nutrient function claim should be based on scientific consensus and should not imply that, by carrying out its function, the nutrient would prevent, treat, or cure a disease or adverse condition.

Health Claims

A health claim is any statement or implication in the labeling or advertising of food that the food is beneficial to health. The area of health claims is controversial, but such claims can be categorized as either:

1. Claims related to dietary guidelines or healthy diets where the composition of the food can contribute to the meeting of the guidelines when consumed as part of the diet; or
2. Disease risk reduction claims where the claim relates to the consumption of a food or food component, which might help reduce the risk of a specific disease or condition. Although it may be considered to come under the concept of 'prevention,' and thus illegal, a claim that a food or food component helps in reducing the risk of a disease is different from the claim that it prevents a disease. In the USA, a limited number of disease-risk reduction claims have been permitted by the Food and Drugs Administration, provided that all the conditions in the permission are met by the food. Examples of these claims are those for:
   - calcium and osteoporosis;
   - dietary lipids and cancer;
   - sodium and hypertension;
   - folate and neural tube defects;
   - fruit and vegetables and cancer.
3. Enhanced function claims that concern the specific beneficial effects of nutrients or other components of a food on the physiological or psychological functions of the body. Such claims can also cover biological activities beyond the established roles of nutrients in growth, development, and other normal functions of the body.

There is little international agreement on which health claims could be permitted, and whilst discussions are taking place within Codex Alimentarius, the European Commission, and a number of countries, there is unlikely to be common consent before about 2005.

Warnings

Through the 1990s, food-related product liability issues and litigation increased significantly. This has led to an increase in warnings on the product labels, mostly related to ingredients. Whereas a number of the warnings are voluntary and relate to possible allergens in the food, some have become statutory. For example, in the USA, food products containing saccharin must, by law, include the statement 'Use of this Product May be Hazardous to Your Health. This Product Contains Saccharin Which Has Been Determined to Cause Cancer in Laboratory Animals.' In addition, products containing the sweetener Aspartame must be labeled with the warning 'Phenylketonurics – Contains Phenylalanine.' A very similar requirement is found in European law when the warning has to be 'Contains a source of phenylalanine.'

In Europe, it is also a legal requirement to include the warning 'Excessive consumption may produce laxative effects,' where a product contains 10% or more by weight of added polyols, regardless of the serving size of the food.

Other Labeling Requirements

There are some aspects of food labeling for which international agreement has not been reached but have already been introduced into the legislation of some countries.

One such requirement is the quantitative declaration of ingredients (QUID), which became part of European labeling law in 2000. A QUID declaration is required when, for example, an ingredient or category of ingredients appears in the name of a product (e.g., ham and mushroom pizza or strawberry yogurt) or where an ingredient is emphasized on the label in words, pictures, or graphics. In such cases, it is required that the percentage of the ingredient in the food product must appear either after the name of the food or in the list of ingredients or category of ingredients in question.

From 1997, there has been consumer-driven concern in a number of countries, particularly some in the EU, about the use of genetically modified organisms (GMOs) or byproducts of GMOs used in foods. As a consequence, from 1998, EU law required the labeling of certain GMO sources if genetically modified protein or deoxyribonucleic acid can be detected. Rapid developments in the use of genetic

modification technology meant that by the end of 2000, the legislation was already becoming outdated, and more comprehensive labeling of GMO sources had to be considered. In many countries, there has not been the same consumer reaction to GMO ingredients, and their labeling has not been a priority.

FOOD POISONING

Contents

Classification

D Roberts, Central Public Health Laboratory, London, UK

Introduction

The term food poisoning is used to describe a disturbance of the gastrointestinal tract following the consumption of contaminated food or water. Some regulatory or surveillance agencies prefer to use the terms 'foodborne disease' or 'foodborne infections and intoxications', but for simplicity and ease of understanding by most people the term 'food poisoning' will be used in this article.

A wide range of agents can give rise to food poisoning and the most common of these are listed in **Table 1**. In Europe and North America by far the most common causes of food poisoning are microorganisms, in particular bacteria and viruses (see **Tables 2** and **3**). The involvement of other agents, such as parasites, naturally toxic foods, and chemicals, will vary according to country, diet of the population, level of hygiene in food production, and level of food-processing technology. For example, in countries where there is a shortage of food containers there is opportunity for accidental contamination of food ingredients when barrels and sacks have been previously used for different commodities which may be toxic. (*See* **Parasites**: Occurrence and Detection *and also* individual agents.)

Symptoms

The symptoms of food poisoning may be very diverse and the combinations which are manifest in a patient, together with the incubation period, are often indicative of the agent involved, and thus a useful diagnostic tool. The most common symptoms are nausea, vomiting, and diarrhea with or without fever. In severe cases and with particular agents there may be more serious effects, such as septicemia or involvement of the nervous system.

Table 2 summarizes the incubation period, symptoms, and duration of illness of the main types of bacterial food poisoning. Full descriptions of these illnesses may be found in the relevant articles elsewhere in this encyclopedia. Refer to individual microorganisms. This table also includes *Listeria monocytogenes* which, although it does not usually give rise to typical food-poisoning symptoms, can be transmitted via food.

A short incubation period of a few hours with a vomiting-type syndrome is usually associated with a toxin or poisonous chemical already present in the food, either by accidental contamination (as with some chemicals) or by growth of bacteria such as *Staphylococcus aureus* and *Bacillus cereus*. The

Table 1 Agents of food poisoning

	Examples
Bacteria	*Salmonella, Staphylococcus aureus, Clostridium perfringens, C. botulinum, Bacillus cereus*
Viruses	Parvovirus; Norwalk agent; small, round, featureless viruses
Molds	*Claviceps purpurans* (ergotism)
	Aspergillus flavus (aflatoxicosis)
Marine protozoa	*Gonyaulax tamarensis* (paralytic shellfish poisoning)
	Gambierdiscus toxicus (ciguatera poisoning)
	Prorocentrum lima and several species of *Dinophysis* (diarrheic shellfish poisoning)
Parasites (helminths, protozoa, amebae)	*Trichinella spiralis, Taenia solium, Giardia lamblia, Cryptosporidium, Entamoeba histolytica*
Chemicals	Heavy metals, e.g., lead, zinc, copper, cadmium, mercury, arsenic. Insecticides, herbicides, fungicides, cleaning agents, disinfectants
Toxic plants	Toadstools, hemlock, deadly nightshade
	Raw or undercooked red kidney beans (*Phaseolus vulgaris* lectin)
	Apricot kernels (glucoside-amygdalin), green potatoes (solanine)
Toxic food animals	Puffer fish (tetrodotoxin), red whelk poisoning (tetramine)
	Scombroid fish, poorly processed (histamine)

toxin produced by *Clostridium botulinum* is a neurotoxin and takes longer to act. With agents that produce an infection within the human gut the incubation period is usually longer – 24 h or more; the organisms require this length of time to pass through the stomach and reach the intestine before they multiply and produce their effect.

Chemical Food Poisoning

In the UK chemical food poisoning is uncommon and probably responsible for not more than 1% of all episodes; however, it may be more common in other countries. The source of the chemical may be accidental contamination, leaching out of chemicals from cooking utensils or pipework (copper, cadmium, lead), mistaken identification of powders, e.g., those resembling flour (nicotinic acid, sodium fluoride), or carry-over from harvested produce previously treated with fungicides, herbicides, or insecticides. With the exception of one or two neurotoxins, the main characteristic of chemical food poisoning is vomiting within a few minutes to half an hour of ingestion of the food – a much shorter incubation period than with bacterial food poisoning, where symptoms rarely appear in less than 2 h. Recovery is usually rapid, although with some poisons there may be a high case-fatality rate. Some foods, of both plant and animal origin, are poisonous to humans because they contain certain naturally occurring toxic materials such as the lectin of the red kidney bean and tetrodotoxin of puffer fish. Others become toxic owing to the concentration of chemical poisons produced by the organisms upon which they feed, e.g., shellfish and fish which feed on the marine protozoa which produce the toxins responsible for paralytic and diarrheic shellfish poisonings and ciguatera poisoning. Scombroid fish, which are rich in histidine, become toxic owing to the breakdown of the histidine to histamine by their own natural microbial flora during poor storage following harvesting. (*See* **Contamination of Food; Fish**: Spoilage of Seafood; **Histamine; Shellfish**: Contamination and Spoilage of Molluscs and Crustaceans.)

Bacterial Food Poisoning

The term 'bacterial food poisoning' is usually restricted to the acute gastroenteritis caused by the presence of bacteria, usually in large numbers, or the products of their growth in food. It may be subdivided into three basic types according to the mode of action of the bacteria responsible:

1. Infection-type bacterial food poisoning results from the in vivo multiplication of bacteria consumed with the food, e.g., *Salmonella, Vibrio parahaemolyticus*. The dose of organisms required to initiate infection is usually large (10^6 or more per g); this enables sufficient organisms to pass through the acid region of the stomach and reach the intestine, where they set up their infection. However, infections may result from a low dose of organisms if the food has a protective effect through the stomach, e.g., if it is high in fat or has a high buffering capacity. Thus outbreaks of salmonella infection have resulted from foods such as chocolate and cheese containing levels of 100 salmonellae or less per gram of food.
2. Toxin-type poisoning results from the ingestion of food in which a toxin has already been formed as a result of microbial growth in the food. Examples of this type include *Staphylococcus aureus* (enterotoxin), *B. cereus* (emetic toxin) and *C. botulinum* (neurotoxin). The organisms need to multiply to levels exceeding 10^5 organisms per g in order for sufficient toxin to be produced to cause illness. The emetic toxins which act on the vomiting

Table 2 The main agents of bacterial food poisoning

Organism	*Incubation period (h)*	*Duration*	*Symptoms*
Salmonella (infection)	6–48 (usually 12–36)	1–7 days	D, Abp, V, F
Staphylococcus aureus (toxin in food)	2–6	6–24 h	N, V, D, Abp; collapse and dehydration in severe cases
Clostridium perfringens (toxin in intestine)	8–22	24–48 h	D, Abp, N
C. botulinum (toxin in food)	12–96 (usually 18–36)	Death in 24 h to 8 days or slow convalescence over 6–8 months	Lassitude, fatigue, dizziness, D followed by C; CNS involvement, disturbance in vision and speech
Bacillus cereus (toxin in food)	Vomiting syndrome, 1–6 Diarrheal syndrome, 8–16	6–24 h 18–24 h	N, V, sometimes D Abp, D, sometimes N
B. subtilis (toxin in food)	< 1–14 (median 2.5)	1.5–8 h	V, D, Abp, N
B. licheniformis (toxin in food)	2–14 (median 8)	6–24 h	D, V, Abp
Escherichia coli (infection and toxin)	12–72	1–7 days	D with blood and mucus in stool
Vibrio parahaemolyticus (infection)	2–48 (usually 12–18)	2–5 days	Profuse D, Abp, V, F, often dehydration
Yersinia enterocolitica (infection)	24–36 (3–5 days)	3–5 days	Moderate D to chronic enteritis
Streptococcus (toxin in food? and infection)	3–22	24–48 h	Abp, V, D
Campylobacter jejuni (infection)	3–5 days	Days or weeks	F, headache, Abp, profuse D with blood and mucus
Listeria monocytogenes[a]	1–70 days	Days to years, high mortality rate (30%)	Mild, flu-like illness, septicemia, meningitis, abortion

D, diarrhoea; N, nausea; Abp, abdominal pain; C, constipation; V, vomiting; F, fever; CNS, central nervous system.
[a]A foodborne infection rather than true food poisoning.

center produce symptoms fairly rapidly, within a few hours of consumption of the food, while the neurotoxin of *C. botulinum* takes longer to act.

3. In intermediate-type poisoning the organism (e.g., *C. perfringens*) releases an enterotoxin, but in the bowel; the toxin is not produced readily in the food. Again, a high dose of organisms is required in the food to insure that some survive through the stomach and reach the intestine, where they sporulate and release the enterotoxin, which causes fluid production and diarrhea.

Viruses, which cannot multiply in foods because they require living cells in which to replicate, cause the infection type of food poisoning. The infectious dose level may be very small.

Introduction of Microorganisms into Foods

Table 3 summarizes the principal food sources of the most common food-poisoning organisms and *L. monocytogenes*. Foods of animal origin are the primary source of many of these microorganisms. Those found in the live animal can be carried through to raw meats after slaughter, may persist through further processing, and may ultimately appear in the final retail product if insufficient attention is paid to hygiene and temperature control. Many animals are mass-reared for food, and a large proportion may arrive at the slaughterhouse excreting organisms, such as *Salmonella* and *Campylobacter*, in addition to the pathogens that form part of their normal fecal flora, such as *C. perfringens, Escherichia coli, Yersinia enterocolitica*, and *L. monocytogenes*. Continuous line processing will increase spread from carcass to carcass. Comminution of meat results in a spread of organisms throughout the product. (*See* **Meat: Slaughter.**)

During laying, eggs may be contaminated on the shell surface by *Salmonella* from chicken feces, which may be transferred to the contents during unhygienic breaking out. A small proportion may also be infected while in the hen's ovary. Milk, when freshly drawn from a healthy animal using hygienic dairy practices, should contain very few bacteria. However, various pathogens may be acquired from the milking animal herself (fecal contamination or udder infection) or from the dairy environment and equipment. Some outbreaks of salmonellosis and campylobacteriosis

Table 3 Principal food sources of the common microorganisms causing food poisoning

Agent	*Food source*
Salmonella	Raw meat and poultry, raw milk, eggs
Staphylococcus aureus	Cold meats and desserts (much handled during preparation); dairy products, especially if prepared from raw milk
Clostridium perfringens	Raw meat, poultry, dried foods, herbs, spices, vegetables
C. botulinum	Improperly preserved meat, fish, and vegetables
Bacillus cereus and other *Bacillus* spp.	Cereals, dried foods, dairy products, meat and meat products, herbs, spices, vegetables
Escherichia coli	Many raw foods, particularly of animal origin
Vibrio parahaemolyticus	Raw and cooked fish, shellfish and other seafoods
Yersinia enterocolitica	Raw meat and poultry, meat products, milk and milk products, vegetables
Streptococcus	Raw milk, raw meat and poultry, foods prepared by infected food handlers
Campylobacter jejuni	Raw poultry meat, raw or inadequately heat-treated milk, untreated water
Viruses	Raw shellfish, cold foods prepared by infected food handlers
Listeria monocytogenes (a widespread environmental organism)	Meat, poultry, soft cheese and other dairy products, vegetables, shellfish

are associated with the consumption of raw milk, and a range of organisms may be found in the product (Table 3). This source of infection can be eliminated by heat treatment of the product. (*See* **Milk**: Processing of Liquid Milk.)

Fish and shellfish may become contaminated either from the water from which they are harvested or from the environment during further processing. When fished from water polluted with sewage they may contain many fecal pathogens (Table 3). *Vibrio parahaemolyticus* is a common marine microorganism and is a frequent contaminant of raw fish and other seafoods. Shellfish are filter feeders and thus can concentrate microorganisms (bacteria, viruses, and protozoa) from the water in which they are breeding. Consumption of raw shellfish, e.g., oysters, or those that have been inadequately heat-treated, can lead to bacterial and viral infections.

Some food-poisoning bacteria are common environmental organisms; they may be present on the soil, in river mud, and on vegetation. Thus many raw foods may be contaminated from this source with organisms such as *C. perfringens, B. cereus*, and other *Bacillus* spp., and *L. monocytogenes*. Fruits, vegetables, and cereals will frequently carry a number of these organisms. Where crops require artificial irrigation and/or fertilization, particularly if polluted water and animal or human excreta are used, there is a risk of contamination with enteric bacterial pathogens.

Thus raw foods and ingredients are frequently contaminated with a range of pathogenic organisms. Many of these will be rendered safer by the application of some form of heat treatment, but they are unlikely to be sterile unless a stringent heat process such as the 'botulinum cook', applied to certain canned foods, is used. Pasteurization temperatures will eliminate most vegetative cells, but the spores of *Clostridium* spp. and *Bacillus* spp. will survive. The spores of some of the clostridia are extremely heat-resistant, and the heat processes applied in the canning industry are aimed at eliminating the most heat-resistant spores of the most serious food-poisoning organism, *C. botulinum*. (*See* **Heat Treatment**: Chemical and Microbiological Changes; **Pasteurization**: Principles.)

The food-poisoning toxins produced by bacteria vary in their ability to withstand a heat treatment. The toxins of *C. botulinum* are heat-labile and readily destroyed by boiling, while some of the enterotoxins produced by *Staphylococcus aureus* are very heat-resistant and will withstand boiling for 30 min. The emetic toxin of *B. cereus* is extremely heat-resistant and remains active after 90 min at 121 °C.

Further manipulation of a product after heat treatment will allow entry of a wide range of organisms. Those of particular concern include *Y. enterocolitica* and *L. monocytogenes* both of which can multiply at refrigeration temperatures – refrigeration being the common means of short-term preservation of foods. Thus care must be exercised with respect to hygiene of production, temperature control during storage and display, and shelf-life of the product, if the introduction and growth of these bacteria are to be prevented.

Organisms may also be transferred to food by the food handler, either directly or by cross-contamination through the use of hands, surfaces, utensils, and equipment that have not been adequately cleaned and disinfected between the preparation of different foods, especially between raw and cooked foods. It is in relation to *S. aureus* food poisoning that the food handler has an important role as a direct source of contamination. This organism is commonly carried in the nose and on the skin of humans, as well as causing skin infections, and can be readily transferred to foods by handling. Subsequent

storage at unsuitable temperatures will allow the organisms to multiply and produce their toxins. Food handlers who continue to work with active symptoms of gastroenteritis are also a hazard because there is an increased risk of fecal organisms reaching food.

Prevention of Food Poisoning

An analysis of food-poisoning outbreaks which occurred in England and Wales between 1970 and 1982 showed that the most common contributory factors related to temperature control (Table 4) – either the temperatures at which the food was held after cooking or those achieved during preparation and cooking. A later study published in 1996 drew similar conclusions in relation to outbreaks occurring between 1992 and 1994 in the UK. In order to prevent outbreaks of food poisoning it is important that everyone involved in food preparation is made aware that very few basic ingredients are sterile, but will be contaminated to a greater or lesser extent depending on their origin and amount of heat processing and other manipulation. Poor hygiene during processing and inadequate temperature control can lead to proliferation of organisms to infectious dose levels or the production of toxins in foods. Improvement in agriculture procedures can lead to the reduction in the presence of some organisms, such as *Salmonella* and *Campylobacter*, in our foods, but good hygienic food preparation and education of those involved in food production are the final lines of defense.

Application of the hazard analysis critical control points (HACCP) program is recommended for all food production processes, from small catering procedures to large-scale manufacturing. Once the sources of contamination (the hazards) and the important points at which, and means by which, they can be controlled (critical control points) are identified, and controls introduced, monitored, and verified, then the food manufacturer can have greater assurance that he or she is producing a safe product. (*See* **Hazard Analysis Critical Control Point**.)

Table 4 The most common factors contributing to outbreaks of food poisoning in England and Wales in 1970–1982

Contributing factor	*Percentage of outbreaks*[a] *in which the factor was recorded*
Preparation too far in advance	57
Storage at ambient temperature	38
Inadequate cooling	32
Inadequate reheating	26
Contaminated processed food	17
Undercooking	15
Contaminated canned food	7
Inadequate thawing	6
Cross-contamination	6
Raw food consumed	6
Improper warm-holding	5
Infected food handlers	4
Use of left-overs	4
Extra-large quantities prepared	3

[a]1479 outbreaks studied.
In some outbreaks several factors contributed.

Tracing Origins and Testing

A C Baird-Parker, Northampton, Hardingstone, UK

Introduction

Foodborne disease (food poisoning) has been defined by the World Health Organization (WHO) as: 'a disease of infectious or toxic nature, caused by, or thought to be caused by, the consumption of food and water.' It involves a large (>40) and diverse range of agents, the number of which continues to increase yearly as new agents are identified. Table 1 lists those agents currently considered to be involved in disease transmitted by foods.

The main sources of many of these organisms are domestic and wild animals (including fish and birds). Enteroviruses, *Salmonella typhi*, and *Vibrio cholerae* are of human origin and *Clostridium botulinum, Bacillus* spp., and mycotoxigenic molds are general environmental contaminants. (Refer to individual microorganisms.)

Food poisoning is usually thought of as acute gastroenteritis (fever, abdominal pain, and diarrhea, often with vomiting) of the type caused by infectious disease-causing bacteria such as *S. enterica* and toxin-forming bacteria such as *Staphylococcus aureus*. However, a number of the newly identified (often called 'emerging') food-poisoning microorganisms cause a wide range of nonintestinal symptoms. For example, *Listeria monocytogenes* causes illness ranging from a mild flu-like illness to meningitis and life-threatening infections of the central nervous system. In addition, it has been recognized within the last 20 years that a number of classical gastroenteritis-causing bacteria, such as salmonellas and *Yersinia enterocolitica*, may cause extraintestinal infections as sequelae to intestinal disease; these include reactive arthritis, Reiter's syndrome, ankylosing spondylitis, and pericarditis. The wide range of symptoms caused by foodborne disease-causing agents, many of which mimic illness of a nonfood-poisoning nature, may cause some difficulty in identifying a food cause and establishing the extent of a foodborne disease incident.

This article considers the epidemiology of foodborne diseases, the procedures used for testing foods for the causative agents, tracing the source and cause of a food-poisoning incident, and the recall of contaminated food.

Table 1 Foodborne disease-causing agents

Bacteria
Aeromonas hydrophila and *veronii* subsp. *sobria*
Bacillus cereus, B. licheniformis, and *B. subtilis*
Brucella melitensis, B. abortus, and *B. suis*
Campylobacter jejuni, C. coli, C. lari, and *C. upsaliensis*
Clostridium botulinum and *C. perfringens*
Escherichia coli (EIEC, ETEC, VTEC, EAggEC)
Listeria monocytogenes
Mycobacterium bovis
Salmonella enterica
Shigella dysenteriae, S. flexneri, S. boydii, and *S. sonnei*
Streptococcus zooepidemicus
Vibrio cholerae, V. parahaemolyticus, V. fluvialis, and *V. vulnificus*
Staphylococcus aureus
Yersinia enterocolitica
Mycotoxigenic molds
Protozoa
Cryptosporidium
Cyclospora
Giardia
Toxoplasma
Prions
vCJD
Viruses
Hepatitis A and E
Small round structured viruses (SRSV)
Dinoflagellates
Shellfish poisoning (PSP, DSP, NSP, ASP)

Epidemiology

When considering the sources of foodborne disease-causing microorganisms it is important to recognize that virtually all raw agricultural products will from time to time be contaminated with low concentrations of such organisms and, as a result of cross-contamination and recontamination, they will also contaminate cooked and other processed food products. Although salmonella are regarded to be zoonotic, and thus of animal origin, they are frequently found in soils and water, and human carriers may be the source. (*See* **Epidemiology; Zoonoses**.) Organisms of human origin, such as the previously mentioned enteroviruses and *Salmonella typhi*, may also contaminate various parts of the food chain, e.g., via human carriers contaminating food during preparation for consumption, or from human sewage contamination of foods during their growing, e.g., the contamination of vegetables with night soil or molluscan shellfish harvested from waters contaminated with raw human sewage.

Thus the original source of an agent causing foodborne disease may be difficult or impossible to establish with any degree of certainty and it may only be possible, and in many cases only appropriate, to identify the circumstances and actual foodstuff that caused a particular food-poisoning incident. In many cases this will be the result of poor food handling (including

preparation in advance for consumption) allowing survival or growth of the pathogen. (*See* **Food Poisoning**: Statistics.) For example, whereas the main source of the contamination of foods with salmonellas and campylobacters is poultry, provided the poultry is properly cooked, these bacteria will be killed and if the cooked poultry is then protected from recontamination they will not cause illness. Thus, while the source of salmonella contamination of cooked poultry is most likely to be the raw poultry, the cause of any salmonellosis arising from its consumption is most likely to be the result of poor hygienic practice during preparation. In this example, identification of the source of the original contamination is much less important than identifying the circumstances that led to the contamination of the cooked poultry. However, where contamination of a raw ready-to-eat food occurs, it is important to identify the source of the contamination to prevent its recurrence. (*See* **Poultry**: Chicken; Ducks and Geese; Turkey.)

Further, when considering the cause of a foodborne disease incident it is important to recognize that such illness is dose-related (the larger the concentration of the organism or the amount of toxin present in a food at the time of consumption, generally the greater the severity and extent of illness within a group of persons consuming the contaminated food). It is seldom that all persons exposed to an infective or intoxicating dose of a pathogen will show disease symptoms and symptoms will often vary widely in those who are ill. The minimum concentration of an agent necessary to cause illness is frequently referred to as the minimum infective dose or MID. The MID of many food-poisoning bacteria is unknown but it is generally accepted that the infective dose of classical causative agents of enteric disease, such as campylobacters, *Salmonella typhi*, and *Shigella*, is 10–100 cells, whereas the MID of others such as the food-poisoning salmonella (now all classified as *Salmonella enterica*) is generally regarded to be of the order of 100 000–1 million cells for a healthy adult. However, the infective dose and hence the risk of illness arising from a contaminated food is affected by many factors. Factors that may reduce the infective dose include: high virulence of a particular strain; age, status of health of individual exposed to the agent – in particular immune status, nutritional deficiencies in diet, and underlying disease. There is much evidence that there are in some foods substances that protect infective agents from destruction by stomach acids. Thus fats in high-fat foods such as full-fat cheeses, chocolates, and salamis may significantly reduce the infective dose of an agent; for instance, the infective dose of salmonellas may be only a few cells (< 10) in these foods. Therefore, when considering the significance of a particular concentration of an agent in a food, in relation to it having caused illness, it is important to take these facts into consideration and also to remember that in any food collected after a food-poisoning incident, numbers of microorganisms may have increased or decreased depending on how that food has been stored subsequent to the incident. With respect to microbial toxins these are often more persistent in foods than their producing organisms but may increase in amount as the result of the presence of the producing organism, or decrease as a result of biological, chemical, or physically induced breakdown.

Case Histories

Hepatitis A and Frozen Raspberries

Twenty-one persons who consumed a mousse made from frozen raspberries developed jaundice found to be caused by the hepatitis A virus. Investigation of the incident suggested that contamination had occurred during harvesting or packaging of the raspberries. Cases of hepatitis had been reported in the area where the raspberries had been picked and the sanitary conditions in the places where the pickers were housed were found to be poor. Sanitary conditions were improved and basic food hygiene instruction was given to the pickers. There were no more reported incidents from this source.

Salmonella and Chocolate

The uncommon salmonella serotype *Salmonella napoli* caused 245 cases of salmonellosis amongst children. These were traced to the consumption of contaminated chocolate bars from a single factory. The factory was very modern and clean but untreated river water was used for the water circulation system which kept the chocolate molten during transportation around the factory; *S. napoli* had previously been isolated from river water in the region of the factory. Contamination of the chocolate probably occurred as a result of microleaks in the pipes of the water circulation system, resulting in the seepage of water into the chocolate. Chocolate manufactures agreed to a code of hygienic practice following this incident.

Salmonella and Salami Sticks

A number of cases of salmonellosis, mainly amongst infants and children, occurred as a result of the consumption of salami sticks. The salami sticks were manufactured using traditional methods but with a very short maturation period. The short maturation period was not sufficiently long to destroy any

salmonella present in the meat used in the manufacture of the salami. Thus very small numbers survived. This survival was prolonged by the practice in retail outlets in the UK of storing the sticks in chill cabinets; no cases were reported in continental Europe where the sticks were stored at ambient temperatures. The manufacturers reviewed their manufacturing procedures, introducing a heating step in the process, thus guaranteeing the destruction of any salmonella that might survive the usual salami-manufacturing process.

Staphylococcus aureus and Pasta

Epidemiological and microbiological tracing attributed 47 cases of staphylococcal food poisoning, occurring in several European countries, to a single source of lasagne. The source of the problem was traced back to contamination of the eggs used in the manufacture of the pasta and was believed to be associated with the hygiene of equipment used to transport the eggs. As a result of this incident a code of practice was drawn up by the pasta industry requiring the use of pasteurized eggs in pasta manufacture and improved hygienic design of the equipment used for the preparation of the pasta.

Clostridium botulinum and Yogurt

After 27 cases of botulism were traced to the consumption of a locally produced yogurt containing hazelnuts, the source was identified as canned hazelnut purée; this was part of a batch of low-calorie products prepared using artificial sweetener. Unfortunately the manufacturer of the hazelnut purée had not recognized that the heat process used for commercially sterilizing the normal high-sugar product was not suitable for the low-calorie product. Sugars reduce the available water (a_w) to a level at which spores of *C. botulinum* are unable to initiate vegetative growth and are thus unable to grow and form botulinum toxin; the organism grew well in the sugar-free product that had a much higher a_w. The outcome of this incident was to inform producers of these and other products of the need to obtain expert advice on the required heat process before reformulating a canned food. Also, the national code of practice for low-acid canned foods was revised to clarify all requirements for the production of microbiologically safe low-acid canned foods.

Testing Foods for Foodborne disease-causing Microorganisms

Foods may be tested for foodborne pathogens for a variety of reasons; the main reasons are listed in Table 2.

Microbiological testing of foods has been widely applied by health authorities and industry as a means of identifying foods that have levels of microorganisms or their toxins in excess of those regarded to be acceptable and therefore are unsafe or unacceptable for human consumption for other reasons. Such testing was at one time believed to give adequate protection to the consumer and was the linchpin of microbiological control strategies practiced by governments and industry for much of the twentieth century. This was despite the recognition more than 30 years ago that such testing gave little or no assurance of microbiological safety or quality. This can be illustrated by reference to the most stringent testing plan applied internationally for examining baby food for salmonella. In this plan, a sample comprising 60 individual sample units is taken from a batch of baby food and from each sample unit an analytical sample unit of 25 g is taken and examined for salmonella (total analytical sample is thus 1500 g); the pass criterion is no detection of salmonella in any of the analytical units examined. Even when this pass criterion is met, there is 50% probability that up to 1% of the sample units in the food batch will be contaminated. Clearly this degree of confidence is not acceptable, particularly when considering that such a sampling plan may be applied to test the acceptability of a baby food.

It is such considerations that have led to a total reappraisal in recent years of the value of such testing as a means of assuring the microbiological safety of a foodstuff. This has led to the wide-scale introduction of Hazard Analysis Critical Control Point (HACCP)-based control systems whereby the potential hazards associated with manufacture of a food in a particular processing plant are identified using a structured hazard analysis procedure and locations where these hazards can be effectively controlled are identified. These locations are called Critical Control Points and means for their proper control (including means of monitoring that control is maintained) are identified. (*See* **Hazard Analysis Critical Control Point**.)

Table 2 Uses of microbiological testing

Investigational testing	Suspect contaminated food
Compliance testing	Governmental regulations; industry standards and purchasing specifications
Monitoring	Authorities monitoring imported and domestic foods; industry monitoring products and processes
Verification	Good manufacturing practice and Hazard Analysis Critical Control Point

As a result of the introduction of HACCP as a prime means of assuring the microbiological quality and safety of foods, microbiological testing has become less important as a primary control function and increasingly is used mainly by industry for the purpose of verification of HACCP. However, where HACCP is not applied, the industry or a health authority may apply microbiological testing if there is a need to obtain a judgment about the acceptability of a foodstuff. For instance, it may be appropriate for use in a buying specification for a microbiologically sensitive raw material from a new supplier or by a health authority on a consignment of imported food, where microbiological testing is the most appropriate acceptance criterion. For such a purpose, it is important that statistically based sampling plans are used so that the degree of confidence in the result obtained is known; methods of analysis should also be agreed. One of two types of sampling plans may be used for such acceptance sampling. The first and most widely used are the two- and three-class attribute plans established by the International Commission on Microbiological Specifications for Foods. Such plans were developed principally for testing foods in international trade for their acceptability, but are also widely used by industry in buying specifications.

Two-class plans have a single limit which distinguishes between an acceptable and unacceptable concentration of a microorganism or toxin and is used in sampling plans for foodborne pathogens.

Three-class plans are used principally for determining acceptability of levels of general microbial contaminants and indicator organisms and have two limits: one is a lower limit generally established by good manufacturing practice (GMP) requirements, while the other is an upper limit based on some index of unacceptable quality. The other main type of plan used is the standard variables plan which is based on knowledge of microbial distributions in batches of foods and can be used when such distributions approximate to log normality. This limits their use principally to industry, where their advantage over attribute plans is greater accuracy and hence greater confidence in decisions based on their use.

The choice of a sampling plan and testing procedures for investigative sampling which may, for example, be used to identify the level of contamination in a suspect consignment of food, or to investigate food involved in a food-poisoning incident, is more difficult than acceptance sampling. One major problem is that there will usually be no information on either the likely incidence of contaminated product units (or the level of contamination); these factors set requirements for the number of units of product that should be examined and the size of the analytical unit that should be tested. In investigative sampling, unlike acceptance sampling, random sampling may not be the most appropriate procedure. For example, the location of the product units in relation to possible source of the contamination may suggest that cluster or stratified sampling may be more appropriate.

Tracing the Origins of a Foodborne Disease Incident

Investigation of the cause of an outbreak or case of foodborne illness will usually require a number of procedures depending on the type and circumstances associated with the incident. These may include extensive testing of food and clinical samples for likely causative agents; the use of epidemiological analytical techniques to link illness to a common source if a number of cases of illness are involved; field investigations by public health and industry experts to find the cause; and specialist food-processing knowledge to identify what measures need to be taken to prevent its recurrence.

The tracing of the source and cause of an outbreak of foodborne disease associated with a well-defined event, such as a banquet, is usually a relatively easy matter. A list of foods consumed by the ill persons is compared against a list of items consumed by persons who are not ill, and using simple statistical correlation procedures, any significant differences in foods consumed by the two groups are identified and further investigated to find the most likely food source. Tracing the source of sporadic cases in a community is much more difficult and, as well as extensive use of well-founded epidemiological procedures, investigators need a certain amount of serendipity, backed up by specialist laboratory resources, in order to be successful.

Laboratory Investigations

Samples of suspect foods, together with clinical samples, should be collected and transported under conditions that protect them from external contamination and minimize changes in the concentration of any food-poisoning agent that may be present, e.g., in sealed sterile containers in a suitably cooled cool box. Details of the history of the sample, e.g., where and when sampled and by whom and how, together with information on symptoms of illness should be submitted to the laboratory as this will help in selecting the most appropriate method of analysis. On receipt by the laboratory the samples should be documented, properly stored, and examined as soon as possible. Such examinations must be undertaken by laboratory staff who have been trained in the microbiological

examination of foods as well as clinical specimens; they should be particularly knowledgeable of the analytical procedures to be applied. These should be performed in accredited laboratories operating to recognized good laboratory practice (GLP) standards and using procedures and methods that have been approved by an appropriate accreditation organization. The microbiological examination of a foodstuff can be problematic and a number of pitfalls may trap the unwary or careless. For instance, examination of food specimens in the same room where clinical specimens are examined is bad practice; a heavy microbial load in a clinical specimen can easily cross-contaminate a food sample, where only light contamination with the same organism in the clinical specimen is sufficient evidence to implicate a food as the source.

Initial laboratory findings should always be interpreted with care. Isolates and where appropriate original specimens should be submitted to a reference laboratory with expertise in the suspect agent of concern in order to confirm an initial finding and, if appropriate, to apply modern 'fingerprinting' and typing methods such as DNA-based subtyping methods. There are many examples of foods being erroneously implicated in a food-poisoning incident because of poor laboratory practice. There have also been many examples where failure to identify a causative agent, or a food source, has been the result of failure of the laboratory to apply the correct isolation or detection method. The microbiological examination of foods is not an exact science, although continued improvements in detection techniques in recent years have considerably improved our ability to detect pathogenic agents in foodstuffs.

Epidemiological Investigations

Two main analytical tools are used by epidemiologists to trace the source of a foodborne disease incident: case-control studies and cohort studies. For both, the first stage is to review and document all available information. In an investigation of an outbreak, a questionnaire is prepared to detail when and what was consumed and symptoms of illness. This questionnaire is used in preliminary interviews with persons affected by the outbreak to obtain basic information as to the likely cause. A case definition is also agreed, i.e., what symptoms should be searched for, as it is important when case searching (in order to identify the extent of an incident) that only the most likely cases are identified.

In a case-control study a series of questions based on the preliminary questionnaire are asked of the persons identified as corresponding to the case definition (case group) and persons who have not been ill (control group). These two groups are matched as far as possible with respect to age, sex, socioeconomic group, and place of work or residence. Controls are often based on consultation with the general practioners of the persons who have been ill. Based on information in the completed questionnaires, differences between items consumed by the ill and well group are identified and any statistically significant differences subjected to further investigation. One problem with this procedure is that it is common in food-poisoning incidents to have symptomless cases and these may well be mistakenly identified as part of the control group.

In the analysis of the case data the following are the most important.

1. Time to onset of illness. Based on knowledge of the incubation period of the illness it is possible to determine the period of exposure to infection. This information may then be plotted as a histogram relating the frequency of cases chronologically to date of onset of illness. This so-called 'epidemiological' or 'epidemic' curve can then be used to identify whether or not there has been secondary transmission of illness and whether or not it is a point-source outbreak, e.g., a single meal, or a common-source outbreak, e.g., a number of cases from the same source, such as a retail establishment, occurring over a particular time period.
2. The place where infection occurs. A map is drawn of known cases, and researchers look for relationships, such as clusters, which may assist in identifying a source.
3. The persons involved. Analysis of information on individual cases such as age, sex, medical history, occupation, home situation and any travel history may also help one to form hypotheses as to the source of infection.

In a cohort study, a group of people is identified by some other means than illness. For example, this might be all the persons who attended a conference at which it is suspected that a meal was consumed that led to illness. The persons are divided into two groups according to whether or not they ate a particular meal; the attack rate in the group eating the meal and that of the group not eating it is calculated. If there is found to be a statistically significant correlation for the consumption of a particular meal, the next stage is to determine the attack rates for persons eating and not eating a particular menu item. By this means, if successful, a particular menu item will be identified as the source of the agent that caused the illness.

Environmental Health Investigations

As part of an investigation into a foodborne disease incident, health inspectors may visit and investigate the identified source, e.g., the place where a foodstuff implicated in a food-poisoning incident was manufactured or prepared for consumption. This may involve a detailed examination of the hygienic practices, and the collection of product and environmental samples for laboratory examination. If an infectious disease is suspected, food handlers may be asked to submit samples for microbiological examination. Where a source of contamination has been identified, the health authority is most likely to require assurance that the condition that caused the contamination has been corrected prior to allowing the product to be returned to the market place. Such assurance may require evidence that checks have been done by a third party to confirm that satisfactory control measures are in place. If a HACCP plan is in place this plan will need to be revalidated.

Withdrawal of a Suspect Food

If a distributed food is found by a health authority or a producer to be contaminated with a concentration of a pathogen or toxin exceeding a legal limit or exceeding a level generally regarded to be hazardous to health, this food should be withdrawn from sale as soon as possible and if necessary the public informed.

Before announcing the public withdrawal of a food it should be ascertained, as far as is technically possible, that this food is unsafe to eat. Wherever possible, results of microbiological analyses or evidence clearly linking cases of illness to an implicated food item should be available to the health authority and/or producer, as adverse publicity is likely to result from a public recall which may cause much damage to the reputation of the producer. The prudent producer may not wish to run the risk of even worse publicity arising from an incident occurring as a result of failure to inform the public and may voluntarily withdraw the product and inform the public of this.

Authorities will take different actions concerning the extent of a recall depending on a judgment as to the health risk involved by allowing food to remain on sale or in the hands of a consumer. Thus a recall may only be required down to the distribution level, e.g., distribution warehouse, if it is judged that any food remaining on sale is unlikely to cause further illness. A similar decision may well be made for a food containing a level of microorganisms exceeding a legal limit but where no illness has been reported. However, if it is judged that serious illness could result from product on sale or in the hands of consumers, recall down to retail level would be the minimum requirement and a public warning (via the media) would usually also be required. It is important that a recall is properly coordinated by the owner or supplier of the food; for this to be effective a food company should have a documented recall procedure in place. As part of this procedure a recall coordinator should be appointed whose role is to coordinate the recall, to liaise with the public and the authorities on progress with the recall, and to act as the spokesperson in contact with the media.

When carrying out a public recall it is important that this is done as fast and thoroughly as possible. Thus there will be the need for press statements via the media and communication to customers (and retailers) via e-mail or fax, advising them of the recall. In the case of a national or international recall the health authorities will inform their contacts via established networks and if a particular ingredient is involved may work with the supplier to identify and advise producers who may be using this ingredient in further products. Effective coding of food batches and maintenance of records of distribution are essential requirements as production failures will inevitably occur from time to time.

Statistics

S Palmer, University of Wales, College of Medicine, Cardiff, UK

Background

The public health significance of food-poisoning statistics can be properly understood only when set in the context of public-health surveillance.

Modern public-health surveillance of disease has been defined as the continued watchfulness over the distribution and trends of incidence through the systematic collection, consolidation, and evaluation of morbidity and mortality reports and other relevant data, and applying these data to prevention and control.

Surveillance needs to be distinguished from research. The former focuses on problem detection and characteristics, whereas research is mainly to do with hypothesis testing. Surveillance systems generate hypotheses and should not be expected to give detailed answers. Surveillance data provide information for action and as such should stimulate investigation. Emphasis has to be on speed of detection of a potential problem rather than full and accurate documentation. Consequently, great care has to be exercised in interpreting surveillance statistics for food poisoning. Surveillance systems by definition require ongoing collection of data and therefore to be sustained over time have to rely on minimal data which are often incomplete. National surveillance systems have often gone into decline because data collection has been driven by a desire for full documentation rather than the overriding requirements of timeliness and sensitivity to trends.

Specific objectives of foodborne disease surveillance include:

1. early detection of clusters or outbreaks of foodborne disease or new exposures and other risk factors, to trigger rapid investigation and control;
2. measuring trends in microbial agents and risk factors in order to set priorities for interventions, and to evaluate foodborne disease control programs; and
3. to describe the basic epidemiology of foodborne disease, such as its geographical spread and the age distribution of cases in order to develop hypotheses about causation, which can be tested by separate research studies.

Methods of Surveillance

The main steps in surveillance are

- systematic collection of data;
- analyses of these data to produce statistics;
- interpetation of the statistics to produce information;
- distribution of this information to all those who require it so that action can be taken; and
- continuing surveillance to evaluate the action.

Data Collection

Surveillance is, by definition, an ongoing activity and can be sustained only when the burden placed on the data providers is light. Surveillance data should be limited to the minimum required to meet its specified objectives. Reporting methods should be simple and streamlined. Successful systems have been developed using modern information technology. Electronic data collection should be linked to electronic systems for dissemination of high-quality surveillance information.

Statistical Analysis

Usually, the routine analysis of surveillance data is simply the presentation of incidence rates by time, place, and person using graphs, histograms, and maps. However, more sophisticated methods are increasingly being used. Particular statistical issues include the use of time series analysis to model epidemics, the early recognition of unusual events in routine data against a variable baseline rate, small area analysis of clustering, adjustment for delays and incompleteness of reporting, and the use of

surveillance data in risk assessment models and in prediction models to evaluate the consequences of possible interventions.

Reporting

Timely reporting to those responsible for public-health action is an essential part of a bona fide surveillance system. Timeliness is defined by the objectives of the surveillance. For foodborne disease, timely reporting may need to be measured in hours so that contaminated food can be removed from the marketplace and warnings given to consumers, a target which can now be achieved globally through the internet. Typically, foodborne disease surveillance reports appear either as specifically produced publications (e.g., the Communicable Disease Report), or as electronic bulletins.

Sources of Data

Foodborne disease surveillance relies on two main sources of statistics; the statutory notifications of food poisoning and the voluntary reporting of laboratory isolations.

Statutory Notifications

In England and Wales, mandatory notification of infectious disease was introduced nationally in 1899. All registered medical practitioners diagnosing certain diseases have a duty by statute to report to the proper officer of the local authority so that suspected cases can be investigated and control measures taken as appropriate. Currently, food poisoning is notifiable under the Public Health (Control) Act 1984. In England and Wales, weekly summaries of these data are now published in the Public Health Laboratory Service (PHLS) Communicable Disease Report (CDR). The data are later corrected and published quarterly and annually by the Office for National Statistics. In addition to those cases formally notified by medical practitioners, local authorities identify other suspected cases informally. The notification system now has the flexibility to record these 'otherwise ascertained' cases which appear separately in reports.

It is important to note that 'food poisoning' is a notifiable disease, although the bacterial causes of food poisoning are not in themselves notifiable. This has led to some confusion. The Advisory Committee on the Microbiology Safety of Food proposed a working definition of food poisoning which was accepted by government departments and circulated to all doctors in the UK in 1992. Its definition of food poisoning is 'any disease of an infectious or toxic nature thought to be caused by the consumption of food or water.' This definition had previously been adopted by the World Health Organization.

Nevertheless, the way in which this definition is applied is subject to various interpretations. For example, verocytotoxic *E. coli* (VTEC) disease is quite likely to be foodborne, even though person-to-person spread and spread from direct contact with animals and the contaminated environment are significant problems. If the source of infection is unknown, a doctor may or may not suspect foodborne disease. If the source is suspected to be direct contact, technically the disease is not food poisoning, even though reporting to statutory agencies might alert them to a foodborne disease risk. It seems prudent, therefore, that suspected and confirmed VTEC infection, together with all *Salmonella* and *Campylobacter* species, however acquired, should be notified as a suspected foodborne disease.

The purpose of notification is to alert local authorities to take appropriate action to investigate and control incidents; data for surveillance are a secondary benefit. However, it is generally accepted that food-poisoning notifications are a poor indication of the true incidence of food poisoning, even though they may provide useful information on trends. This is because people with the symptoms of food poisoning often do not visit their general practitioners (GPs). When a GP does see a patient with foodborne disease, it is usually not possible to distinguish this from other more common causes of gastroenteritis. In individual cases, the food history is seldom helpful. Only when a feces sample yields a foodborne pathogen is a measure of confidence obtained. However, from a clinical point of view, there is usually little, if any, benefit to the patient from the results of a feces sample, and therefore, GPs do not routinely send samples to the laboratory. When they do, it tends to be because of the severity or persistence of symptoms.

Figure 1 shows that in England and Wales, notifications, ascertained both formally and otherwise, increased greatly from 1982 to 2000. Interpretation of these data is difficult since over this same period, considerable efforts have been made in the National Health Service and local authorities to improve reporting. Inevitably, this means increasing the numbers of cases notified. It is therefore unclear how much of the increase is due to better reporting and how much is due to a real increase in the incidence of food poisoning in the community.

Laboratory Reporting of Microbiological Data

Reports by diagnostic laboratories provide the backbone of infectious disease surveillance in the UK. In England and Wales, the PHLS developed reporting

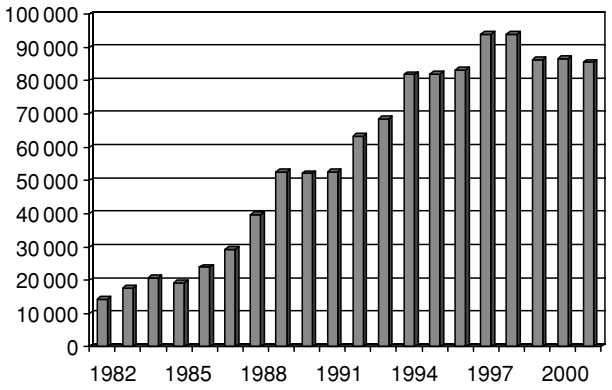

Figure 1 Notifications of food poisoning in England and Wales.

in the 1940s and 1950s. Data are analyzed within a week of receipt by the Communicable Disease Surveillance Centre (CDSC) to produce tables and line lists, which are used in compiling narrative reports for publication to the CDR. The recent introduction of OSURV (business name of electronic reporting system) has substantially replaced manual and electronic reporting.

The PHLS receives reports from over 200 clinical and public health laboratories and also uses the data held by the PHLS Laboratory of Enteric Pathogens, which is the national reference laboratory for *Salmonella*, *Campylobacter*, and VTEC infections. In Scotland, the SCIEH (Scottish Centre for Infection and Environmental Health) receives laboratory reports. Although these data are highly specific because they are based on the most comprehensive diagnostic tests, the number of reports received represents only a small fraction of the true incidence of these pathogens because of both the low level of microbiological investigation in general practice and incomplete laboratory reporting. Information accompanying these reports is limited, and there are no data on the outcome of infected patients. The data do not include patient identifiable details, so the area of residence cannot be mapped.

The main benefits of laboratory reports are that they are highly specific, since they are based on laboratory-diagnosed infections and the fine typing of the infecting organism, they often include clinical and epidemiological details, and they allow free-text comment. The reporting system is flexible, and unusual or new infections can be reported, even though they have not been included in the original reporting instructions. However, the reports are limited to infections for which there is a suitable laboratory test.

Figure 2 shows that reports of *Salmonella* infection in England and Wales tripled from 1981 to 1990. From 1990 to 1997, the high level of reports was maintained. From 1998 to 2000, *Salmonella* reports fell steadily, but in 2001, provisional data suggest an increase. These data correspond to the epidemic of *Salmonella enteritidis* that affected egg production internationally. The effect of the control measures, especially the vaccination of laying flocks, is thought to explain the sudden reversal of the epidemic in 1998.

Figure 3 shows the trends for *Campylobacter* infection in England and Wales. The steady increase in reports in the early years of its recognition could be due to increasing numbers of laboratories involved in testing and reporting. The sensitivity of laboratory methods has continued to improve, but these data are also compatible with a real increase in incidence of the infection in the community.

Figure 4 shows data for *E. coli* O157. In the UK, the incidence of laboratory reported cases rapidly increased through the 1980s following the first report in 1982. This was certainly due to increasing numbers of laboratories introducing screening tests for VTEC.

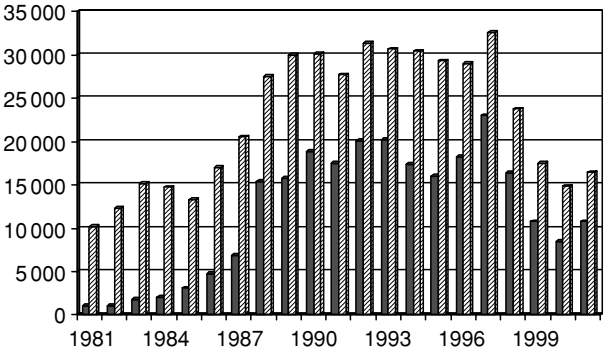

Figure 2 Reports of *Salmonella* infection in England and Wales. ■ : *Salmonella enteritidis*; ▨: total Salmonellas.

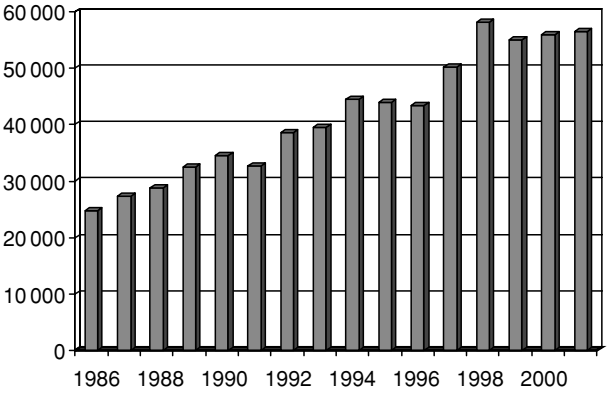

Figure 3 Reports of *Campylobacter* infection in England and Wales.

Throughout the 1990s, the annual number of cases in England and Wales fluctuated, but there is an overall increasing trend. By 1997, the number of reported cases was over 1000.

Reports from Scotland are far higher than those from England and Wales. In part, this may be due to its higher profile there. For example, in 1989, *E. coli* O157 was one of a list of 32 informally selected organisms which were made 'reportable infections' by laboratories in Scotland, in addition to the statutorily notifiable diseases, and this coincided with a doubling (at least) of the recorded incidence in a 12-month period. However, during 1992 and 1993, and against the background of heightened awareness and increased screening, the incidence dropped to about half of the 1991 level (2.3 per 100 000 compared to 4.0 in 1991). The subsequent marked increase, in 1994, also cannot be attributed to changes in reporting rates or screening, suggesting that Scotland does have a higher incidence than the rest of the UK and that there are real significant variations in the incidence of VTEC from year to year.

Figure 5 shows the trends in SRSV infections. Viral gastroenteritis is much more common than these data suggest. Most cases are not investigated through laboratories. When they are, diagnosis requires electron microscopy of feces taken within the first hours of the onset in order to have a high chance of success. Viral gastroenteritis can be foodborne from contamination of any food by dirty hands, or airborne contamination following vomiting or from food contaminated from sewage such as oysters.

Figure 6 shows the laboratory reports of *Listeria* infection, which is usually foodborne in origin. People affected are almost exclusively the elderly, pregnant women, or immunosuppressed patients. The peak in cases in 1987–89 coincided with an outbreak from pâté produced in Belgium and led to health advice for the public and considerable work by the food industry to address the risks from cook-chilled foods.

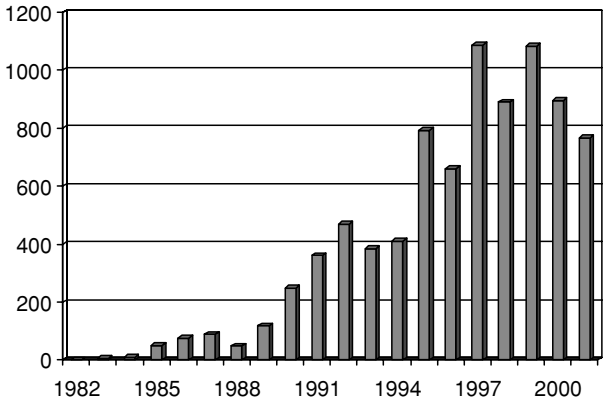

Figure 4 Reports of *E. coli* O157 in England and Wales.

The Reporting Pyramid

In order to gain a better appreciation of the true incidence of gastrointestinal infections, a national study, the Infectious Intestinal Disease (IID) in England study, was commissioned by the Department of Health. This provides the best data to date of the true incidence of enteric pathogens in the country. The objectives of the study were: first to estimate the number, and microbiological causes, of cases of intestinal infectious disease people presenting to their GPs and from whom stool specimens are routinely sent for laboratory examination; second, to compare these data with the data from the national reporting surveillance system; and third, to estimate the prevalence of asymptomatic infection with these agents.

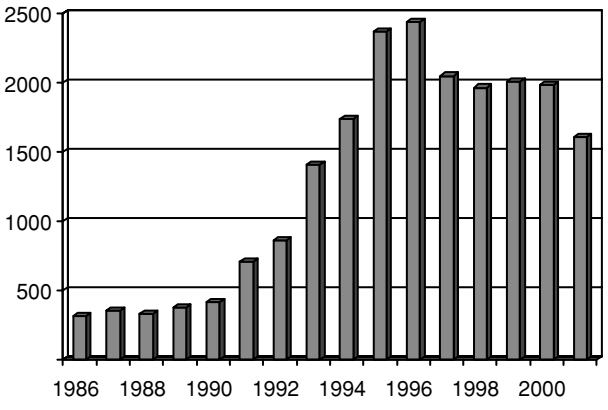

Figure 5 Reports of SRSV infections in England and Wales.

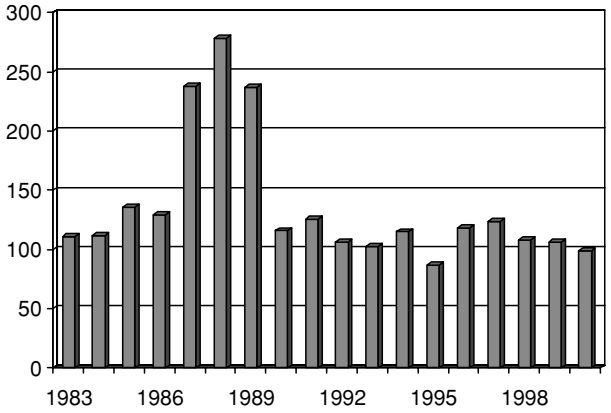

Figure 6 Laboratory reports of *Listeria* infection in England and Wales.

Seventy practices were selected to be representative of the socioeconomic characteristics of the area and to represent an urban and rural mix. Cases of infectious intestinal disease were defined as persons with loose stools or significant vomiting lasting less than 2 weeks in the absence of a known non-infectious cause and preceded by a symptom-free period of 3 weeks. Vomiting was considered significant if it occurred more than once in the 24-h period and if it incapacitated the case or was accompanied by other symptoms such as cramps or fever. One component of the study was to draw at random a cohort of people registered with the 70 GPs, who were followed up for a period of 6 months. These volunteers agreed to fill out diary cards every week and return them to the GPs. These cards stated whether the person had suffered gastrointestinal (GI) illness or not. If someone developed an illness, a stool sample was submitted.

Of particular interest in this study was the estimate of the carriage of potential pathogens in otherwise healthy people. Ten out of 2264 controls (0.4%) were found to be excreting *Salmonella*, 16 out of 2264 (0.7%) were excreting *Campylobacter*, but none out of 2264 were excreting *E. coli* 0157. These data confirm that VTEC is a rare infection in this country at the moment.

The IID study was able to quantify the reporting pyramid referred to above using the cohort component of the study. For all IIDs, it was estimated that for every case reported to the CDSC, six patients were investigated by routine laboratory tests, 23 presented with GI symptoms to their GP, and there were 136 actual cases in the community. For *Salmonella* cases, however, the ratios were much smaller. For every case reported to CDSC, it was estimated that there were 2.3 cases presenting to their GP and 3.2 actual cases in the community (see Figures 7 and 8).

Outbreak Reports

In addition to the reporting of individual cases, national surveillance centers receive reports of foodborne disease outbreaks. A general outbreak is

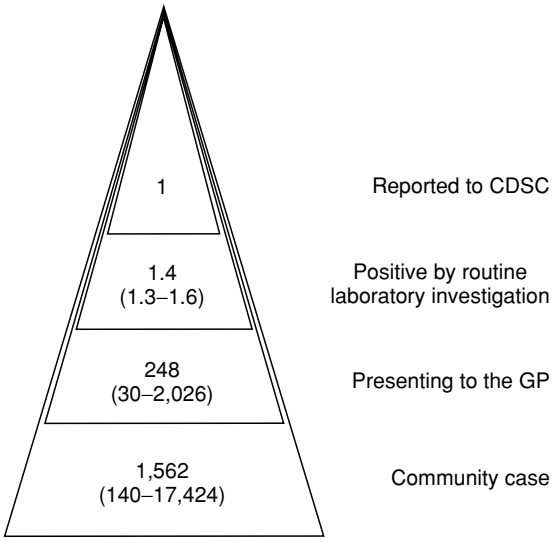

Figure 8 Reporting pyramid for SRSV.

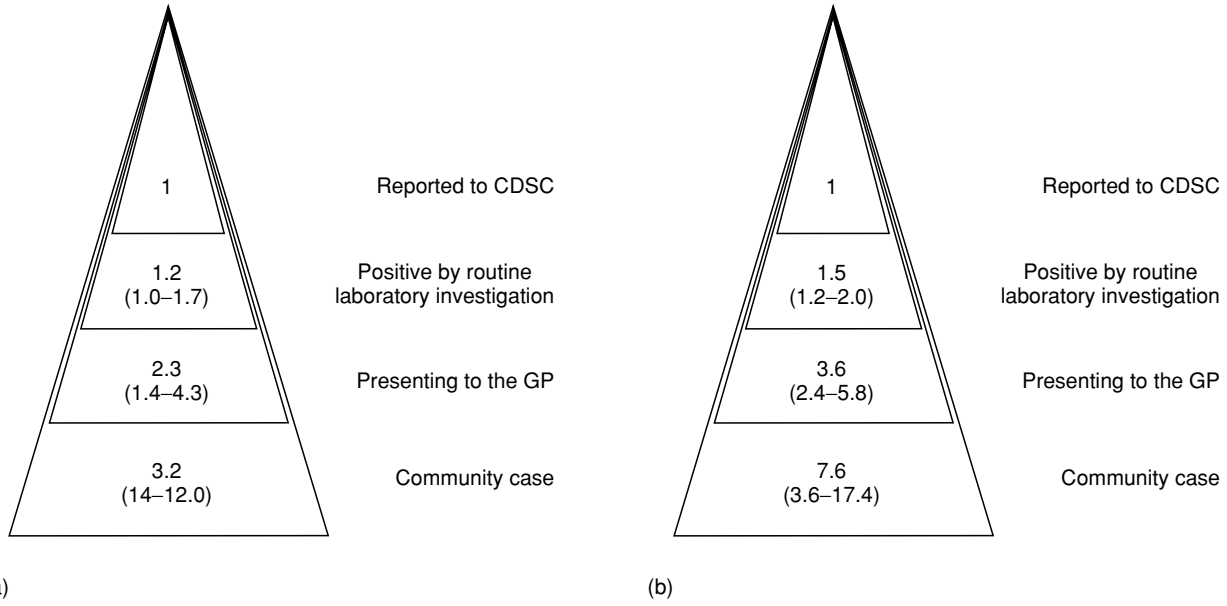

Figure 7 Reporting pyramids for (a) *Salmonella* and (b) *Campylobacter*.

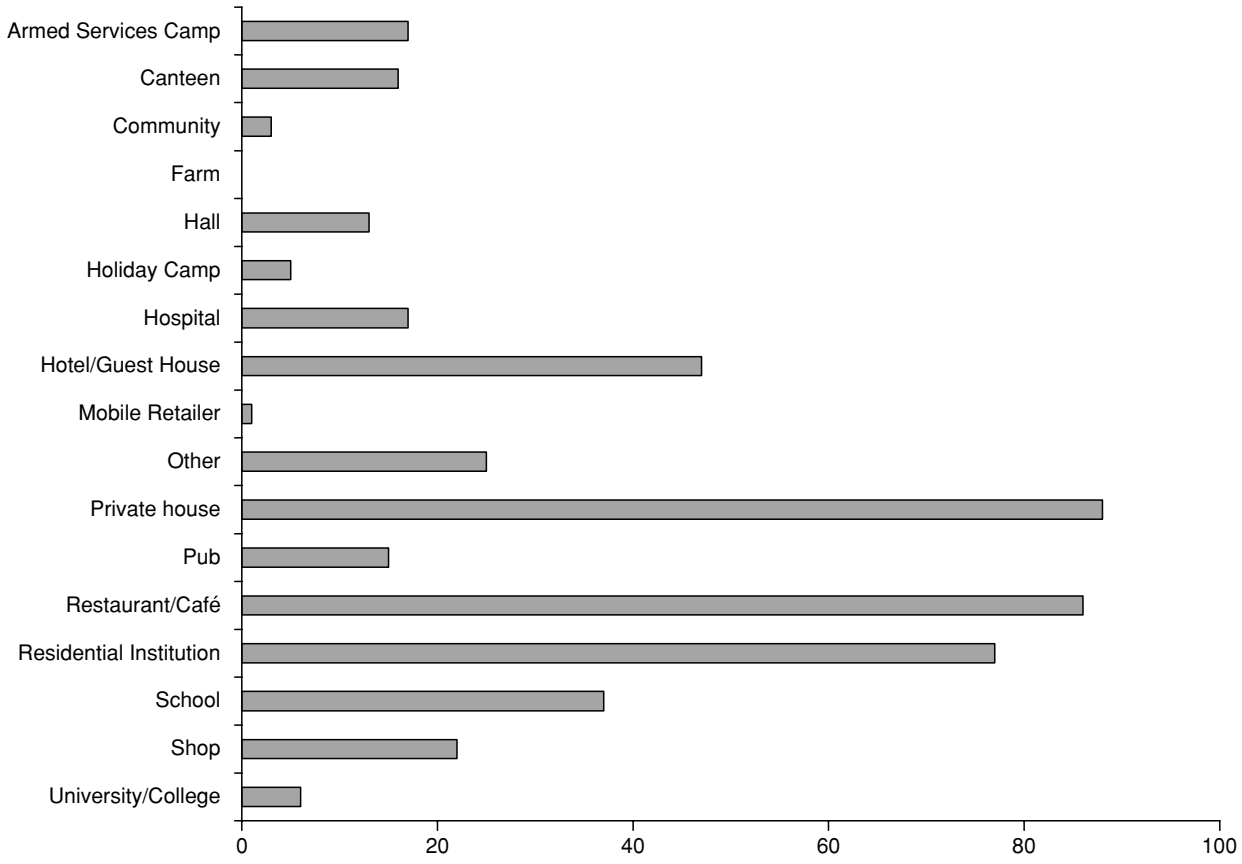

Figure 9 *Salmonella enteritidis* PT4 outbreaks in England and Wales, by place of outbreak, from 1992 to 1997.

defined as 'affecting members of more than one private residence or residence of an institution.' General outbreaks are distinguished from family outbreaks affecting members of the same private residence only. In 1992, an improved systematic surveillance system for outbreaks was developed by the PHLS in England and Wales in response to the Richmond's Committee recommendations. The CDSC is made aware of outbreaks from laboratory reports, consultants in communicable disease control, environmental health officers, and others. Outbreaks are then followed up using a standard request form that documents basic details. Participation in the surveillance scheme is entirely voluntary. Figure 9 shows the number of outbreaks of *Salmonella enteritidis* PT4 in England and Wales for 1992–97.

Enter-net

An international surveillance network (Enter-net) for human gastrointestinal infections involving 15 countries of the European Union and the USA has been set up (see Figure 10). The aim of the network is to conduct international surveillance of human salmonellosis and verocytotoxin producing *E. coli* 0157. This project began first of all with *Salmonella* cases in 1994 and was funded by the EU. The network consisted of the microbiologists in charge of the national reference laboratories in participating countries and epidemiologists responsible for national surveillance. The minimum dataset is collected for each isolate and reported to a central unit.

A dynamic database has been created, which shows that trends in salmonellosis declined throughout Western Europe from 1996 (see Figure 11). As a result of this network, international outbreaks were recognized. Individual countries identifying apparently isolated incidents were linked together to identify wider outbreaks. One of these outbreaks involved 12 cases of *E. coli* 0157 in Denmark, England, Wales, Finland, and Sweden in visitors to Fuerteventura in the Canary Islands.

Other Sources of Statistics

Registrations of Deaths

Most countries have statutory deaths registrations systems that seek to record the causes of death. These are of limited use in foodborne diseases, since

Figure 10 Enter-net participating countries.

such diseases rarely are primary causes of death, and even when they are contributory causes, the registration data may not systematically record this.

Hospital Admissions Data

Many countries have statistics on the numbers of patients admitted or discharged from hospital by disease. Once again, these data are of very limited use in developed countries, since foodborne disease rarely causes admission to hospital. Even when it does, the microbiological causes may not be recorded.

Clinical Reporting Networks

When a new foodborne disease emerges, special reporting systems may be set up, such as the UK collaborative study of childhood hemolytic uremic syndrome (HUS), which began at the end of February 1997 and is conducted by the British Pediatric Surveillance Unit (BPJU), the PHLS, Scottish Centre for Infection and Environmental Health (SCIEH) and the Scottish 0157 Reference Laboratory. Pediatricians report cases of clinically diagnosed HUS directly to the PHLS, CDSC, or SCIEH by telephone at the time of the diagnosis and also follow this up with a standard report card to the BPSU. Clinical and epidemiological data are collected directly from pediatricians. Routine feces and serum samples are sent for standard examination and isolation and subtyping of VTEC. During the first two years of the study, data

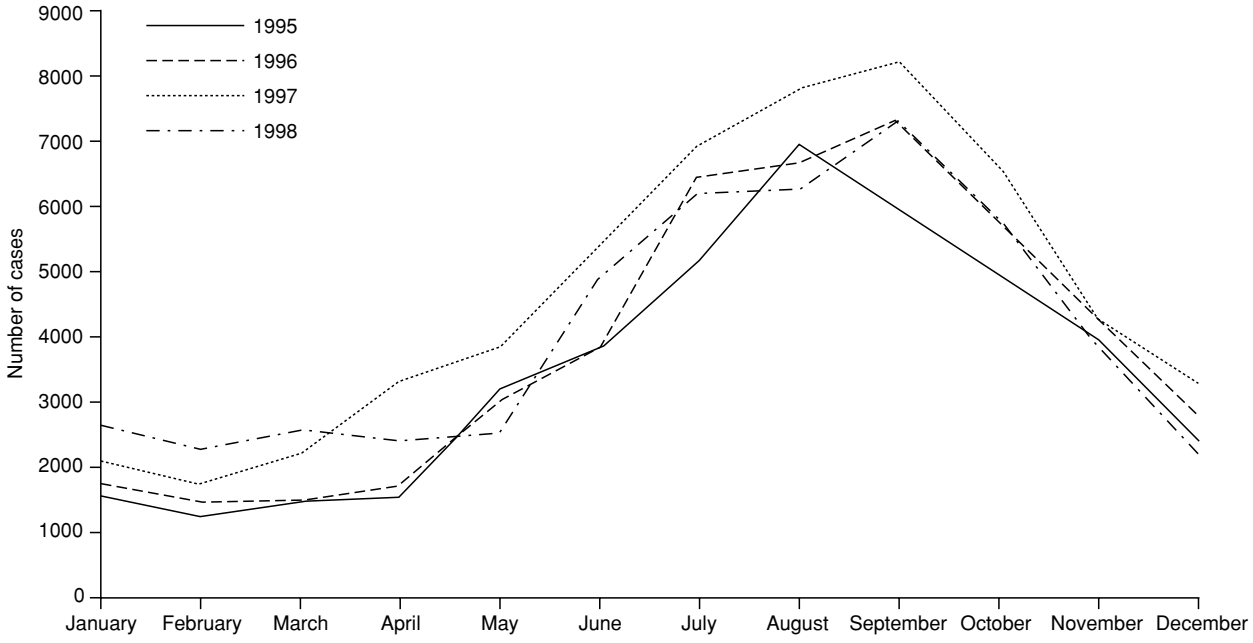

Figure 11 *Salmonella enteritidis* cases in Western Europe from 1995 to 1998.

were collected from 193 clinically confirmed cases, and five children were reported to have died. One hundred and eighty-six cases presented with a diarrheal illness, and 156 of these suffered bloody diarrhea. Stool and/or serum specimens were obtained from 185 cases, and of these, 165 were shown to have suffered VTEC infection.

Economic Implications

R B Raybourne and K M Williams, Center for Food Safety and Applied Nutrition, Laurel, MD, USA
T Roberts, Economic Research Service, Washington, DC, USA
Arthritis Working Group[1]

Background

Foodborne diseases are caused by ingesting bacteria, fungi, parasites, viruses or their toxic metabolites through contaminated food or water or through person-to-person contact. Each year, microbial pathogens cause an estimated 76 million cases of foodborne illness, including 5200 deaths in the USA, according to the study by Mead *et al*. at the Centers for Disease Control and Prevention (CDC). The Economic Research Service (ERS) in the United States Department of Agriculture and the Center for Food Safety and Applied Nutrition (CFSAN) in the Food and Drug Administration have estimated the annual human illness costs for a number of causes of foodborne illness. The ERS estimates that the total cost of five major bacterial pathogens is $6.9 billion annually. CFSAN estimates a cost of $27.9 billion for nine major causes of foodborne illness. In their estimates for human foodborne illness costs, both ERS and CFSAN include medical costs, productivity losses from missed work, and an estimate of the value of premature deaths. CFSAN also includes an estimate of the cost of pain and suffering due to illness.

The vast majority of foodborne illnesses are classified as 'acute.' These are usually self-limiting and of short duration, although the cases can range from mild to severe. Gastrointestinal problems and vomiting are common acute symptoms of many foodborne illnesses. Deaths from acute foodborne illness, while rare, are more likely to occur in the very young (including the fetus), the elderly, or patients with compromised immune systems (such as those suffering from AIDS and cancer).

[1]The other participants in the Arthritis Working Group of the Risk Assessment Consortium (RAC) are: ERS – P Frenzen; Centers for Disease Control and Prevention – J Sobel and S O' Connor; and Food and Drug Administration – A Jessup, C McGlaughlin, C Nardinelli, and R Scharff. The RAC's members are United States government agencies with food safety research and management responsibilities. The RAC enhances communication and coordination among the member agencies and promotes the conduct of scientific research that facilitates risk assessments. The RAC's web page is: http://www.foodriskclearing house.umd.edu/Risk_Assessment_Consortium.htm.

Complications of foodborne illness, called chronic sequelae, can occur in any part of the body including the joints, nervous system, kidneys, or heart. These chronic illnesses may afflict the patients for the remainder of their lives or result in premature death. For example, *Campylobacter* infections are estimated to be responsible for 20–40% of Guillain–Barré syndrome (GBS) cases (a major cause of paralysis unrelated to trauma) in the USA. About 1.5% of *E. coli* O157:H7 disease patients develop hemolytic uremic syndrome (HUS), which usually involves red blood cell destruction, kidney failure, and neurological complications, such as seizures and strokes.

We will focus on a group of chronic sequelae of foodborne infections composed of reactive arthritis, Reiter's syndrome, and ankylosing spondylitis, known collectively as the spondyloathropathies. We will use these chronic sequelae as an in depth example of how cost estimates are developed. These arthritis-like conditions occur in the aftermath of acute infection with several genera of Gram-negative Enterobacteriaceae including *Salmonella* spp., and all involve at a minimum some form of joint inflammation. The reported incidence of postacute joint inflammation can vary widely. The degree of severity and duration of arthritis is also highly variable. However, in the most severe or chronic cases, the consequences may be life-long, and there is potential to significantly increase the economic impact beyond the initial cost of acute foodborne illness.

Exposure to Pathogens and Associated Costs

Actions by the food industry, consumers, and the public health sector all influence how food is produced, marketed, prepared, and consumed. These actions influence the probability that a food item contains pathogens. People who consume contaminated food have some probability of becoming ill. Foodborne illness generates costs that are borne by the food industry, households whose members become ill, and/or the public health sector (Figure 1). A full accounting of the costs of all sectors of the economy would include estimates for all the costs listed in Table 1. Depending on the purpose of the study, different cost categories can be selected, though medical costs are those most commonly estimated.

Cost Estimates for Foodborne Disease

The Centers for Disease Control and Prevention estimates that out of a total of 76 million cases of foodborne illness each year in the USA, as many as 62 million cases are of unknown origin. Thus, in 82% of cases of foodborne illness, the disease or agent has not been identified, and costs have not been estimated. ERS and CFSAN have estimated costs for the most common identifiable causes of foodborne illness. As the pioneer of cost estimates for US foodborne illness, ERS has estimated costs for five common foodborne pathogens, likely to be associated with meat and poultry. As the agency with the responsibility for regulating the safety of the most food groups, CFSAN has estimated the cost of almost 20 causes of foodborne illness. Table 2 illustrates the estimated costs of the most common foodborne illnesses that have been studied by the two agencies.

For each agent or disease that causes foodborne illness, ERS and CFSAN estimate an annual cost of illness based on the estimated number of cases, the expected severity of illness, and whether we expect an acute illness to result in chronic sequelae. Estimated costs include medical costs, lost productivity costs, other illness-specific costs (such as special education and residential-care costs), and an estimate of the value of premature deaths. CFSAN also measures quality-adjusted life year (QALY) losses to value the pain and suffering associated with foodborne illness. Costs have not been estimated for the vast majority of complications associated with foodborne illnesses. The cost estimates do, however, cover the following chronic complications in our cost estimates: paralysis following *Campylobacter* spp. infections (called the Guillian-Barré Syndrome), kidney failure following *E. coli* O157:H7 infections (HUS), and chronic disability or impairment following congenital and newborn infections from *Listeria monocytogenes*. CFSAN estimates also include costs for arthritic complications that result from illnesses due to *Salmonella* spp. and *Shigella* spp.

Medical costs ERS and CFSAN use similar methods to estimate medical costs. Disease-outcome trees are developed for each illness to put the medical data in perspective. The total number of cases are divided into different levels of severity of disease:

- cases who recover without seeking medical care,
- cases who visit a physician and recover,
- cases who are hospitalized and recover,
- cases who develop chronic complications (can overlap with an acute survivor category), and
- those who die prematurely because of their illness.

For the different severity groups, the percentage recovering fully, partially recovering, or dying prematurely is estimated and entered into the disease outcome tree. (The disease outcome tree approach will be illustrated later when discussing the medical evidence connecting foodborne illness to arthritis.) Medical costs are estimated for physician and

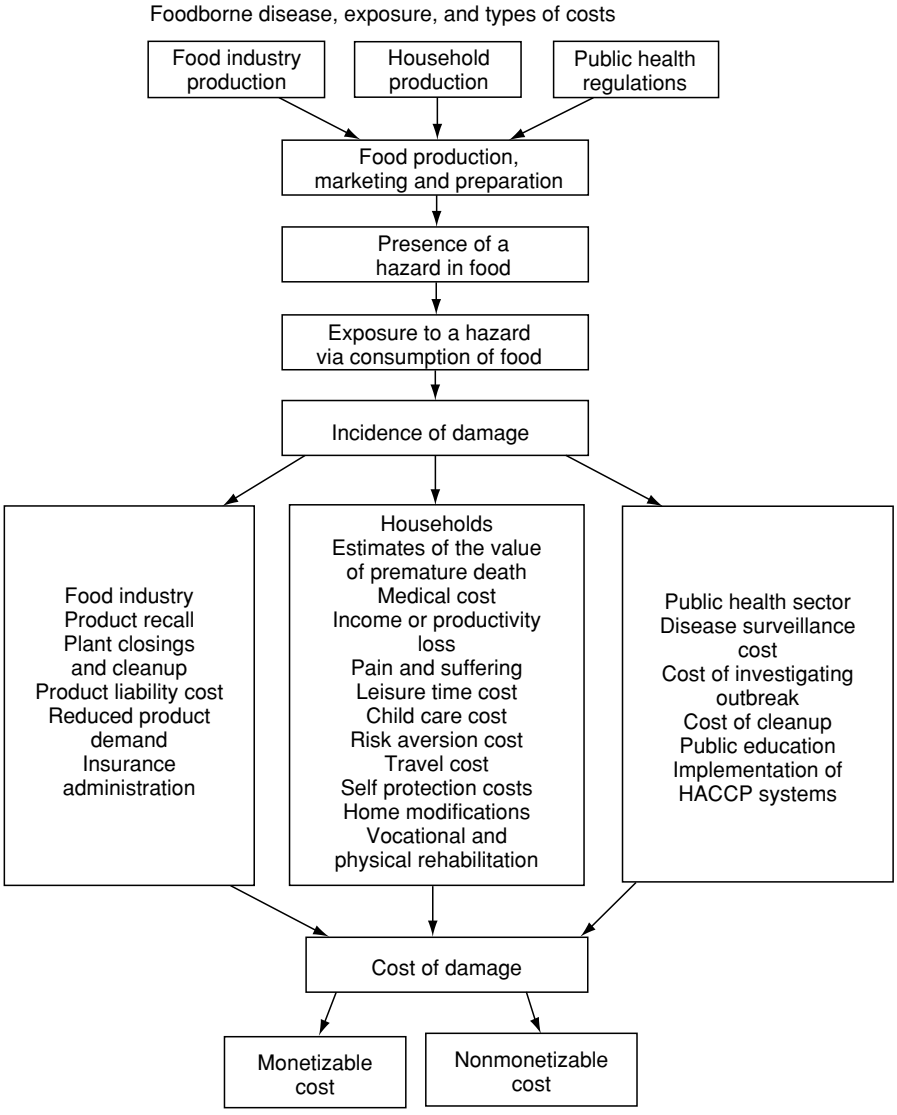

Figure 1 Foodborne disease, exposure, and types of costs.

hospital services, supplies, medications, and special procedures unique to treating the particular foodborne illnesses. Such costs reflect the average number of days or treatments of a medical service, the average cost per service or treatment in the USA, and the number of patients receiving such service or treatment.

ERS estimates of nonmedical costs For the 2000 cost estimates, ERS revised the methodology for valuing premature deaths due to foodborne illness. ERS previously assigned all deaths the same value regardless of age at time of death, based on information about the wage premiums for high-risk occupations (the 'labor market approach'). Now, the updated cost estimates use information about the age distribution of deaths to adjust this value to account for age at death.

In essence, the labor market approach values the economic cost of premature deaths based on the risk premium revealed by the higher wages paid for dangerous jobs. Under this approach, the value of a statistical life equals $6.5 million in August 2000 dollars after updating Viscusi's original 1990 estimate of $5.0 million to account for inflation. The labor market approach assumes that risk preferences observed in job choices are indicative of risk preferences for food safety.

ERS modified the labor market approach by taking the age distribution of deaths from each pathogen

Table 1 Social costs of foodborne illness

Costs to individuals/households
- Human illness costs:
  - Medical costs:
    - Physician visits
    - Laboratory costs
    - Hospitalization or nursing home
    - Drugs and other medications
    - Ambulance or other travel costs
  - Income or productivity loss for:
    - Ill person or fatal case
    - Caregiver for ill person
  - Other illness costs:
    - Travel costs to visit ill person
    - Home modifications
    - Vocational/physical rehabilitation
    - Child care costs
    - Special educational programs
    - Institutional care
    - Lost leisure time
  - Psychological costs:
    - Pain and other psychological costs
    - Risk aversion
  - Averting behavior costs:
    - Extra cleaning/cooking time costs
    - Extra cost of refrigerator, freezer, etc.
      - Flavor changes from traditional recipes (especially meat, milk, egg dishes)
      - Increased food cost when more expensive but safer foods are purchased
  - Altruism (willingness to pay for others to avoid illness)

Industry costs
- Impact of pathogens on animal production costs:
  - Morbidity and mortality of animals on farms
  - Reduced growth rate/feed efficiency and increased time to market
  - Costs of disposal of contaminated animals on farm and at slaughterhouse
  - Increased trimming or reworking at slaughterhouse and processing plant
  - Lost productivity due to illness among workers caused by handling contaminated animals or products
  - Increased meat product spoilage due to pathogen contamination
- Control costs for pathogens at all links in the food chain[a]:
  - New farm practices (age segregated housing, sterilized feed, etc.)
  - Altered animal transport and marketing patterns (animal identification systems, feeding/watering)
  - New slaughterhouse procedures (hide wash, knife sterilization, carcass sterilizing)
  - New processing procedures (pathogen tests, contract purchasing requirements)
  - Altered product transport (increased use of time/temperature indicators)
  - New wholesale/retail practices (pathogen tests, employee training, procedures)
  - Risk assessment modelling by industry for all links in the food chain
  - Price incentives for pathogen-reduced product at each link in the food chain
- Outbreak costs:
  - Herd slaughter/product recall
  - Plant closings and cleanup
  - Regulatory fines
  - Product liability suits from consumers and other firms[b]
  - Reduced product demand because of outbreak:
    - Generic animal product – all firms affected
    - Reduction for specific firm at wholesale or retail level
  - Increased advertising or consumer assurances following outbreak
  - Impact of outbreaks on tourism industry

Regulatory and public health sector costs for foodborne pathogens
- Disease surveillance costs to:
  - Monitor incidence/severity of human disease by foodborne pathogens
  - Monitor pathogen incidence in the food chain
  - Develop integrated database from farm to table for foodborne pathogens
- Research to:
  - Identify new foodborne pathogens for acute and chronic human illnesses
  - Establish high-risk products and production and consumption practices
  - Identify which consumers are at high-risk for which pathogens
  - Develop cheaper and faster pathogen tests
  - Risk assessment modelling for all links in the food chain
- Outbreak costs:
  - Costs of investigating outbreak
  - Testing to contain an outbreak (for example, serum testing and administration of IG in persons exposed to Hepatitis A)
  - Costs of cleanup
  - Legal suits to enforce regulations that may have been violated[b]

Other considerations
- Distributional effects in different regions, industries, etc.
- Equity considerations, such as special concern for children

[a]Some industry costs may fall with better pathogen control, such as reduced product spoilage, possible increases in product shelf-life, and extended shelf-life permitting shipment to more distant markets or lowering shipment costs to nearby markets.
[b]In adding up costs, care must be taken to assure that product liability costs to firms are not already counted in the estimated pain and suffering cost to individuals. However, the legal and court expenses incurred by all parties are social costs.

into account, in effect treating the value of life as an annuity paid over the average US life span at an interest rate of 3.0%. Following age adjustment, the assumed cost of each death ranges from $8.9 million for individuals who died before their first birthday to $1.7 million for individuals who died at age 85 or older.

Since the five microbial pathogens have different health outcomes for different age groups, adjusting for the age of death raises the cost of some foodborne illnesses and lowers the cost of others. For example, the annual cost of foodborne illness caused by *Salmonella* spp. decreases to $2.2 billion, because over two-thirds of the deaths from salmonellosis occur among people over 65 years of age. Adjusting foodborne illness costs for *E. coli* O157:H7 by age at time of death increases the estimates by $200 million, because most deaths are children under the age of five.

Table 2 Economic costs of foodborne illness in the USA: estimated annual costs due to selected US foodborne pathogens, 2000[a]

Pathogen	*Estimated annual foodborne illnesses*[b]			*ERS costs*[c]	*CFSAN costs*[d]
	Cases	*Hospitalizations*	*Deaths*	*Billion 2000 dollars*	
Bacterial infections					
Campylobacter spp.	1 963 141	10 539	99	1.2	–
Salmonella	1 341 873	15 608	553	2.4	17.2
Clostridium perfringens	248 520	41	7	–	0.2
Shigella	89 648	1 246	14	–	0.3
E. coli O157:H7	62 458	1 843	52	0.7	2.2
E. coli, non-O157 STEC[e]	31 229	921	26	0.3	–
Listeria monocytogenes	2 493	2 298	499	2.3	2.5
Parasitic infections					
Giardia lamblia	200 000	500	1	–	0.2
Cryptosporidium parvum	30 000	199	7	–	0.1
Viral infections					
Norwalk-like viruses	9 200 000	20 000	124	–	5.3
Hepatitis A	4 170	90	4	–	0.1
Totals					
ERS total	3 401 194	31 209	1 229	6.9	–
CFSAN total	11 179 162	41 825	1 261	–	28.1

[a]As these new estimates of foodborne illness costs are based on new data and improved methodologies for valuing these costs, the estimates presented here are not directly comparable with earlier ERS and CFSAN estimates of the costs of foodborne disease.
[b]Data from the Centers for Disease Control and Prevention published in Mead PS, Slutsker L, Dietz V *et al*. (1999) Food-related illness and death in the United States. *Emerging Infectious Diseases* 5: 607–625.
[c]The ERS total estimated costs include specific chronic complications in the case of *Campylobacter* (Guillain–Barré syndrome), *E. coli* O157:H7 (hemolytic uremic syndrome), and *Listeria monocytogenes* (congenital and newborn infections resulting in chronic disability or impairment). Estimated costs for *Listeria monocytogenes* exclude less serious cases that do not require hospitalization.
[d]The CFSAN total estimated costs include specific chronic complications in the case of *Salmonella* (arthritic conditions), *Shigella* (arthritic conditions and hemolytic uremic syndrome), and *E. coli* O157:H7 (hemolytic uremic syndrome). CFSAN uses QALYs to estimate the value of pain and suffereing.
[e]STEC stands for Shiga toxin-producing *E. coli*.

One difficult issue is assigning a value to the productivity losses associated with individuals who become ill and are unable to return to work, or for those illnesses that result in a lifetime of disability (such as prenatal exposure to *Listeria monocytogenes*). ERS currently measures the productivity losses due to nonfatal foodborne illness by the value of forgone or lost wages, regardless of whether the lost wages involved a few days missed from work or a permanent disability that prevented an individual from returning to work. Using the value of lost wages for cases resulting in disability probably understates an individual's willingness to pay to avoid disability because it does not account for the value placed on avoiding pain and suffering. The willingness to pay measure derived from labor market studies that ERS uses to value a premature death is not an appropriate measure of willingness to pay to avoid disability because it measures the higher wages paid to workers to accept a higher risk of premature death, not disability. Methods have been suggested to adjust willingness to pay to reduce the risk of premature death downward to estimate willingness to pay to avoid disability, such as the approach based on measuring QALYs. As yet, there is no consensus among economists about how to use these methods to value willingness to pay to avoid the disability, pain, and suffering associated with foodborne illnesses. ERS's conservative estimates of the annual costs due to foodborne illness (particularly the chronic conditions associated with *Campylobacter* spp.) would be substantially increased if willingness to pay to avoid disability, pain, and suffering were also taken into account.

CFSAN estimates of nonmedical costs Medical costs are a small fraction of the total social cost of foodborne illness. In addition to the cost of medical care, economists are concerned with the loss of productivity and the loss of well-being (through pain and suffering) that accompany foodborne illness. CFSAN routinely estimates these nonmedical costs of foodborne illness.

CFSAN was one of the first government agencies to use the labor market approach to estimating the economic cost of premature death. Economists have long favored this method, because it is based on observed tradeoffs that individuals make between dollars and risk. An unadjusted figure of $5.0 million per premature death is generally used in CFSAN analyses. As noted above, this value does not take into account economic changes that have occurred since 1990.

Economists at CFSAN are currently working on an adjustment factor based on both nominal and real changes in society's valuation of health. As a result, the figures that are reported in Table 2 are likely to be an underestimate of the true value of foodborne illness.

The value of productivity losses and pain and suffering are measured by placing values on quality adjusted life years (QALYs). This method uses a two-step procedure for valuing health losses. In the first step, the effect of a condition on health is estimated to be between zero (well-being in the full health state) and one (death). For example, a QALY loss of 0.14 for arthritis means that for every day of suffering with arthritis, the affected individual has a level of well-being 14% lower than they would have had in the absence of arthritis. In the next step, the value of a QALY is estimated and multiplied by expected QALY losses to calculate the value of health losses. QALYs are designed to measure the loss of well-being both from symptoms and from activity limitation. Consequently, both pain and suffering and productivity values are captured by this measure.

ERS and CFSAN use different methods of measuring the nonmedical costs of illness. The net effect of the differing approaches is that CFSAN estimates for the value of foodborne illness include a value for pain and suffering, whereas ERS estimates do not. The inclusion of a value for pain and suffering is demonstrated in Table 2. CFSAN estimates of the cost of foodborne illness are uniformly larger than estimates made by ERS. In the case of *E. coli* O157, CFSAN based its medical cost estimates on estimates calculated by ERS. Nonetheless, the inclusion of QALY losses boosts CFSAN estimates of economic loss due to *E. coli* O157 to $2.2 billion, as opposed to $0.7 billion for ERS.

Chronic Sequelae of Foodborne Illness

A listing of the association of foodborne pathogens with chronic sequelae (Table 3) illustrates that many or most of these agents are associated with some type of complication. Of particular interest is the fact that several bacterial pathogens are associated with arthritic sequelae. In addition to identifying the various disease conditions, determining the economic impact of chronic sequelae associated with foodborne illness requires not only a systematic method of estimating costs but also some understanding of the clinical aspects of these entities. This is particularly true with respect to the degree of variation that may

Table 3 Chronic complications associated with foodborne pathogens

Bacterial and parasitic infection transmitted by foods	*Complications/sequelae*
Bacterial infections	
Aeromonas hydrophila enteritis	Bronchopneumonia, cholecystitis
Brucellosis	Aortitis, epididymo-orchitis, meningitis, pericarditis, spondylitis
Campylobacteriosis	Arthritis, carditis, cholecystitis, colitis, endocarditis, erythema nodosum, Guillain–Barré syndrome, hemolytic uremic syndrome, meningitis, pancreatitis, septicemia
Escherichia coli (EHEC-types) enteritis	Erythema nodosum, hemolytic uremic syndrome, seronegative arthropathy, thrombotic thrombocytopenic purpura
Q-fever	Endocarditis, granulomatous hepatitis
Salmonellosis	Aortitis, cholecystitis, colitis, endocarditis, epididymo-orchitis, meningitis, myocarditis, osteomyelitis, pancreatitis, Reiter's disease, rheumatoid syndromes, septicemia, splenic abscesses, thyroiditis, septic arthritis (sickle-cell anemic persons)
Shigellosis	Erythema nodosum, hemolytic-uremic syndrome, peripheral neuropathy, pneumonia, Reiter's disease, septicemia, splenic abscesses, synovitis
Vibrio parahaemolyticus enteritis	Septicemia
Yersiniosis	Arthritis, cholangitis, erythema nodosum, liver and splenic abscesses, lymphadenitis, pneumonia, pyomyositis, Reiter's disease, septicemia, spondylitis, Still's disease
Parasitic infections	
Cryptosporidiosis[b]	Severe diarrhea, prolonged and sometimes fatal
Giardiasis[b]	Cholangitis, dystrophy, joint symptoms, lymphoidal hyperplasia
Taeniasis	Arthritis, cysticercosis (*T. solium*)
Toxoplasmosis	Encephalitis and other central nervous system diseases, pancarditis, polymyositis
Trichinosis	Cardiac dysfunction, neurologic sequelae

[a]Suspected of being foodborne or waterborne.
[b]Waterborne.

be encountered in severity and duration. An additional factor is whether there are certain populations that are more susceptible to the development of a particular chronic condition. These factors apply in varying degrees to all of the sequelae listed in Table 3, but many of the complications either occur very rarely, or are associated with pathogens that are themselves rare. Arthritis can be a relatively frequent complication of foodborne illness and is associated with some of the more common bacterial pathogens in food. In addition, arthritic sequelae are one of the more complex examples in terms of severity, duration, and susceptible populations. For these reasons, arthritic sequelae will serve as a paradigm for examining various economic and clinical considerations involved in developing cost estimates.

Arthritis Connection to Foodborne Illness

Arthritic sequelae associated with foodborne illness are organized into three entities: Reactive Arthritis (ReA), Reiter's syndrome (RS) and Ankylosing Spondylitis (AS) (Table 4). The incidence of these three conditions is increased in individuals that possess the human Class I histocompatability antigen HLA-B27. This association was one of the first documented examples of genetic predisposition to disease. The interest focused on this connection, the mechanisms involved, and the diseases themselves have resulted in numerous research and review articles. The genetic connection and a commonality of symptoms (joint inflammation) have led experts to group the three conditions together as 'HLA-B27-related spondyloarthropathies.'

- ReA is characterized by the inflammation of one or more joints and generally occurs 1–3 weeks following acute foodborne illness. Viable organisms of the causative pathogen cannot be isolated from the inflamed joints, making it a sterile arthritis, but there are reports that bacterial antigens or DNA may be present in inflamed joints.
- RS is a complicated form of ReA that includes joint involvement as well as at least one extra-articular feature such as inflammation of the urethra (primarily in males) and/or uveitis (eye inflammation). In some cases, no preceding infection can be identified. Those cases that have an identifiable preceding infection are sometimes called Reactive RS. Infections leading to RS can be derived from food (e.g., *Salmonella* and *Yersina*) or from sexually transmitted organisms such as *Chlamydia* spp. Because RS associated with foodborne illness is similar to ReA with respect to articular features and may only have one extra-articular feature, the term ReA will be used to capture both entities.
- AS is the most chronic and debilitating of the spondyloarthropathies, characterized by progressive degeneration of the lumbar spine. AS can take many years to develop, and in most cases, it is difficult to make a specific association with a preceding foodborne infection. The relationship of AS to foodborne illness derives from its strong link to HLA-B27, its inclusion in the spondyloarthropathies, and studies of foodborne disease outbreaks in which patients have been followed for several (many) years. These studies have provided evidence that ReA or RS can progress to AS in some individuals and support the theory that the sponsyloarthropathies are a spectrum of related diseases. Clinically, this relationship has been useful in the early diagnosis of AS, when doing a long-term follow-up of foodborne outbreaks. Progression to diagnosed AS is not the only potential chronic outcome of ReA, which can sometimes lead to recurrent or chronic arthritis of joints other than the spine. The frequency with which these various scenarios occur has a great bearing on the potential economic consequences of foodborne illness.

Before questions surrounding the development of long-term arthritic sequelae can be addressed, the frequency of primary joint inflammation (ReA) after foodborne illness must be estimated. An assessment of the circumstances surrounding the initial episode of illness is also relevant to development of ReA and long-term sequelae. Most of the available information in this area comes from outbreaks of foodborne illness. However, most outbreak investigations focus on the acute, gastrointestinal phase of infection, whereas follow-up surveys to detect arthritic and other sequelae are rare. There is even less information

Table 4 HLA-B27-associated spondyloarthropathies

Condition	*Temporal relationship to infection*	*HLA-B27 association*	*Prognosis*
Reactive arthritis	1–3 weeks after enteric illness	30–80%	Usually self-limiting
Reiter's syndrome	Follows enteric or sexually transmitted infection (1–3 weeks)	60–80%	May be self-limiting non-articular inflammation
Ankylosing spondylitis	Difficult to link	90+%	Progressive

on the occurrence of ReA following sporadic foodborne illness. (Sporadic cases are foodborne illnesses that have not been identified as part of an outbreak.) Clinical information gathered from outbreaks has suggested that several factors influence the incidence and severity of ReA. These include the duration or severity of diarrhea, which is influenced by the virulence of the pathogen and the number of pathogens ingested. The primary host factors appear to be the presence of HLA-B27 or other antigenically related antigens from the HLA-B cross-reactive group of antigens. With respect to factors that influence progression from ReA to chronic joint problems, including AS, severity of initial joint symptoms, and presence of HLA-B27 are the most prominent. Recent studies on AS have also suggested that other host genetic components related to the production of inflammatory mediators such as interferon and tumor necrosis factor play a role as well. With respect to the frequency with which primary and chronic joint problems occur, there is considerable variation in published reports.

Disease-outcome Tree – Node 1

Our goal was to develop a flow chart or disease-outcome tree for arthritic sequelae that expressed the probabilities of various short term and chronic outcomes based on available clinical literature. This tree was developed to distribute the cases into different categories that are likely to have different average costs. Several common variables from published reports of both short- and long-term sequelae were used to develop the tree. These included the duration of patient follow-up, the size of the initial outbreak, response rate to follow-up surveys, the pathogen involved, and bias within the affected population. With regard to potential bias in the populations under study, the incidence of HLA-B27 varies among national and ethnic groups and tends to be higher among Northern European groups where many outbreaks have been studied for arthritic sequelae. Studies from these countries were included, because to exclude them would have omitted several valuable reports. When the data were compiled, there was no obviously higher incidence of *Salmonella*-associated ReA among the European versus North American outbreaks (Table 5).

Numerous studies or case reports involving small numbers of patients were not included, because these studies provided no basis for determining an initial incidence of ReA. Most of the information on the initial incidence of arthritis following infection after *Yersinia enterocolitica, Shigella flexneri*, and *Campylobacter jejuni* was derived from review articles. In general, original reports involving the incidence of ReA following outbreaks of salmonellosis with various serovars were more frequent and were also included. These data were incorporated into the first node of the disease-outcome tree (Figure 2). Only the four pathogens above were considered, because they occur with sufficient frequency in the USA to be captured by FoodNet active surveillance. In Europe,

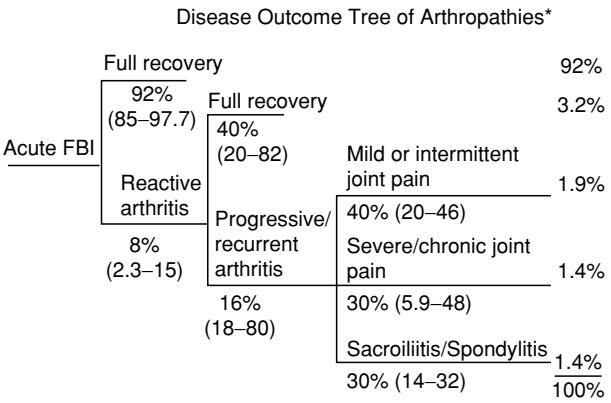

Figure 2 Arthritis–foodborne illness disease outcome tree.

Table 5 Initial incidence of reactive arthritis following foodborne illness

Source	*Type (cases)*	*Location*	*Incidence of ReA (%)*
Keat (1983)	Review	Multiple outbreaks	2–3 (2.5)
Maki-Ikola and Granfors (1992)	Review	Multiple outbreaks	1.2–7.3 (3.5)
Yu and Thomson (1994)	Review Outbreaks	Multiple	6–10 (8.0)
Simonet (1999)	Review	Multiple outbreaks	0.5–15 (4.3)
Ike *et al*. (1986)	Outbreak (565) *Salmonella* – milk	US survey 30% response rate	2.3
Inman *et al*. (1988)	Outbreak (260) *Salmonella*	Canada survey	7.3
Thomson *et al*. (1992)	Outbreak (83) *Salmonella* – luncheon	Canada survey 92% response rate	8.2
Locht *et al*. (1993)	Outbreak (126) *Salmonella* – dinner	Sweden survey 90% response rate	15
Samuel *et al*. (1995)	Outbreak (919) *Salmonella* – restaurant	US survey 33% response rate	14
Thomson *et al*. (1995)	Outbreak (423) *Salmonella*	Canada survey 97% response rate	6.4
Mattila *et al*. (1998)	Outbreak (210) *Salmonella*	Finland survey 91% response rate	11.5

Yersinia pseudotuberculosis has been associated with outbreaks of foodborne illness featuring a high incidence of ReA. This organism was not included, because cases of infection with this pathogen are rare in the USA, with no confirmed cases from 1996–1999, based on FoodNet surveillance. The clinical picture of ReA with all of the four included pathogens appears to be similar. In looking at a number of outbreaks, the overall incidence of initial arthritis also appears to be similar among the above four organisms, but the incidence of arthritis may vary widely between different outbreaks involving the same pathogenic species. This is probably due to variation in pathogen virulence, dose, host population, or even the effectiveness of tracking arthritis. For this reason, in developing the disease-outcome tree, each report or review was treated as a distinct entity and given equal weight, rather than pooling cases from different outbreaks. The reports contributing to the first node of the tree give a range of 2.3–15% for the initial incidence of arthritis following foodborne illness. This results in an average of approximately 8% of foodborne illnesses that result in ReA.

Disease-outcome Tree – Node 2

The second node of the disease-outcome tree distinguishes between ReA that resolves completely and does not recur after the initial episode, and ReA in which the joint inflammation shows any form of progression or periodic recurrence. This node is based on studies that report some progression, or lack of resolution of joint disease, but do not measure or define progression to a particular clinical state. This includes studies with relatively short follow-up times of less than 1 year. Compared with studies on the initial incidence of ReA, studies involving progression or recurrence were fewer and involved outbreaks of salmonellosis more often than other pathogens (Table 6). Therefore, most of the data used for the second node of the disease-outcome tree were also derived from studies involving *Salmonella*. However, our purpose was to quantify, within reasonable bounds, the possible sequelae of foodborne infection from self-limiting to chronic joint disease. To focus exclusively on *Salmonella* would have resulted in omission of two important long-term follow-up studies with *Shigella* and *Yersinia enterocolitica*.

It is conceivable that there is some difference in the methodology and criteria for detection of ReA between older studies and more current reports. For example, a large outbreak of *Shigella* in 1948 in Finland reported a very low 0.2% incidence of arthritis, yet, upon follow-up of 100 of these cases 20 years later, 80% had shown some progression with 32% showing signs of AS. The figure of 80% progression is quite high compared with other studies and may have resulted from initial recognition of arthritis in only the most severe cases. These cases would be the most likely to progress to chronic status. Other review articles reported the proportion of cases that progress to chronic status using a qualitative approach, based on the clinical experience of the authors. In considering the percentage of cases in which initial ReA does not completely resolve, or progresses, the second node of the tree gives a range of 18–80%. This results in an average of 60% of cases that do not evidence full recovery.

Disease-outcome Tree – Node 3

The third node of the tree measures the progression to chronic joint disease, based on the data from relevant studies, making a distinction between AS and other forms of chronic joint inflammation. Fewer data points were available for this node. In the various studies, there was considerable variation in the number of subjects, the duration of follow-up, and the clinical criteria and terminology for progression and for severity. Chronic symptoms were categorized in these reports on the basis of which joints were affected, radiological criteria, patient histories, or a combination of these criteria. If progression was severe enough to cause radiologically detectable

Table 6 Progression of reactive arthritis

[a]Original number of ReA cases.

spinal damage, these cases tended to be identified as sacroiliitis or spondylitis (AS). These cases were distinguished in a separate category because AS is readily diagnosed as a distinct entity in the HLA-B27-associated spondyloathropathies. Two additional categories were used to capture other types of chronic or recurrent symptoms. These included cases in which symptoms manifested as periodic flare-ups, and cases in which there was chronic joint pain not associated with the back. Approximately 40% of cases in this node involve minor or recurrent symptoms. Sixty per cent of the cases are more severe or chronic joint inflammation, divided approximately equally between those that show radiologic evidence of spine and lower back inflammation and those having inflammation of other joints.

Conclusions

The disease-outcome tree is a useful tool for economic evaluation that establishes estimates for the likelihood of various arthritic sequelae following an outbreak of foodborne bacterial illness. The pathways are based on reported patterns of clinical disease. The estimates are necessarily inexact, because of limitations of the available data. The estimates are based on incidence data that were all derived from outbreaks of foodborne illness. It is possible that the incidence of arthritis following sporadic cases might be different than the incidence associated with outbreaks. The use of outbreaks might be biased toward more virulent pathogen strains. At present, there is no information on the incidence of ReA following sporadic foodborne illness. An active surveillance system for foodborne illnesses such as FoodNet may prove to be an excellent mechanism from which to determine the incidence of ReA in sporadic illness and to conduct long-term follow-ups for progressive or chronic joint disease. As more definitive data become available, the disease-outcome tree can be updated and modified.

The next issue is the economic valuation method used. The Economic Research Service's annual foodborne illness cost estimates use a cost-of-illness approach for illnesses and a willingness-to-pay (WTP) approach for premature deaths. CFSAN has routinely used the value of QALYs lost in its regulatory impact analyses of food safety regulations. To date, no standardized method has been chosen by the economic profession. Ongoing research is developing WTP estimates for morbidity outcomes. In comparison with cost-of-illness approaches for chronic sequelae, such as arthritis, both the WTP and QALY estimates can substantially increase the economic valuation. The reason is the more comprehensive nature of these estimates that include an implicit valuation for pain and suffering, lost leisure time, and other implicit costs that are not included in the cost of illness estimates based on medical costs, productivity losses, and other out-of-pocket costs.

In the disease-outcome tree developed here, around 8% of the cases of salmonellosis can be expected to develop reactive arthritis. Forty per cent of the reactive athritis cases will fully recover. The remaining 60% can be expected to have recurring episodes of varying severity (40% mild/intermittent joint pain, 30% severe joint pain, 30% spondylitis). In summary, the disease-outcome tree encompasses all the possible lifetime consequences of those in the US population who have been exposed to foodborne pathogens. The tree predicts that on average, 92% of acute cases will have a full recovery; 3.2% will have full recovery with reactive arthritis symptoms for a few weeks; 1.9% will have lifelong mild, intermittent joint pain; 1.4% will have a lifelong progression to severe joint pain; and 1.4% of cases will have a lifelong progression to spondylitis. Valuation of avoiding just the pain and suffering associated with these arthritic outcomes can be expected to be significant. An early study by Thompson suggested that those afflicted would give up 22% of their household income to be rid of rheumatoid arthritis. The disease-outcome tree encompasses all the possible lifetime consequences of those in the U.S. population who have been exposed to foodborne pathogens. The life-long nature and severity of many chronic sequelae, such as arthritis, indicate that these will make substantial contributions to the estimates of the cost of foodborne illness.

FOOD SAFETY

R Rooney, World Health Organization, Geneva, Switzerland
P G Wall, Food Safety Authority of Ireland, Dublin, Ireland

Background

Contaminated food is one of the most widespread public health problems of the contemporary world and causes considerable morbidity and mortality. Globally, millions of people are affected by foodborne disease. Food poisoning can be very serious in vulnerable groups such as the elderly, infants, young children, pregnant women, and immunocompromised individuals. The proportion of vulnerable groups such as the elderly and immunocompromised is increasing in industrialized countries.

A number of high-profile food-safety emergencies and scares, in recent years, have shaken consumer confidence in the production of food and have focused attention on the way food is produced, processed, and marketed. These incidents have included an epidemic of bovine spongiform encephalitis (BSE) in cattle, possible links between BSE and variant Creutzfeldt–Jakob disease (CJD) in humans, and the discovery of dioxin contaminated animal feed entering the food chain. New foodborne pathogens such as *Escherichia coli* O157:H7, *Cyclospora cayentanensis*, and *Listeria monocytogenes* have also emerged. Infection with *Escherichia coli* O157:H7 can be fatal in young children, the elderly, and the immunocompromised, and within the last 10 years, serious outbreaks have occurred in the USA, Scotland, and Japan. *Listeria monocytogenes* can result in meningoencephalitis and/or septicemia in newborns and adults and abortion in pregnant women. Parasites such as *Cyclospora cayentanensis* and *Cryptosporidium parvuum* have emerged as a serious health threat for immunocompromised individuals, particularly AIDS patients.

Chemicals in food have also caused concern. Veterinary medicines, growth promoters, pesticides, and other man-made chemicals are widely used in the food industry. Improper use of these substances in primary production can result in unsafe residues in food. Chemicals are also added to foods during processing in the form of food additives, flavorings, and colors. Many consumers are worried about the long-term impact of mixtures of chemicals and chronic as well as acute effects on vulnerable groups.

Food safety is a sensitive political and economic issue as well as an important public health issue. This

paper aims to highlight the factors that have contributed to food-safety problems over recent decades such as intensive farming, globalization of the food industry, and changes in consumer demands. The biological, chemical, and physical hazards in food and possible control and prevention strategies for the industry will be discussed.

Food Safety Hazards

The term contaminant covers harmful substances or microorganisms that are not intentionally added to food. Contaminants may enter the food accidentally during growth, cultivation, or preparation, accumulate in food during storage, form in the food through the interaction of chemical components, or may be concentrated from the natural components of the food. There are three main types of hazard: biological, chemical, and physical.

Biological Hazards

Biological agents of concern to public health include pathogenic strains of bacteria, viruses, helminthes, protozoa and algae, and certain toxic products they may produce. Foodborne infections are caused when microorganisms are ingested, and these can multiply in the human body. Intoxications result when microbial or naturally occurring toxins are consumed in contaminated foods. Microorganisms or toxins may be introduced directly from infected food animals or from workers, other foods, or the environment during the preparation or processing of food. Poisonous substances may also be produced by the growth of bacteria and molds in food. Table 1 lists pathogenic organisms of public health importance, which may be transmitted through contaminated food.

Chemical Hazards

Foodborne toxicants can be categorized according to their chemical nature. Some foodborne toxicants are inorganic, e.g., lead and arsenic, whereas others are organic, e.g., saxitoxin and polychlorinated biphenols (PCBs). The main categories of man-made chemicals that occur in foods are shown in Table 2. Chemical hazards may result from pollution arising from industrial and other human activities (e.g., lead, mercury, cadmium, and PCBs), from agricultural practice (e.g., pesticides, fertilizers, and residues resulting from improper use of veterinary drugs in food-producing animals) or from food processing and packaging (e.g., nitrosamines and certain polycyclic aromatic hydrocarbons). These contaminants may present a potential hazard for human health if exposure exceeds tolerable levels.

Physical Hazards

Physical hazards are foreign matter, including dirt and glass, that accidentally get into food They can be the result of environmental contamination during production, processing, storage, packaging, and transport, or from fraudulent practices. The potential for

ionizing radiation to have long-term health effects, not only on the people living nearby but also the health of the ecosystem, is considerable. Following the nuclear reactor failure at Chernoble (Ukraine) in 1986, food contaminated with radionucleides with long half-lives, such as cesium 137, is the major source of exposure for people living in this area. Table 3 lists examples of physical hazards in food.

Food Safety Emergencies

The ultimate objective of the food industry and government regulators is to insure that food reaching the consumer is safe and wholesome. Feed manufacturers, farmers, and food operators have the primary responsibility for food safety. Government regulators and consumer associations also have a role to play. However, food-safety emergencies over the last two decades have exposed weaknesses in the food industry from farm to fork. They have shown that considerable progress is needed to come to grips with the preventive aspects of foodborne disease.

Many factors have contributed to recent food emergencies. The food production chain is becoming increasingly complex because of mass production. Modern farming practices are intensive and can result in microorganisms contaminating a large number of crops or infecting a large number of animals. Healthy animals may carry pathogens that cause disease in humans. Examples include *Salmonella* spp., *Listeria* spp., and some strains of *Escherichia coli* and *Campylobacter*. Animals may be infected from feed, from other animals, or from the environment.

Food distribution systems have expanded dramatically over recent decades. This has lengthened the food chain adding opportunities for contamination to occur. Ingredients may come from many different countries and be combined in a single product. The Food and Agricultural Organization (FAO) of the United Nations estimates that over 500 million tonnes of food move in international trade, valued at around $400–500 billion, each year.

Trends show that consumers are relying increasingly on convenience and ready-prepared foods. Such foods have few barriers to microbial growth, such as salt and preservatives, and simple mistakes could easily result in an outbreak of foodborne disease.

World Trade

The Food and Agriculture Organization (FAO) and the World Health Organization (WHO) have complementary food-safety mandates to protect the health of consumers, to prevent the spread of disease and to ensure that the procedures followed in food trade are fair. The Codex Alimentarious Commission (CAC), which manages the joint FAO/WHO food-standards program, sets international standards for food. It was established in 1961 and 1962 by the FAO and WHO and aims to protect the health of consumers and ensure fair practices in food trade.

The World Trade Organization (WTO) rules provide a framework for the application of food-safety measures in international trade. The standards and guidelines of the CAC are recognized by the WTO as the international benchmark standards, guidelines, and recommendations to be used as the basis of harmonizing food safety measures affecting human health and world food trade.

International standards influence trade as well as food safety, and national governments are under pressure to ensure that their regulatory programs are comprehensive and conform to these global standards. Owing to the complexity of the food-production chain, the traditional role of government as the food-safety inspector has changed, with the food industry taking more responsibility for the implementation of quality-assurance programs throughout food production, distribution, and retail. However, a strong national food control agency is required to bring about cooperation between government departments and industry, and to set standards and targets for health protection.

Risk Analysis

The concept of risk analysis is gaining acceptance internationally as a very important component of national food control programs, and its principles are being integrated more fully into the work of food safety regulators and policy-makers. This principle consists of three components: risk assessment, risk management, and risk communication.

Risk assessment is a science-based investigation that can provide an estimate of the probability and impact of adverse health effects attributable to potentially contaminated foods. The aim is to identify, in some quantitative or comparable way, the relationship between hazards and actual exposure to harm. The detail and complexity of a given risk assessment will vary, depending on the availability of time, resources, and scientific information. A full risk assessment may not always be carried out, because data may be incomplete, and resources may be inadequate. However, decisions that are made by well-focused assessments, using whatever data are available, will usually be more reliable and transparent than subjective judgement. Risk assessment links into the other two components of risk analysis, the others being risk management and risk communication. The stages of the risk analysis process are closely linked and cannot be separated easily. Consideration of the ways in which a risk might be managed is necessarily part of the assessment and communication.

Risk assessment consists of four steps: hazard identification, hazard characterization, exposure assessment, and risk characterization (Figure 1). In hazard identification, the association between disease and the presence of a pathogen or contaminant in food is documented. Hazard characterization involves obtaining quantitative information about the hazard, including, where possible, information on dose–response relationships. Exposure assessment estimates the intake or exposure to a chemical or pathogen, in terms of its magnitude, duration, and frequency, for the general population, for subgroups or for individuals. Risk characterization is the integration of hazard identification, hazard characterization, and human intake/exposure assessment. It assesses the likelihood of a particular event. This is the framework adopted by the CAC, the international standard setting body for foods in international trade.

Risk assessment is already fairly well developed for chemical hazards. The estimation of chemical health risks often relies on data obtained in the customary

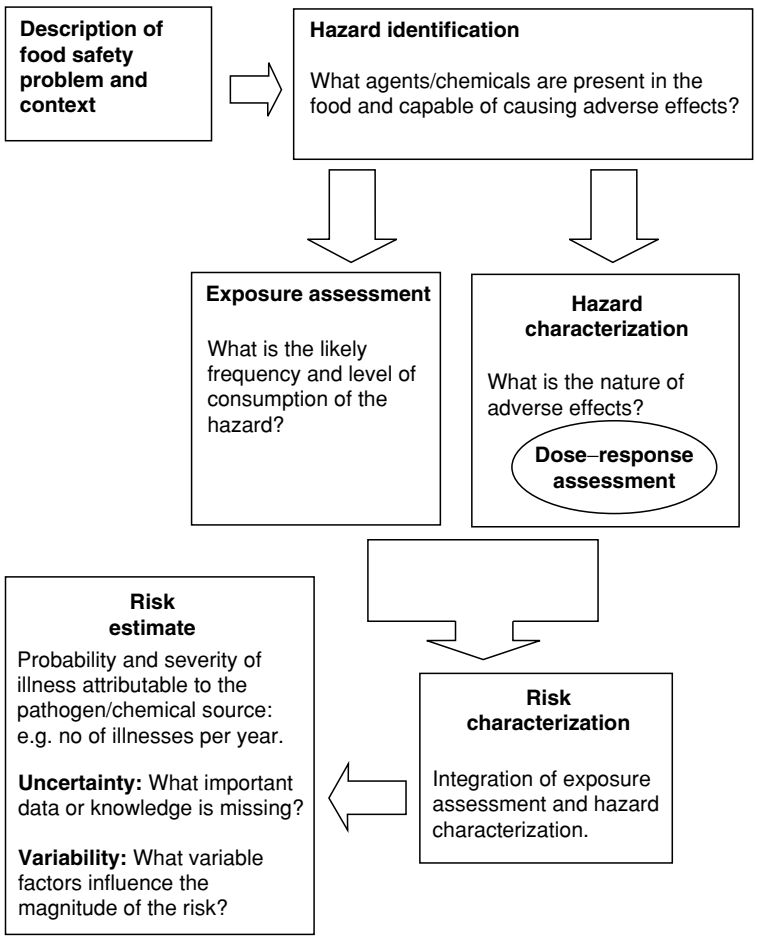

Figure 1 Steps of food-safety risk assessment. Adapted from Lammerding AM and Fazil A (2000) Hazard identification and exposure assessment for microbial food safety risk assessment. *International Journal of Food Microbiology* 58: 147–157, with permission.

rodent feeding assays using standardized safety margins. Such assessments call for an extrapolation of response data derived from animal studies to humans. The setting of advisory standards, such as acceptable daily intakes (ADIs) for food additives, pesticides, and veterinary residues in food, is a key component in the overall risk assessment of many chemicals subject to regulatory control. Quantitative risk assessment is an emerging tool in the field of microbial food safety. Estimation of microbiological hazards presented by foods is more complex, because of biological diversity and variability. However, such estimations are usually more accurate than estimates on adverse effects from chemicals in foods. This is because incidents are frequent, in sharp contrast to those resulting from exposure to chemicals. This allows for a better risk assessment.

Risk Management and Risk Communication

Food scares such as salmonellae in eggs, *Escherichia coli* O157 in beef and BSE have all damaged consumer confidence in regulatory agencies. Such problems were compounded when government departments had the dual role of promoting farming and the food industry as well as protecting the consumer. Such roles resulted in a conflict of interest. A regulatory agency should ideally be independent of trade and economic interests and have consumer interests as its primary function. Although it is the primary responsibility of the food industry to comply with the laws and regulations, the regulatory agency should provide an integrated inspection system from farm to fork. This may best be achieved by establishing a national food standards agency that has responsibility for all sectors of the food chain. Many countries have established such agencies and coordinate the work of all government departments involved in food safety. Such coordination overcomes the problems of duplication of work and conflicts of interest.

A foodborne disease surveillance program is also an essential part of a food control program. Surveillance is necessary to identify foodborne contaminants, their sources, and their modes of transmission in order to determine the best short- and long-term control measures. Interpretation of trends and investigation of outbreaks can help identify the mechanisms by which contamination and disease transmission occurred. When an outbreak occurs or a chemical contamination incident is identified, it is vital to learn from the investigation what went wrong in order to devise strategies to prevent similar events in the future.

Quality Assurance

Food quality and safety can only be insured through the application of quality-control systems throughout the entire food chain. They should be implemented at farm level with the application of good agricultural practices and good veterinary practices at production, good manufacturing practice at processing, and good hygiene practices at retail and catering levels. One of the most effective ways for the food sector to protect public health is to base their food management programs on Hazard Analysis Critical Control Point (HACCP).

HACCP consists of seven principles that outline how to establish, implement, and maintain a quality-assurance plan for a food establishment. It is a systematic approach to the control of potential hazards in a food operation and aims to identify problems before they occur. Control is proactive, since remedial action can be taken. The HACCP principles have international recognition, and the seven principles are listed in Table 4.

HACCP plan adoption has greatly improved the food industry's ability to design programs to insure the safety of food. It was introduced in the early 1970s and has become the premier system for preventing foodborne hazards, particularly those of microbiological origin. The basic process in creating HACCP plans is that the main hazards associated with a food product are determined, and key steps in the production, processing, distribution, marketing, and preparation of food are controlled

Table 4 Seven principles of HACCP

Principle 1
Conduct a hazard analysis. Prepare a list of steps in the process where significant hazards occur and describe the preventive measures. Assess the likelihood of occurrence of the hazard(s) and identify the measures for their control.

Principle 2
Identify the Critical Control Points (CCPs) in the process. Determine the points, procedures or operational steps that can be controlled to eliminate the hazard(s) or minimize its (their) likelihood of occurrence.

Principle 3
Establish critical limits for preventative measures associated with each identified CCP.

Principle 4
Establish CCP monitoring requirements. Establish procedures from the results of monitoring to adjust the process and maintain control.

Principle 5
Establish corrective actions to be taken when monitoring indicates a deviation from an established critical limit.

Principle 6
Establish effective record-keeping procedures that document the HACCP system.

Principle 7
Establish procedures for verification that the HACCP system is working correctly.

Source: Mortimore S and Wallace C (1997) *HACCP: A Practical Approach*. London: Chapman & Hall, with permission.

within preestablished limits to insure the safety of food. A program of monitoring, verification, and record keeping is then implemented to insure that the system functions correctly.

The Codex General Principles of Food Hygiene recommend a HACCP-based approach to enhance food safety. This management tool is internationally recognized as essential to ensure food safety and is recommended by governments, industry, and consumers.

Conclusion

Food safety in the early twenty-first century is an international challenge requiring close cooperation between countries in agreeing standards and in setting up transnational surveillance systems. The lessons of the past two decades are plain to those engaged in the food industry. No longer can farmers grow just what they want or use technical aids to farming without taking into account the effect on the quality of the food produced. Food will always present some risk, and it is the task of the food industry to keep the level of risk to the minimum, which is practicable and technologically feasible. It should be the role of official bodies and the food industry to use risk analysis to determine realistic and achievable risk levels for foodborne hazards and to base food-safety practices on the practical application of the results of these analyses, thus continuously improving the safety of food and thereby lowering the disease risk. By providing effective food-control, countries not only provide public health benefits but enable themselves to participate in international food trade with greater confidence.

The lasting solution to the problems, which have shaken the food industry in recent years, can only be overcome if all those involved – farmers, food processors, wholesalers, transporters, retailers, caterers, scientists, regulators, and government – work together towards common goals.

FOOD SECURITY

J T Cook, Boston University School of Medicine, Boston, MA, USA

Background

This article is about food security in the USA and the factors that promote it. It is also about poverty-related food insecurity and hunger, their prevalence in the US population, and some of their causes and consequences. The article is not about normal hunger *per se*, although normal hunger is a critical element of the definition and measurement of food insecurity severe enough to include hunger. Instead, this article is about hunger that people in civilized societies agree should not exist. It is about hunger experienced involuntarily in a country that claims to be the wealthiest in the world; hunger experienced by several million people because they lack adequate resources to afford enough food for an active and healthy life. This kind of hunger is most accurately seen as a social problem, and the circumstances and managed process within which it occurs are known as food insecurity.

In pursuit of objectives of the National Nutrition Monitoring and Related Research Act of 1990, the US Department of Agriculture's (USDA) Food and Consumer Services (FCS) and the Department of Health and Human Services' National Center for Health Statistics (NCHS) were assigned responsibility for establishing a research program to develop standardized measures of food security, food insecurity and hunger for the US population. That research program was initiated in 1992 as the Food Security Measurement Project (FSMP). In the first phase of this ongoing research program, a household-level survey instrument was developed for annual administration by the US Census Bureau as a supplement to its nationally representative Current Population Survey (CPS). In the second phase, data from the CPS Food Security Supplement, administered to a sample of approximately 60 000 households, were used to create and validate a food security scale for the US population.

The remainder of this article, briefly describes the food security measures, their application over the period 1995–2000 in the FSMP, and some of the main findings from this research. I also discuss aspects of the social, political, and economic contexts within which the food security measures were applied during this period as they relate to the causes and consequences of food insecurity and hunger in the USA.

What is Food Security?

The term food security came into usage over the past two decades to describe a person's, household's, or community's ability to obtain enough nutritious food for a healthy life. The concept of food security initially emerged during the 1980s in international

development work.[1] It was adopted in the early 1990s as a useful framework for describing, researching, and designing policies to address poverty-related food access problems at the household level in the USA. Research conducted during the 1980s and 1990s in the USA found that household food security is a managed process rather than a state or condition. Within this framework, a household's 'food manager' obtains, prepares, and makes food available to household members in a way determined by the household's overall resources and preferences.

When a household's resources (usually derived from money income and/or benefits from social safety-net programs) are plentiful, it is likely to be food-secure. If, however, household resources become scarce for a period of time, the food manager (usually the mother or another adult in the household) undertakes a managed process aimed at ensuring that sufficient food will be available to enable household members to avoid hunger.

This managed process often involves a variety of coping strategies undertaken to supplement the household's food supply. These include actions such as putting off paying rent or bills, borrowing money or food from friends or family members, reducing the variety of foods prepared and served (often by cutting out fresh fruits and vegetables), and relying on low-cost 'filling' foods. The process of managing household food insecurity often involves considerable emotional stress for members of the household as worries about whether available food will last, or whether there will be money available to buy food, intensify. Households in this condition are said to have become food-insecure.

If a food-insecure household's resource scarcity or food insufficiency persists or worsens, the household food manager may be forced to take actions that lead to reductions in the quality and/or quantity of food available to household members. In food-insecure US households with children, it is typical for adults to reduce their food intake below normal levels (by reducing the size of meals, or skipping meals) to spare the children from experiencing hunger. However, if the household's food insecurity continues or becomes more severe, food intake by children in the household eventually also will be reduced below normal levels. This usual pattern of rationing makes it possible to identify two levels of severity of hunger in US households; moderate hunger and severe hunger. When the former occurs in households with children, usually only adults in the household experience hunger. With the latter, both adults and children experience hunger.

[1]The term food security appears extensively in the work of the United Nations' Food and Agriculture Organization (UN/FAO), the Consultative Group on International Agricultural Research (CGIAR), the International Food Policy Research Institute (IFPRI), the World Bank, and other international development organizations during the 1980s and 1990s. In 1994, the UN/FAO launched the Special Program for Food Security, 'a multidisciplinary program that combines expertise and experience from a wide range of fields to promote an integrated and participative approach to food security'. In November 1996, representatives from 185 countries and the European Community met in Rome for the World Food Summit. Out of that week-long conference emerged the Rome Declaration on World Food Security and an accompanying Plan of Action to reduce food insecurity and hunger by half in all countries by 2015.

What is Hunger?

Hunger is a feeling that everyone has some understanding of because all animals experience hunger, as far as we know. At the individual level, hunger is a physiological state or condition, a set of neurological sensations, and a psychological drive. Hunger is an uneasy or painful sensation caused by a lack of food, and it is a motivation to obtain and consume food. We all know when we are hungry, and we can even say how hungry we are and how it feels. We may be 'so hungry we could eat a horse,' or we may 'just need a little something.' For humans, hunger is usually a normal and healthy response to emptying of food and nutrients from the stomach and upper gastrointestinal tract.

But what about hunger that poor people in developing countries experience, or poor people in developed countries who do not have enough money or other resources to buy, store, and prepare sufficient food for a healthy active life? How is this hunger different from 'normal' hunger? When does hunger become problematic? At what point does it rise to the level of a social concern? Is it when the motivation to obtain and consume food cannot be satisfied due to a lack of resources? How often must this condition exist, for how long, and for how many people and families before it is seen as a social problem that merits a policy response? Historically, concerns about food insufficiency have been articulated in terms of malnutrition, undernutrition, and nutrient deficiencies. How are food insecurity and hunger related to malnutrition? Are these conditions synonymous, or can they exist independently?

These kinds of questions are critical to a clear understanding of food insecurity and hunger as social problems. They are also central to accurate definition and measurement of food security, food insecurity, and hunger, and to the design and implementation of effective policies to prevent or reduce these conditions.

Measuring Food Security

To design an effective research program for developing measures of food security, food insecurity, and

hunger for use in the public policy arena, a federal interagency team first identified an appropriate measurement framework. This measurement framework expressed practical limits for the scope of the measures and clarified the contexts to which they would be applied and the type of instruments, data, and analytical methods from which they would be derived.

Consensus conceptual definitions of food security, food insecurity and hunger for the US context were derived and published by the Life Sciences Research Office (LSRO) of the Federation of Associations for Experimental Biology (FASEB) in collaboration with the American Institute of Nutrition (AIN) in 1990. These conceptual definitions were operationalized, and empirical measures of food security developed under sponsorship of USDA/FCS and CDC/NCHS in the Food Security Measurement Study (FSMS) of 1995–1997.

Data from initial administration of the Food Security Supplement in 1995 were used in a split-sample procedure to create and validate a food security scale. Population-weighted data were also used to produce estimates of the prevalence of food security, food insecurity, and hunger in the US population. The Food Security Supplement has been administered by the Census Bureau annually since 1995 as part of the CPS. A time-series of annual food security data and resulting prevalence estimates for the noninstitutionalized US population by major sociodemographic characteristics is available for the period 1995–2000. In addition, overall state-level prevalence estimates are available for 1995–1998.

Definition and Measurement of Food Security

The conceptual definitions of food security, food insecurity, and hunger synthesized by the LSRO's expert panel have been stated as:

> *Food security*: Access by all people at all times to enough food for an active, healthy life.
>
> *Food insecurity*: Limited or uncertain availability of nutritionally adequate and safe foods or limited or uncertain access to food.
>
> *Hunger*: The uneasy or painful sensation caused by a lack of food. The recurrent and involuntary lack of access to food ... Hunger, in its meaning of the uneasy or painful sensation caused by a lack of food, is ... a potential, although not necessary, consequence of food insecurity. Malnutrition is also a potential, although not necessary, consequence of food insecurity.

Item response theory methods involving nonlinear (logistic) factor analytic scaling models were used to develop the 18-item food security scale from responses to a larger number of questions in the Food Security Supplement to the CPS. When operationalized, the three conceptual categories listed above were shown to represent adjacent levels of severity of a single well-ordered phenomenon. Food security emerged as a continuum, with households at the least-severe level termed food secure, and those at the most severe level termed food insecure with severe hunger, as follows:

> *Food secure*: Household shows no or minimal evidence of food insecurity.
>
> *Food insecure without hunger*: Food insecurity is evident in households' concerns and adjustments to household food management, including reductions in diet quality, but with no or limited reductions in quantity of food intake.
>
> *Food insecure with moderate hunger*: Food intake for adults in the household is reduced to an extent that implies that adults experience hunger due to a lack of resources. If children are present, the quality of food available to them may be reduced, but usually not its quantity.
>
> *Food insecure with severe hunger*: Households with children reduce the children's food intake to an extent that implies that the children experience hunger as a result of inadequate household resources. Adults in households with or without children experience extensive reductions in food intake.

The two categories including hunger are based on survey responses indicating that food intake has been reduced below normal levels (e.g., by reducing the size of meals, skipping meals, or going a whole day without eating) for adults or children in the household, or both, and that these reductions occurred specifically because the household did not have enough food or money to buy food. Cut-point selection procedures required that a pattern of repetition of such intake reductions occur for two or more months out of the previous 12 months for hunger to be confidently inferred. Thus, even though hunger is a normal state experienced by all people, the Food Security Scale was designed to capture recurrent resource-constrained hunger, experienced because a household does not have sufficient food or financial resources to buy food.

Prevalence of Food Insecurity and Hunger in the USA

The Food Security Scale produces continuous interval-level (without a true zero value) household food security scores for all households in which an adult respondent completes the survey. The continuous scores are then used to categorize households into one of the four categories just described on the basis of cutoff values determined in the initial FSMS and

validated with data from the five successive implementations of the scale (in 1996–2000).

In recent years, with high rates of growth in the US economy and very low unemployment, increasingly smaller proportions of most demographic subgroups experienced food insecurity with severe hunger. As a result, USDA analysts combined the two severity levels involving hunger and now report prevalence estimates for three levels of severity only (food secure, food insecure *without* hunger, and food insecure *with* hunger). Table 1 shows the prevalence of these three food security categories for US households and residents by selected characteristics in 2000, the latest year for which estimates are available.[2]

Overall, 11.1 million US households (10.5%) were food-insecure at some level of severity in 2000. In 3.3 million households (3.1%), at least one adult or child experienced hunger.[3] Just over 33.0 million people (12.1%) lived in food-insecure households in 2000, and 9.0 million lived in households where hunger was experienced. Examination of Table 1 shows that people in households with children (ages < 18 years) have almost two and a half times the risk of being food-insecure as those in households without children (relative risk (RR): 0.164/0.067 = 2.4). People in female-headed households with children and no spouse have nearly three times the risk of being food-insecure as those in married-couple households with children (RR = 2.8).

Other notable comparisons of the prevalence of food insecurity and hunger include those by race/ethnicity of household, ratio of household income to poverty, and area of residence. People in non-Hispanic Black and Hispanic households have nearly three times the risk of being food insecure as non-Hispanic White households (RR = 2.8 and 2.9, respectively, compared to non-Hispanic Whites), and people in central-city households have nearly twice the risk of being food insecure as people in metropolitan households not in central cities (RR = 1.9). Households with incomes below 185% of the poverty threshold have over six times the risk of being food insecure as those with incomes greater than or equal to 185% of poverty (RR = 6.3). The prevalence of food insecurity and hunger rises steadily as the ratio of household income to poverty decreases (similar to a dose–response effect), with the highest prevalence among households whose incomes are below 100% of poverty.

Food Insecurity, Hunger, and Malnutrition

It is important to note the relationships among poverty, food insecurity, hunger, and malnutrition. In the consensus conceptual definitions derived by the LSRO/AIN expert panel (listed above) and operationalized in the FSMS, hunger and malnutrition are described explicitly as 'potential, although not necessary' consequences of food insecurity. Resource-constrained hunger is 'nested' within food insecurity, occurring at its more severe levels. It is accurate to say that hunger, so defined, is both a necessary and sufficient condition to imply food insecurity.

Malnutrition in its broadest meaning, however, is neither a necessary nor a sufficient condition to imply food insecurity or hunger, though it may. Malnutrition, both as undernutrition and overnutrition, can occur in the absence of food insecurity or hunger, though either or both of these latter conditions may be associated with malnutrition and may even cause it. Clinically, however, there can be multiple causes of malnutrition, some of which do not involve food insecurity or hunger.

It is unlikely, in the absence of morbidity, congenital anomaly, or pathology, that protein–calorie undernutrition occurs in the US population, unless it is accompanied by relatively severe food insecurity or hunger. However, it is not at all uncommon for micronutrient undernutrition or deficiencies to occur under conditions of food insecurity without hunger, or even under food-secure conditions. Indeed, prominent clinical concerns often arise due to micronutrient deficiencies associated with food insecurity short of measurable hunger, or with only moderate hunger.

In the past two decades, consequences of overnutrition have emerged as important factors in some of the most serious threats to human health (e.g., diabetes, hypertension, cardiovascular disease, orthopedic conditions, sleep apnea, asthma, and cancer). Overweight and obesity are epidemic in the USA across nearly all age levels, with growing concerns regarding emergence of obesity at earlier childhood ages and implications for later body composition and health. Trends in the US economy and society, including effects of technological change on prices and availability of food, patterns of food advertising, marketing, consumption and eating behavior, work, and physical activity, have led to conditions that

[2]As of writing, the data for 2001 have been collected but not analyzed. The USDA and the Census Bureau are preparing for implementation of the 2002 CPS survey.

[3]Since questions in the Food Security Supplement do not ask specifically about the conditions of each member of the household, it is not possible to ascribe hunger status to all members of households with more than one adult and one child. One can, however, ascribe overall food insecurity status to all members of any household that is not food-secure. In addition, if a household is categorized as 'food insecure with hunger,' it is appropriate to say that all members live in a household where hunger is experienced. This minor unintended limitation results from the specific form of the survey and the questions it contains.

Table 1 Prevalence of food security, food insecurity without hunger, and food insecurity with hunger for persons by selected characteristics of households: 2000[a]

Category	*Total*	*Food-secure*		*Food-insecure (all)*		*Food-insecure with no hunger*		*Food-insecure with hunger*	
	(1000s)	*(1000)*	*(%)*	*(1000)*	*(%)*	*(1000)*	*(%)*	*(1000)*	*(%)*

[a]Totals exclude households whose food security status is unknown.

From Nord M, Kabbani N, Tiehen L *et al*. (2002) *Measuring Food Security in the United States: Household Food Security in the United States, 2000. USDA/ERS Food Assistance and Nutrition Research Report No. 21*. Washington, DC:

support widespread overconsumption of calories relative to daily needs.

Since the 1970s, research literature has accumulated, suggesting that food insecurity may play a role in the onset of overweight and obesity among some low-income subpopulations. Though the evidence is not yet conclusive, there are several lines of research currently underway whose results to date are consistent with hypothesized associations between food insecurity and obesity. To the extent that there are associations between food insecurity and obesity, affected low-income subpopulations may be doubly challenged in their efforts to maintain healthy body composition, diets and lifestyles.

Poverty, Food Insecurity, and Social Welfare Programs

A clear understanding of food insecurity and hunger in the USA requires knowledge of their relationships to poverty, and the range of social policies and programs that have emerged to address both. By definition, resource-constrained food insecurity is primarily an issue for low-income families, or families with limited resources. However, the nature of the US economy, food system, and social welfare system adds to heterogeneity in expression of food insecurity. The way in which poverty and food security are defined and measured in the USA also adds complexity to relationships between these two conditions.

US Poverty Measures

When created in 1963, the US poverty levels were based on the cost of a minimally nutritious diet. Though these thresholds have been updated annually since 1963 for inflation, they have not yet been revised to reflect the change in proportion of total household expenditures spent for food. In the 1960s, the average household spent roughly one-third of its total monthly expenditures for food (averaged over

all households at all income levels). In principle, this implied that multiplying the average cost to households of a minimally nutritious diet by a factor of three would provide an indication of the poverty threshold, or the minimum amount of income needed to meet basic needs.

Using the cost of the USDA's Thrifty Food Plan for different size families as estimates of the costs of minimally nutritious diets, the poverty thresholds were obtained by multiplying these dollar values by three. This remains the basis of poverty measurement in the USA today. Elegant as it is in logic and simplicity, this measure only succeeds when the relative proportion of the average household budget spent on food is accurate. Setting aside the question of whether this is the most accurate approach to estimating the cost of households' basic needs, a more fundamental concern is whether the proportion of household income spent on food has remained constant over time.

Since 1963, the average annual proportion of household expenditures spent for food has declined consistently to about 11% in 2000. Over the same period, the average annual proportion of expenditures spent on other basic needs (most notably housing and transportation) increased consistently. As a result, using the same multiplier logic underlying the initial definition of the poverty thresholds with current proportions of expenditures on food implies a multiplier of approximately 9 instead of 3. Obviously this would lead to much higher income levels being identified as poverty thresholds, and much larger numbers and proportions of people identified as being in poverty.

Another peculiar anachronism in US poverty measurement is that households headed by elderly persons (ages 65 and over) have lower poverty thresholds than similar households headed by people under 65 years of age. This practice dates to an era in which most Americans worked in occupations involving extensive physical exertion, retirement from which ostensibly reduced energy and other nutrient requirements and hence the cost of food for people over age 65. Depending on the size and characteristics of the household (e.g., the number of related children under the age of 18 years), poverty thresholds for households headed by elderly people are 4–10% lower than for comparable households headed by nonelderly. Thus, elder-headed households must have lower incomes (be worse off financially) than nonelder-headed households before they are classified as being in poverty. As a result, the number and proportion of elderly households and persons reported in poverty understate the actual extent and dimensions of poverty among the elderly. In turn, this affects eligibility for assistance from various social welfare programs among some elderly who may be in need.

Support for the view that the current poverty thresholds understate the costs of basic needs and therefore lead to underestimation of the level and proportion of the US population at risk for health issues associated with poverty comes from several sources. The National Research Council (NRC) of the National Academy of Science conducted a review of the US poverty measures in the mid-1990s, finding them deficient in several respects and recommending a number of changes. The overall effect of implementation of the NRC recommendations would be to increase the number and proportion of people identified as living in poverty.

Another relevant set of studies attempts to determine the minimum income levels actually needed by different size and type of families in different geographic locations within the USA for basic economic self-sufficiency. These studies use actual current data on costs of basic goods and services in different states and regions together with existing taxes and tax credits to estimate actual minimum economic self-sufficiency income levels. Generally, the resulting self-sufficiency income estimates fall above 200% of the federal poverty thresholds.

The food-insecurity prevalence estimates summarized in Table 1 for 2000 also provide useful information regarding the relevance of the current poverty thresholds. Data in Table 1 show that, at income levels at or above 185% of poverty, the prevalence of food insecurity and hunger is quite low, with overall food insecurity at 4.9%, food insecurity without hunger at 3.9%, and only 1.1% of households experiencing hunger (numbers do not sum due to rounding). Households with incomes equal to, or greater than, 130% but less than 185% of poverty have higher rates of food insecurity, with 18.4% food insecure overall, 14.5% without hunger, and 3.9% with hunger.

The numbers and proportions of people in poverty by selected household characteristics are shown in Table 2. These data reflect similar patterns to those for food insecurity shown in Table 1. People living in households with children have higher poverty rates than those in households without children, people in households headed by single females have higher poverty rates than those in households headed by married couples, and people in Black and Hispanic households have higher rates of poverty than non-Hispanic Whites.

Table 3 contains state-level average poverty rates and food-insecurity prevalence rates for the years 1996–1998 from the CPS. Calculation of the Pearson correlation coefficient for these two measures indicates a strong positive relationship between poverty

Table 2 Number and percentage of persons in poverty by selected characteristics: 2000

Characteristics	*Total in population/group (1000s)*	*Number in poverty (1000s)*	*Percentage in poverty*
All persons	275 924	31 054	11.3
Children under 18	71 936	11 553	16.1

and food insecurity ($R = 0.72$). The resulting coefficient of determination for poverty and food insecurity is also sizeable ($R^2 = 0.51$), indicating that approximately 51% of the variance in food insecurity among states is explained by poverty.

Social Safety-net Programs

Public policies and programs that provide support for low-income individuals and families are increasingly important in reducing and preventing food insecurity, especially in urban areas. One of fifteen food assistance programs funded and overseen by the federal government, the Food Stamp Program (FSP) is the nation's largest nutrition safety-net program for low-income people. Gross income eligibility for receipt of food stamps is 130% of poverty, making most households with incomes below this level, and that fulfill other eligibility requirements, able to receive food assistance if they apply.

However, the Personal Responsibility and Work Opportunity Reconciliation Act (PRWORA) of 1996, the most recent US welfare reform law, changed several aspects of the FSP, making many legal permanent residents and single adults without children ineligible. In addition, provisions of PRWORA aimed at diverting or deterring applications for cash assistance, and sundry new rules aimed at enforcing compliance with behavioral expectations, appear to have led many households eligible for food stamps not to apply. There is evidence that the magnitude and extensiveness of changes made by PRWORA may have created so much uncertainty about the new welfare system that many current and potential recipients are frequently uninformed or misinformed regarding their eligibility and other critical aspects of program operation.

PRWORA eliminated entitlement status from cash assistance to families with dependent children (AFDC) and replaced it with Temporary Assistance for Needy Families (TANF), while transforming federal funding for AFDC/TANF into a system of block grants to states. New rules and regulations under PRWORA enabled states to place additional restrictions on eligibility and impose a wide range of new behavioral requirements for continued receipt of aid, along with punitive sanctions for failure to comply with these requirements. The new law placed an overall 5-year limit on the receipt of benefits for most recipients and transferred primary responsibilities for design, implementation, and oversight of

welfare programs to state and local governments. These changes allowed states wide latitude in imposing even stricter time limits and other eligibility requirements.

A primary goal of welfare reform was to move recipients off the case loads and into jobs. In many states, innovative approaches to delivery of services in support of this transition from welfare to work emerged. As a result of the welfare reform changes and growth in the economy during the 1990s, between 1994 and 1999, the national AFDC/TANF caseload declined by 8.0 million recipients (56.0%). Over the same period, the average national monthly FSP caseload declined by 9.3 million recipients (33.8%).

Several studies have documented extensive declines in participation in the FSP during the 1990s and show that a large part of the decline was due to growth in the economy and falling unemployment raising the incomes of previously eligible households above the income eligibility level. However, these and other studies also show that a majority (56%) of the decline in FSP caseloads resulted from a decline in the participation rates, the proportion of eligible households participating.

Food-security prevalence data from the USDA show that from 1995 to 1999, even though food insecurity declined overall, among households with incomes at or below 130% of the poverty level (the gross income eligibility cutoff for the FSP), food insecurity actually increased from 23 to 28%. This indicates that many low-income households stopped receiving food stamps, or did not apply for them, even though they were food-insecure and felt they needed more food. In addition, studies of the private emergency food-assistance system over the same period indicate that many households leaving the TANF and FSP caseloads are relying more heavily on food from private emergency sources such as food pantries, soup kitchens, and shelters.

Summary and Conclusion

Poverty-related food insecurity and hunger are realities experienced by millions of US households. They are associated with both overnutrition and undernutrition but are not congruent with malnutrition. Food insecurity impacts human development and health throughout the life-cycle, but can be particularly harmful during critical or vulnerable stages early and late in life. Understanding the causes and consequences of food insecurity and knowing how to identify and measure them can improve the quality and effectiveness of social policies, and facilitate prevention and reduction of many kinds of health problems.

Numerous public policies and programs exist to ameliorate and prevent poverty-related food insecurity and hunger. However, the resources to support them ebb and flow with the politics of annual state and federal budgetary cycles. Support and need for these social safety-net programs also vary with business cycles. Unfortunately, need often expands as support shrinks along with employment and government revenues during recessions, and shrinks as support expands along with employment and government revenues during expansions.

In March 2001, the US economy reached the peak of an unprecedented 10-year period of expansion and has been in recession for more than a year. It is worth noting that the record expansionary period from March 1991 to March 2001 began with an unemployment rate at 6.8%, and 8.6 million workers unemployed. During the 10-year expansion, the unemployment rate remained above 6% until September 1994, continued above 5% until April 1997, only dipped below 4% for the two months of September and October 2000, and remained at or above 4% through the peak month of March 2001, when it stood at 4.3% with 6.1 million workers unemployed.

This strongly suggests that the 'full employment' unemployment rate (i.e., the lowest unemployment rate that the US economy can reach and sustain for any appreciable length of time) is probably not lower than 4%, and may be even higher (e.g., 5%). The importance of this is that under known conditions, unemployment is not likely to fall below 4% for very long (if at all), and poverty, food insecurity, and hunger are not likely to disappear altogether, even during economic booms. A clear understanding of the causes and consequences of poverty-related food insecurity and hunger, and of effective policies to reduce and prevent them is critical to the public well-being. Such understanding is more attainable now that valid and reliable food security measures are available and being used.

FREEZE-DRYING

Contents

The Basic Process

J D Mellor and G A Bell, formerly of CSIRO, North Ryde, Australia

Introduction

Freeze drying, which is also known as lyophilization, is the process of removing water from a product by freezing it then subliming the ice to vapor. Sublimation is a physical phenomenon by which solid ice is converted directly into vapor without it passing through the liquid state. Removing water from food, by sublimation, protects the material against loss of important constituents and against chemical reactions that are associated with withdrawing or vaporizing liquid water.

Freeze drying occurs in nature through the combined effects of solar heating, cold dry winds, and rarified atmospheres of mountainous regions. These natural conditions are used to produce freeze-dried 'stock' fish in Norway and a dried potato product called chuno in Peru. Freeze drying is also used in a peculiar way by the North American red squirrel which is known to spread pieces of food in the forks of trees at the beginning of winter, thereby freeze drying its food supply.

Dried foods offer convenience of storage and transport derived from their long shelf-life and low weight. Freeze-dried foods enjoy these properties and are generally of higher quality than products dried by other processes. As a result, freeze-dried foods tend to be preferred in culinary arts over other dried products. (*See* **Drying**: Theory of Air-drying.)

Loss of water vapor from the product depends mainly on two influences: heat available to the product; and the vapor pressure differential across the subliming interface between frozen and dry layers. In practice, these two factors are often compromised in the interest of production economics. Despite widespread use of freeze drying in biological laboratories and in drug and vaccine production, the development of freeze drying as a food technology has been fraught with cost and scale-up problems. Its application to large-scale food processing has been limited to a small number of products including instant coffee, soup mixes, military rations, and herbs.

The final quality of a freeze-dried product can be determined by optimizing conditions in three steps in the process: the primary phase, the drying phase, and the supplementary phase.

Primary Phase

Before freezing, certain preparations are necessary, depending on the product in question. For example, slicing, dicing, and mincing will alter the surface area of the product from where drying can proceed, blanching the product will alter its enzymatic properties, while cooking causes reductions in the free and bound water in the product. These preparations will also tend to enhance heat transfer in the product during the drying phase and, therefore, the speed and quality of the result. (*See* **Freezing**: Operations.)

The water content of a food comprises both free water and water bound to proteins. When a food freezes, a large portion of the free water becomes frozen and is disposable as ice for sublimation. The disposable proportion varies from product to product, and is determined by the final temperature arrived at after freezing. Water remaining in the product after drying may promote microbes and deterioration. Therefore, the temperature to which the

product is frozen can be of critical importance. Table 1 illustrates the influence of temperature on the amount of water frozen out for various foods, determined experimentally. Similar values can be calculated by thermodynamic analysis provided the initial water content and freezing point of the product are known. (*See* **Water Activity**: Principles and Measurement; Effect on Food Stability.)

Drying Phase

Sublimation

In practice, sublimation of ice crystals usually begins at about $-20\,^{\circ}C$ in a vacuum of less than 1.33 mbar, provided sufficient heat is available from the surroundings (benign heat). How long will a product take to dry by sublimation? Ideally, the rate of sublimation is derived from a classical kinetic model of sublimation which assumes: (1) a dynamic equilibrium between the ice surface and its vapor; (2) the rate of escape of water molecules depends on the temperature of the ice; and (3) the tendency of molecules to return to the ice depends on the temperature and pressure of the vapor. This model has limited value in practice. Of greater value in understanding the rate of freeze drying of a food product, is to take account of the rate of vapor diffusion as the water molecules migrate through the vacuum space (containing fewer air molecules than vapor molecules) between the product and the condenser. The migration rate is described by the following equation:

$$G_m = \frac{MD_eP}{RTl} \ln \frac{P - p'_c}{P - p'} \qquad (1)$$

where G_m is the migration rate, M the molecular weight of water vapor, D_e the effective diffusion coefficient, P the vacuum pressure, R the gas constant, T the temperature, l the distance in the vacuum space, p' the vapor pressure outside the product surface, and p'_c the vapor pressure outside the condenser surface. If the freeze drier is considered as a closed system, then the rates for sublimation ($G_s(\alpha p_s - p')$), condensation ($G_c\alpha(p'_c - p_c)$), and migration (G_m) are equal, i.e., $G_s = G_c = G_m$, where p_s is the sublimation vapor pressure and p_c the condensation vapor pressure. Apart from the separate vapor pressure differences ($p_s - p'$ and $p'_c - p_c$), the difference in vapor pressure overall ($p_s - p_c$) is usually regarded as the driving force for sublimation. This model of freeze drying is illustrated in Figure 1.

Vapor Flow

As a piece of food freeze dries, the porous dry product formed around the subliming ice core can cause a severe restriction to vapor flow, and may prevent continuation of the drying process. A useful model of the above conditions assumes the pores in the dry material resemble a bundle of circular cylinders or tubes, with a porosity E expressed as a ratio of pore volume to the intrinsic volume of the layer of dried product, and a tortuosity factor $(L_e/L)^2$ taken as the square of the ratio of the effective flow path L_e to the thickness of the layer L. It can be shown mathematically that:

$$D_e = ED/(L_e/L)^2 \qquad (2)$$

where D_e is the effective diffusion coefficient, and D is the water vapor diffusion coefficient in air. In the

White bread	46	50	87	97	99	100	0.30
Peas	78	68	86	92	96	100	0.2–0.3

Data from Kuprianoff J (1964) In: Rey R (ed.) *Advances in Freeze-Drying*, p. 48. Paris.

porous layer, D_e varies inversely with vacuum pressure P and directly with temperature T to the 1.75 power; therefore:

$$D_e = \frac{E}{(L_e/L)^2} D \frac{1013.3}{P} \left(\frac{T}{273}\right)^{1.75} \quad (3)$$

The value D_e increases with decreasing pressure until the mean free path of the gas molecules at intermediate pressures becomes comparable with the pore diameter, so that wall collisions begin to compete with collisions in the gas stream itself in limiting flow by diffusion. This condition is known as transition flow and is the dominating vapor flow in the freeze drying of food.

Heat Flow

In food freeze driers, heating the product is the rate-controlling variable when it is applied to the inner core of ice crystals through an outer layer of dry product. If heat is applied directly through the ice layer by conduction, as is common in laboratory and medical freeze driers, then vapor diffusion is the rate-controlling variable. Food freeze driers usually apply heat by radiation to the product surface which proceeds by conduction through the dry layer. However, the dry product layer insulates the product and limits the radiated heat supply.

Various attempts have been made to compensate for this insulating effect by maximizing heat distribution to the product. These include: (1) the accelerated freeze drying (AFD) technique, illustrated in Figure 2, which employs heat-conducting expanded metal sheets that are hydraulically pressed against the frozen product's surface and serve to conduct heat to the product while also allowing water vapor to escape, and (2) the tempomatic or ribbed-tray method which exploits the conducting properties of a number of ribs that reach into the bulk of the product. Both these methods have seen extensive industrial use. The latter has been used extensively for drying of coffee, berries, and dairy products.

Refrigeration Condensers

It is common to condense the escaping water vapor, produced by sublimation at the product surface, on a refrigerated coil, where condensation is the reverse of sublimation, from vapor to solid without passing through the liquid phase. As ice builds up on a refrigerated coil, it insulates the condenser and renders it less effective. Heat flow through the ice deposit can be modeled to give an indication of the build-up of ice with time, and the resulting temperature deficit (difference between ice surface temperature and coil temperature).

The available surface area of the condenser determines the thickness of ice that will be condensed on to it. The surface area of the condenser is, therefore, an important consideration in designing a food freeze drier.

Condensers have some special characteristics which have been generally neglected in considering the basic physical processes in freeze drying.

It is one of the phenomena of freeze drying that the partial pressure of air near the condenser is always relatively high, this air having been liberated from the product during sublimation, and having come from leaks in the vacuum chamber. The larger the space available to be screened by the condenser, the lower will be the vapor pressure of air in the rest of the

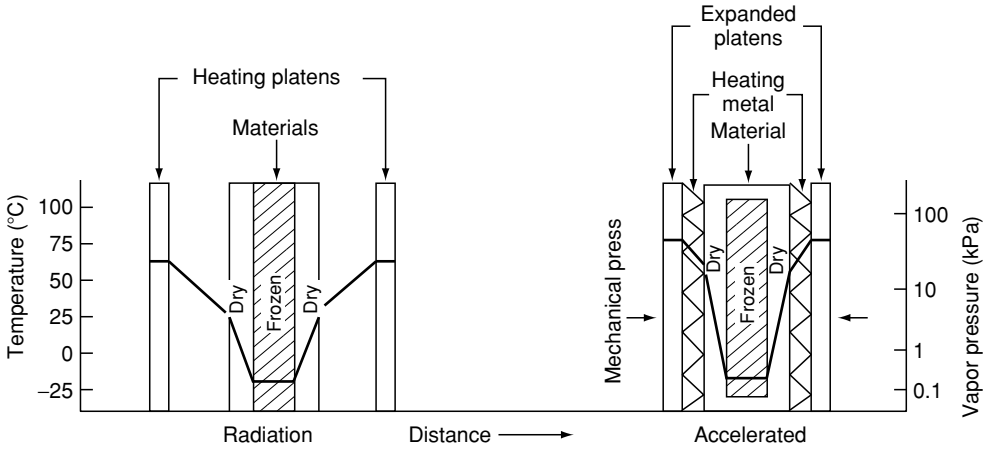

Figure 2 Temperature and vapor pressure gradients (heavy black line) in freeze drying with heating through the dry layers. Reproduced from Freeze Drying, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

vacuum chamber, and hence less air pressure will interfere with the escape of water vapor from the subliming product.

Desorption (Secondary Drying)

After the disappearance of the ice from the freeze-dried product, the residual moisture (nonfreezable water content and, as frequently occurs in practice, incompletely sublimed ice) can be reduced by a secondary drying step called desorption. This consists of heating the product while under a vacuum of between 0.13 and 0.67 mbar. The effect of heating is diminished by the insulating effect of the vacuum in the porous dry product.

An endpoint to secondary drying should be determined to prevent a result in which the product either retains too much water or becomes overdried and damaged by secondary heating. The endpoint can be determined by plotting the ratios of the pressures in the vacuum line before and after isolating the vacuum pump from the chamber by means of a valve. The endpoint is reached when the ratio approaches unity, though values in the range 1.1–1.2 may be practicable. This method assumes the chamber has a low leak rate.

A more exact endpoint can be determined by trapping a sample of the vapor/air mixture from above the desorbing product, then condensing the vapor component outside the vacuum chamber. As in the previous method, the ratio of the partial pressure before and after trapping approaches unity at the endpoint of drying. Precise calibration can be achieved by reference to moisture content predicted by a vapor pressure isotherm for the particular product being dried.

Breaking the Vacuum

A dry inert gas, such as nitrogen, is often used to break the vacuum, and thereby prevent entry of moisture-laden air (and oxygen) into the dry product.

Supplementary (Conditioning) Phase

A freeze-dried product is dry, light, and porous, and ideally retains its original shape. It can be stored for long periods provided its container excludes moisture and oxygen. Residual moisture should be evenly distributed and should not exceed 2% (dry-weight-basis measurement). A conditioning procedure is often necessary to achieve even distribution of residual moisture through the entire mass of the product, since freeze driers with multiple shelves usually have a temperature gradient between the top and bottom shelves and, therefore, do not achieve exactly the same drying conditions on every shelf. Conditioning is achieved by combining the product from all shelves and allowing the mixture to stand for 24 h in an airtight drum before packaging into smaller quantities.

Rehydration

Rehydration restores the lyophile (dry product) to its original physical and organoleptic properties. However, rehydration by immersion of the product in water can only proceed with difficulty in some cases, where pores may have collapsed and protein chains may have changed positions. Protein can be partly digested by adding a proteolytic enzyme to the fluid, and so assist rehydration. The product should be allowed to stand incompletely immersed in the fluid during rehydration, thereby minimizing resistance to rehydration by air becoming entrapped in the porous product.

Technological Improvements

Freeze-drying rates and results for certain food products can be improved by variants of the basic process.

Microwave Heating

This is best applied to remove residual moisture in the desorption stage, since it can speed up this final stage most advantageously. Use of microwave heating in the primary phase is not recommended, because of the danger of ionization of the air under vacuum pressures of less than 1.33 mbar, and possible explosive effects.

Cyclic Pressure

If the vacuum pressure is deliberately increased periodically (two-thirds of the cycle), and then reduced again (one-third of the cycle), a vapor flash occurs at the product surface, as a result of raising the thermal conductivity of the gas, and a small increase in ice interface temperature. The result of this process is a reduction in overall drying time of up to 34% for products such as cooked meat, whole egg, and apple.

Adsorbents

The adsorption process removes water vapor by means of a desiccant rather than refrigeration coils. The desiccant creates a high and well-sustained vapor pressure driving force, particularly at moderately low temperatures, since the equilibrium water vapor pressure of the desiccant decreases as the temperature is lowered.

At $-20\,^{\circ}C$ and 1.04 mbar vacuum, silica gel provides a vapor pressure force to 'drive' freeze drying equivalent to refrigeration coils at $-40\,^{\circ}C$

and similar vacuum pressure. An adsorption system can, therefore, be set at $-20\,^{\circ}C$ and many of the engineering complexities, involving low-temperature refrigeration, high vacuum, and problems of drying the vacuum chamber after defrosting the refrigeration coils, are eliminated.

In an adsorption system, secondary drying can be achieved at $-20\,^{\circ}C$ instead of $+20\,^{\circ}C$, with a greatly reduced risk of overheating the product.

Background

Freeze-drying is a dehydration process especially suited to the conservation of biological products. In comparison with other drying processes, freeze-drying is considered as a reference for manufacturing high-quality dehydrated product. The direct transition of water from solid to vapor (sublimation), without a liquid phase, helps to preserve most of the initial raw material's properties such as appearance, shape, taste, color, and flavor. As an important functional property, the freeze-dried product has a high rehydration capacity. The main limit to the industrial development is its cost due to the low productivity. Consequently, except the application for biological active material (bacteria, vaccine), the use of freeze-drying is restricted in food industry to high added-value products like coffee, ingredients for ready-to-eat foods (fruits and vegetables, meat and fish), and aromatic herbs.

Freezing

Freezing, the first step of the process, determines the structure of the freeze-dried product. The rate of freezing and the temperature level, depending on the nature and the composition of the product, define the number (nucleation) and size (growth) of the ice crystals (**Figure 1**).

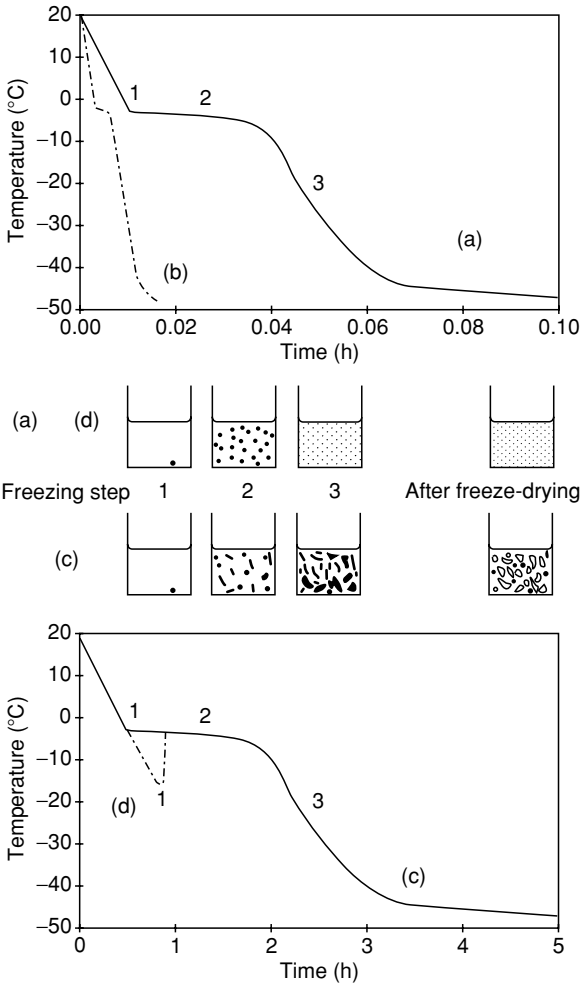

Figure 1 Influence of freezing rate on the final structure of freeze-dried products. (a) Rapid freezing rate; (b) very rapid freezing rate; (c) slow freezing rate; (d) slow freezing with subcooling. The liquid product is shown schematically with black points representing ice. Step 1, appearance of the first ice crystal; step 2, ice nucleation and crystal growth; step 3, end of freezing step. Porosity of the freeze-dried product is shown in relation to freezing rate.

In the case of rapid freezing (more than several centimeters per minute), ice crystals remain small, and the high nucleation rate leads to the creation of numerous crystals. In food products, water crystallizes simultaneously inside and outside the cell, and the microcrystals yield small pores after freeze-drying. This method of freezing preserves the structure of the material as much as possible, but at the same time, the absence of a high porous network tends to decrease the rate of subsequent drying steps and the rehydration capacity of the freeze-dried product.

In the case of slow freezing (less than one centimeter per hour), ice crystal formation is based on two mechanisms. If crystallization begins at a temperature lower than but close to 0 °C (−1 to − 3 °C), the ice crystal growth is faster than the ice nucleation and takes place preferentially outside the cell. Owing to the resulting osmotic effect, water inside the cell tends to move out, and the large crystals obtained in the interstitial areas can cause mechanical injury to the structure. In a few cases, subcooling may occur (several degrees under freezing point without ice), and very rapid crystallization suddenly occurs, yielding a final structure similar to that obtained by quick freezing.

In noncellular systems (gel, juices), the result of slow freezing is a heterogeneous medium with a large dendritic crystal structure and a highly concentrated phase that can form an impermeable layer at the surface of the product. During subsequent drying, if the vapor is thus prevented from leaving the product, the vapor pressure inside the product will increase and make the product foam. To a lesser extent, a nonhomogenous freezing step, based on rapid freezing at the surface (with a refrigerating effect of the superficial water evaporation in a dry cold atmosphere) and a slow freezing inside the product, also creates a less porous layer on the surface. This layer constitutes a barrier to the elimination of the water vapor.

Quenching in liquid nitrogen prevents any crystallization (vitrification) but is not usually carried out in food processing. Meanwhile, if the temperature achieved at the end of the freezing process is sufficiently low, often far below − 20 °C, the frozen product is in an overall amorphous state. This is a good condition to maintain the stability of the frozen structure. Moreover, a lower storage temperature has to be applied in order to preserve the structure obtained after a rapid freezing than after a slow freezing rate.

The freezing step gives the high porosity of the freeze-dried product but explains the main part of the texture loss when damaging the cell wall structure. The volume difference between the fresh and freeze-dried product is generally considered negligible. A rapid (homogeneous) freezing will contribute to preserve the structure and overall texture of the material, while creating the uniform porous network of the freeze-dried product. Slow freezing is nevertheless preferred because the interstices and openings are larger and facilitate mass transfer during drying and rehydration before eating.

Drying

The drying steps (primary – sublimation, and secondary – desorption) may also affect the structure of the product, and the most important factors affecting the criteria of final product quality are the heating temperature and the working pressure.

Temperature

Large differences between the temperature values from the frozen part to the dried layer are observed during freeze-drying.

In the frozen core, it is well known that the temperature must remain under the melting point in order to prevent fusion. Moreover, the structure resulting from the freezing step is stable if the temperature also remains under another lower temperature level, which is characteristic of the glass transition step of the concentrated medium around the ice crystal (Figure 2). As an example, when the vitreous region is obtained (area (3) in Figure 2), the reactions like the recrystallization, also called 'Ostwald maturation,' are highly reduced. Moreover, if

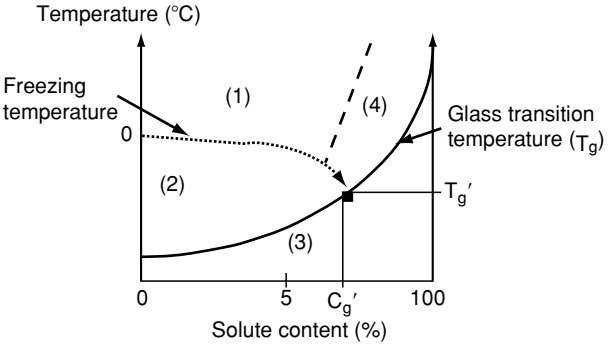

Figure 2 Phase state diagram for a binary mixture. Curves showing transition temperatures – glass transition and melting – are plotted against moisture content. There are four regions: (1) liquid, (2) ice crystal with concentrated liquid, (3) amorphous solid, and (4) liquid with solute crystal. In the amorphous solid region, the viscosity of the matrix is higher than 10^{12}–10^{14} Pa.s. These diagrams may be experimentally determined for a material by differential scanning calorimetry. T_g': Glass transition temperature, of the maximally frozen concentrated solute, C_g'.

the temperature in the frozen core during the primary drying phase is below the melting point but above the glass transition temperature (T_g'), the structural damage may be significant, and the product may collapse when the frozen ice crystal is sublimated. A low temperature (under T_g') maintains a high apparent viscosity; shrinkage and, consequently, collapse are avoided. The product-collapse temperature is closely related to the glass transition temperature but sometimes appears higher than T_g, especially for cellular material (biological tissue). For foods with a high sugar content, the collapse temperature is low (-40 to $-60\,^{\circ}C$) and can be raised by the addition of high-molecular-weight additives (polysaccharides).

The glass transition temperature decreases strongly with the water content, due to the plasticizing effect of water (Figure 2). In the dried layer, a higher temperature, allowing a higher drying rate, can be applied without product damage. But over a critical value of $60\,^{\circ}C$, another kind of damage occurs in the biological product, i.e., protein degradation. This results in a change in the product structure, especially in protein-based foods (meat, fish), and a reduced tenderness and hydration capacity.

During the freeze-drying process, the passage of the product from the frozen state to the dried state is a critical step in which there is a wide variation in water content as well as the temperature. The probability of structural changes (i.e., collapse) is important. As a general rule, to preserve the original structure, the product temperature should remain under the glass transition temperature (T_g), which depends strongly on the water content.

On a practical point of view, the control of temperature is based on the temperature and energy supplied from the heating source. Among the traditional techniques, conductive heating is more preferable for use with thermally sensitive products than a radiation heat source. With microwave heating, it is more difficult to control a homogeneous supply of energy inside the frozen core of the product, and this often leads to a reduction in final product quality.

Pressure

In the atmosphere of the freeze-drier under vacuum, the total pressure is generally assumed to be close to the vapor pressure. Following the equilibrium rule, the vapor pressure is directly related to the temperature at the sublimation front inside the product where the vapor is created. Thus, a control of the total pressure is an indirect way to monitor the product temperature at the sublimation front. At first, the total pressure has to be sufficiently low to avoid the melting of ice. After a rapid abnormal increase in pressure in the freeze-drier, the food product foams and shrinks due to an increase in front temperature above the melting point. Furthermore, during primary drying, if the pressure is sufficiently low to avoid the melting point but higher than the glass transition, shrinkage and collapse mechanisms can be observed. In order to maintain the quality of the product, the total pressure should be sufficiently low in comparison with the sublimation front temperature.

In conclusion, the main modification of the structure of the product is a consequence of the freezing step, assuming that the drying steps are well controlled (no recrystallization and no collapse). During the subsequent drying steps, low values of pressure and temperature (levels depending on the nature of the dry matter of the product) tend to preserve the shape and texture of the frozen product. Knowing that an increase in temperature is a good way to reduce the freeze-drying time, an optimum temperature has to be defined for industrial applications.

Flavor Losses

Freeze-drying is often considered the best drying process as far as flavor compound retention is concerned, due in a first approximation to the low temperature level.

Molecules, responsible for food flavor, usually have a high relative volatility to water and a low molecular weight (less than $300\,g\,mol^{-1}$). Owing to the low concentration of aroma compounds in the food products (p.p.b. to p.p.m.), food flavor is usually evaluated using two kinds of tools: analytical measurements (gas chromatography and mass spectrometry analysis) and/or sensory panel. From these properties, it is difficult to imagine removing water as a vapor phase, without any other volatiles like flavor compounds. Also, flavor losses, even in low proportions, are rapidly considered to be significant. As a matter of fact, the loss of flavor compounds can be limited during freeze-drying with regard to water elimination. The freeze-drying operating conditions that improve the drying rates give an increased retention of volatiles. Rapid primary drying is expected to result in higher levels of volatiles. This can be explained from the principle of selective diffusion. The diffusion coefficient (mobility) of the volatile decreases more rapidly with the water content inside the product than the diffusion coefficient of water itself (Figure 3). The loss of volatile decreases and stops as soon as a critical moisture is attained. One way to decrease the first drying duration is to increase, in a preliminary step, the dry matter (additives, osmotic dehydration). Based on the techniques of encapsulation, additives can also decrease the

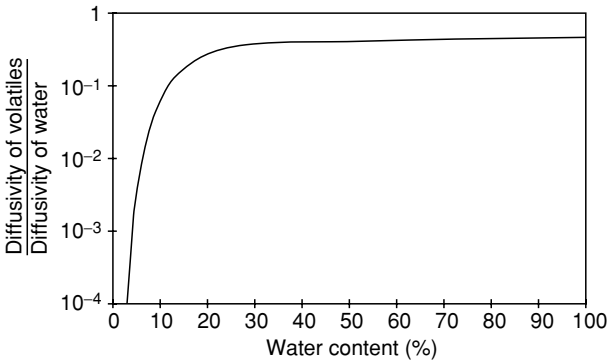

Figure 3 Influence of water content inside food products on the ratio between the diffusion coefficients of volatile compounds and water vapor.

flavor mobility in the matrix during drying. With this approach, a decrease in flavor losses has been observed in coffee, fruits, and vegetables when slow freezing is applied.

Using a constant heating temperature source, retention of flavor decreases when the total pressure increases. Shrinkage and collapse phenomena (high pressure and low apparent viscosity of the medium) are correlated to a poor aroma retention. Considering flavor compounds (or lipids) encapsulated in the amorphous part of the freeze-dried product, recrystallization (either water or solutes) above T_g results in the release of entrapped compounds. Thus, crystallization is related to a loss of flavor. Moreover, exposure of lipids to ambient oxygen is enhanced, which promotes oxidation and creates off-odors. Low-fat meats like chicken, turkey, and ham are easier to freeze-dry. During secondary drying, low heating temperatures are recommended to obtain a freeze-dried product without a cooked flavor, thus preventing new and often undesirable aroma compounds.

Lowering the driving force is another way to reduce the mass transfer of flavor compounds. Reducing the total pressure under vacuum implies that a vacuum pump continually extracts the volatiles from the chamber. Freeze-drying under atmospheric pressure has been proposed to remove less volatiles, but it is necessary to use a highly selective adsorbent that depletes only the water vapor in the freeze-drying atmosphere.

The flavor losses remain low during the freeze-drying process. Under vacuum freeze-drying, the low total pressure prevents oxidation. The storage condition, especially the temperature, can also be detrimental to flavor sensory components.

Packaging and Storage of the Freeze-dried Product

The moisture of the freeze-dried material associated with the temperature during the storage has to be finely controlled in order to preserve the high quality of the freeze-dried product.

The freeze-dried product has a very low water content (less than 5%), and so it is very hygroscopic and necessitates the use of packaging film that is impermeable to water. If there is a gain of a few percent of water, the product can become rubbery at ambient temperature (temperature above the glass transition temperature). Its structure becomes sticky, and the product collapses into lumps after a few weeks. In high-sugar products, there is also a risk of solute crystallization. This loss of structure is associated with an increase in all kinetic reactions inside the product.

Moreover, because of the high porosity of the freeze-dried product, the ambient oxygen is very efficient, and the oxidation reaction can be accelerated (flavor losses, browning).

Depending on the product, a vacuum seems to be better than an inert gas like nitrogen, in order to prevent off-flavors from developing.

A good stability of the freeze-dried product is achieved with a nonpermeable packaging, referring to water vapor and oxygen. Packaging under vacuum and at a low storage temperature (above ambient temperature) is always favorable to increase the time of preservation of the original flavor to several months.

Other Quality Criteria: Nutrients, Color, and Rehydration

Freeze-drying is definitively taken as a reference when quality criteria should be maintained close to the original product. Superior retention of nutrients and a better preservation of the color are also obtained when freeze-drying operating conditions have been chosen to maintain the structure and flavor of the product.

Fruits and vegetables are major sources of vitamins and provitamins, with a reported anticancer activity, which are highly unstable and oxidizable. Freeze-drying at low heating temperatures and under an inert gas gives the best preservation of nutrients compared with other processes (drying, canning). High-activity enzyme extracts from fruits have also been obtained with freeze-drying processes.

In freeze-dried foods, the color is brighter than that of products dried by other techniques. Browning due to Maillard reactions, if compared with other drying

processes, is reduced because of the low temperature used. Nevertheless, a slow freezing rate gives a more pronounced color and higher luminance than a high freezing rate but disappears after rehydration. Referring to the chemical reaction, slow freezing, associated with the cryoconcentration effect, tends to increase the intensity of the red color in freeze-dried products like strawberries and beef meat. This risk of enzymatic browning reactions in fruits is higher with slow freezing. The effect of freeze-drying pressure has been observed after rapid freezing on freeze-dried coffee, with a darker product at high pressure. Secondary drying at more than 60 °C will promote browning (Maillard reactions). Eventually, freeze-dried products are very sensitive to UV light. This is particularly true for vegetables like garlic and carrots, which may become virtually white after a few weeks' storage under light. A layer of aluminum is usually introduced in the packaging film to make it impermeable to UV radiation.

The rehydration capacity is an interesting functional property for industrial use of the product as well as for the consumer. The freezing step, associated with negligible shrinkage, leads to the characteristically high porosity of the freeze-dried product. A low freezing rate promotes a high rehydration capacity. This effect on different freeze-dried food products is not obvious if recrystallization has taken place during freeze-drying. The percentage of sublimed water, which often occupies 80–90% of the volume of biological materials, coincides with the porosity index of the freeze-dried product. The freeze-dried structure explains the instantaneous and high rehydration capacity, which may reach up to 90% of the lost water. Deformation as well as protein denaturation, due to high temperatures during freeze-drying, can decrease this ratio. Nevertheless, it will not achieve the rehydration ratio observed for traditional drying processes, i.e. not higher than 10–20%. During rehydration in boiling water, hot liquid rapidly reenters the pores, and freeze-dried products such as beverages (coffee or tea), vegetables, and all ready-to-eat meal preparations can be instantaneously heated and cooked.

Background

Preservation of food is one of the most significant applications of refrigeration. It is known that cooling and freezing of food effectively reduces the activity of microorganisms and enzymes, thus retarding deterioration. In addition, crystallization of water reduces the amount of liquid water in food items and inhibits microbial growth.

Thermodynamics of the Cooling and Freezing Process

The cooling and freezing of food is a complex process, as illustrated in the cooling/freezing curve shown in Figure 1. Prior to freezing, sensible heat must be removed from the food to decrease its temperature from the initial temperature. As the temperature of the food is decreased, it will pass through its initial freezing point to become undercooled prior to the formation of ice. Then, the formation of ice nuclei releases energy to bring the temperature of the undercooled food back to its initial freezing point. Once ice nuclei have formed, ice crystals will grow as energy is removed.

The number, size, and location of the ice crystals are determined by the rate of energy removal. If the heat transfer rate is much higher than the rate of energy release due to crystal growth, the food will become undercooled, resulting in the formation of additional ice nuclei, and hence, a large number of small ice crystals will form within the food. If the rate of energy release due to crystal growth is more nearly equal to the heat transfer rate, fewer nuclei will form, and the existing crystals will grow to a larger size. In addition, a high freezing rate will not allow sufficient time for water migration from within the cells, thus resulting in intracellular ice crystal nucleation and growth. Conversely, a lower heat transfer rate will provide sufficient time for water migration through the cell walls as extracellular ice crystals remove free water external to the cells, thus resulting in the growth of larger extracellular ice crystals.

Initial Freezing Point

Foods do not freeze completely at a single temperature, but rather they freeze over a range of temperatures, and some foods that are high in sugar content may never be completely frozen. Thus, foods do not have a distinct freezing point but rather an initial freezing point at which the crystallization process begins.

The initial freezing point is important in the determination of proper storage conditions and in the calculation of thermophysical properties. Fresh fruits and vegetables, for example, should be stored above their initial freezing point to avoid frost damage, and since the thermophysical properties of a food change drastically as it freezes, knowledge of its initial freezing point is necessary to accurately model its thermophysical properties.

Freezing Point Depression

The initial freezing point is somewhat lower than the freezing point of pure water because of dissolved substances in the moisture within the food. At the initial freezing point, a portion of the water within the food crystallizes, and the remaining solution becomes more concentrated. Thus, the freezing point of the unfrozen portion of the food is reduced further. As the temperature continues to decrease, the formation of ice crystals increases the concentration

of the solutes in solution and depresses the freezing point further.

Ice Fraction

To predict the thermophysical properties of frozen foods, which depend strongly on the ice and water fractions within the food, it is necessary to determine the mass fraction of water that has crystallized. For temperatures below the initial freezing point, this mass fraction is a function of temperature.

As the food item is cooled to its initial freezing temperature, it will contain ice, unfrozen water, soluble solids, and insoluble solids. As the temperature decreases further, there is an increase in the mass fraction of ice, w_{ice}, and a decrease in the mass fraction of unfrozen water, w_w, which are related as follows:

$$w_{wo} = w_{ice} + w_w, \tag{1}$$

where w_{wo} is the total mass fraction of water within the food.

Assuming that the high moisture content food items can be modeled as ideal dilute solutions, an ice fraction equation can be derived from Raoult's law:

$$w_{ice} = (w_{wo} - w_b)\left[1 - \frac{t_f}{t}\right], \tag{2}$$

where t_f is the initial freezing point of the food (°C), t is the food temperature (°C) and w_b is the mass fraction of water that is bound to solids within the food, and thus is unavailable for freezing. This bound water fraction may be estimated as follows:

$$w_b = 0.4w_p, \tag{3}$$

where w_p is the mass fraction of protein in the food item.

Because eqn (2) underestimates the ice fraction at temperatures near the initial freezing point and overestimates the ice fraction at lower temperatures, the following empirical relationship has been proposed to estimate the mass fraction of ice:

$$w_{ice} = w_{wo}\left[\frac{1.105}{1 + \frac{0.7138}{\ln(t_f - t + 1)}}\right]. \tag{4}$$

Energy Transfer During Freezing

In many food cooling and freezing processes, transient convective heat transfer occurs between a fluid medium and the food item. Knowledge of the corresponding surface heat transfer coefficient is required in order to design the equipment in such processes. Newton's law of cooling defines the surface heat transfer coefficient, h, as follows:

$$q = hA(t_s - t_m), \tag{5}$$

where q is the heat transfer rate, t_s is the surface temperature of the food, t_m is the surrounding fluid temperature, and A is the surface area of the food through which the heat transfer occurs.

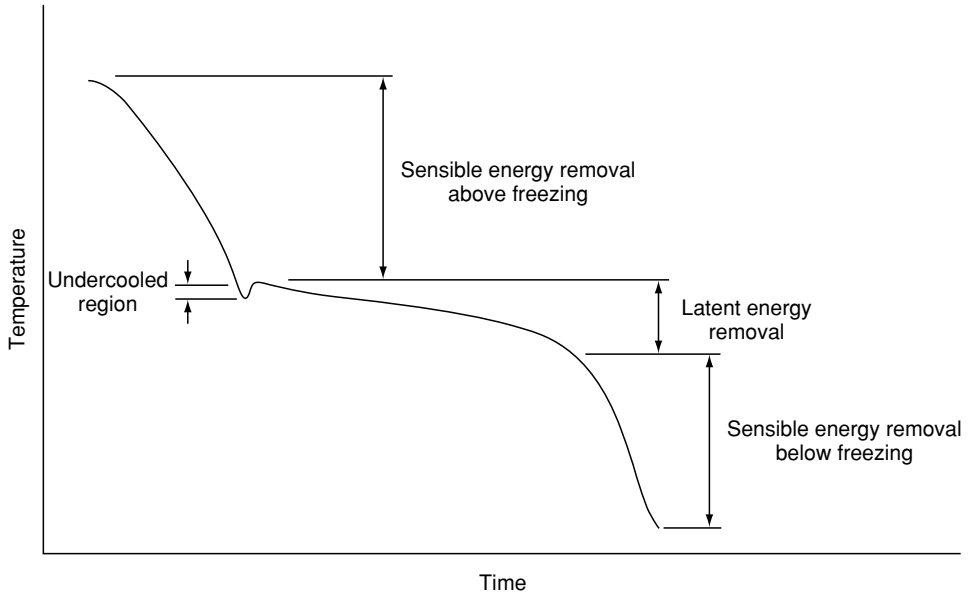

Figure 1 Cooling/freezing curve.

During a convective heat transfer process, energy is theoretically transferred by convection alone. However, in practice, conduction, radiation, and mass transfer may also occur at the same time. In blast cooling/freezing operations, the conductive heat transfer component is usually very small and can be neglected. The significance of the radiation heat transfer and evaporative cooling due to mass transfer must be considered on an individual basis, and their effects upon the total heat transfer must be properly incorporated. Researchers often define an 'effective' heat transfer coefficient, which includes the effects of convection and radiation heat transfer, as well as the energy transfer due to evaporation of moisture from the surface of the food item.

Thermal Properties of Foods

The thermal properties of foods are important in the design of food storage and refrigeration equipment as well as in the estimation of process times for refrigerating, freezing, heating, or drying of foods. Because the thermal properties of foods are strongly dependent upon chemical composition and temperature, the most viable option is to predict these thermal properties using mathematical models that account for the effects of chemical composition and temperature.

Composition data for foods are readily available in the literature. These data consist of the mass fractions of the major food components: water, protein, fat, carbohydrate, fiber, and ash. Food thermal properties can be predicted by using these composition data in conjunction with temperature-dependent mathematical models of the thermal properties of the individual food components.

Equations for predicting the thermal properties of these food components have been developed as functions of temperature in the range of -40 to 150 °C. These equations are presented in Table 1. Because water is the predominant constituent in most food items, the water content of food items significantly influences the thermophysical properties of foods. Therefore, equations for predicting the thermal properties of water and ice have also been developed. These equations are presented in Table 2.

In general, the thermophysical properties of a food item are well behaved when the temperature of the food item is above its initial freezing point. However,

[a]For the temperature range of -40 to 0 °C.
[b]For the temperature range of 0 to 150 °C.

below the initial freezing point, the thermophysical properties of a food item vary dramatically with temperature.

Specific Heat Capacity

Specific heat capacity is a measure of the energy transfer required to effect a temperature change and can be used to calculate the heat load imposed on the refrigeration equipment by the freezing of foods. In unfrozen foods, specific heat capacity is relatively constant with respect to temperature. However, for frozen foods, there is a large decrease in specific heat capacity as the temperature decreases.

Unfrozen

The specific heat capacity of an unfrozen food item, c_u, can be obtained from the mass average of the specific heat capacities of its components:

$$c_u = \sum c_i w_i, \tag{6}$$

where the c_i denotes the specific heat capacities of the individual food components, and w_i denotes their mass fractions.

If detailed composition data are not available, a simpler equation for the specific heat capacity of an unfrozen food item can be used:

$$c_u = 4190 - 2300 w_s - 628 w_s^3, \tag{7}$$

where c_u is the specific heat capacity of the unfrozen food item ($J\,kg^{-1}\,K^{-1}$), and w_s is the mass fraction of the solids in the food item.

Frozen

Below the initial freezing point of the food item, the sensible energy due to temperature change and the latent energy due to the fusion of water must be considered. Because latent heat is not released at a constant temperature, but rather over a range of temperatures, an apparent specific heat capacity can be used to account for both the sensible and latent heat effects. To develop expressions for apparent specific heat capacity, first consider the specific enthalpy of a frozen food. The specific enthalpies of the food constituents are additive. Further, assume that the food is composed of solids, liquid water, and ice. Then, the specific enthalpy of the frozen food, h, can be modeled as:

$$h = h_s w_s + h_w w_w + h_{ice} w_{ice}, \tag{8}$$

where h_s is the specific enthalpy of the solid constituents, h_w is the specific enthalpy of water, and h_{ice} is the specific enthalpy of ice. Differentiating eqn (8) with respect to temperature at constant pressure yields an expression for the apparent specific heat capacity, c_a:

$$c_a = \frac{\partial h}{\partial T} = c_s w_s + c_w w_w + c_{ice} w_{ice} + h_w \frac{\partial w_w}{\partial T} + h_{ice} \frac{\partial w_{ice}}{\partial T}, \tag{9}$$

where c_s is the specific heat capacity of the solid constituents, c_w is the specific heat capacity of water, and c_{ice} is the specific heat capacity of ice.

Assuming that high moisture content food items can be modeled as ideal dilute solutions, and noting that $\partial w_w/\partial T = -\partial w_{ice}/\partial T$, the following equation for the apparent specific heat capacity of high moisture content food items can be derived:

$$c_a = c_u + (w_b - w_{wo})\Delta c + E w_s \left[\frac{R T_o^2}{M_w t^2} - 0.8\Delta c\right], \tag{10}$$

where Δc is the difference between the specific heat capacities of water and ice ($\Delta c = c_w - c_{ice}$), E is the ratio of the molar masses of water, M_w, and food solids, M_s, ($E = M_w/M_s$), R is the ideal gas constant, T_o is the freezing point of water ($T_o = 273.2$ K), and t is the food temperature (°C).

A slightly simpler apparent specific heat capacity equation, which is similar in form to that of eqn (10), is given as follows:

$$c_a = 1550 + 1260 w_s + \frac{w_s R T_o^2}{M_s t^2}. \tag{11}$$

Specific Enthalpy

The change in specific enthalpy of a food item can be used to estimate the energy that must be removed from a food item in order to effect a temperature change. Above the freezing point, specific enthalpy consists of sensible energy, whereas below the initial freezing point, specific enthalpy consists of both sensible and latent energy.

Specific enthalpy may be obtained from the definition of the constant pressure specific heat capacity:

$$c_p = \left(\frac{\partial h}{\partial T}\right)_p, \tag{12}$$

where c_p is the constant pressure specific heat capacity, h is the specific enthalpy, and T is temperature. Equations for specific enthalpy may be obtained by integrating expressions of specific heat capacity with respect to temperature.

Unfrozen

The specific enthalpy of an unfrozen food item, h, may be determined by integrating eqn (6) as follows:

$$h = \sum h_i w_i = \sum \int c_i, w_i \mathrm{d}T, \qquad (13)$$

where h_i is the specific enthalpy of the individual food components, and w_i is the mass fraction of the food components.

Integration of eqn (7) from the initial freezing point of a food item, t_f, to a temperature, t, above the freezing point would yield:

$$h = (t - t_f)(4190 - 2300w_s - 628w_s^3). \qquad (14)$$

This equation, however, would predict zero specific enthalpy at the initial freezing point of the food item, t_f. Typically, in the literature for food refrigeration, the reference temperature for zero specific enthalpy is $-40\,^{\circ}\mathrm{C}$. Thus, in order to make eqn (14) consistent with zero specific enthalpy at $-40\,^{\circ}\mathrm{C}$, an additional term must be added to eqn (14), namely, the specific enthalpy at the initial freezing point, h_f:

$$h = h_f + (t - t_f)(4190 - 2300w_s - 628w_s^3). \qquad (15)$$

The specific enthalpy at the initial freezing point, h_f, may be estimated by evaluating eqn (17) at the initial freezing temperature of the food, as discussed below.

Frozen

Integration of eqn (10) between a reference temperature, T_r, and the food temperature, T, leads to the following expression for the specific enthalpy of a frozen food:

$$h = (T - T_r)\left[c_u + (w_b - w_{wo})\Delta c + Ew_s\left(\frac{RT_o^2}{M_w(T_o - T_r)(T_o - T)} - 0.8\Delta c\right)\right]. \qquad (16)$$

Generally, the reference temperature, T_r, is taken to be 233.2 K ($-40\,^{\circ}\mathrm{C}$) at which point the enthalpy is defined to be zero.

By integrating eqn (11) between a reference temperature, T_r, and the food temperature, T, the following expression for specific enthalpy below the initial freezing point may be obtained:

$$h = (t - t_r)\left[1500 + 1260w_s, + \frac{w_s R T_o^2}{M_s t t_r}\right]. \qquad (17)$$

Thermal Conductivity

Thermal conductivity is the material property that relates the conduction heat transfer rate to the temperature gradient. The thermal conductivity of a food item depends upon many factors, including the composition, structure, and temperature of the food item.

Early work in the modeling of food thermal conductivity includes an adaption of Maxwell's equation. This model is based upon the thermal conductivity of dilute dispersions of small spheres in a continuous phase:

$$k = k_c \frac{1 - [1 - a(k_d/k_c)]b}{1 + (a - 1)b}, \qquad (18)$$

where k is the conductivity of the mixture, k_c is the conductivity of the continuous phase, k_d is the conductivity of the dispersed phase, $a = 3k_c/(2k_c + k_d)$, $b = V_d/(V_c + V_d)$, V_d is the volume of the dispersed phase, and V_c is the volume of the continuous phase.

In an effort to account for the different structural features of foods, thermal conductivity models for both homogeneous and fibrous food items have been developed. The differences in thermal conductivity parallel and perpendicular to the food fibers are taken into account in these fibrous food thermal conductivity models.

For an isotropic, homogeneous two-component system composed of continuous and discontinuous phases, in which the thermal conductivity is independent of the direction of heat flow, the following expression may be used to determine thermal conductivity, k:

$$k = k_c\left[\frac{1 - L^2}{1 - L^2(1 - L)}\right], \qquad (19)$$

where k_c is the thermal conductivity of the continuous phase, and L^3 is the volume fraction of the discontinuous phase. In eqn (19), it is assumed that the thermal conductivity of the continuous phase is much larger than the thermal conductivity of the discontinuous phase.

For an anisotropic, fibrous two-component system in which the thermal conductivity is dependent upon the direction of heat flow, two expressions for thermal conductivity have been developed. For heat flow that is parallel to the food fibers, the following expression may be used to determine thermal conductivity, $k_{\|}$:

$$k_{\|} = k_c\left[1 - N^2\left(1 - \frac{k_d}{k_c}\right)\right], \qquad (20)$$

where N^2 is the volume fraction of the discontinuous phase in the fibrous food product. If the heat flow is perpendicular to the food fibers, the following expression for thermal conductivity, $k_{\perp}$, applies:

$$\mathrm{k}_{\perp} = k_c\left[\frac{1 - P}{1 - P(1 - N)}\right], \qquad (21)$$

where $P = N(1 - k_d/k_c)$.

For multicomponent systems, numerous researchers have proposed the use of parallel and perpendicular (or series) thermal conductivity models based upon analogies with electrical resistance. The parallel model is simply the sum of the thermal conductivities of the food constituents multiplied by their volume fractions:

$$k = \sum_{i=1}^{n} \phi_i k_i, \tag{22}$$

where ϕ_i is the volume fraction of constituent i. The volume fraction of constituent i can be found from the following equation:

$$\phi_i = \frac{\frac{w_i}{\rho_i}}{\sum_{j=1}^{n} \frac{w_j}{\rho_j}}. \tag{23}$$

The perpendicular model is the reciprocal of the sum of the volume fractions divided by their thermal conductivities:

$$k = \frac{1}{\sum_{i=1}^{n} \frac{\phi_i}{k_i}}. \tag{24}$$

These two models have been found to predict the upper and lower bounds of the thermal conductivity of most food items.

Operations

B R Becker and B A Fricke, University of Missouri-Kansas City, Kansas City, MO, USA

Introduction

Freezing operations can be grouped by their basic method of extracting heat from foods. Blast freezing utilizes convection heat transfer to remove heat from foods while contact freezing makes use of conduction heat transfer to remove energy from foods. Cryogenic freezing may utilize convection and/or conduction heat transfer to remove heat from foods.

Blast Freezers

Blast freezers use air as the heat transfer medium and depend on contact between the product and the air. Sophistication in air flow control and conveying techniques varies from crude blast freezing chambers to carefully controlled impingement-style freezers. (*See* **Freezing**: Blast and Plate Freezing.)

Blast-Cell Freezer

The blast-cell freezer, shown in Figure 1, is the simplest design and consists of an insulated enclosure equipped with refrigeration coils and fans that circulate the air over the food items in a controlled way. Products are placed on trays, which are then placed into racks in such a way that an air space is left between adjacent layers of trays. The racks are moved in and out of the tunnel manually. Almost all products may be frozen either individually or in cartons in a blast-cell freezer. Because labor requirements are relatively high and product flow is cumbersome, blast-cell freezers are suitable for small quantities of varied products.

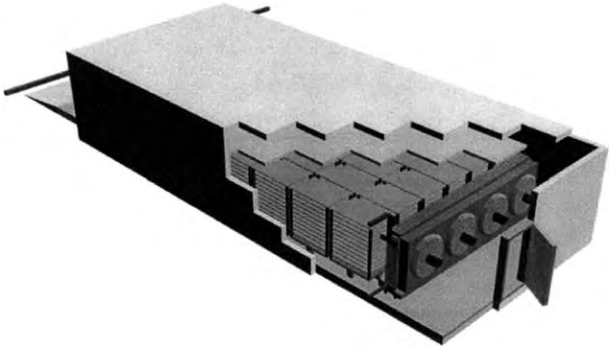

Figure 1 Blast-cell freezer (Ingvar).

Straight-Belt Freezer

The straight-belt freezer, shown in Figure 2, utilizes a wire mesh belt conveyor in a blast room, which provides continuous product flow. Vertical air flow is used, which forces cold air up through the product layer, thereby creating good contact between the air and the product. Straight-belt freezers are generally used with fruits, vegetables, French fried potatoes, cooked meat toppings (e.g., diced chicken), and cooked shrimp.

Straight-belt freezers usually incorporate a two-stage belt composed of two mesh conveyor belts in series. The first stage initially precools or crust-freezes the outer layer of the product before it is transferred to the second stage for final freezing and sensible cooling to −18 °C or below. Freezing times range from 3 to 50 min.

For products with longer freezing times or higher capacity requirements, the freezer footprint can be reduced by stacking belts above each other to form a multipass system, as shown in Figure 3. However, this type of freezing system has the potential for product damage and jams at the belt transfers.

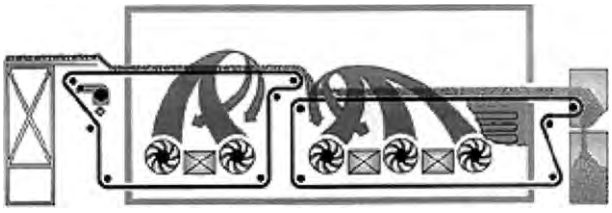

Figure 2 Straight-belt freezer (Advanced Equipment, Inc.).

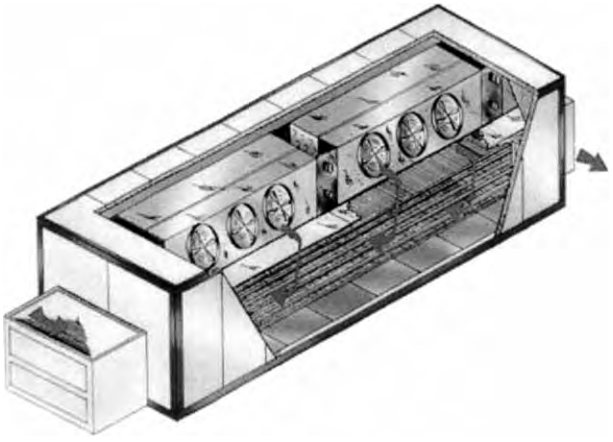

Figure 3 Multipass belt freezer (Advanced Equipment, Inc.).

Spiral-Belt Freezer

The spiral-belt freezer, shown in Figure 4, is often used for products that require gentle handling or a long freezing time (generally 10 min to 3 h). This freezer consists of an endless conveyor belt that is wrapped cylindrically, one tier above or below the last, to form a configuration which requires minimal floor space for a relatively long belt. The number of tiers in the spiral can be varied to accommodate different capacities and two or more spiral towers can be used in series for products with long freezing times. Modular and field-erected spiral freezers are available in a range of belt widths and lengths to accommodate various upstream processes and capacity requirements.

In spiral freezers, horizontal air flow is usually supplied by axial fans mounted along one side of the spiral which blow air horizontally across the spiral conveyor. Some freezers incorporate more sophisticated air flow control utilizing extensive baffling and high-pressure fans.

Typical products frozen in spiral-belt freezers include raw and cooked meat patties, fish fillets, chicken portions, pizza, and a variety of packaged products.

Fluidized-Bed Freezers

The fluidized-bed freezer, shown in Figure 5, utilizes air for product transport and heat transfer. The high degree of fluidization improves the heat transfer rate and is well suited for small, uniform-sized particulate products such as peas, resulting in a freezing time of 3–11 min.

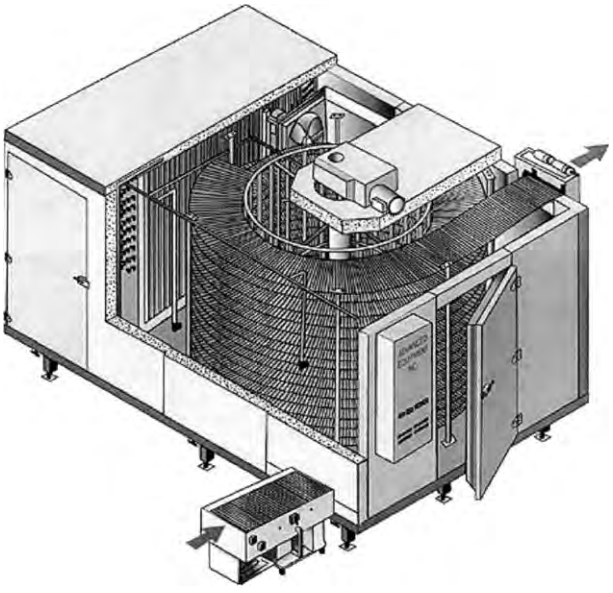

Figure 4 Spiral-belt freezer (Advanced Equipment, Inc.).

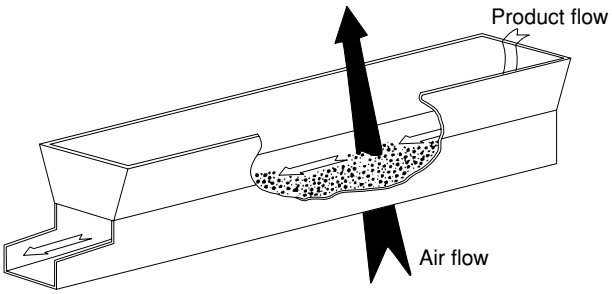

Figure 5 Fluidized-bed freezer (ASHRAE).

Fluidized-Belt Freezers

The fluidized-belt freezer is a hybrid of the belt and fluidized-bed freezers which incorporates a fluidizing section in the first belt stage. It is designed to provide fluidizing conditions for wet incoming product with a belt to assist the transport of heavier products that do not fluidize fully. Once crust-frozen, the product can be loaded deeper for greater efficiency on the second belt.

Contact Freezers

Contact freezers utilize conduction heat transfer whereby the product or package is placed in direct contact with a refrigerated surface. (*See* **Freezing**: Blast and Plate Freezing.)

Plate Freezers

The most common type of contact freezer is the plate freezer, in which the product is pressed between metal plates, as shown in Figure 6. Refrigerant is circulated inside channels in the plates, insuring efficient heat transfer and short freezing times. Plate freezers are especially suited for products that are good conductors of heat, such as fish fillets, chopped spinach, or meat offal. The plate freezer's heat transfer advantage is reduced with increasing product thickness, which is often limited to 5–8 cm.

For packaged products, an additional advantage of plate freezers is that pressure from the plates minimizes any bulging that may occur during freezing, resulting in packages that are even and square. However, packages or cavities should be well filled to insure efficient freezing.

Contact plate freezers are available in horizontal or vertical arrangements with manual loading and unloading. Horizontal plate freezers are also available with automatic loading and unloading, resulting in higher capacities and continuous operation. Automatic plate freezers can accommodate up to 200 packages per minute, with freezing times from 10 to 150 min.

Figure 6 Plate freezer (Ingvar).

Specialized Contact Freezers

A combination of air and contact freezing is often used for wet fish fillets and similar soft, wet products with relatively large, flat surfaces. The product is placed on to a continuous, solid stainless-steel belt and freezing is usually accomplished both by conduction through the belt to a cooling medium below the belt and by convection through controlled air flow above the belt. Another specialized contact freezer conveys food products on a continuous plastic film over a low-temperature refrigerated plate, thus eliminating product deformation or wire mesh belt markings on products which are flat, wet, and sticky, soft, or in need of hand-shaping before freezing. These freezer designs produce attractive product, but a drawback is the physical size of the freezer. Freezing times of less than 30 min can be achieved with these types of freezer.

Cryogenic Freezers

Cryogenic freezers use liquid nitrogen or liquid carbon dioxide as the refrigeration medium, and the freezers may be batch cabinets, straight-belt freezers, spiral conveyors, or liquid immersion freezers. While cryogenic freezers represent a low initial investment, they have a high operating cost. Consequently, cryogenic freezing is often utilized for small-scale production, new products, overload situations, or seasonal products.

The most common type of cryogenic freezer is a straight-through, single-belt tunnel. Liquid nitrogen at $-196\,^{\circ}\mathrm{C}$ or carbon dioxide at $-79\,^{\circ}\mathrm{C}$ is introduced at the outfeed end of the freezer, directly on to the product. As the liquid nitrogen or carbon dioxide vaporizes, the cold vapors are circulated toward the infeed end, where they are used for precooling and initial freezing of the product. The warmed vapors (typically $-45\,^{\circ}\mathrm{C}$) are then discharged to the atmosphere. The low temperature of the liquid and vaporous nitrogen or carbon dioxide provides rapid freezing, which can improve quality and reduce dehydration for some products. However, the freezing cost is high, and the surface of products having a high water content may crack if precautions are not taken. (*See* **Freezing**: Cryogenic Freezing.)

Freezing Time Estimation Methods

In order for food freezing operations to be cost-effective, it is necessary to design the refrigeration equipment optimally to fit the specific requirements of the particular freezing application. This requires estimation of the freezing times of foods, as well as the corresponding refrigeration loads.

Theoretically, the freezing of foods can be described via the Fourier heat conduction equation:

$$\frac{\partial T}{\partial t} = \frac{1}{\rho c}\left[\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right) + \frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right)\right] \tag{1}$$

where T is temperature, t is time, ρ is the density of the food, c is the specific heat of the food, k is the thermal conductivity of the food, and x, y, and z are the coordinate directions. For ideal, regularly shaped food items with constant thermophysical properties, uniform initial conditions, constant external conditions, and a prescribed surface temperature or a convection boundary condition, exact analytical solutions for eqn (1) exist which allow for the estimation of the freezing times of foods. However, for realistic freezing processes, the food items are generally irregularly shaped with temperature-dependent thermophysical properties and therefore it is not possible to derive exact analytical solutions for the freezing times of foods.

As a result of this difficulty, most of the research effort has been in the development of semianalytical/

empirical food freezing time prediction methods which make use of various simplifying assumptions. Numerous such methods have been proposed, and the designer is thus faced with the challenge of selecting an appropriate estimation method from the plethora of available methods.

In the following section, the basic freezing time estimation method developed by Plank is discussed first, followed by a discussion of those methods which are based upon modifications of Plank's equation. The discussion then focuses on those freezing time estimation methods in which the freezing time is calculated as the sum of the precooling, phase change, and subcooling times. The last section deals with freezing time estimation methods which account for irregularly shaped food items.

Plank's Equation

The most widely known method for estimating the freezing times of foods was developed by R. Plank in 1913. In this method, it is assumed that only convective heat transfer occurs between the food item and the surrounding cooling medium. In addition, it is assumed that the food item is at its initial freezing temperature and that this temperature is constant throughout the freezing process. Furthermore, a constant thermal conductivity for the frozen region is assumed. Plank's freezing time estimation method is given as follows:

$$t = \frac{L_f}{T_f - T_m}\left[\frac{PD}{h} + \frac{RD^2}{k_s}\right] \tag{2}$$

where L_f is the volumetric latent heat of fusion, T_f is the initial freezing temperature of the food, T_m is the freezing medium temperature, D is the thickness of the slab or the diameter of the sphere or infinite cylinder, h is the convective heat transfer coefficient, k_s is the thermal conductivity of the fully frozen food, and P and R are geometric factors. For the infinite slab, $P = \frac{1}{2}$ and $R = \frac{1}{8}$. For a sphere, P and R are $\frac{1}{6}$ and $\frac{1}{24}$, respectively, and for an infinite cylinder, $P = \frac{1}{4}$ and $R = \frac{1}{16}$.

The geometric factors, P and R, provide insight as to the effect of shape upon freezing time. Plank's shape factors indicate that an infinite slab of thickness D, an infinite cylinder of diameter D and a sphere of diameter D, if exposed to the same conditions, would have freezing times in the ratio of 6:3:2. Hence, a cylinder will freeze in half the time of a slab and a sphere will freeze in one-third the time of a slab.

Various researchers have noted that Plank's method does not accurately predict the freezing times of foods because it assumes that freezing of foods takes place at a constant temperature, and not over a range of temperatures, as is the case in actual food freezing processes. In addition, the thermal conductivity of the frozen food is assumed to be constant, but in reality, the thermal conductivity varies greatly during freezing. Another limitation of Plank's equation is that it neglects the removal of sensible heat above the freezing point. Furthermore, Plank's method is only applicable to infinite slabs, infinite cylinders, and spheres. Researchers have subsequently focused upon development of improved freezing time estimation methods which account for precooling and subcooling times, nonconstant thermal properties, irregular geometries, and phase change over a range of temperatures.

Modifications to Plank's Equation

Modifications to Plank's equation include corrections to account for the removal of sensible heat both above and below the initial freezing point of the food as well as temperature variation during freezing. Regression equations were developed to estimate the geometric parameters, P and R, for infinite slabs, infinite cylinders, and spheres. In these regression equations, the effects of surface heat transfer, precooling, and final subcooling are accounted for by means of the Biot number, Bi, the Plank number, Pk, and the Stefan number, Ste, respectively.

The Biot number, Bi, is defined as follows:

$$Bi = \frac{hD}{k} \tag{3}$$

In the literature for freezing of foods, it is accepted that the characteristic dimension, D, is defined as twice the shortest distance from the thermal center of a food item to its surface. For an infinite slab, D is the thickness. For an infinite cylinder or a sphere, D is the diameter. These definitions will be adopted for this article, unless otherwise noted.

In general, the Plank number, Pk, is defined as follows:

$$Pk = \frac{C_l(T_i - T_f)}{\Delta H} \tag{4}$$

where C_l is the volumetric specific heat of the unfrozen phase and ΔH is the volumetric enthalpy change of the food between T_f and the final food temperature. The Stefan number, Ste, is similarly defined as follows:

$$Ste = \frac{C_s(T_f - T_m)}{\Delta H} \tag{5}$$

where C_s is the volumetric specific heat of the frozen phase.

The freezing times of foods are then calculated with a modified version of Plank's equation. Plank's original geometric factors, P and R, are replaced with the modified values given in Table 1, and the latent heat, L_f, in Plank's equation is replaced with the volumetric enthalpy change of the food, ΔH_{10}, between the freezing temperature, T_f, and the final center temperature, assumed to be $-10\,^{\circ}\mathrm{C}$. As shown in Table 1, the geometric factors P and R are functions of the Plank number, Pk, and the Stefan number, Ste. Both of these parameters should be evaluated using the enthalpy change ΔH_{10}. Thus, the modified Plank equation takes the following form:

$$t = \frac{\Delta H_{10}}{T_f - T_m}\left[\frac{PD}{h} + \frac{RD^2}{k_s}\right] \tag{6}$$

Precooling, Phase Change, and Subcooling Time Calculations

Numerous researchers have taken a different approach to account for the effects of sensible heat removal above and below the initial freezing point. In these methods, the total freezing time, t, is the sum of the precooling, phase change, and subcooling times:

$$t = t_1 + t_2 + t_3 \tag{7}$$

where t_1, t_2, and t_3 are the precooling, phase change, and subcooling times, respectively.

An example of a freezing time estimation method in which sensible heat effects are included by calculating precooling, phase change, and subcooling times separately is given below. The use of a mean freezing point, which is assumed to be 1.5 K below the initial freezing point of the food, accounts for freezing which takes place over a range of temperatures. The freezing time estimation method is stated in terms of the volume and surface area of the food item and is therefore applicable to food items of any shape. This method is given as:

$$t_i = \frac{Q_i}{hA_s\Delta T_{mi}}\left(1 + \frac{Bi_i}{k_i}\right); \quad i = 1,2,3 \tag{8}$$

with the variables defined as shown in Table 2.

Geometric Considerations

Equivalent heat transfer dimensionality A geometric correction factor, called the equivalent heat transfer dimensionality, E, was introduced to calculate the freezing times of irregularly shaped food items. In this method, the freezing time of an irregularly shaped object, t_{shape}, is related to the freezing time of an infinite slab, t_{slab}, via the equivalent heat transfer dimensionality, E, as follows:

$$t_{\text{shape}} = \frac{t_{\text{slab}}}{E} \tag{9}$$

The freezing time of the infinite slab is then calculated from one of the many suitable freezing time estimation methods available for infinite slabs.

Expressions for determining the equivalent heat transfer dimensionality of infinite slabs, infinite and finite cylinders, rectangular bricks, spheres, and two- and three-dimensional irregular shapes are given as follows:

$$E = G_1 + G_2E_1 + G_3E_2 \tag{10}$$

where:

$$E_1 = X(2.32/\beta_1^{1.77})\frac{1}{\beta_1} + [1 - X(2.32/\beta_1^{1.77})]\frac{0.73}{\beta_1^{2.50}} \tag{11}$$

$$E_2 = X(2.32/\beta_2^{1.77})\frac{1}{\beta_2} + [1 - X(2.32/\beta_2^{1.77})]\frac{0.73}{\beta_2^{2.50}} \tag{12}$$

Table 1 Expressions for P and R

Shape	P *and* R *expressions*
Infinite slab	$P = 0.5072 + 0.2018Pk + Ste\left[0.3224Pk + \frac{0.0105}{Bi} + 0.0681\right]$
	$R = 0.1684 + Ste(0.2740Pk - 0.0135)\{$
Infinite cylinder	$P = 0.3751 + 0.0999Pk + Ste\left[0.4008Pk + \frac{0.0710}{Bi} - 0.5865\right]$
	$R = 0.0133 + Ste(0.0415Pk + 0.3957)\{$
Sphere	$P = 0.1084 + 0.0924Pk + Ste\left[0.231Pk - \frac{0.3114}{Bi} + 0.6739\right]$
	$R = 0.0784 + Ste(0.0386Pk - 0.1694)\{$

Table 2 Definition of variables for precooling, phase change, and subcooling time calculations

Process	*Variables*
Precooling	$i = 1$ $k_1 = 6$ $Q_1 = C_l(T_i - T_{fm})V$ $Bi_1 = (Bi_l + Bi_s)/2$ $\Delta T_{m1} = \dfrac{(T_i - T_m) - (T_{fm} - T_m)}{ln\left[\dfrac{T_i - T_m}{T_{fm} - T_m}\right]}$
Phase change	$i = 2$ $k_2 = 4$ $Q_2 = L_f V$ $Bi_2 = Bi_s$ $\Delta T_{m2} = T_{fm} - T_m$
Subcooling	$i = 3$ $k_3 = 6$ $Q_3 = C_s(T_{fm} - T_c)V$ $Bi_3 = Bi_s$ $\Delta T_{m3} = \dfrac{(T_{fm} - T_m) - (T_o - T_m)}{ln\left[\dfrac{T_{fm} - T_m}{T_o - T_m}\right]}$

A_s is the area through which heat is transferred.
Bi_l is the Biot number for the unfrozen phase.
Bi_s is the Biot number for the frozen phase.
C_l is the volumetric specific heat for the unfrozen phase.
C_s is the volumetric specific heat for the frozen phase.
L_f is the volumetric latent heat of fusion.
Q_1, Q_2, and Q_3 are the heats of precooling, phase change, and subcooling, respectively.
ΔT_{m1}, ΔT_{m2}, and ΔT_{m3} are the corresponding log-mean temperature driving forces.
T_c is the final thermal center temperature.
T_i is the initial temperature.
T_{fm} is the mean freezing point, assumed to be 1.5 K below the initial freezing point.
T_m is the freezing medium temperature.
T_o is the mean final temperature.
V is the volume of the food item.

$$X(x) = x/(Bi^{1.34} + x) \tag{13}$$

and the geometric constants, G_1, G_2 and G_3, are given in Table 3. The dimensional ratios, β_1 and β_2, are defined as follows:

$$\beta_1 = \frac{\text{second shortest dimension of the food item}}{\text{shortest dimension of the food item}} \tag{14}$$

$$\beta_2 = \frac{\text{longest dimension of the food item}}{\text{shortest dimension of the food item}} \tag{15}$$

Mean conducting path Knowledge of the Biot number of a food item is required to utilize freezing time estimation methods. To calculate the Biot number of a food item, its characteristic dimension must be known. Because it is difficult to determine the characteristic dimension of an irregularly shaped food item, the concept of the mean conducting path was introduced. The mean conducting path, $D_m/2$, is the mean heat transfer length from the surface of the food item to its thermal center. This mean conducting path is used to calculate the Biot number which, in turn, is used in the calculation of the freezing time. Thus, the Biot number becomes:

$$Bi = \frac{hD_m}{k} \tag{16}$$

where D_m is twice the mean conducting path.

For rectangular blocks of food, the mean conducting path is proportional to the geometric mean of the block's two shorter dimensions. Based upon this result, an equation to calculate the Biot number, Bi, for rectangular blocks of food is given as follows:

$$\frac{Bi}{Bi_o} = 1 + \left\{\left[1.5\sqrt{\beta_1} - 1\right]^{-4} + \left[\left(\frac{1}{\beta_1} + \frac{1}{\beta_2}\right)\left(1 + \frac{4}{Bi_o}\right)\right]^{-4}\right\}^{-0.25} \tag{17}$$

where Bi_o is the Biot number based on the shortest dimension of the block, D_1: $Bi_o = hD_1/k$. The Biot number, Bi, calculated with eqn (17) is then substituted into a freezing time estimation method, such as eqn (8), to calculate the freezing time for rectangular blocks.

It has been noted that for squat-shaped food items, the mean conducting path, $D_m/2$, could be reasonably estimated as the arithmetic mean of the longest and shortest distances from the surface of the food item to its thermal center.

Table 3 Geometric constants for equivalent heat transfer dimensionality

Shape	G_1	G_2	G_3
Infinite slab	1	0	0
Infinite cylinder	2	0	0
Sphere	3	0	0
Squat cylinder	1	2	0
Short cylinder	2	0	1
Infinite rod	1	1	0
Rectangular brick	1	1	1
Two-dimensional irregular shape	1	1	0
Three-dimensional irregular shape	1	1	1

Equivalent sphere diameter The concept of the equivalent sphere diameter can also be used to calculate the freezing time of irregularly shaped food items. In this method, a sphere diameter is calculated which is based upon the volume and the volume-to-surface-area ratio of the irregularly shaped food item. This

equivalent sphere is then used to calculate the freezing time of the food item.

In the equivalent sphere diameter technique, the volume–surface diameter, D_{vs}, is defined as the diameter of a sphere having the same volume-to-surface-area ratio as the irregular shape:

$$D_{vs} = \frac{6V}{A_s} \tag{18}$$

where V is the volume of the irregular shape and A_s is the surface area of the irregular shape. In addition, the volume diameter, D_v, is defined as the diameter of a sphere having the same volume as the irregular shape:

$$D_v = \left(\frac{6V}{\pi}\right)^{1/3} \tag{19}$$

Then, the equivalent sphere diameter, $D_{\mathrm{eq,s}}$, is defined as follows:

$$D_{\mathrm{eq,s}} = \frac{1}{\beta_2 + 1} D_v + \frac{\beta_2}{\beta_2 + 1} D_{vs} \tag{20}$$

Thus, the prediction of the freezing time of the irregularly shaped food item is reduced to predicting the freezing time of a spherical food item with diameter $D_{\mathrm{eq,s}}$.

Blast and Plate Freezing

M F G Boast, MBA Consulting Engineers, Markyate, UK

Background

The provision of low temperature for freezing is obtained from closed-circuit compression–expansion refrigeration systems, or by a cryogenic process of exposing the product to a cold atmosphere of liquid nitrogen or liquid carbon dioxide.

Various refrigerants have been used for the compression–expansion system, which forms the major source of food freezing, probably 90% of all installations.

Ammonia and sulfur dioxide are excellent media for the refrigeration process, but they carry the hazard of being inflammable and the risk of explosion. This led to the development during the 1930s of

the first chlorofluorocarbon (CFC) refrigerants, R11 and R12. These refrigerants replaced SO_2 in domestic refrigeration and NH_3 for small freezing systems. The later development of R22 (a hydrochlorofluorocarbon, or HCFC) and R502 (an azeotrope), displaced NH_3 from all but the largest of industrial freezing systems. Table 1 shows the characteristics of common refrigerants.

During the 1980s, the environmental effect of CFCs and HCFCs, in terms of ozone depletion potential and contribution to the greenhouse effect, became apparent. This has led to the restriction in the use of some refrigerants under the Montreal Protocol, and the development of new refrigerants called hydrofluorocarbons (HFCs).

Refrigerants and the Environment

Ozone Depletion

The ozone-depleting effect of refrigerants is important, because the ozone layer filters out ultraviolet (UV) radiation, which might otherwise reach the surface of the earth. This radiation could have seriously damaging effects on germinating crops and on the photoplankton of the oceans. In addition, increased doses of UV light can cause malignant skin cancer in fair-skinned races.

Greenhouse Effect

Ecological systems of the world are finely dependent on temperature. Small changes in average temperature can affect the distribution of crops and animals. There is evidence that the average global temperature has been increasing since the mid-nineteenth century because of carbon dioxide from the burning of fossil fuels. If it is not halted, mean sea levels will rise.

The consequences of even a small rise in sea level in certain areas of the world, where strong seasonal winds might coincide with high tides, would be disastrous. It is impossible to predict the likely rise of mean sea level, but it could be significant. In the remote past, the earth had no polar ice caps, presumably because of high concentrations of carbon dioxide in the atmosphere, which had not by then been absorbed by forests and oceans.

Chlorofluorocarbons are greenhouse chemicals more potent than the present greenhouse chemicals (carbon dioxide and methane) and should therefore not be released into the atmosphere.

Recommendations

Refrigerants known as CFCs are typically R11, R12, R115, R13B1, and R502 and have now been phased out, although some installations may still exist using the above refrigerants. New systems are not being constructed from the refrigerants.

The destruction of CFCs present problems in terms of safety and the need for environmental protection. Therefore, any system being decommissioned containing CFCs must be addressed in a controlled manner by personnel with the appropriate experience and qualifications.

Table 1 Characteristics of common refrigerants

Substance	*Type*	*Formula*	*Montreal Protocol*	*Ozone depletion potential (R11 = 1)*	*Greenhouse potential (CO_2 = 1)*	*Flammability*
R11	CFC	CCl_3F	Yes	1	3 300	No
R12	CFC	CCl_2F_2	Yes	2	10 000	No
R22	HCFC	$CHClF_2$	No	0.05	1 100	No
R113	CFC	CCl_2FCClF_2	Yes	0.8	4 500	No
R114	CFC	$CClF_2CClF_2$	Yes	1.0	1 300	No
R115	CFC	$CClF_2CF_3$	Yes	0.6	25 000	No
R123	HCFC	$CHCl_2CF_3$	No	0.02	50	No
R124	HCFC	$CHClFCF_3$	No	0.02	300	No
R125	HFC	CHF_2CF_3	No	0	1 900	No
R134a	HFC	CF_3CH_2F	No	0	900	No
R141b	HCFC	CH_3CCl_2F	No	0.08	300	Slight
R142b	HCFC	CH_3CClF_2	No	0.06	1 200	Slight
R152a	HFC	CH_3CHF_2	No	0	100	Moderate
R500	Azeotrope	R12/152a	Yes	0.74	7 400	No
R502	Azeotrope	R22/115	Yes	0.33	13 300	No
R717	Ammonia	NH_3	No	0	0	Moderate
R407C	Azeotrope	R32/125/134a	No	0	1 610	No
R404A	Azeotrope	R125/143a/134a	No	0		No
R410A	Azeotrope	R32/125	No	0	1 890	No

The construction of new systems for small to medium-sized uses refrigerant R404A. Large industrial systems use refrigerant R717 (ammonia).

Refrigerant R717 should only be used by companies and specialists with knowledge of this refrigerant owing to its pungent smell and hazard potential.

Maintenance

Plants should be constructed to the appropriate codes of practice and standards. Routine leak testing must be conscientiously carried out. In addition to being environmentally correct, this will produce cost savings and improve plant reliability.

Leak detectors should be fitted to all systems with a large refrigerant charge and should report to a central monitoring station.

Substitutes for CFCs

The substitute for refrigerant 12 is refrigerant R134A. The substitute for refrigerant R502 is refrigerant R404A. These refrigerants are not suitable for use with mineral oils, and polyester lubricants have been developed. Changing the system from refrigerant R12 or refrigerant R502 requires specialist knowledge and should only be carried out by suitably experienced companies and personnel. Changing the system refrigerant from R12 or R502 requires system flushing and thoroughly cleaning to insure that all traces of the previous refrigerant have been removed.

At the present time, systems using refrigerant R22 can continue to operate and can be serviced with new virgin refrigerant until the year 2005.

Freezing Considerations

Freezing Times

Freezing times vary, and each product has an associated freezing time that will depend on its composition, dimensions, and packaging. Dimensions and packaging have a direct effect on the freezing time, as heat can only leave the product through its surface. Products that are unpacked and have a large surface area-to-weight ratio, such as peas, will freeze in a minimum time, whereas a dense block of meat products, with heavy packaging or boxing, may take days to be fully frozen to the core.

The influence of freezing time is more apparent on some products than others. For strawberries, the drip loss is reduced from 20% to nearly 0% with shorter freezing times. A difference in drip loss from 20% for strawberries frozen in 12 h, to 8% for strawberries frozen in 15 min, is significant. Cryogenic systems perform the same freezing function in 8 min or less, reducing the drip loss to less than 5%.

A modern mechanical freezer or a cryogenic freezer can crust products very rapidly, minimizing the loss of natural juices and locking in the qualities that make the product more marketable.

Packaging

Packaging must be of good quality, odor- and taint-free, and it must totally enclose the product. The container should not be capable of being opened without recognizable damage. It should also protect the product against normal transit and storage hazards and inhibit dehydration by incorporating a moisture vapor barrier. All packaging should carry clear identification and should be coded so that stock rotation can be carried out. The inner carton should be marked with an appropriate identification code that would enable the producer concerned to establish the date of production and the location of the producing factory, and gain easy access to daily production records.

As the product is wrapped, the operator must insure that the inner layer is in good contact with the actual food and that all air has been excluded. Unless this is established, reasonable cooling rates will not be obtained. The packages should then be placed and arranged to insure good contact with the freezing surface in the case of a plate freezer, or be in the air flow of an air blast freezer.

Cooked food must be chilled to around 10 °C or lower before it enters the freezer. The placing of a hot product in the freezer will considerably slow the freezing process as the outer surface will quickly freeze, leaving the hot interior to give up initially larger amounts of sensible heat than would have been necessary had the product been allowed to stabilize and cool prior to freezing.

Food cooked in a domestic kitchen should be first allowed to cool close to ambient temperature and then transferred to the refrigerator to chill down before being placed in the freezer. The use of an immersion thermometer to check core temperatures prior to freezing is recommended. (*See* **Packaging**: Packaging of Liquids; Packaging of Solids.)

Weight Loss and Economics

Freezing equipment will represent the single largest investment in a food production line, yet its operating costs will normally only be 3–5% of the total product cost. Packaging costs vary widely but are normally several times greater than the total cost of freezing.

An important factor to consider when selecting freezing equipment is the weight loss of the product

that occurs during freezing. This loss may be about the same as the operating costs of the freezing facility. This applies to inexpensive products like peas and is even more significant for expensive products, such as seafoods and soft fruits.

Weight loss during freezing may be caused by mechanical losses, downgrading, and dehydration. Mechanical loss refers to products dropping to the floor, sticking to conveyor belts or dripping juice. A modern freezer should have almost no loss in these categories. Downgrading losses refer to damaged products, breakages, and similar occurrences that render the product unsaleable at the top quality price. Dehydration losses will always be present in any freezing system. The evaporation of water vapor from unpacked products during freezing can be seen as frost on the refrigeration plant freezing surfaces. This frost is also caused by excessive infiltration of warm, moist air into the freezing chamber. Still air inside the vapor-proof product carton can create larger dehydration losses than an unpacked product frozen in a cryogenic quick freezer. The heat transfer is poor because no circulation of air occurs within the package. The result is evaporation of moisture, which can be significant, with the frost staying inside the carton.

A poorly designed freezer or freezing tunnel can have dehydration losses as high as 5%, as against a well-designed freezing system in which losses are maintained below 1.5%. Cryogenic liquid nitrogen tunnels normally operate with a dehydration loss of between 0.25 and 1.25%. These losses usually occur when the nitrogen gas circulates over the product at the in-feed end of the freezer. It may be necessary at the in-feed end to temper the product so as to use the heat capacity of the nitrogen more efficiently. Nitrogen immersion freezing tends to have even lower dehydration losses but uses more liquid nitrogen. Carbon dioxide freezing operations use jet impingement, and dehydration losses are similar to that experienced with liquid nitrogen.

Freezing Methods

Freezing equipment can be divided into groups with regard to the basic method of extracting heat from the product to be frozen:

1. *Air blast freezing*: Air at high velocity (between 4 and 7 m s^{-1}) is circulated over the product. The air picks up heat, which is then recooled by means of an air-to-refrigerant heat exchanger before the air is recirculated.
2. *Contact freezing*: Food (packed or unpacked) is placed between metal plates or surfaces, and the heat is extracted by direct conduction through the metal surface, which is refrigerated by the circulation of a cooling medium.
3. *Immersion freezing*: Food is immersed in a low-temperature, nonfreezing solution that is cooled by evaporators in a conventional refrigeration system.
4. *Cryogenic freezing*: Food is exposed to an atmosphere below $-60\,^{\circ}C$, which is achieved by spraying liquid nitrogen (LN) or liquid carbon dioxide into the freezing chamber.

All of the above methods are used in food freezing processes. However, the more favored systems are those that can be operated in line with the proceeding processing and preparation operations and the subsequent packing functions.

Types of Freezing Equipment

Storage Rooms

The storage room must not be considered as freezing equipment, although it may sometimes be used for this purpose. Freezing in a storage room has many disadvantages and should only be used in exceptional cases. The freezing process is slow, and the quality of almost all products suffers. If products are already being stored in the room, their quality is jeopardized, because flavors may be transferred from the warm products yet to be frozen.

Because the storage room is not designed for freezing, the cooling coils may frost up quickly, and total refrigeration capacity may be reduced. The temperature of the products already frozen may rise considerably, affecting their quality. Without doubt, freezing in a storage room leads to a lower product quality.

Blast Freezer

A blast freezing room is usually equipped with more forced-air cooling units or larger coolers than would normally be found. These coolers are often of sufficient size to warrant floor mounting. The air coolers are equipped with fans that create considerable air turbulence. Products may be laid in trays that are then loaded into a freezing trolley or rack; this is moved in and out of the blast freezer by hand or with a forklift truck.

The racks must be designed to provide air space between the trays, which is equal to approximately 50% of the product thickness. Because there is no control over air circulation, the resulting heat transfer of the product to air may be less effective. Blast freezer rooms offer acceptable conditions for a limited range of products with the freezing cycle and

the quality of freezing dependent on the experience of the operator.

Stationary Freezing Tunnels

A stationary freezing tunnel is the simplest type of freezer (Figure 1), designed to produce satisfactory results for the majority of products. It consists of an insulated enclosure, equipped with refrigeration coils and fans that circulate air in a controlled pattern over the product. The air circulation system design influences the freezing rate and the product weight loss.

Products are placed on trays that are then placed in a rack. The racks are arranged to provide an air space between each level of trays and are moved in and out of the tunnel manually. The human element becomes important when positioning the racks inside the tunnel to prevent air bypass; this is essential for efficient freezing processes.

Most products can be frozen in a stationary freezing tunnel. Whole, sliced, or diced vegetables may be frozen either in cartons or unpacked, provided that the layers are limited to 30–40 mm in depth on the trays. Spinach, broccoli, meat patés, fish fillets, and prepared foods are often frozen in packages, using this type of equipment. By using different rack designs, thick packages and whole meat carcasses can also be frozen. The system capacity depends on the product thickness and composition, as well as on the existence of packaging.

This type of freezer is reasonably flexible in use, making it suitable for the initial development stage of the new frozen food product, but does require heavy outlay for manpower and may result in considerable weight loss, if not properly used.

Push-through Tunnels

Some simple mechanization is achieved in a push-through tunnel (Figure 2). Tracks are provided in the floor, and the racks are fitted with casters or wheels. The mechanization system is often hydraulically powered with a special stroking facility that feeds the racks through the freezer. The time of the hydraulic stroking operation can be adjusted to vary the time the product is in the freezer.

This type of equipment may require open ends to allow product entry and exit. If doors are provided, they have to be interlocked with the hydraulic track system, so that they open and close, permitting a rack to be drawn into the tunnel and also ejected at the other end. This type of freezer has a number of advantages over a stationary tunnel: there is improved

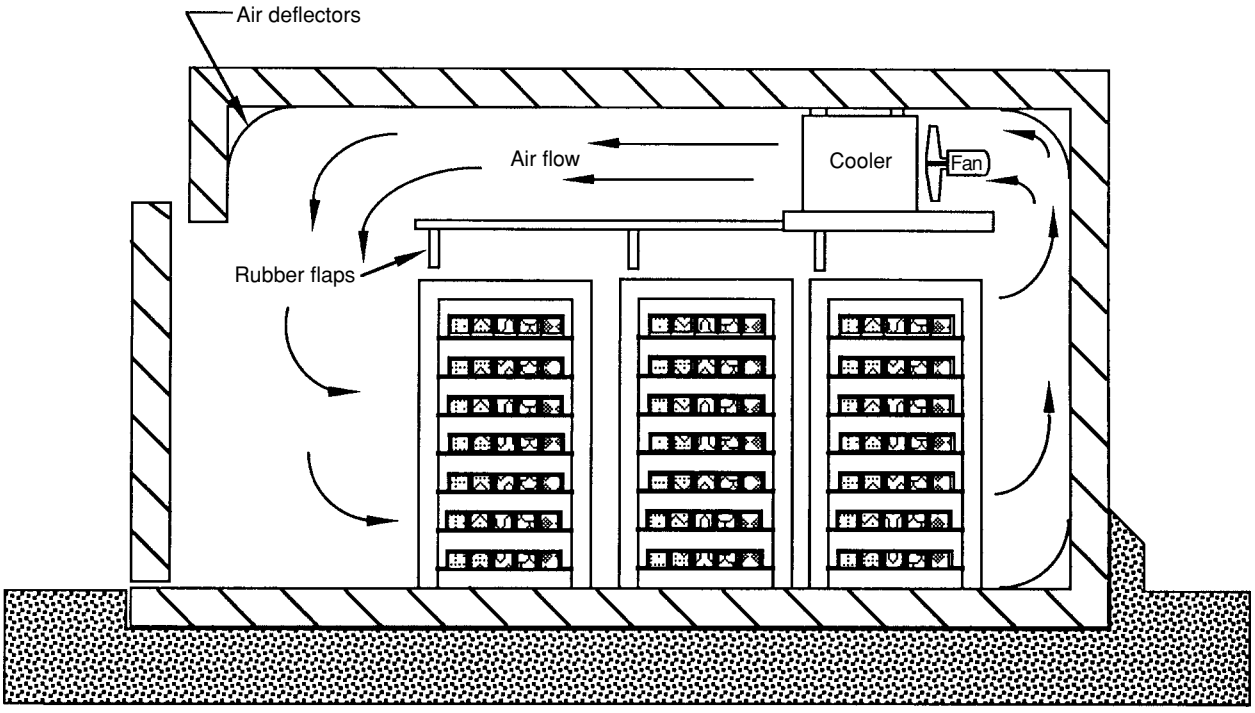

Figure 1 Stationary freezing tunnel (Michael Boast Associates). Reproduced from Blast and Plate Freezing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

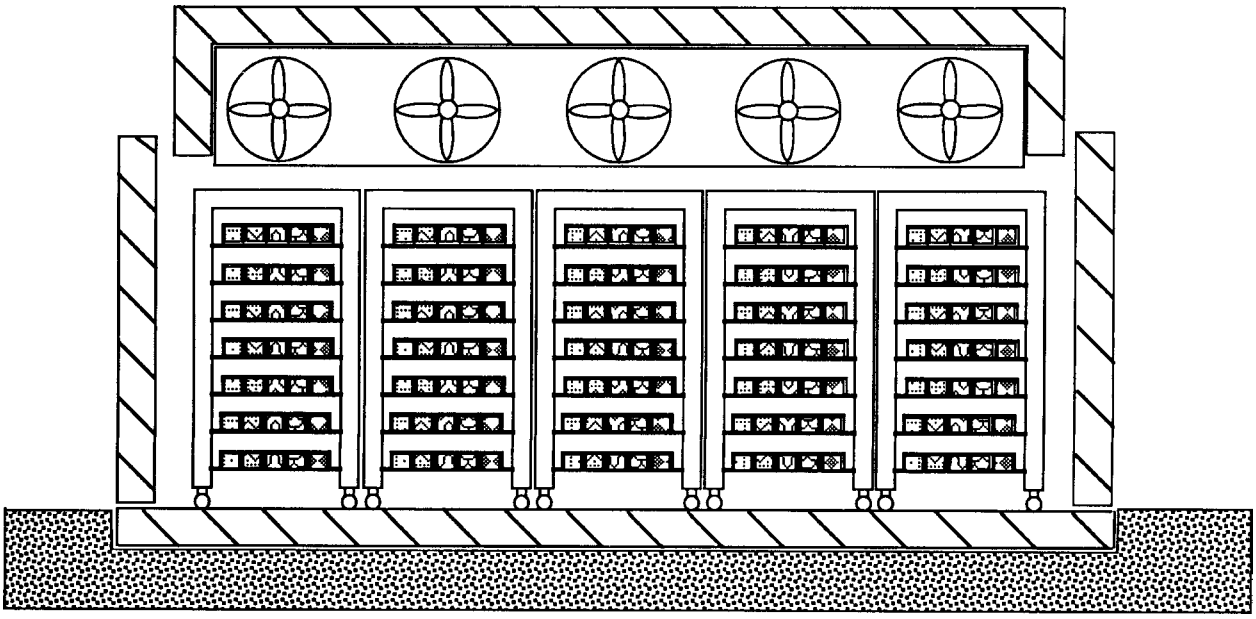

Figure 2 Push-through tunnel (Michael Boast Associates). Reproduced from Blast and Plate Freezing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

air circulation over the product as it moves at a steady rate through the tunnel; labor costs are considerably decreased; and there is added flexibility with the facility of varying the freezing time.

Some tunnels may have three or four lines, each with independent hydraulic stroking facilities, and this makes different product freezing times available in a single installation.

Belt Freezers

Modern belt freezers use vertical air-flow patterns and require uniform distribution of product over the entire belt surface for effective freezing.

The single-belt freezer, multiple-belt freezer, and spiral-belt freezer are the main types available. The simplest is the single-belt freezer, consisting of the single belt exposed to an updraught of air. This is suitable for deep-fried or relatively dry products that do not tend to freeze to each other or form clumps, i.e., fish sticks, French fried potatoes, and bakery products.

Multiple-belt freezers are suitable for individual freezing of fried fish sticks, fish portions, bakery items and other products.

The spiral-belt freezer (Figures 3 and 4) offers a design that maximizes the belt surface area in a given floor space. It is achieved by using a product belt that can bend around a rotating drum; by stacking up to 40 tiers of belt on a drum, floor space occupied is kept to a minimum. The continuous belt eliminates

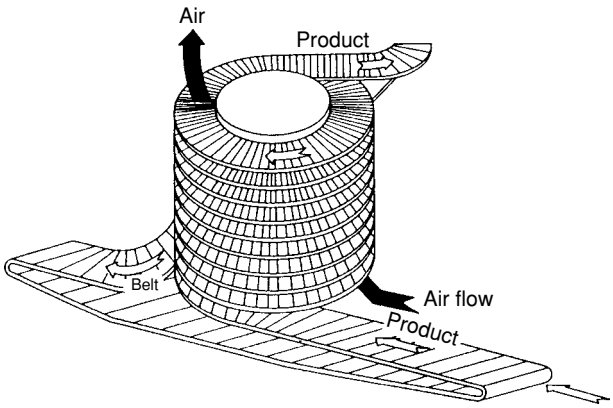

Figure 3 Spiral-belt freezer (Michael Boast Associates). Reproduced from Blast and Plate Freezing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

product transfer points internal to the system. The product is transferred only at the in-feed and out-feed ends of the freezer. Spiral-belt freezers are suitable for unpacked meat, fish, and poultry products, including meat patés, meat balls, fish fillets and chicken portions.

Fluidized Bed Freezers

Fluidization is defined as a method to keep solid particles floating in an upward direction (Figure 5)

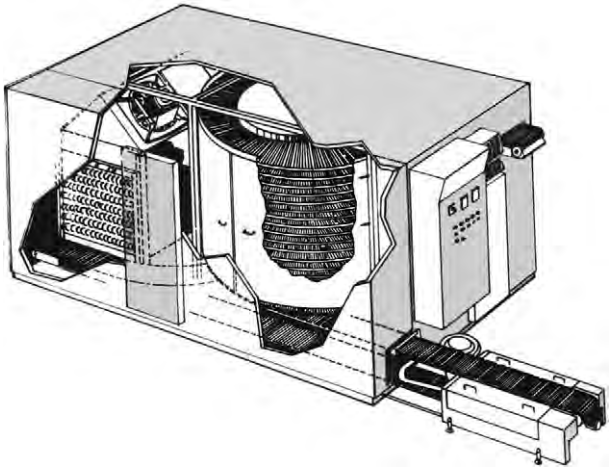

Figure 4 Diagrammatic arrangement of a spiral-belt freezer. Reproduced from Blast and Plate Freezing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

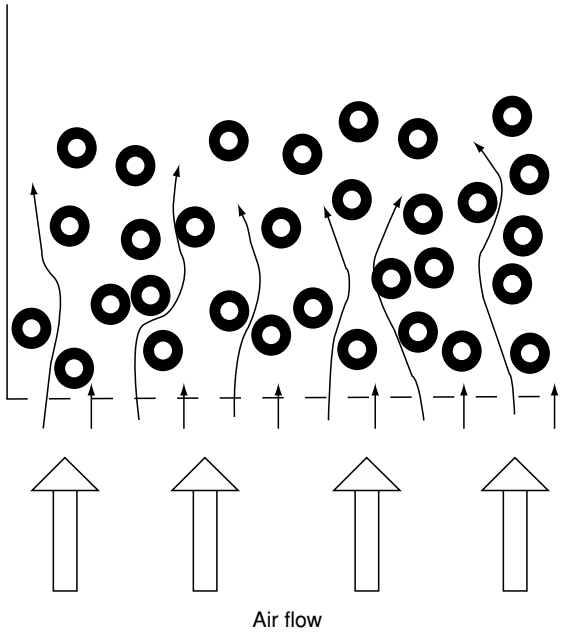

Figure 5 Fluidization principle (Michael Boast Associates). Reproduced from Blast and Plate Freezing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

in a flow of gas or liquid. In freezing, fluidization occurs when particles of a similar shape and size are subjected to an upward stream of low-temperature air. At certain air velocities, particles float in the airstream, with each particle be separated from the other but surrounded by air and free to move. In this

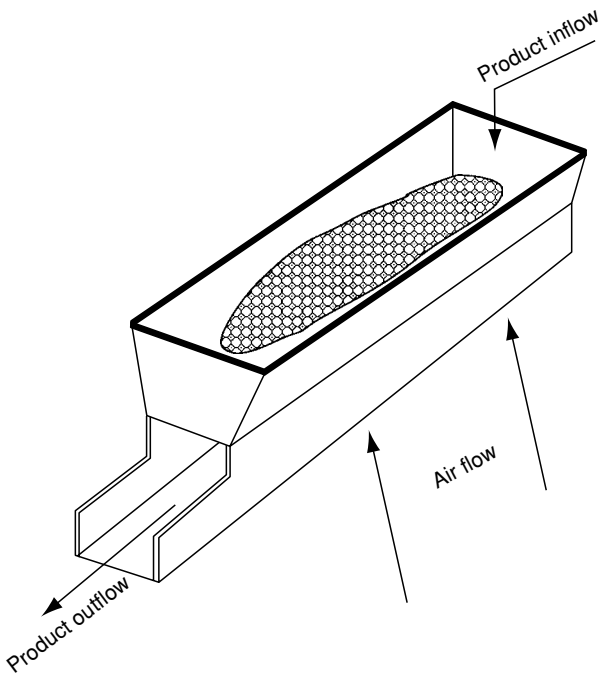

Figure 6 Fluidized bed freezer (Michael Boast Associates). Reproduced from Blast and Plate Freezing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

state, the particle mass assumes the properties of a liquid or a fluid. By utilizing low-temperature air to achieve fluidization, the product is simultaneously frozen and conveyed by the same air without the aid of a mechanical belt.

Using the fluidization principle for freezing provides several advantages over the conventional belt. Most products that tend to stick together, i.e., sliced green beans, sliced carrots, and sliced cucumbers, are individually quick-frozen. The fluidized bed freezer (Figure 6) is effective and reliable in freezing wet products, as it can accept products with a high surface water content. Another advantage of the fluidized bed freezer is its complete independence from product variations and flow. Even when running at reduced capacity, the same evenly distributed air pattern is maintained.

Plate Freezers

In a plate freezer (Figure 7), the product is pressed firmly between top and bottom metal plates. The refrigerant is circulated in channels, housed inside the plates. This insures good heat transfer and reasonable freezing times.

Because heat transfer at the surface is gradually reduced with increasing product thickness, package

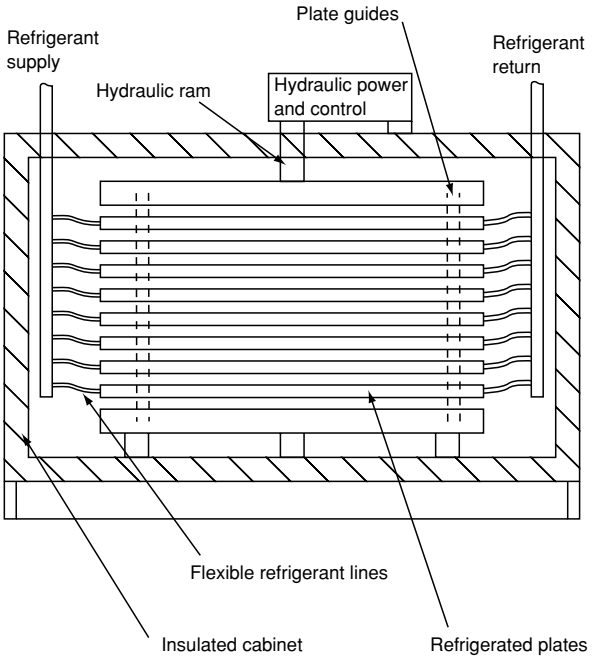

Figure 7 Horizontal plate freezer (Michael Boast Associates). Reproduced from Blast and Plate Freezing, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

thickness has to be limited to a maximum of 50 mm. Pressure from the plates has the additional advantage that it eliminates the bulging of the packages during the freezing cycle, so that the packages are discharged with straight sides and within close tolerances.

The two main types of plate freezers are horizontal or vertical in design; either type can be manual or automatic. In general, manual horizontal plate freezers have 15–20 plates. The product is placed on metal trays at the end of a packaging line, loaded in a rack or trolley, and transported to the freezer. The trays are loaded manually between the plates.

The vertical plate freezer was developed specifically for the freezing of fish at sea; it comprises a series of vertical freezing plates that form partitions in the container. Products are fed from the top, and the finished block of frozen products are discharged to the side, top, or bottom. Usually, this operation is mechanized. Whole unpacked fish are frozen, but fillets may also be handled in a vertical plate freezer. The block thickness varies from 25 to 100 mm.

Drum Freezer

An alternative to the flat plate freezer is the drum freezer, consisting of a rotating drum containing a refrigerant at low temperature, resulting in a cold surface for freezing. The product to be frozen is placed on the stainless steel refrigerated drum, which rotates at a preset speed depending on freezing time required. The product must be frozen, within one rotation. This rotation will last for less than 1 min if the product is only 3 mm thick, such as chopped spinach paste. A 6-min rotation would be required for a 10-mm-thick plaice fish fillet and 16-min rotation for a 20-mm-thick cod fillet.

Immersion Freezing

For irregularly shaped products such as chickens and turkeys, high heat transfer can be achieved in an immersion freezer, which normally consists of a tank that houses a refrigerated brine. The brine is most often of glycol or sodium chloride solution. The product is immersed in the brine or sprayed while it is conveyed through the tank.

Immersion freezers are most commonly used for plastic-bagged chickens or turkeys. The product must be protected from contact with the brine by using a high-quality packaging that gives an absolute tight seal. The brine residues on the packages are normally washed off with water at the freezer exit.

Cryogenic Freezing

C James and S James, University of Bristol, Langford, UK

Introduction

Freezing methods can be divided into two main classes: (1) those involving direct contact between

the refrigerant and the food; and (2) those involving the use of a secondary medium, e.g., air, brine, or metal plate, which is cooled by the refrigerant.

Cryogenic freezing uses refrigerants, such as liquid nitrogen or solid carbon dioxide, directly. The boiling-off of the refrigerant when it comes in contact with the product brings about cooling. As well as using the latent heat absorbed by the boiling liquid, sensible heat is absorbed by the resulting cold gas.

Most cryogenic systems use total loss refrigerants, i.e., the refrigerant is released to the atmosphere and not recovered. Due to environmental and economic factors, total loss refrigerants must be both readily available and harmless, which limits the choice to atmospheric air and its components.

Table 1 Properties of cryogenic materials

Material	*Boiling point °C at 1 atm*	*Latent heat of vaporization (kcal kg^{-1})*
Helium	−268.8	108.8
Nitrogen	−195.8	47.3
Carbon monoxide	−190.6	53.5
Argon	−184.4	37.0
Methane	−161.1	136.0
Ethane	−88.9	109.0
Nitrous oxide	−88.9	90.0
Propane	−42.2	100.6
Carbon dioxide	−57.6 (5 atm)	75 (approx.)
Carbon dioxide (solid)	−79 (sublimation point)	135.4

History

Cryogenic freezing was first carried out commercially using liquid air, in the 1930s. However, liquid air contains a high proportion of liquid oxygen, which is a powerful oxidizing agent. Theoretically it can be produced on site, eliminating the need to purchase and store 'gas.' Although companies have promoted the use of liquid air, in practice it has been superseded by less harmful liquid nitrogen and liquid, or solid, carbon dioxide.

Food freezing using liquid nitrogen or carbon dioxide became established in Europe from the early 1960s onwards as manufacturers looked for uses of these byproducts. Liquid nitrogen is the byproduct produced when liquid oxygen is made by air distillation, while carbon dioxide is a byproduct of fermentation processes and a constituent of natural gas. By the early 1990s an estimated 10% of all frozen food in the UK was produced using cryogens.

An alternative to the air-based total loss cryogens, liquid dichlorodifluoromethane (food grade R 12, freon, CCl_2F_2), was introduced commercially in 1968 by Du Pont. R 12 had the advantage over other cryogens of being easily recoverable and having a higher operating temperature (−29.8 °C), reducing the problems of thermal shock. It was claimed that such gentle handling allows 'true' individual quick freezing (IQF) of products such as soft berries, meat patties, raw shrimps, breaded scampi, fried onion rings, etc. in less than 6 min. However, its use was not permitted in all countries and it was not widely used.

Physical Properties

The major problem with most cryogenic materials is that they are extremely cold (Table 1). Direct immersion can be inadvisable since an extremely high temperature gradient can be imposed on the food, which is often sufficient to cause it to disintegrate. Research studies have concluded that the ideal cryogen would have a boiling point of −50 °C and a latent heat of evaporation as high as possible.

Liquid nitrogen is produced by liquefaction of air, either as a principal product or as a byproduct of liquid oxygen. Nitrogen is the main constituent of atmospheric air and at atmospheric pressure liquefies at a temperature of −196 °C. It is usually supplied and stored at a pressure of 3–6 bar, with corresponding boiling points of −185 °C to −177 °C. A useful rule of thumb is that 1 t h^{-1} of liquid nitrogen is approximately equivalent to 100 kW of mechanical refrigeration.

Since liquid nitrogen is made from air, its costs are entirely those of manufacture, i.e., the capital cost of the plant, electricity, and transportation. The energy required to produce 1 kg of liquid nitrogen is around 3000 kJ, or eight times the consequent stored refrigerating effect.

Carbon dioxide's physical properties are unusual, in that it does not exist in liquid form at atmospheric pressure. If stored as a pressurized liquid and released into the atmosphere, the liquid changes partly to gas and partly to a frozen solid at −78.5 °C, which sublimes directly into gas without going through a liquid phase.

Liquid carbon dioxide is generally supplied either at ambient temperature (e.g., 25 °C and 65 bar), giving a refrigerating capacity of 199 kJ kg^{-1}, or at −16 °C and 22 bar, giving a refrigerating capacity of 311 kJ kg^{-1}. At the point of use, spray nozzles reduce the pressure of the liquid, generating a mixture of cold vapor and solid carbon dioxide 'snow.'

The majority of the 'refrigeration effect' stored in solid CO_2 is latent, whereas in liquid nitrogen almost half the effect is due to sensible heat transfer to the cold gas. The available refrigerating effect from 1 kg

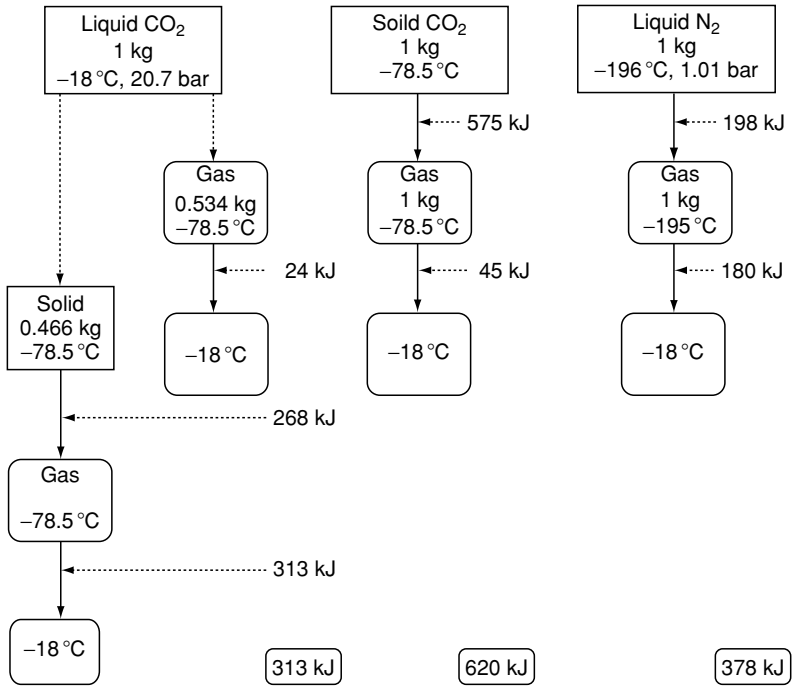

Figure 1 Available refrigeration effect from 1 kg of total loss refrigerant.

of both liquid and solid carbon dioxide and liquid nitrogen is shown in Figure 1.

Comparison of Cryogenic Freezing Systems with Mechanical Freezing Systems

The generally perceived advantages of cryogenic compared with conventional refrigeration are given in Table 2.

Table 2 Advantages and disadvantages of total loss refrigerants in comparison with mechanical refrigeration

Advantages	*Disadvantages*
Low capital investment	High operating cost
High refrigerating capacity	High refrigerating capacity
Compact (small 'footprint')	Poor temperature control
Flexible	Limited duration without filling
Low weight when out of use	High weight at start of use
No residual weight (dry ice)	Reduced humidity
Silent operation	Suffocation hazard
Advantageous storage atmosphere (N_2)	Limited availability
Bacteriostatic affect (CO_2)	
Low maintenance requirements	
Long life	
Foolproof once installed (dry ice)	

Capital Cost

The low capital cost and simplicity of design permit cryogenic systems to be used in a standby or back-up role in emergencies or for 'peak lopping' during periods of exceptional freezing demand.

The overall economics can be favorable for short road deliveries. For static standby installations, or those with very low loading factors, low capital cost can be a major attraction.

Running Costs

In overall energy or fuel terms, there is no way in which cryogenic refrigerants can compete with the best mechanical refrigeration systems. Generally speaking, cryogenic refrigeration offers lower capital and maintenance costs but incurs higher running costs. Many cryogenic freezers are leased from the gas suppliers, reducing capital cost further.

The consumption of the cryogen (Table 3) contributes the major proportion of the freezing costs (about 75%). Refrigerant consumption is measured as a 'consumption ratio' equal to weight of refrigerant used divided by the weight of product frozen. Table 4 shows some approximate quantities of liquid nitrogen and carbon dioxide required to freeze a range of products. High refrigerant consumption can be

[a]Theoretical requirements assuming foodstuff temperature reduction from 20 to −18 °C.

significant with cryogenic tunnels, especially following a change in throughput or product type. The reason for this is poor control. A quantity of the cryogen is also required to cool the equipment down prior to start-up and to maintain temperature during idle periods. With efficient plant usage this need not account for more than an additional 2%, over and above that used for actual product freezing.

Maintenance

Cryogenic freezers have few moving parts so maintenance is far easier than for mechanical systems. There are obvious benefits for long rail journeys in using dry ice for which no further attention is required once the cargo and refrigerant have been loaded.

Weight Loss

In several freezing applications, the advantages listed in Table 2 are sufficient to overcome the penalties of cryogenic systems. The potential saving in weight loss in freezing unwrapped products in comparison with air-blast freezing can be substantial. For products of great value such as shellfish this is of particular economic significance, since the lost weight/water has the same value per unit weight as the product.

Flexibility

The flexibility factor has other ramifications. Mechanical systems are limited in their output of cold – both above and below the norm. Overloading affects quality; underloading increases unit costs. With cryogenic systems the 'cold' is on tap. This is particularly important with a new product or a seasonal product when demand is unpredictable and variable.

Cryogenic systems are also often flexible in the type of product that can be fed through them. In a conventional blast freezer, the maximum air velocity inside the freezer limits the amount of heat given up by the evaporator coils. In a cryogenic tunnel, the rate at which refrigerant is added is more or less independent of the gas velocity. This gives cryogenic tunnels considerable flexibility in responding to changes in production rate.

Size

Cryogenic freezers tend to be more compact than those using mechanical refrigeration, in some cases needing only half the floor space for the same throughput. Carbon dioxide systems are extremely compact, for example 1360 kg of product per hour can be produced using an area of 3.6×3.6 m. Also the equipment supplying the refrigeration itself takes up substantially less room than mechanical refrigeration equipment.

Weight

Low weight is a particularly attractive aspect for airline catering applications, and other transport applications.

Noise

Cryogenic systems operate relatively quietly compared with the noise and vibration caused by mechanical compressors. With the growing concern over noise pollution, this may become more of an issue. In

road transport, overnight parking of mechanically refrigerated vehicles is sometimes difficult in noise-sensitive areas, and cryogenic systems overcome this problem.

Safety

In comparison with nitrogen, carbon dioxide is safer. Carbon dioxide is sensed by humans at levels less than 0.5%, although much higher concentrations of nitrogen are tolerable it is not sensed and a potential hazard stems from fainting due to hypoxia (shortage of oxygen to the brain).

Synergism

The rapid freezing rates possible with cryogenic freezing may be employed to enhance mechanical systems. An example is the crust freezing of delicate product, such as fish fillets, using cryogens before freezing in spiral freezers to prevent mechanical damage as the product travels through the spiral. Crust freezing can also be employed to reduce dehydration. However, legislation can complicate this issue. In countries where practices to compensate for weight loss, such as misting of burgers, are allowed, the economics don't favor crust freezing.

Crust freezing can also be used to reduce frosting problems. Moisture loss during freezing can cause frosting of refrigeration coils, reducing the efficiency of the systems and requiring defrosting. Crust freezing traps the water, preventing moisture migration.

Equipment

Cryogens are typically employed as sprays in tunnel or batch cabinet systems, or direct immersion tunnels. Operation of cryogenic systems is relatively straightforward. The two basic functions to regulate are: (1) conveyor speed to give the required retention time, and (2) refrigerant flow rate to give the desired product temperature.

Tunnel Freezers

Essentially a tunnel freezer is a countercurrent heat exchanger. The cryogen is sprayed at one end and the gas passed countercurrent to product traveling on a belt in the opposite direction. This enables the exit temperature to be only 20 °C below the product inlet temperature. Thus product can be precooled before being subjected to the full force of the refrigeration effect. Approximately 50% of the product's heat can be extracted before it reaches the cryogen spray. Straight or spiral tunnels are utilized. As a rule, carbon dioxide tunnels tend to be longer than liquid nitrogen tunnels for the same capacity.

A tunnel freezer operates by conveying the product through an enclosed space within which the cryogen is discharged. Economy of cryogen consumption is improved by insulation and isolation of the freezing tunnel, and by control of the cold gas within the tunnel. The product passes through three distinct zones in the tunnel: the precool zone, the freezing zone, and the postcool zone. In the precool zone, the product is cooled using gas and fans force gas vertically past the product. In the freezing zone, sprays discharge cryogen directly on product and belt, while in the postcool zone, which is a gas-cooled section, with more fan circulation, some temperature stabilization takes place.

Rotary Freezers

Rotary freezers have also been developed to IQF freeze products such as shrimps, cubed chicken meat, or meat balls. A fine mist of cryogen is used to freeze the surface of the product and prevent individual pieces sticking to one another before they enter a rotating drum, which keeps them separated during the freezing process.

Immersion Freezers

Immersion freezers are the simplest and most inexpensive way of using cryogens to freeze foodstuffs. Immersion freezers are best suited to high volumes of product where crust freezing is required or where the product is sufficiently robust to withstand the thermal shock of a high temperature differential. Very fast heat transfers are possible, but the system is wasteful in that only the latent heat of the liquid is used and cold vapor is lost.

Cabinet Freezers

Batch cabinet freezers utilizing cryogens have been developed for freezing prepared and precooked food, particularly for airline meals. Liquid cryogen is injected at time intervals into a cabinet containing the food on racks; circulation fans are usually utilized to provide even and efficient freezing. Freezing times vary from 5 min to 1 h, depending on the product and its temperature.

Pellet Freezers

Liquids and semiliquids are often frozen into pellets. This can be carried out using contact freezing between belts or in molds, or cryogenic freezing using liquid nitrogen and a forming device. Belt freezers employ a similar contact method of freezing to plate freezers. Single-band and double-band freezers are designed to freeze thin layers, usually of liquid or

semiliquid products such as vegetable purées, fruit pulps, egg yolk, sauces, soup, etc. In double-band systems the product is frozen between two endless belts, of which the top is flat and the lower belt corrugated. The product is spread into the corrugations; the top belt encloses the exposed surface, thus freezing the product as IQF pellets.

Combined Freezers

A cost-effective alternative to 100% cryogenic freezing is a combined freezer. The principle is to use a cryogenic freezing unit for initial freezing of the outer surface of the product, followed immediately by mechanical freezing to reduce the temperature of the bulk of the product. One advantage of this type of approach is that the cryogenic stage can often be retrofitted.

Freezing Rate

Most food freezing systems rely on convection as the principal means of heat removal. The rate of heat removal from the product depends on the surface area available for heat flow; the temperature difference between the surface and the medium; and the surface heat transfer coefficient. Much higher coefficients are achieved in cryogenic systems than in most conventional refrigeration (Table 5).

The rate at which heat can be conducted away from the surface is not the sole criterion that governs the time taken to freeze a product. Heat must also be conducted from within the product to its surface before it can be removed. Most foodstuffs are poor conductors of heat and this imposes a severe limitation on attainable freezing times for either large individual items or small items frozen in bulk.

Cryogens are particularly suited to food products that have a high surface-area-to-volume ratio and in which the thermal diffusivity of the food does not restrict the transfer of heat from the product to the freezing medium. Typical examples are fish fillets, shellfish, pastries, burgers, meat slices, sausages, pizzas, and extruded products.

Table 5 Published surface heat transfer coefficients for different cooling processes

Method	*Heat transfer coefficient ($W m^{-2} K^{-1}$)*
Still air	5–10

Immersion, still	50–200
Immersion, agitated	< 1000
Cryogenic, R 12	1000
Cryogenic, liquid nitrogen	1500

Product

Typical product freezing times in nitrogen systems are shown in Table 6.

Rapid freezing has been claimed to improve taste, texture, aroma, nutritive value and appearance, bacteriological, enzymic, oxidative and chemical degradation, and to reduce drip loss upon thawing.

Ice Crystal Formation

The most apparent influence of the freezing rate on product quality is related to the size of the ice crystals, which are formed during the freezing process.

It has long been shown by photomicrographs that the faster meat and fish are frozen, the smaller the ice crystals produced, and that above a certain rate these are predominantly intracellular, when by implication the damage to cell walls should be minimal. However, extracellular ice crystal formation is not necessarily disruptive because muscle cell wall membranes are elastic, unlike those of vegetable tissue. Nevertheless, largely on the strength of the photomicrographs, plausible advocacy of rapid freezing equipment throughout the 1930s and 1940s resulted, and these views remain.

Quality

The debate about the relationship between freezing rate and quality has gone on for many years. Many trade publications indicate that a considerable improvement in quality can be obtained by ultrarapid freezing with cryogens. However, it is doubtful whether the rate of freezing has any detectable effect on drip or on palatability of meat after thawing and cooking over a wide range of freezing rates. Recent

Table 6 Freezing times of nitrogen freezers

Product	*Freezing time (min)*
Fruit and vegetables	0.5–6
Meat and meat products	3–20[a]
Meat patties, hamburgers	3–5
Pastry products	4–8
Precooked foods (warm)	4–8

[a]Large, bulky meat products.

studies with beefburgers show no differences in eating quality between those frozen to −18 °C in 22 or 2.7 min. For fish, it has been concluded that freezing times of up to 26 h do not significantly influence the quality of the product.

A number of authors have classified foods according to their sensitivity regarding freezing rate into four groups:

1. Products that remain practically unaffected by variations in freezing rate, i.e., products with a high content of dry matter, such as peas, meat products with a high fat content, and certain ready meals.
2. Products which require a minimum freezing rate (0.5–1 °C min^{-1}), but are relatively unaffected by higher freezing rates, i.e., fish, lean meat, and many starch- and flour-thickened ready meals.
3. Products whose quality improves when freezing rates are increased (3–6 °C min^{-1}), e.g., many fruits, egg products, and flour-thickened sauces.
4. Products in which high freezing rates are advantageous for the product quality, but where temperature tensions in the product result in a destruction of the tissue, e.g., fruits and vegetables such as raspberries, tomatoes, and cucumbers.

Some work has indicated that there is an interaction between freezing rate and cooking method. When meat was cooked after thawing, no differences were found between freezing rates (13, 2, or 0.04 cm h^{-1}) in terms of flavor, juiciness, tenderness, thaw loss, or TBA (thiobarbituric acid) values. However, meat that had been cooked from frozen was found to show a favorable effect of faster freezing rates.

With mushrooms, while the quantity of the drip loss is almost independent of the freezing rate, the color of the lost juice changes conspicuously. It contains more coloring and flavoring ingredients the slower the freezing.

Among the products that obtain a decisive and lasting quality improvement by rapid freezing are carrots, corn on the cob, mushrooms, egg products, sauces, cream, shrimps, and prawns.

Appearance

Freezing rate does affect the appearance of many food products. For example, fast freezing of poultry tends to produce a lighter-colored product as the small ice crystals scatter the light more than larger crystals. This lighter color is preferred by many consumers. In fish, rapidly frozen fillets have a dense white, opaque appearance, in comparison with the dark, translucent, vitreous product produced by very slow freezing.

Drip Loss

When ice crystals grow they may puncture the cell walls so the juice bleeds out. This causes 'drip loss' when the product is thawing. The larger the average crystal size is, the greater the number of punctured cells and the greater the drip loss. The loss of juice can result in a loss of firmness and flavor.

The drip loss from some food (i.e., strawberries) can be clearly related to freezing rate. Slow freezing can produce drip losses of 20%. Fast freezing without surface cracking can reduce losses to approximately 5%. With meat and meat products freezing considerably increases drip. However, other factors inherent in the animal and its processing before freezing have more effect on the magnitude of drip than differences in freezing rate.

There are many products that are situated between these two types.

Dehydration–Weight Loss

Lower weight loss, during the freezing of unwrapped food, is one of the main advantages of cryogenic freezing. Weight loss during freezing of beefburgers can be as high at 3% in a poorly designed air blast freezing system compared with 0.4% in a liquid nitrogen tunnel.

However, technological advances in conventional freezing systems can substantially reduce – if not completely remove – this saving. In a modern spiral freezer operating at −30 °C air temperature, the weight loss will be approximately 1.2%. In an air impingement freezer operating at a −46 °C air temperature, the weight loss from a burger can be <0.4%

Cracking

Some products, delicate soft fruits and light pastry products, may crack when they are submitted to very high freezing rates or very low temperatures. Research suggests that crust freezing produces a shell that prevents further volume expansion, when the internal portion of the unfrozen material undergoes phase transition. If the internal stress is higher than the frozen material strength, the product will crack during freezing. Products with high void spaces, which allow internal stresses to dissipate, show a lessened chance of freeze-cracking. Precooling prevents freeze-cracking because it reduces the differences in temperature between the product and the freezing medium, and reduces the difference between freezing time at the center and at the surface. When the phase change of the core region occurs before the surface becomes brittle, food products can support

the internal pressure and freeze-cracking does not occur.

Summary

Cryogenic systems can be used effectively to freeze, transport, and store a wide range of foodstuffs, and a wide range of equipment and techniques is available using either nitrogen or carbon dioxide. While there are many practical, as well as economic, disadvantages to cryogenic refrigeration systems, there are many situations in which low capital or maintenance cost and/or rapid freezing rates make these techniques worthwhile.

Storage of Frozen Foods

G Löndahl, Helsingborg, Sweden
T Nilsson, Enebyberg, Sweden

Introduction

The quality of frozen foods depends on the quality and nature of the product to be frozen, on the processing of the product prior to freezing, the freezing process, and the packaging of the product.

During storage, reactions of a physical as well as chemical and biochemical nature will cause changes in the food which gradually lead to a loss of quality. The changes are cumulative and the shelf-life of frozen food is limited by, and dependent on, the nature and speed of the reactions.

Some of the most important changes during storage, which will influence the quality, are as follows:

- loss of water
- loss and transfer of volatile compounds
- oxidative changes in fats
- denaturation of proteins
- color changes
- transfer of aromatic compounds from product to product

These changes, which will be dealt with in more detail in the following sections, are in most cases interacting, and their influence on the overall quality of the food is complex in its nature. It is therefore difficult to find a single objective method to determine the shelf-life of a product. However, much work has been directed with this goal in mind. In some cases, valuable information can be gained from such tests, e.g., determining the rancidity of fatty products, loss of vitamins, weight loss, color changes, etc. However, in most cases organoleptic tests are the most common methods used to determine the shelf-life for frozen products stored under various conditions.

All changes during storage are temperature-dependent. In general, the lower the temperature, the slower the speed of the deteriorative changes. (*See* **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability.)

Loss of Water, Dehydration

During storage, the water vapor pressure over the surface of the product is higher than that of the surrounding air. Since the surface of the cooling coils always has a lower temperature than the air in the storage room, ice will form on the coils. Thus a less than saturated relative humidity is maintained in the air, and also a difference in vapor pressure between the surface of the product and the surrounding air. As a consequence, sublimation of ice from the product will occur and continue as long as this pressure difference is maintained.

Not only does the loss of water mean a loss of weight of the product, which may have economical consequences, but also, in many cases, drying may severely impair the quality of the product. The water evaporates from the surface of small ice crystals. Such crystals have, in relation to volume, a larger area than bigger ones and are therefore prone to evaporate and disappear first. The contact surface between the product tissue and the surrounding air (oxygen) is thereby considerably enhanced, which will increase the

oxidative reactions in the product. In some cases, combinations of oxidative reactions in the proteins and drying will lead to a condition known as freezer burn. This is a severe quality change in the surface of the product. (*See* **Drying**: Theory of Air-drying.)

Prevention of Water Loss and Drying

Packing

If the product is packed in a tight-fitting, water-vapor-proof material, evaporation cannot take place. However, it is important that the packing material is tight-fitting; otherwise, sublimation will take place within the package. The packing material will follow the temperature changes caused by temperature fluctuations in the room faster than the product itself. When the temperature is lowered, evaporation from the product will form ice on the inside of the packing material, and when the temperature conditions are reversed the ice will be deposited on the surface of the product. If there are big variations in the storage temperature, ice formation within the package can be quite important. Small spaces within the package and a storage temperature as even as possible are measures to avoid this condition. If the temperature differences between the surface of the cooling equipment (coils) and the storage temperature are small, sublimation from the product will be low. Good insulation and efficient cooling sytems are effective tools to achieve this. Temperature abuses, which will allow warm air or warm products to enter the room, should be avoided.

Glazing

Glazing is the term used for the application of a thin layer of ice on the surface of a frozen product either by dipping the product in water or by spraying (Table 1). This is an effective method of preventing drying of the product. The sublimation is less pronounced since it takes place from an even surface which occupies a much smaller area than the ice crystals in the product. In addition, the loss of water comes from added water; the amount can be calculated to prevent any sublimation from the product during the intended storage period.

The lower the storage temperature, the lower the sublimation losses as the water vapor pressure decreases with the temperature. At $-10\,^{\circ}C$, it is 2.0 mmHg over ice as compared to 0.3 mmHg at $-30\,^{\circ}C$.

Table 1 Storage life: acceptability for frozen shrimps (*Pandalus borealis*)

Product	*Acceptability (months at −18 °C)*
Block-frozen, vacuum-packed	6–7
IQF, Polybag	3–4
IQF, vacuum-packed	6–7
IQF, vacuum-packed, + 4% glaze	8–9
IQF, vacuum-packed, + 8% glaze	>10

IQF, individually quick frozen.

Loss and Transfer of Volatile Compounds

Water is not the only substance that will escape from a frozen food during storage. Many substances which cause the typical smell and aroma of a food are also volatile at frozen storage temperatures and will evaporate from the surface of the product and enter the surrounding air. As a result, some of the aroma characteristics of the product are diminished or even lost during storage, and this will affect the quality of the product. (*See* **Sensory Evaluation**: Aroma.)

A more severe quality consequence of this phenomenon, however, concerns other products stored in the same environment. If a 'foreign' aroma compound is deposited on a product and dissolved in either the fat or water phase of the product, it can severely affect the quality of the product. Meat, dairy products, including icecream, and other foods with a high fat content are most susceptible to pick up aroma from other products, e.g., fruits, especially citrus fruits and strawberries, some vegetables, fish, etc. This phenomenon is well known during chilled storage, but it is also important during cold storage. It has led in some cases to considerable economic losses.

The only effective method of preventing aroma transfer during cold storage is packing the product in a material which will act as a barrier for the compound in question. Since the compounds responsible for the damage are not easily identified, choice of packing material must in most cases be based on experience and tests. A low storage temperature will reduce the release of volatile compounds and subsequently diminish the problem, but cannot prevent it. A suitable packing material is therefore the only method left. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Oxidation of Fat

One of the most important quality changes in frozen food during storage is the formation of off-flavors caused by rancidity of fats. Rancidity is caused by oxidative changes of polyunsaturated fatty acids. The higher the proportion of polyunsaturated fatty acids, the more prone the fat is to undergo oxidative changes. Some species of fish (e.g., herring, salmon)

are rich in fat with a high content of polyunsaturated fatty acids, and oxidative changes (rancidity) are more pronounced in these species than in lean ones (e.g., cod). In lean species, oxidative reactions take place, but to a much lesser degree. One compound causing off-flavors – 'cold-store flavor' – has been identified as *cis*-4-heptenol, which results from the oxidation of ω-3 polyunsaturated fatty acids. (*See* **Oxidation of Food Components**.)

Off-flavors are the most important quality factors resulting from oxidation of fatty acids but, in addition, color changes in the tissue can occur as a result of reactions between proteins and the oxidation products.

Rancidity changes in fat are also caused by lipolytic enzymes, such as lipases and phospholipases. Since these enzymes are active at low temperatures, lipolytic changes with an accummulation of free fatty acids can take place during cold storage. Interactions between fatty acids and other components in the food can cause changes in fat-rich food which will affect the quality. Normally, however, oxidative changes in fat are the most important factors influencing the quality of fat during frozen storage.

Oxidation of fatty acids takes place not only in fat from fishes, but also in fat from other animals. In beef the fat contains only a small amount of polyunsaturated fatty acids, and rancidity caused by oxidation plays a minor role. In pork, however, the fat contains a much higher amount of polyunsaturated fatty acids, and pork meat is consequently much more prone to oxidative changes during frozen storage. The composition of the fat in pork depends to a large extent on the composition of the fat in the feed, and the keeping quality of different pork lots can differ considerably even if stored under identical conditions.

Oxidation of fat is enhanced by the presence of certain catalytical factors, e.g., special metal ions, heme products, or salt, but the process is slowed down or inhibited by so-called antioxidative substances. If the contact area between oxygen and the tissue is increased, as is the case when ice crystals disappear due to drying, oxidation is considerably enhanced. (*See* **Antioxidants**: Natural Antioxidants.)

Oxidation of fatty acids can be inhibited by preventing oxygen (air) from coming into contact with the fat. As has been shown in numerous investigations, close-fitting packing in an oxygen-proof material, e.g., vaccum-packing, will minimize the oxidative reactions and considerably prolong the shelf-life of the product. The same result can also be achieved by substituting air within the package by an inert gas, e.g., nitrogen. In addition, glazing gives good protection against oxygen reaching the fat.

Changes in Proteins

During frozen storage, changes in the quality of frozen food of both vegetable and animal origin take place as a result of alterations and reactions of the proteins. Many of these protein alterations are still poorly understood, while others have been thoroughly studied in numerous investigations.

Animal Proteins

A well-known characteristic of frozen fish and mammals is a decrease in the water-binding capacity of muscle tissue, resulting in a loss of juice at thawing (drip). In addition, an increase in the firmness of the meat flesh is often observed. These changes, which are more pronounced in fish, also take place in meat (beef and pork) but to a lesser degree. (*See* **Fish**: Processing; **Meat**: Preservation; **Water Activity**: Effect on Food Stability.)

The most important changes take place in the myofibrillar proteins, especially in the myosin globular head of the molecule, and lead to a decrease in its solubility, while the thin filaments show a much higher stability during storage at low temperatures. The alterations have been shown to be temperature-dependent and occur more rapidly at higher storage temperatures. Even if the rate of naturally occurring metabolic changes in the muscle tissue is minimized during frozen storage, some reactions play a role during storage. The activity of the enzymatic calcium adenosine triphosphatase ((Ca^{+})-ATPase) complex, which is of importance for the quality of the meat, is highly temperature-dependent. If the freezing process is slow, a great loss of the enzymatic activity takes place compared to a fast freezing rate. During storage, loss of activity of the enzyme complex continues at a rate dependent on the storage temperature. If the meat has been frozen in prerigor state and kept at a low storage temperature, remaining enzymes are able to cause a very fast reaction when the temperature is raised during thawing. The condition can lead to a phenomenon known as thaw rigor, in which a sudden contraction of muscle fibers leads to a big drip loss.

The changes during freezing and frozen storage in the myofibrillar proteins of muscles from both fish and mammals are of the same biochemical nature. However, the effects on the quality of the product during frozen storage are different. The changes in fish muscles are generally more pronounced than those in meat. During frozen storage of fish, an increased firmness and dryness will result in a tougher, drier product, while beef and pork normally lose much less of their tenderness and juiciness during frozen storage.

Vegetable Proteins

Vegetables and fruits are harvested when ripening of the product is at its peak with regard to flavor, texture, and color. Since these properties are related by enzymatic reactions in the cells of the living plant, which will continue even at low temperatures after harvest, the quality of the product will soon deteriorate if the enzymes in question are not inactivated. In vegetables this is normally achieved by different methods of heat treatment (blanching). Lipoxygenases, catalases, and peroxides are enzymes involved in the deteriorative processes. Of these, peroxide is the most heat-resistant and, therefore, determination of peroxide activity is widely used to check the effect of blanching processes. (*See* **Ripening of Fruit**.)

If some enzymatic activity is left, or if a reaction takes place, changes will occur during storage which may affect the quality of the product. One example is the change of chlorophyls to pheophytines. The desirable green color of some vegetables changes to a yellow or gray color, severely affecting the quality of the product. Enzymatic reactions during frozen storage can also cause off-flavors of the product.

Hygienic Considerations

At normal storage temperatures for frozen food, i.e., $-18\,^{\circ}C$ or lower, all microbiological activity, including growth, has ceased. Some organisms will die or be injured during freezing and storage, the number depending on factors such as the species involved and the nature of the food. From a practical point of view this is of little importance. When the temperature rises at thawing, surviving organisms will resume their activity, including growth. The hygienic quality of frozen food should therefore be regarded as equal to the condition in the product immediately before freezing.

Structural and Flavor (Flavour) Changes

C James and S James, University of Bristol, Langford, UK

Background

The main aim of freezing is to extend the storage life of the raw material or food product beyond that achieved at temperatures above the initial freezing point of the material. In a number of cases, freezing is used to produce a product, i.e., icecream, sorbet, ice lollies, etc., that cannot be produced in any other way.

If the temperature of the food is reduced to below $-10\,^{\circ}C$ within a few hours and maintained below that temperature, microorganisms, bacteria, molds, or yeasts will not grow. Microbially, the food will always remain as safe to eat as it was before freezing, irrespective of the length of frozen storage. Some microbiologists consider $-5\,^{\circ}C$ to be a practical maximum temperature to prevent the growth of microorganisms on food.

The textural quality of the food will change with time and conditions of storage. More importantly, the flavor will deteriorate with time. Ultimately, these changes will result in an unacceptable product.

Textural Changes

Most of the textural changes that occur as a result of freezing and frozen storage only become apparent when the food is thawed. A few changes can be observed while the food is still frozen. The most noticeable of these is called 'freezer burn.'

Changes Apparent in Frozen Product

Freezer burn Moisture is lost from the surface of a food when the vapor pressure at its surface is higher than that in the surrounding environment. Freezing considerably reduces the vapor pressure at the surface of a food, but it is still likely to be higher than that in a frozen storage room or display cabinet. Ice from the exposed surface of unwrapped frozen food sublimates directly into the surrounding environment. The rate of the subsequent desiccation depends mainly on the rate of air movement over the surface and its humidity, and extreme desiccation results in a layer of spongy, dry dark material developing on the surface. This is known as 'freezer burn.'

In-package frosting Tight packaging in a heavyweight, moisture-resistant wrapping prevents freezer burn. Loose packaging reduces freezer burn but can allow another problem, 'in-package frosting,' to develop. In-package frosting, occurs when moisture from the surface of the food freezes on the inner surface of the package, and the main cause of this is poor temperature control in the store or cabinet.

Light surfaces Rapid freezing of products such as poultry joints produces very small reflective ice crystals at the surface. These give the product a very light appearance that is very desirable in some markets. Poor temperature control during storage causes the small crystals to grow, merge, and lose their lightness.

Changes Apparent on Thawing

Most of the textural changes caused by freezing are not noticeable until thawing. During the freezing process as the water turns to ice, it expands, and the ice crystals formed cause the cell walls to rupture. Consequently, the texture of the product becomes much softer when the product thaws.

These textural changes are more noticeable in fruits and vegetables that have a higher water content and especially those that are eaten raw. For example, when a frozen tomato is thawed, it turns into mush and liquid. This explains why celery, lettuce and tomatoes are not usually frozen and why frozen fruit are best served before they have completely thawed. In the partially thawed state, the effect of freezing on the fruit tissue is less noticeable.

In the case of vegetables, blanching (exposure of the vegetable to boiling water or steam for a brief period of time) has a marked softening effect, but further changes during freezing or frozen storage are comparatively small. However, if the vegetable is frozen in the raw state or is not correctly blanched, the enzymic action on pectic substances may lead to unacceptable changes in texture.

Textural changes due to freezing are not as apparent in products which are cooked before eating because cooking also softens cell walls. These changes are less noticeable in high-starch vegetables, such as peas, corn, and lima beans.

Consumers expect to purchase frozen meat at a unit price lower than that of a similar chilled product. This price differential results from the belief that the quality of frozen meat is inferior to that of chilled meat. There is little in the published scientific literature to substantiate this view. Some publications show that freezing, frozen storage, and thawing have beneficial effects on the textural properties of pork loins. Taste panels have found the meat to be slightly tenderer with improved juiciness and an easier breakdown of particles, as evidenced by the samples being less cohesive, easier to chew, and releasing more moisture during mastication.

Meat which is frozen just after slaughter before the rigor process is complete and, after being thawed rapidly, contracts vigorously and exudes much drip. The resulting meat is very tough, and this toughness does not disappear with extended cooking. The phenomenon is called 'thaw rigor' or 'thaw shortening' and can be avoided by waiting some time prior to freezing. A long thawing process, in which the meat remains in the -5 to $-2\,^{\circ}C$ range for a long period, alleviates the effect. A similar phenomenon is observed in fish filleted prerigor and frozen individually.

Freezing rate The effect of variations in freezing rate on the tenderness of ground beef patties has been investigated using conditions which achieved freezing times to $-18\,^{\circ}C$ of 24, 48, 72, and 97 h. In one study, immediately after freezing, patties frozen in 24 h were less tough than those frozen in 96 h (Table 1). This difference was still found after 6 months storage. After 18 months, patties frozen in 48 h were tenderer than those frozen at faster or slower rates. Slight reductions in flavor and juiciness were also found in patties frozen in 96 h. Taste panel and sensory scores for the tenderness of ground beef patties frozen in air at $-43\,^{\circ}C$ were higher than for those frozen at $-20\,^{\circ}C$. Freezing rates were not detailed, and patties were stored for 2 weeks at $-30\,^{\circ}C$.

Table 1 Effect of freezing rate on tenderness of ground-beef patties (ranging from 1, extremely tough, to 8, extremely tender)

Storage time	*Freezing rate (hours to −18 °C)*				
	24	*48*	*72*	*96*	*SE*
Just before freezing	6.1[d]	5.6[f]	5.8[e]	6.0[d]	0.03
Just after freezing	5.1[d]	4.7[d,e]	4.8[d,e]	3.7[e]	0.25
6 months	4.9[d]	4.9[d]	4.2[e]	4.3[e]	0.10
18 months	4.5[e,f]	5.2[d]	4.7[d,e]	4.1[f]	0.09

[a, b, c, d, e, f]The same letters indicate no statistical differences.

From Berry BW and Leddy KF (1989) Effects of freezing rate, frozen storage temperature and storage time on tenderness values of beef patties. *Journal of Food Science* 54: 291–296.

Frozen storage Three factors during storage, storage temperature, degree of fluctuation in the storage temperature, and type of wrapping/packaging in which the food is stored, are commonly believed to have the most influence on frozen storage life.

Storage temperature has a marked effect on the behavior of ice crystals that could be detrimental to the ultimate quality of the food. It has been demonstrated that frozen tissue stored for 180 days at −20 °C has small ice crystals of irregular shape in the extracellular spaces. Storage for the same period at −3 °C results in the development of large rounded ice formations with a concomitant compression of the muscle fibers. It is thus desirable that frozen meat should be stored at a sufficiently low temperature to prevent the growth of ice crystals in the extracellular spaces. Such growth occurs if the temperature of the frozen tissue is allowed to rise above its eutectic point. (The eutectic point is the lowest freezing point of all combinations or constituents of the food.) However, quoted values for the eutectic point of meat range from 'probably just below −20 °C' to −52 °C.

Generally, fluctuating temperatures in storage are considered to be detrimental to the product. It has been found that temperature fluctuations produced during storage and transport of frozen food lead to activation of the recrystallization processes, causing enlargement of the ice crystals and diminishing advantages obtained in quick freezing of products. However, it has been reported also that repeated freeze–thaw cycles do not cause any essential change in the muscle ultrastructure and that several freeze–thaw cycles during a product's life cause only minor quality damage (in terms of juice loss) or possibly no damage at all. A slight but significant improvement has been found in samples that have been frozen and unfrozen several times when tested by a taste panel.

If the temperature cycles are so severe that the surface temperature of the food rises above 3 °C during the process, this could create a potential microbiological hazard.

Minor temperature fluctuations in a stored product are generally considered to be unimportant, especially if they are below −18 °C and are only of the magnitude of 1–2 °C. Well-packed products and those that are tightly packed in palletized cartons are also less likely to show quality loss. When ground pork and beef are stored under fluctuating conditions of between −18 and −23 °C for a 6-month period, the well-packed samples show no deterioration. However, poorly packed samples are severely affected by the temperature swings.

The proteins of fish differ from those of meat in their higher susceptibility to damage in frozen storage. Frozen storage results in an increasing tendency to lose moisture on thawing and an increased firmness, leading to toughness and dryness on cooking. These changes are the result of denaturation and cross-linking reactions predominantly of the myofibrillar proteins.

Drip Freezing, always tends to decrease the water-holding capacity and hence increases drip. When meat is frozen quickly, the water, released by the fibrils as the meat has gone into rigor, and that which is still held are frozen simultaneously. Consequently, there is no change in their relative positions or amounts. At slower freezing rates, however, the water balance is altered, the extracellular water freezing first. As freezing continues, the existing ice crystals grow at the expense of water from the intrafibrillar space. This can result in salt crystallization and pH changes which can cause protein denaturation. This has been well documented for frozen fish, which is much more susceptible to freezing damage than meat.

A number of scientific investigations have defined the effect of freezing rate on drip production in meat, demonstrating that the optimal conditions for freezing portioned meat are those that achieve freezing rates between 2 and 5 cm h^{-1} to −7 °C. 'Sow freezing' up to 0.39 cm h^{-1} resulted in a decreased solubility of myofibrillar proteins, increase in weight loss during, freezing thawing, and cooking, lower water-binding capacity, and tougher cooked meat. 'Very quickly frozen' meat (> 4.9 cm h^{-1}) had a somewhat lower

myofibrillar protein solubility, lower water-binding capacity, and somewhat tougher and drier texture. In these studies, samples were thawed after storage periods of 2–3 days at −20 °C, so the relationship between freezing rates and storage life was not investigated.

The results on freezing rate are scientifically very interesting, but in industrial practice, most meat is air-frozen in the form of large individual pieces or cartons containing smaller portions. In commercial situations, freezing rates of 0.5 cm h^{-1} in the deeper sections would be considered 'fast,' and there would be considerable variation in freezing time within the meat. The mutton samples frozen in these studies were much smaller (77.6 g in weight) than most commercial products. Even with such small samples, there was no significant difference in drip after 48 h between cryogenic freezing at −90 °C and a walk-in freezer operating at −21 °C (Table 2).

Experiments have been carried out on freezing samples similar in size to a domestic joint. There was no significant difference in drip loss from 700-g samples of pork l. dorsi frozen in air at −20 or −80 °C. At −20 °C, samples required approximately 6 h to pass from −1 to −6 °C, compared with half this time at −80 °C. Average drip losses were 3.7% at −20 °C and 5.2% at −80 °C. In commercial situations, freezing times typically range from tens of hours to a few days. Freezing rates are therefore outside the values that influence drip potential.

Drip loss in frozen storage has been shown to increase with storage time and increase in storage temperature. After approximately 42 and 63 days, drip from beef stored at −10 or −15 °C had reached 80 and 90%, respectively, of its maximum. At −25 °C, it required over 120 days to reach the 80% value.

Drip loss during thawing from ground beef patties was also found to increase with the length of time the patties had been in frozen storage. For higher-fat-content samples, drip loss increased from 1.8% in fresh samples to 12.5% after 20 weeks in storage. Higher drip losses in thawing were found for samples stored at −12.2 °C than lower temperatures. However, there was no difference between storage temperatures of −23.3 and −34.4 °C.

Flavor Changes

No marked changes in fruit flavor occur on freezing except after an extended process at elevated temperatures. Changes in flavor constituents of frozen fruit are generated during prolonged storage and increase as the storage temperature is increased. The first significant change in stored frozen fruits is a loss of fresh aroma. After this, some off-flavors may develop that are dependent on the type of fruit. Some fruits are known to be more stable than others, but the exact reason is not known.

Enzymes in fruits and vegetables are slowed down, but not destroyed, during freezing. If not inactivated, these enzymes can cause color and flavor changes as well as a loss of nutrients.

Enzymes in vegetables are inactivated by blanching, then rapidly cooled in ice water to prevent cooking. Blanching is essential for top-quality frozen vegetables.

Another type of chemical change that can take place in frozen products is the development of rancid, off-flavors. This can occur when fat, such as in meat, is exposed to air for a certain period of time.

Species has an influence on rancidity development. Investigations have been carried out on rancidity development in cooked and uncooked ground meat patties made from chicken, beef, or pork. In one study, the TBA (thiobarbituric acid) values in uncooked patties were higher in beef than in those made from either pork or chicken (Figure 1). Levels in chicken patties did not change appreciably during 150 days, storage at −20 °C. After 150 days, the TBA values in beef were approximately 7 times higher than those in chicken, and the values in pork were 4–5.5

Table 2 Drip loss (%) from 77.6-g samples of Mm. longissimus lumborum et thoracis frozen under different methods and thawed at 4 °C

Freezing conditions	*Freezing time to − 2.2 °C*	*Freezing rate (cm h^{-1})*	*Storage time at −20 °C*	
			48 h	*2.5 months*
Cryogenic − 90 °C	15 min	6.4	3.34^{a}	9.49^{a}
Cryogenic − 65 °C	22 min	4.4	$4.70^{a,b}$	9.72^{a}
Blast freezer − 21 °C	1.83 h	0.55	5.53^{b}	12.74^{b}
Walk-in freezer − 21 °C	1.88 h	0.53	$4.71^{a,b}$	13.18^{b}
Domestic freezer − 25 °C	1.96 h	0.51	5.26^{b}	11.72^{b}

times as high as those in chicken. Cooked chicken patties had a higher lipid oxidation potential than cooked beef or pork patties.

Other studies have found a temperature and species interaction for pork and beef. In experiments, the practical storage life (PSL) and high-quality life of pork were superior to beef at −5 °C, but at −10 and −20 °C, the storage life of beef was much longer. In other trials where more than one species was compared, storage times were not fully presented, or direct comparisons were not possible.

It seems fair to conclude that most work indicates differences in frozen storage life between species. However, we currently lack the understanding to use data on the frozen storage life of one species under a given condition to predict the likely storage life of other species under that condition.

Animal-to-animal variation is believed to cause wide variations in storage times. Investigations in New Zealand have found that animal-to-animal variation can lead to storage-life differences as great as 50% in lamb but do not give any definite reason for this variation. Two trials were carried out in which lamb was stored at −5 °C. In the first trial, the lamb was judged rancid after 20 weeks, and in a duplicate trial using identical temperature, processing, and packaging conditions, the lamb was found to keep for 40 weeks. The only variation that could be determined was that different animals were used in the two trials.

Processing of meat prior to freezing generally results in a lengthened storage time. It has been found that the amount of TBA-reactive substances, in prerigor cooked boar, did not change during 3 months, storage at −20 °C. Heating prior to freezing can result in a 50% longer PSL for sausages and is thought to be due mainly to inactivation of some of the enzymes present or, possibly, inactivation of the catalytic activity of hemoglobin. However, the heating process may be critical, since muscles cooked at higher temperatures are most susceptible to oxidative changes during storage. Investigations have also found that pressure-cooking chicken breast at $0.36\,kg\,cm^{-2}$ produce higher TBA values than cooking at atmospheric pressure.

Smoking is generally advantageous due to the antioxidant properties of the smoke. It has been suggested that wood smoke may not only aid frozen storage, due to its antioxidant properties, but also mask off-flavors. Smoked broilers have been found to keep well for over a year without any major quality change. Smoked ham has also been found to store well for a year at −18 °C without any loss of flavor or weight.

Studies on chicken breast and salmon have shown that fast and slow freezing, at undefined rates, have no effect on the rate of development of lipid oxidation during storage, slightly higher levels being found in the fast frozen muscle. In studies on buffalo meat, plate-frozen meat was scored higher for color, texture, and overall quality than blast-frozen samples. Tests were carried out after 3 months' storage at −15 °C, and the freezing times, for 500- to 600-g pieces, from 4 to −30 °C were 280 and 140 min, respectively, for the plate- and blast-freezing operations. After 1 month's storage, the TBA values in plate frozen cuts were significantly higher than in those blast-frozen, but the difference had disappeared after 3 months.

Few would disagree that storage temperature influences frozen storage life and that, in general, the lower the temperature, the longer the PSL. However, there appear to be few papers with data from experiments on the PSL of food at different storage temperatures. Most of the studies published to date concern products that do not meet the lower-temperature longer-storage rule (normal stability).

It has been shown that rancidity in bacon is increased by a higher salt content and that the rates of chemical reactions are accelerated as the temperature is lowered when packed in permeable wrapping.

Studies have shown that free fatty acids accumulate more readily in bacon stored at −30 °C than in bacon stored at −12 °C. The highest rate of free fatty acid accumulation in bacon was found to be at −62 °C. A similar trend was found in trials with liver paste. Cured pork products are known to have an abnormal temperature profile between −5 and −60 °C and do not keep as well between −30 and −40 °C.

Pork chops, Vienna sausage, and pork sausages have been found to have straight-line quality-loss data at lower temperatures but were nonlinear at higher temperatures. Their storage trials were carried out at −40, −30, −24, −18, and −12 °C. Ground veal and pork were also found to have cubic curves at all temperatures.

Improved aroma scores have been found to be only moderately related to lower freezing temperatures but were not related to flavor. Aroma scores for minced beef improved during 6–12-month storage at −12.2, −17.8, or −23.3 °C, although a slight increase in rancidity also occurred. Temperature abuse of −6.7 °C for 48 h caused rancidity on the outside of the samples but did not affect the inner portion. After 24 weeks' storage at −12, −18, or −23 °C, no differences due to storage temperature were found in ground beef patties containing mechanically recovered meat. Ground beef patties stored at −7 °C were found to be tougher than those stored at −18 or −23 °C. Severe quality deterioration was found in patties stored for 6 months at −7 °C. Little difference was found between storage temperatures of −18 or −23 °C over an 18-month period.

Consumer panels are often not very sensitive to quality changes. When a consumer panel was used, it could not tell the difference between samples of lamb stored at −5 and −35 °C. A trained taste panel could differentiate between the two temperatures and scored the samples stored at −5 °C as being rancid.

In recent years, energy-conservation requirements have caused an increased interest in the possibility of using more efficient storage temperatures than have been used to date. Researchers have questioned the wisdom of storage below −20 °C and have asked whether there is any real economic advantage in very-low-temperature preservation. There is a growing realization that storage lives of several foods can be less dependent on temperature than previously thought, and since research has shown that meat and poultry often produce nonlinear time–temperature curves, there is probably an optimum storage temperature for a particular product. Improved packing and preservation of products can also increase storage life and may allow higher storage temperatures to be used. It has been suggested that foods should be split into high-, medium-, and low-stability categories, with −12 °C for products with high stability and −28 °C for products with low stability. Some believe that, based on storage at −18 °C, low-stability meats such as mechanically recovered meat should be stored for 8 months or less. Medium-stability meats such as pork and processed meats should be stored for between 8 and 15 months. High-stability meats, which include all meat and poultry except pork, could be stored for more than 15 months.

Nutritional Value of Frozen Foods

J S Pai, University of Mumbai, Mumbai, India

Background

Freezing of foods has been practiced for a long time, and frozen foods have become very common today. All types of frozen foods are available on the market, from butter, meat, fish, and poultry to semiprocessed foods like frozen vegetables, orange juice concentrate, frozen cake and biscuit dough, French fries, ready-to-eat processed foods like icecream, and some items that simply need to be heated in the oven and are ready to eat. Several decades ago, the frozen food market consisted of only a few vegetables. In recent years, the range and quantity of frozen food have increased tremendously. Some

cooked dishes and meals are also being offered in frozen form.

Freezing has improved the convenience in the preparation of foods. Foods are available out of season and have a very similar quality to that of fresh foods. Frozen foods have been evaluated by experts who observed that when properly prepared and stored, frozen foods have a nutritional value not only as good as the fresh commodity but at times even higher than the commodity procured from the fresh food market and cooked at homes.

Freezing is used as a method of preservation, since most microorganisms do not grow at temperatures below 0 °C. Spoilage-causing microorganisms normally grow on foods and cause spoilage at ambient temperatures. When the foods are chilled to below 20 °C, the growth of most spoilage organisms slows down but does not stop. Enzymes present in foods and microbial enzymes also bring about changes, resulting in spoilage. These enzymes prefer milder temperatures. Their activity is reduced when the temperature is lowered. However, chilling temperatures above 0 °C may allow various microbial and enzymic activities to continue. There are many microorganisms, called 'psychrophiles', that grow quite rapidly at temperatures around 0 °C. Thus, although they have a longer shelf-life than fresh foods, chilled foods are more perishable than frozen foods. Whereas chilled foods may last for a few days to a couple of weeks, frozen foods that are frozen and stored properly may have a shelf-life of a few months to even a couple of years.

The spoilage organisms can be destroyed or stopped from growing and spoiling foods by different methods, including pasteurization, canning, low-temperature storage, including chilling and freezing, chemical preservatives, etc. Heating is the oldest method, but as well as killing the spoilage organisms, heat also degrades the components responsible for color, flavor, texture, etc., affecting sensory properties. It also destroys many nutrients. Chemical preservatives are undesirable, as people prefer natural, additive-free foods. Some preservatives have caused undesirable side-effects in some sensitive individuals. Drying removes the water from foods, and microbes and enzymes need water for their activity. Dried food after rehydration does not completely regain all its original sensory qualities, and there is also a significant loss of nutrients. Chilling and freezing have therefore gained acceptance with consumers as the preferred method of food preservation.

Although chilled and frozen foods may not spoil, their sensory quality and nutritive value may not remain unchanged. Some nutrients are degraded during the processing itself. Losses depend on the process design and rate of freezing. Some nutrients are lost during frozen storage, and here, also, the rate and amount of loss depend on the conditions of storage, including the storage temperature, packaging, type of food being stored, and its composition, etc. Same factors also affect the color, flavor, appearance, texture, etc.

Process of Freezing

Food is at ambient temperature when it is harvested and may undergo deteriorative changes unless it is chilled as soon as possible. If a food is to be stored unprocessed for long periods, it is normally cooled. Pretreatments such as washing, cutting, trimming, sorting, peeling, removal of pit, feathers, skin, bones, etc., removal of certain parts, and blanching are carried out prior to freezing. Washing, trimming, and peeling remove dirt and foreign material and reduce the microbial load. Blanching is a process of heating in water or steam and achieves several objectives in different products. It fixes color in green vegetables, wilts leafy vegetables like spinach, so it can be packed tightly into cartons, and removes undesirable odors associated with some vegetables and fruits. It also deactivates enzymes naturally present in many foods, which, if not removed, cause odor formation during storage, and it removes dissolved gases from food tissues. Finally, it reduces the microbial load, and in the case of certain harmful pathogenic organisms, it might be the only way to control such organisms.

These processes affect the nutrient contents as washing leaches out some water-soluble nutrients, and cutting, trimming, peeling, and pitting, etc. remove parts of the foods that may contain some nutrients. Blanching not only degrades some temperature-sensitive nutrients but also leaches out water-soluble nutrients if hot water is used. Blanching also disrupts the cells and tissues, so the mixing of different components of foods takes place. Some of these components react and degrade each other.

Freezing Damage

The freezing process also causes changes in the tissues of food of animal and plant origin. Some irreversible changes are brought about as a result of freezing, so even after thawing, some changes in the food are evident. When certain commodities, especially those of tropical origin, are chilled, changes take place in membrane lipids and in the structure of proteins. This affects the integrity of the cells, and nutrient loss results from mixing with degrading enzymes or other chemicals.

When food is frozen, the water in both intracellular and extracellular solutions forms ice crystals, increasing the solute concentration and affecting many nutrients. Proteins become denatured as a result of the loss of water from the protein structures as well as the increase in solute concentration. Some vitamins become degraded, as a result of the change in pH and the increase in concentration of degrading chemicals.

Ice crystals can cause mechanical damage by causing excessive stress. Water freezes first from the extracellular area, and ice crystals start forming there, increasing the osmotic pressure outside the cells. This causes the water from inside the cells to move outside, leading to cellular collapse. The loss of cellular integrity not only allows various chemicals to mix and react with each other resulting in degradation of nutrients, but also causes leakage of watery solution as drip loss or exudates when frozen food is thawed. This may lead to further nutrient loss. (*See* **Freezing**: Principles.)

Food Preservation and Nutritive Value

People believe that foods purchased raw and cooked at home are more nutritious than foods prepared in factories. It is generally considered that the housewife or cook at home has a greater expertise and that foods cooked at home are nutritionally superior to factory products, as large-scale cooking may not preserve the nutrients adequately. Although this was probably true about a century ago, today, factory processes can be designed scientifically to preserve nutrients and taste by controlling the processes involved. This is possible because of the advances in scientific knowledge about foods and the better design of the equipment used for processing. The degree of nutrient loss depends on the process used: freezing is by for the least damaging process. (*See* **Preservation of Food**.)

Foods are preserved to feed large populations, especially in urban areas, as well as to make foods available out of season. Traditional preservation processes have included sun drying, smoking, and salting. Later, other processes such as canning, pasteurization, sterilization, and, more recently, chilling, freezing, and freeze-drying were introduced. In the ancient times, knowledge of nutrition was limited and also the motivation of profit overrode concerns for public health. However, gradually, the knowledge of nutrients has evolved, and several food laws have been introduced to ensure the safety and high nutritive value of food. Factory food processed by food technologists today using newer techniques and more efficient processes, is highly nutritious and sometimes even superior to home-cooked food.

Raw food is often associated with freshness. It looks fresh, but it may not have been harvested recently and may have been stored at ambient temperature for several hours or days. This is called 'market fresh', as opposed to 'garden fresh', which means that a food has been harvested recently. After harvest, when a food has been kept at room temperature (which sometimes may be up to 40–50 °C in the summer), there are many changes to nutritive values, including vitamin contents. Many nutrients like vitamin C and folate are degraded quite rapidly in a matter of hours or days after harvest. Green leafy vegetables in warm climates lose 5–18% of their vitamin C 2 h after harvest and as much as 90% within 24 h. Garden peas can lose 7% of their total vitamin C each day, so after a week, they may lose up to 50% vitamin C.

Processing plants, however, have access to freshly harvested foods, and within hours of harvest, they may either process them or precool them and store them until processing, resulting in less nutrient loss. Thus, processed foods may have a higher nutrient content in the raw material than those in fresh food markets. Even after cooking, processed food may often be more nutritious than market fresh food cooked at home, particularly with frozen foods.

There are several different mechanisms of nutrient loss during food processing. Nutrient losses can be due to physical separation, as in peeling, trimming, etc., leaching during blanching, or chemical degradation. When water is involved in the process, water-soluble nutrients like vitamin C, folate, B vitamins, etc. and, to lesser extent, soluble carbohydrates, proteins, and mineral are lost because of leaching. Boiling or steeping in water is an example. Heat damages nutrients that are sensitive to higher temperatures like thiamin, carotene, vitamin A, and vitamin C. However, when food processing includes heat treatment, the food is partly or completely cooked, so it does not have to be cooked again, and brief heating to warm it is enough. Thus, the loss of nutrients incurred in the factory is instead of, and not in addition to, that incurred at home.

Nutritive Value of Frozen Fruits and Vegetables

Fruits and vegetables are important dietary sources of vitamin C, folate, minerals, carotenoids, and anthocyanins, especially in colored fruits, but poor sources of B vitamins and macronutrients. Some years ago, a study was undertaken to evaluate frozen foods from 150 factories with respect to vitamins and minerals. The vitamin contents are listed in Table 1.

Table 1 Vitamin contents of some frozen vegetables (mg/100 g)

Frozen vegetable	*Vitamin*	*Content (approx.)*
Asparagus	Thiamin	0.10–0.25
Broccoli	Carotene	1–3
Brussels sprouts	Ascorbic acid	70–110
Lima beans	Niacin	1–2
Spinach	Ascorbic acid	10–50

The ranges are quite wide, and, besides experimental error, this may be because original nutrient contents vary in fruits and vegetable owing to varietal differences and cultivation and harvest practices. The freezing process includes precooling, washing and other pretreatments, blanching and cooling, freezing, and frozen storage with respect to temperature and time. All these parameters affect the nutrient contents.

Prefeezing storage at warm or ambient conditions causes substantial losses. Raspberries left to stand at ambient temperatures for 24–48 h prior to freezing have been shown to lose 17 and 30% of their vitamin C. Strawberries stored at 0 °C or lower for 2–4 days showed only slight losses in vitamin C.

Freezing itself has very little effect on nutrients, but most studies have indicated losses during blanching and cooling prior to freezing, during frozen storage, and during thawing. Blanching is carried out before freezing to deactivate the enzymes that might be active and cause deteriorative changes in nutrients and sensory quality. Blanching may be carried out in hot water or steam or by using microwave heating.

The losses include water-soluble nutrients such as vitamins C, B complex, and folate, and much less important losses of minerals and a small fraction of proteins and carbohydrates have been reported. Figure 1 shows the losses occurring mostly during blanching and very little during freezing. Not only does water leach out the vitamins, but heat during the blanching causes losses of vitamin C and thiamin, which are heat-sensitive. The type of food, enzyme to be inactivated, size of pieces, etc. determine the length of treatment, which in turn affects the vitamin losses.

Losses depend on the area-to-volume ratio of the material being blanched. Almost half the total vitamin C is lost from vegetables like peas, sliced beans, broccoli, spinach, and diced carrots because of the large surface area-to-volume ratio. Smaller losses of only about 30% occur in whole beans, potatoes, and sprouts, which have smaller ratios. Losses are mostly because of leaching out of water-soluble vitamins. Microwave blanching does not involve water, so much less losses are reported. Microwaving is also more rapid, so heating losses are less. Green beans, when blanched, lose 9% by microwaving, 14% by hot water, and 18% by steam. Some studies have reported almost the same losses by the three methods. Blanching is followed by cooling before freezing, and if water is used, the losses are higher compared with air cooling (see Figure 2).

Although blanching causes losses of vitamins, when vegetables are not blanched, there are greater losses during frozen storage. Without blanching, green beans lose 35% and spinach loses 54% vitamin C during frozen storage at −19 °C for 9 months, whereas blanched vegetables lose only 10 and 24%, respectively. The vitamin B_1 and B_2 losses of unblanched green beans during 1 year's storage at −20 °C are 74 and 39%, whereas after blanching, the losses are 22 and 3% only.

Nutrient losses in fruits and vegetables are negligible during the freezing process. Studies on various vegetables like asparagus, green beans, lime beans, broccoli, sprouts, cauliflower, kale, peas, potatoes, and spinach have shown that the losses of vitamins

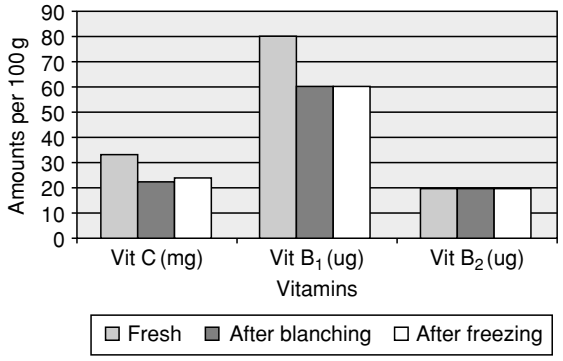

Figure 1 Vitamin losses from green beans.

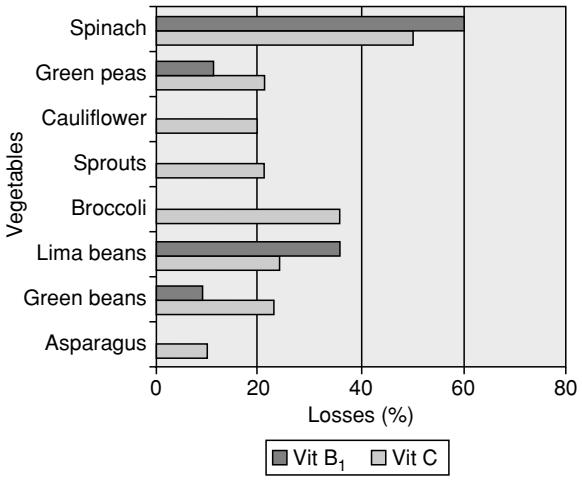

Figure 2 Vitamin losses during blanching.

C, B_1, B_2, niacin, and carotene are either nil or negligible.

Frozen storage, however, causes some losses, and these are affected by the temperature and packaging method. Losses at the usual recommended temperature of −18 °C are quite low. More rapid losses have been reported in vitamin C when frozen peas are stored at higher temperatures. Other vegetables show some losses in vitamins C, B_1, B_2, carotene, etc. when stored at − 18 °C, but besides vitamin C, other vitamins are less sensitive to storage at higher frozen temperatures (see Figure 3).

Losses of vitamin C from many fruits can be large, particularly if fruits are not packed in syrup. Raspberries packed in syrup lose only small amounts of vitamin C. Losses of vitamin C from peaches and strawberries are generally moderate during frozen storage, and this depends also on the oxygen barrier properties of the package. Metal cans are much better packages in that respect compared with composites with metal ends. Citrus juice concentrates are reasonably stable with respect to vitamin C during frozen storage for 9–12 months at − 18 °C. Vitamin C degradation of frozen boysenberries, strawberries, and peaches is greater when they are stored at higher temperatures at − 12, − 7, and − 1 °C, rather than − 18 °C. Citrus juices from grapefruit, orange, and tangerine are more stable at different temperatures. The stability of citrus juices may be due to their low pH and low oxygen content.

Thawing conditions have little effect on vitamin losses, according to the few studies that have been carried out on vegetables and fruits. Losses of vitamin C from citrus juice concentrates during thawing are insignificant. Also, peaches, apricots, nectarines, and fruit salad packed in syrup lose little vitamin C during various thawing procedures of different times ranging from 20 min to 19 h. However, holding the fruits after thawing at ambient conditions will incur losses of vitamin C. Raspberries and peaches after thawing lost up to 15% vitamin in a period from 2 h to 1 day (see Table 2).

Losses of vitamin C in fruits and vegetables during the entire freezing process have been studied. In some vegetables, 10–65% of the original vitamin C is lost. When fruits are protected by syrup and properly packaged to keep oxygen out, the losses are less, as in the case of strawberries, apricots, and peaches. Without sugar syrup, they may lose up to 65–85%, whereas with syrup and good packaging, their losses can be reduced to about 15–30% in up to 9 months of storage at − 18 °C.

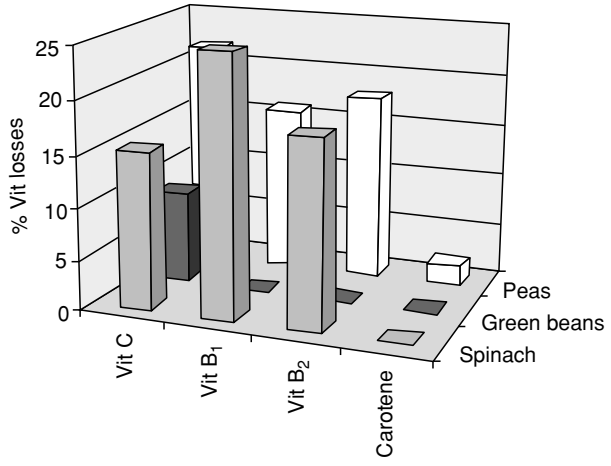

Figure 3 Vitamin losses in vegetables stored for 6 months at − 18 °C.

Nutritive Value of Frozen Animal Foods

Meat is an important source of many vitamins and minerals such as vitamins B_1, B_{12}, niacin, and iron. Other vitamins are available, like B_2 from offals and vitamin A from liver. There is no blanching in meat processing, but an important treatment prior to freezing of meat is aging. In one study, beef was aged for 21 days at 1 °C, resulting in no loss of thiamin and riboflavin but a 35% loss of total niacin. Another study on beef reported no significant losses of vitamin B_6 and pantothenic acid. When pork roast was aged for 7 days at − 1 °C, the amounts of thiamin, riboflavin, pantothenic acid, and nicotinic acid were not affected consistently. Short-term aging with a low nonfreezing temperature did not destroy vitamins significantly. Phosphate treatment of fish did not affect the vitamin and mineral contents, except that the sodium tripolyphosphate treatment increased the sodium content by three to seven times that in untreated samples.

B vitamin losses in various animal meat products such as beef steak, beef liver slices, beef stew, Chicken à la king, Shrimp Newburg, oysters, and pork chops have been investigated during freezing. No significant

Table 2 Losses of Vitamin C in different frozen vegetables stored for 6–12 months at −18°C

Frozen vegetable	*Vitamin in fresh vegetable (mg/100 g approx.)*	*Percent loss after storage (approx.)*
Asparagus	35	10
Green beans	20	45
Lima beans	30	50
Broccoli	110	50
Cauliflower	80	50
Peas	30	45
Spinach	50	65

Table 3 Vitamin B_1 losses from thawing

Frozen food	*Percent thiamin loss (approx.)*
Beef liver, slices	20
Beef stew	1–10
Chicken a la king	2–10
Shrimp Newburg	4–10

losses of thiamin, riboflavin, niacin, pantothenic acid, and pyridoxine have been reported in these products (see Table 3). Some losses have been indicated in pork wherein both freezing and thawing losses were combined.

Losses have been monitored during frozen storage of several meat products at −18 °C for 6 months. Losses have been shown mostly in pyridoxine (18–59%) in beef steak, pork chops and roast, and oysters with minor losses of niacin and pantothenic acid. Oyster incurred significant losses of most B complex vitamins.

Most losses from frozen meats occur when they are improperly thawed. The amount of drip loss or thaw exudates depends on several factors such as time taken to thaw, pH of the meat, state of rigor, ageing prior to freezing, size of cuts, and freezing rate. The amount can range from 1 to 10%. The water-soluble vitamins are lost along with the drip or exudates, and their retention is better, when meat is thawed at room temperature or at 0 °C, than in warm ovens (see Table 3).

The effects of various thawing methods have been investigated. Losses of B vitamins from unpackaged beef steak are generally greater when water is used for thawing, rather than air. Thiamin losses are lowest when a microwave is used for thawing, slightly greater with infrared heating, and greatest with boiling with water. In packaged products, the method of thawing is less significant with respect to losses of B vitamins. Nutrients lost in thaw exudates have been estimated for beef and pork (see Figure 4).

The total losses during the entire freezing process have been evaluated. The meat was aged, frozen, stored for several months at −18 °C to −23 °C before thawing. The losses are shown in Figure 5.

In a more recent study, when rib steaks were aged for 5 days, then frozen and stored at −18 °C and thawed at room temperature for 15 h, the losses were found to be about 10% for each of B_1, B_2, B_6, niacin, and folate, whereas about 30% of pantothenate was lost. Almost all of these losses could be traced to drip losses, and it might be good sense to include drip or thaw juices with meat before cooking, so as to recover most of the lost nutrients. There will of course be a small loss due to heating.

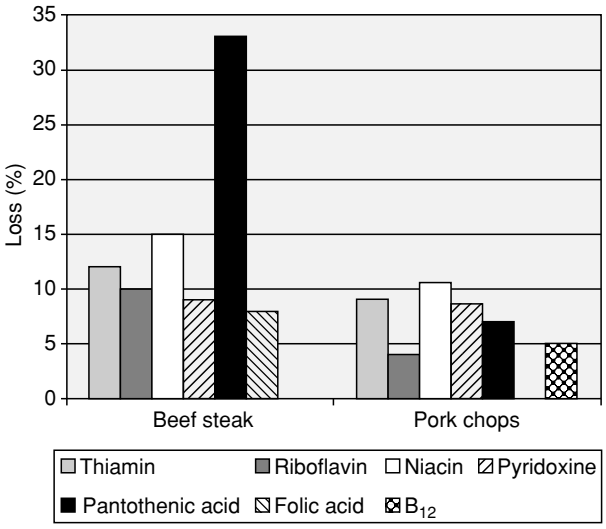

Figure 4 Losses in thaw exudates.

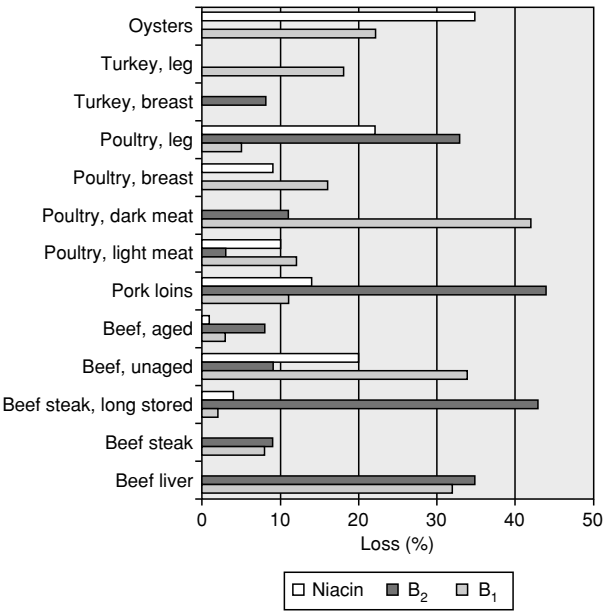

Figure 5 Vitamin losses in the entire process.

Nutritive Value of Frozen Dairy Products

Some products like butter, margarine, and ice creams are stored frozen. Butter loses only a small amount of vitamin D when stored at −10 °C for 2 years, whereas butter and margarine lose about 17% of vitamin A. Ice cream is frozen at lower temperatures. When frozen and stored at −23 °C for 7 months, it loses 5% of riboflavin, 16% of carotene and all of the vitamin C (there is very little vitamin C in ice cream

anyway). When frozen milk is stored for 19 weeks at −14 °C, the losses in biotin and nicotinic acid are nil.

Comparison of Nutritive Value with Other Methods

There have been many types of processed foods available commercially, and there has always been an interest in evaluating these for the losses of nutrients. This is a difficult task, as foods have different varieties as well as degrees of maturity suitable for a particular method of processing. Thus, if the same raw material is used for all the processes and unprocessed for control, it would be an unfair comparison. Also, raw materials of different degrees of maturity would have different amounts of nutrients, and any comparisons would be meaningless. Studies have been undertaken to determine the nutrient losses resulting from different processes. Green peas have been processed by different methods and analyzed for their vitamin C content, the most vulnerable of all the vitamins (see Table 4).

Cooking losses from fresh food have been compared with those from frozen foods, and the losses have been shown to be comparable. Many commercial samples have been purchased and cooked and compared with fresh foods cooked. The amounts of vitamins B_1, B_6, and B_{12} show no difference, whereas some foods such as beef stew, fish cakes, codfish, and Brussels sprouts show higher values for frozen samples. Also, the amount of vitamin C is higher in frozen sprouts. Some experiments have been carried out with cooked meals that have been stored frozen. These have been found to have a higher vitamin C content than conventionally prepared fresh food meals roughly the some amounts of other vitamins like B_1 and B_2, and a slightly higher retention of available lysine.

Frozen Prepared Meals

Frozen prepared meals are either complete meals or portions of meals that are precooked, packed in trays, and frozen for retail. Their popularity is due to the diversity in menu and convenience in preparation. Typical packs may include meat dishes, vegetables, pasta products, sauces, and desserts. Meats are often a major component, which is cooked or fried after treatments like marinating and tenderization. Heat treatment removes pathogens and improves the flavor. While chicken may be completely cooked, delicate foods like fish are heated for a short time, allowing the consumer to complete the cooking while reheating the product. Sometimes, heating may be carried out after packing meat and applying a vacuum. Vegetables are either procured frozen, or raw vegetables are frozen on site after cooking. Other items are normally prepared fresh and included in the meal and frozen.

Different items are assembled on trays composed of aluminum foil, paperboard, or plastic. These trays are embossed to compartmentalize each item. The package is made so that it can be conveniently reheated in either an electric oven or a microwave oven. An alternative is boil-in-bag meals, which have flexible bags in which meals are packed, and the frozen packaged is simply immersed in hot water to heat the contents, which can be poured on to a plate after cutting open the bag.

Each item may be stored frozen before being added to the tray, or the freshly prepared items may be deposited on the tray and then frozen. These products are fed into the depositing machines, which deposit them on to the trays, and these filled trays are then conveyed to the freezer. A belt freezer is commonly used, in which trays are placed on a wire mesh belt, which takes the product through a freezing chamber operated at −40 °C. Freezing is accomplished in a short time, usually about 90 min. Alternatively, a spiral or plate freezer can be used. After freezing, the product is packed into cartons and stored at low temperatures during storage, transport, and marketing.

Freezing *per se* does not damage nutrients to a great extent, but the rate of freezing and the different chemical substances present in the environment of nutrients may affect the retention of nutrients during freezing, frozen storage, and reheating. Nutrients are preserved to a greater extent if individual components of a meal are frozen optimally and separately and then assembled on to a tray. However, some or all of the components are assembled and then frozen because of the ease of production and economics. When different items are to be frozen simultaneously, the ideal conditions are difficult to maintain for each. Thus, losses may occur to a greater extent. Secondly, reheating also affects nutrient retention with the method used (such as oven or microwave heating)

Table 4 Ascorbic acid losses during complete processing by different methods in green peas

Process of preservation	*Percent loss after cooking (approx.)*	*Cooked product content (mg/100 g)*
Dried in air	55	11–12
Canned	60	8–11
Freeze dried	35	13–18
Frozen	40	12–16
Fresh peas	30	16–19

being an important pronounced factor besides the storage conditions. The microwave oven leads to fewer losses, as heating is rapid. Using a higher freezer temperature leads to greater losses of vitamins such as vitamin C.

There are many manufacturers of frozen prepared meals and many different products available. Although seemingly similar, many have different ingredients and processing procedures. The inherent differences make it difficult to generalize the nutrient losses in such products. In one study, it has been shown that a 300-gram frozen chicken dinner supplies half the RDA of protein, more than 100% of the RDA of vitamin A, and substantial amounts of thiamin, riboflavin, vitamin C, niacin, iron, and calcium, whereas a 300-gram beef dinner provides the following RDAs: 50% protein, 25% P, 60% Fe, 14% vitamin A, 25% thiamin, 30% riboflavin, and 95% niacin. A different recipe and processing method might give different results which will be further affected by the storage time, temperature, and reheating procedure. Thus, it is very difficult to state the nutrient contents of these foods and their losses during processing and just prior to consumption.

Conclusions

Nutrient losses in the freezing process are primarily due to blanching in fruits and vegetables, frozen storage in all the frozen foods, and during thawing if water is used with unpackaged frozen food. These losses can be minimized if the frozen storage is maintained at the recommended temperature of $-18\,^{\circ}C$, and if the proper packaging method and material is used to prevent the food coming into contact with oxygen. Blanching can be carried out without water, e.g. by using microwave heating. Thawing should be carried out without contact with water or without removing the packaging material, preferably at room or refrigerated temperature. There will be some drip or thaw exudate losses, which can be reduced if the thaw juices are used with the food during cooking. Modern technology has allowed raw material of the highest quality to be processed under ideal conditions, thus incurring minimum losses of nutrients. Such frozen foods, upon cooking yield highly nutritious products often containing nutrients in quantities at least as much as that of home-cooked unprocessed food.

FRUCTOSE

J M Johnson and F D Conforti, Virginia Polytechnic Institute and State University, Blacksburg, USA

Introduction

Fructose as a commercial sugar has been evolving for several years in its application to food processing. Fructose is a monosaccharide and is a natural constituent of many foods. This chapter will discuss fructose in both its syrup and crystalline form and its application in food products. The physical, chemical, and sensory properties will be discussed.

Sources

Fructose is a monosaccharide. Fructose bonded with glucose, another monosaccharide, forms sucrose, or table sugar. Fructose also occurs naturally in abundance in fruits (Table 1) and in lesser amounts in tuberous vegetables such as onions and potatoes. These sources alone contribute some 40–60% of an individual's total fructose intake. However, the major source of fructose as an ingredient in food is from the hydrolyzation of starch to glucose, which is then converted to fructose. (*See* **Carbohydrates**: Classification and Properties.)

Fruits are a rich source of mono- and disaccharides. Dates contain up to 48.5% sucrose, and dried figs contain a mixture of 30.9% fructose and 42.0% glucose. The sucrose content of most fruit and fruit juices is low, though some varieties of melons, peaches, pineapple, and tangerine contain 6–9% sucrose, and mango contains 11.6% sucrose. Reducing sugars (primarily a mixture of fructose and glucose) are the main soluble carbohydrate of most fruits and account for 70% of seedless raisins. Vegetables contain substantially less fructose and glucose than fruits, and the only significant source of sucrose is sugar beets.

Adapted from: The Food Resource, Oregon State University. *http://osu.orst.edu/food-resource/sugar/com2.htm*.

In the late 19th century corn or potato starch was hydrolyzed with dilute acid to yield glucose and dextrins for commercial purposes. In the 1940s, cornstarch was the primary choice for the production of glucose and the introduction of enzyme technology for hydrolysis reactions contributed to the development of glucose syrups to fructose syrups of specified glucose content. The conversion of glucose syrups to fructose syrups by immobilized enzyme technology was introduced in the 1960s.

The major source of fructose as a food ingredient is high-fructose corn syrup. The production of high-fructose corn sweetener requires the following manufacturing steps: (1) wet milling corn to extract the starch; (2) saccharification and liquefaction to hydrolyze polymer starch to monomer dextrose; (3) isomerization to convert dextrose to fructose; and (4) fractionation to enrich the concentration of fructose in the isomerization product stream. An additional step of crystallization is required for the production of dry, crystalline fructose.

Fructose Crystallization

The solubility of fructose at 25 °C is 4 g g^{-1} H_2O. Fructose has the highest solubility of most, if not all, sugars and sugar alcohols. For this reason fructose is difficult to crystallize from aqueous solution. Several processes have been patented for the production of a fructose product in its most stable, pure crystalline form. These procedures include crystallization from methanol, ethanol, and water. The most successful process in use today is based on the crystallization of fructose from aqueous solution. The procedures utilize various combinations of concentration under atmospheric or reduced pressure conditions and seeding to initiate crystallization, followed by a cooling step to allow for crystal growth. Batch and continuous crystallization processes have been devised that incorporate preprogrammed concentrating, cooling, warming, and recooling cycles. Crystalline fructose products are produced in a variety of forms: powdered (90% through a US 200-mesh screen) and products with an average particle size of

300 and 450 μm. Crystalline fructose syrup is similar to physical properties of traditional high-fructose syrups, but has greater clarity, sweetness, and improved color stability. Both crystalline fructose and crystalline fructose syrup are used in many food products.

Isolation and Purification

The manufacture of high-fructose sweetener (HFS) requires the complete depolymerization of starch to its constituent monosaccharide, dextrose. Saccharification and liquefaction are names for the hydrolysis reactions used to accomplish this. Starch from wet milling is prepared for hydrolysis by a process called jetting: the starch slurry is pumped under high pressure through a small orifice with simultaneous injection of steam. Hydrolysis of the starch polymer to oligomers of intermediate molecular weight is initiated with dilute mineral acid or the enzymes α- and β-amylase. Mineral acid and α-amylase make random breaks in the starch backbone, producing soluble oligosaccharides and relatively small amounts of low- and medium-molecular-weight saccharides. β-amylase releases disaccharides units of dextrose (maltose) as it hydrolyzes starch. Glucoamylase completes the enzymatic hydrolysis of di- and oligomeric products of amylase by breaking the α-1, 4 and α-1, 6 bonds that join consecutive dextrose units. Isomerization is the next major refining step. Glucose isomerase is able to catalyze the conversion of dextrose to fructose without the need for cofactor regeneration. This enzyme remains one of the largest industrial uses for immobilization technology worldwide. The amount of fructose enzymatically produced from dextrose at 60 °C is restricted by an equilibrium constant of about 1. Theoretically, the highest fructose yield possible from the 94% dextrose feed stream is 47% at equilibrium. Manufacturing plants typically settle for yields of less than 42% because of the amount of enzyme and reactor time required to achieve equilibrium fructose concentrations. For many applications, the sweetness of glucose–fructose syrup has to be increased to the equivalent of sucrose. This means raising the fraction of fructose in the syrup by chromatographic enrichment to 55% (HFS-55). An attractive alternative method of preparing HFS has now been developed. Fructose is separated from a fructose–glucose mixture using a microporous polypropylene-supported liquid membrane containing a boronic acid carrier (2% wt; flux (10^{-8} mol m^{-2} s^{-1}), −1), glucose 2.9, fructose 55). Furthermore, adding immobilized glucose isomerase to the glucose solution in the source compartment of the liquid membrane transport cell allows glucose isomerization and fructose enrichment to be carried out in a single operation. This gives a receiving phase mixture that is more than 80% fructose.

Chemistry of Fructose

Fructose is a monosaccharide which is found widely in nature both free and combined forms. Unlike glucose, and the related sugars, mannose and galactose, fructose contains a ketone carbonyl. Five hydroxyl groups are also present and the keto group is on the 2-carbon. Fructose is a structional and functional isomer of glucose. Fructose shows a strong levorotation. The equilibrium value of the specific rotation is $[\alpha]_D^{20} = -92°$. A long-used name for this sugar is levulose, corresponding to the use of dextrose for glucose. Fructose shows mutarotation by ring formation through the addition of one of the –OH groups across the ketone carbonyl. The result is the hemiketal and there are two forms, depending on which side of the carbonyl group is used for the addition. However, the system is more complicated than glucose because both five- and six-membered rings are involved, depending whether the –OH group of the five-carbon or the six-carbon reacts in the ring-forming addition to carbonyl.

Fructose is hydroscopic and does not crystallize easily from solution. At 20 °C, approximately 78 g of fructose is soluble in 100 ml of water compared to 65 g sucrose and 20 g lactose. The crystalline hydrate form is less soluble than the anhydrous crystalline form and has very low solubility in nonpolar solvents. Fructose is a reducing sugar and is a reactive component of nonenzymatic browning (Maillard browning). (*See* **Browning**: Nonenzymatic.)

Analysis

In food composition tables, the carbohydrate content is usually given as total carbohydrates by difference, that is, the percentage of water, protein, fat, and ash subtracted from 100. Another widely used term is nitrogen-free extract, calculated as components other than water, nitrogenous compounds, crude fiber, crude fat, and minerals. The characteristics of fructose as a ketose and reducing sugar are utilized for analysis methodology.

A qualitative method for ketose determination is when a purple-pink color develops when 100 μl of a ketose solution is mixed with 0.5 ml of a phenol–acetone–boric acid reagent (5% phenol, 2% acetone, 4% boric acid) and treated with 1.4 ml of 96% sulfuric acid. Absorbency is measured at 568 nm after 60 min at 37 °C. This method allows for the determination of 3–50 nmol of D-fructose with a coefficient

variation of 2.8–7.8%. Carbohydrates other than ketoses do not interfere.

In alkaline solution reducing sugars, which contain an aldehyde or keto group, can reduce copper, silver, bismuth, and mercury salts to compounds of lower valence or to a metallic state. The best known reagent, based on the reduction of copper, is Fehling's solution (two solutions: (1) cupric sulfate; (2) sodium potassium tartrate and sodium hydroxide). Depending on the concentration of sugars in a solution, heating in the presence of Fehling's solution gives a yellowish orange to red solution or precipitate.

The available assay methods for mono- and oligosaccharides include chemical, colorimetric, chromatographic, electrophoretic, optical, and chemical procedures. Today, more and more assay techniques involve preliminary separation by chromatographic and electrophoretic techniques prior to actual assay by classic chemical procedures or colorimetric tests. Microbiological assays have found relatively little application, while the use of enzymes as aids in sugar analysis or in actual assays is gaining in popularity with the commercial availability of pure, selective, and stable preparations.

The separation of sugar by paper chromatography has been developed into the versatile form of qualitative and quantitative carbohydrate microanalysis. Qualitative paper chromatography is the simplest method to distinguish between various sugars in a food. The development of the chromatography is done by the application of compound sprays to identify spots. Separation of 1% sugar solutions containing a maximum of 60 μm of an individual sugar gives best results. Resolution is more rapid with phenol–water or colloidin–water systems. In a phenol-containing system fructose moves faster than xylose.

In enzymatic methods, selective cleavage to monosaccharides and/or enzymatic assay of the monosaccharide is specific and widely used. The use of amylase and amyloglucosidase is an example of the first type; determination of glucose with glucose oxidase is an example of the second type. Microorganisms and enzymes can also be used in the pretreatment of substrate prior to assay by chemical or physical methods. For example, hydrolysis of sucrose by invertase is much more specific than acid hydrolysis, and invertase is used in various procedures requiring sucrose inversion.

Sensory Properties

Fructose is perceived to be sweeter relative to sucrose. β-D-fructose in solution has been rated with values from 100 to 175 compared to a sucrose sweetness value of 100. In the crystalline form, β-D-fructose was rated 180 relative to crystalline sucrose at 100. The most common theories of why some molecules vary in perceived sweetness is based on the hydrogen bonding and geometrical shape of the molecule. Intramolecular hydrogen bonding enhances sweetness, as well as intermolecular bonding with a receptor site that has a complementary configuration to the molecule to allow for efficient bonding. Typically, a proton donor site, designated as AH, is located approximately 0.3 nm from an electronegative site, designated as B. The fructose molecule meets these requirements to elicit the sweet taste. The AH is designated to be the anomeric hydroxyl group and B is designated as the oxygen atom of the primary alcohol group. A third site capable of hydrophobic bonding designated as γ is the methylene carbon atom.

The sweetness of fructose has been reported to decrease with time or age of the solution and is accounted for by mutarotational equilibrium with other forms which are not perceived as sweet. Increased temperature of the solution also depresses the sweetness value of a fructose solution: at the same time the specific rotation is increased and there is a shift in the equilibrium. The age and temperature of the solution may account for the reported differences of the sweetness of fructose when compared with sucrose, ranging from twice to one-third as sweet. The specific rotation of fructose increases with increasing concentration, although not as rapidly as with increased temperature. The relative sweetness of different concentrations is temperature–concentration-dependent. At lower temperatures, the relative sweetness of fructose decreases with increasing concentration but, at higher temperatures (37 °C), the relative sweetness increases. This reflects a complex dependence on the shift in equilibria, shift of forms, and other phenomena.

Sweetness is system-dependent, i.e., the perceived sweetness in a food or beverage system depends on several factors, including temperature, pH, solids content, and the presence of other sweeteners. Fructose exhibits a synergy with other sweeteners: the relative sweetness of 50/50 fructose–sucrose mixture is 128. Similar synergies occur when fructose is used in combination with aspartame, saccharin, and/or sucralose. This synergy allows for a formulator either to obtain higher degrees of sweetness in the finished product without increasing the total level of sweeteners, or to retain a satisfactory degree of sweetness while reducing the amount of sweeteners used and the cost. Either way, fructose both sweetens and improves the sweetness profile.

The sweetness intensity profile of fructose is different from those of sucrose and dextrose. The sweetness

of fructose is perceived earlier than that of sucrose or dextrose and the taste sensation reaches higher than sucrose and diminishes more quickly than sucrose. Because of this, use of fructose most often results in an enhancement of other flavors in the system. Many flavors such as fruit, some spices, and acids come through more clearly and distinctly after the fructose sweetness dissipates, because they are not masked by the lingering sweetness of sucrose. Thus, fructose may improve the flavor profile and possibly reduce cost for these flavors. (*See* **Sensory Evaluation**: Taste.)

Food Applications

Fructose is hygroscopic, which means it readily absorbs water from its environment. Fructose is an excellent humectant, in that it retains moisture for a long period of time at low relative humidity. This humectant can be used to impart improved eating quality, better texture, and longer shelf-life to the food products in which it is used. The use of fructose with other sugars can also help control unwanted crystallization.

Another property fructose imparts because of its relatively small molecular weight is depression of the freezing point of a food. Fructose will lower the freezing point more than will di- or oligosaccharides. In systems in which this may be undesirable, such as soft-serve or hard-frozen dairy desserts, care must be taken to balance the formulation with sugars of higher molecular weights (e.g., corn syrups) or to add the correct combinations of gums and stabilizers. In other products, however, freezing point depression can be used to an advantage. Depressing the freezing point of frozen fruit, for example, helps protect the integrity of the fruit pieces by reducing damaging ice crystal formation.

The presence of a reducing sugar, such as fructose, in a formulation facilitates color development via the classical Maillard browning reaction. Bakers depend on this reaction to give bread crust its distinctive brown color and to provide a baked color to microwaved products. The reducing property is also useful in maintaining the bright red color of tomato ketchup and strawberry preserves. The browning reaction can be controlled to some extent by manipulation of pH and/or time and temperature of processing and storage.

Fructose enhances starch functionality in food systems. Fructose causes viscosity to develop more quickly and the system to achieve a higher final viscosity compared to sucrose. In products that require the starch to cook, fructose will lower the temperature required to gelatinize the starch and ultimately cause a higher final viscosity to be developed.

The major applications of HFS are carbonated beverages and leavened bakery products. Bakers found that the HFS yielded a finished product identical to those sweetened with sucrose. The carbonated beverage industry is the largest user of HFS-42 and -55. The 42% fructose product is used primarily in noncola beverages, often acidified with an organic acid system that is easier to sweeten. Many cola systems, however, use phosphoric acid, which requires the higher sweetness of HFS-55 to give the correct flavor balance; alternatively, an increased amount of HFS-42 may also be used. The National Soft Drink Association has developed stringent guidelines for the improvement in quality of the syrup: color, taste, odor, floc, ash, fructose, other carbohydrate amounts, and microbiological standards. (*See* **Sweeteners**: Intensive.)

Flavor enhancement and a natural compatibility with fruit flavors are two reasons the fruit canning industry has become the third major user of HFS. HFS is frequently blended with liquid sugar and corn syrups to get the right balance of sweetness and fruit flavor. Corn syrups help add eye appeal to the fruit by imparting a shiny, glossy surface appearance when the fruit is served in a dish or tray. HFS-42 is used because of its compatibility with organic acid systems.

HFS is used extensively as a sweetener such as in dairy products like yogurt, chocolate milk, and icecream. Quality and economy are once more the primary reasons, in addition to improved flavor perception and rapid fermentability in yogurt, and mouth feel and viscosity in icecream and chocolate milk. The makers of jams, jellies, and preserves are also major users of HFS. High-solids systems can be formulated by using HFS and corn syrups without the storage problem of crystallization common to sucrose and dextrose. HFS enhances fruit flavors and stabilizes the color of these products throughout their storage life.

Crystalline fructose was positioned early as a nutritionally advantageous sweetener because of the way it is metabolized by the body. Therefore, many of the products first sold that contained crystallized fructose were those that went to diet and/or health-conscious consumers. These included various powdered diet beverages and meal supplements, nutritional candy bars, and other specialty food items. These applications were successful in introducing fructose to many consumers, but cost prevented it from being used as an ingredient in mainstream food products. The development of the technology for crystallization of fructose from HFS-90 led to the commercialization of fructose on a larger scale and at a lower cost than was previously possible.

Application areas for crystalline fructose now include dry-mix beverages, for which the intense sweetness of fructose allows for a reduction in total sweetener content and a parallel reduction in energy. Energy reduction, simple sugar reduction, and flavor profile enhancement are three popular formulation trends that fructose can favorably impact. Other applications that capitalize on the sweetener synergy to reduce energy include 'lite' pancake syrups and 'lite' carbonated beverages. The use of crystalline fructose and sucrose in these products can reduce the energy value by at least one-third, qualifying it for a reduced-energy label. Other application areas include breakfast cereals (flavor enhancement, sweetness synergy); yogurt, chocolate milk, and eggnog (flavor enhancement, energy reduction); baked goods (humectancy, starch synergy, flavor enhancement); fruit packs (flavor enhancement, storage stability); energy supplement in sports drinks (solubility, flavor enhancement, sweetness); and confections (sweetness, starch synergy, humectancy).

Food consumption surveys show an increase in fructose consumption: the ratio of fructose intake as a proportion of total sugars has increased by nearly 30% from the 1977–1978 and 1987–1988 Nationwide Food Consumption Surveys. High intakes of fructose have implications for gastrointestinal health, blood glucose control, and lipid metabolism. Fructose is primarily absorbed from the gut by facilitated diffusion. Persons vary in their abilities to absorb fructose – some experience symptoms of malabsorption with a 20- to 50-g load (a 12-oz (336-g) sweetened soda or fruit drink has between 14 and 22 g fructose; 8 oz apple juice has 14 g fructose). Some of the malabsorption of fructose-containing products may be the result of other nutritive sweeteners that are poorly absorbed (e.g., sugar alcohols in apple juice). Fructose is better absorbed when consumed in sucrose than in products where the amount of free fructose exceeds the amount of glucose (e.g., in honey, prunes, apples and juice, HFS, or crystalline fructose). Because of the method of absorption, fructose intake may lead to a slower rise in blood glucose than sucrose-based sweeteners. This fact, along with rapid clearance of fructose from blood serum, may improve glycemic control. High intakes of fructose could, theoretically, increase production of lipid precursors and increase the risk of hypertriglyceridemia. However, this effect is not consistently seen, even in those who are at high risk of elevated plasma triglycerides.

Only two rare inborn metabolic problems with the ingestion of fructose have been reported: essential fructosuria and fructose intolerance. In essential fructosuria, fructokinase is deficient and, with fructose intolerance, fructose-1-phosphate aldolase is deficient. In both cases, individuals should avoid foods containing fructose and sucrose. Other digestive problems have been reported in individuals who have an allergy to corn products since the primary source of fructose added to foods is HFS from corn.

Commercial and Dietary Importance

L G Smith and S M Somerset, Queensland Department of Primary Industries, Hamilton, Queensland, Australia

Commercial and Dietary Importance

Definition

'Temperate-climate fruits' refers to all fruits that normally grow further than 23.5° from the equator, but also includes avocado and citrus, fruits often classified as subtropical. Some temperate fruits can be grown at higher altitudes in tropical latitudes, although poor fruit set may occur in some species. 'Fruits' could be defined as seed-bearing plant organs that undergo a characteristic process, called ripening, changing from unpalatable to palatable (vegetables have no such sequence). Much of the information in this article is applicable to all fruits, and some tropical fruits are listed here for comparison. Horticultural products that could be classified as temperate fruits (such as many nuts and the tomato) are addressed in separate entries.

Production

Temperate fruit production is a major industry. The production and marketing of fresh fruits are much more labor-intensive than that of broadacre crops, so that the temperate fruit industry is a major source of employment. As a consequence of the high labor content of production, large-scale fruit production by major companies is tending to shift towards suitable regions with access to cheap labor.

The estimated world production of the major temperate fruits in listed in Table 1. The production for individual countries is shown in Table 2. For many temperate fruits, large quantities are processed in one form or another (e.g., canned, dried, wine, juice, glacé), and the production data in Tables 1 and 2 include that for processed fruit. The specific details of world fruit production are difficult to determine since, in many countries, fruit-production data are unavailable, and reporting countries also lack standards of uniform data presentation.

Grapes are the major temperate fruit in terms of tonnes produced, with large quantities going into wine and dried fruits. The major grape-producing countries are Italy, France, the USA, Spain, and countries of the former USSR. Second, in terms of quantity produced, are oranges, many of which are processed into juice, and third are apples, probably the temperate fruit most often eaten fresh, although large quantities are also juiced, dried, and canned. Buying patterns in British households for 12 common fruits are presented in Table 3.

Dietary Importance

There are many different aspects to fruit in the diet. Not only is fruit an important source of dietary fiber, carbohydrate, and vitamin C and A, but because of its flavor, it also influences the intake of many other foods and therefore can exert indirect effects on the diet. Although different fruits are morphologically and botanically diverse, in fruit consumption studies, the nutritional composition is generally considered collectively, rather than in terms of distinct fruits. It is therefore more appropriate to discuss the nutritional impact of fruits as a whole.

Historical

Man has been attracted to the sweet taste and full aroma of fruit since prehistoric times, and attempts by man to cultivate various fruits date back over 8000 years. It is not surprising then that the word 'fruit' is often used to imply a pleasure or reward (e.g., in expressions such as 'fruit of our labor'). Their sweet taste is due to the high content of sugars, in particular fructose, sucrose, and glucose. The high sugar content has been recognized for centuries and is exploited, for

example, in the drying of fruits, the high sugar content allowing their preservation and a water content sufficient to make the fruit palatable in the dried form. The production of alcohol from grapes and other fruits also depends on a high sugar content. Fruit consumption patterns now relate largely to consumer preferences. In the past, the traditional dietary role of temperate fruits was more of a luxury than a staple, but with the vast improvement of cultural practices, postharvest techniques and distribution systems, the availability of both fruit and fruit products has increased dramatically. Fruit is now more available, at an affordable price, to more of the world's population than ever before. The modern role of fruit in the diet has thus changed from previous generations.

The Modern Dietary Role

In the diets of peoples in temperate zones, the most important nutritional features are fruits of high contents of fiber, carbohydrate, and vitamin C, and low fat and protein contents. Fruit is prominent in the official dietary guidelines of many countries. Most developed countries encourage increased consumption of complex carbohydrates and fiber, which are abundant in fruits, and dietary recommendations in the UK and Germany specifically advise increased fruit consumption. One recent study in the USA found that 41% of the test population had no fruit or fruit juice on the day of survey. Substantial public health benefits might be gained if fruit consumption increased among the less affluent groups of people in the USA, and, probably, in other industrialized nations.

[a]Source AC Nielson 1998. From Hughes D (1999) Marketing fruit in Europe. In: *Good Fruit and Vegetables*, pp. 34–35. Melbourne: Rural Press, with permission.

Direct Nutritional Attributes

Fruit is generally high in dietary fiber and low in fats and oils, and is therefore an important food in diets designed to reduce the risk of coronary heart disease in developed countries. An exception is the avocado, which has an unusually high oil content (containing up to 30% fat, depending on the production area), but recent studies indicate a beneficial role of the avocado with respect to heart disease, possibly because 50–75% of the fat is monounsaturated.

One dietary feature of fruit in general is the high content of water, ranging from 65% in apples to 88% in papaya. This feature enables fruit to quench thirst in addition to satisfying hunger.

Vitamins

Ascorbic acid (vitamin C) is the principal vitamin supplied by fruit in the diet. Some fruit are particularly rich in this vitamin. Citrus have about 50 mg per 100 g, kiwi fruit about 100 mg per 100 g, and blackcurrants and bell peppers (*Capsicum annum*) have between 200 and 300 mg per 100 g.

The orange-colored fruits such as rockmelon, peach, persimmon, tomato, and apricot are rich in β-carotene, which is converted to vitamin A in the body. Certain fruits can be rich in particular vitamins. For example rockmelon strawberry and orange have significant amounts of folic acid. Pantothenic acid is found in appreciable quantities in watermelons currants and berries, and nicotinic acid in apricots, nectarines, peaches, passion fruit, and guavas.

Fiber

Fruit is a rich source of pectins and gums, components of fiber, and thus fruit constitutes an important source of dietary fiber. Pectins have been shown to delay gastric emptying, which can lead to favorable changes in glycemic responses to particular foods. Pectin may also introduce a satiety effect.

Indirect Nutritional Consequences

Fruit can be consumed in a number of different forms apart from fresh. The drying of fruit has been a popular preservation technique for many generations. The dehydration process concentrates those nutrients that are not heat- or light-labile. Vitamin C is the major casualty of this process. The dehydration process also decreases the water activity, thus increasing the keeping quality by making microbial growth less likely.

Processed fruit is being increasingly used in the dairy industry, as an additive in fermented milk products such as yogurt. This use of fruit has led to a wider acceptability of yogurt and has therefore influenced the intakes of certain nutrients such as calcium and milk protein. This also applies to fruit jams and conserves. Although these fruit products may not have a remarkable nutrient composition themselves, they can be used to improve the palatability of foods such as wholemeal bread, thus increasing the intake of nutrients such as grain fiber and the B-group vitamins. Fruit derivatives are also used in the confectionery-manufacturing industries.

Large quantities of fruit are used in the production of fruit juices. The physical processing to which fruit is subjected for juice production leads to a significant reduction in the content of ascorbic acid, but vitamin C is added to processed fruit juice, primarily as an antioxidant preservative, but also to increase consumer appeal. Fruit juice, either processed or fresh, is a significant source of vitamin C in many developed countries.

Pharmacological and Therapeutic Properties

Many therapeutic drugs in modern use originated as plant products. It is not surprising, then, that certain fruit components exert pharmacological or therapeutic effects. Limonin and nomilin and other liminoids are present in citrus such as orange, lemon, lime, and grapefruit. These compounds are believed to have a role in inhibiting the development of certain forms of cancer, and research has indicated that the antioxidant forms of β-carotene may also play a role in the prevention of some forms of cancer. Prunes (a variety of dried plums) contain hydroxyphenylostatin derivatives that stimulate colonic smooth muscle, thus explaining their traditional use as a laxative.

The effects of some pharmacological agents that occur in some fruits add to the importance of fruit in the diet.

Commercial importance

Production

The suitability of a region for commercial fruit production depends on a combination of climate, adequate water, suitable soils, and access to labor and markets. Climatically, the rainfall pattern is most important, as rain can cause major losses from foliar diseases, fruit splitting, and fruit disease, leading to direct losses or downgrading. Consequently, a dry summer climate with abundant good water for irrigation is ideal for fruit production since the water can be applied precisely as required.

In production areas with high labor costs, much research is directed towards methods of reducing the labor component of both production and postharvest procedures. Such research includes the use of new dwarfing rootstocks to reduce the cost of harvesting and tree management, planting parameters to facilitate machine pruning, trellising parameters to facilitate machine harvesting, tree shakers for fruit harvest, bulk methods for handling, netting for hail and pest control, and improved postharvest practice and facilities.

Varieties and propagation Nearly all major varieties of the major commercially important temperate fruit trees are clonally propagated (rather than grown from seed), either directly by cuttings or by grafting scion varieties on to rootstocks. The grafting process allows a productive variety (the scion) of good eating quality to combine with a different variety (the rootstock) that better resists endemic root diseases. An additional desirable trait of some (dwarfing) rootstocks can be a reduction of tree vigour (wasteful leaf and shoot growth) in the scion, using the incompatibility between rootstock and scion. New varieties introduced from other regions or countries need to be assessed for local suitability, since varieties that produce well in one geographic area often produce poorly in other areas. At rural horticultural research centers ('field stations') around the world, a substantial proportion of the work on all major commercial fruits is continually developing new and improved scions and rootstocks and assessing various rootstock–scion combinations. New varieties are selected from either superior bud mutations in existing varieties or, more commonly, concurrent breeding programs, considering fruit quality, crop yield, and freedom from disease. While some varieties have a long history of productive quality, there is a continual search for new varieties to improve both scion and rootstock performance. Many new varieties of many temperate fruits are now being developed purely to meet changing consumer demands rather than for production factors such as yield or disease resistance.

Some important fruits (e.g., certain apples, plums, cherries) require cross-pollination for adequate fruit set, and orchards of these fruits are interplanted with different varieties.

Fertilization Fruit tree production can require fewer applied fertilizers than broad-acre farming. The deeper roots have access to nutrients that are more abundant deeper in the soil. Calcium and potassium concentrations can also significantly affect fruit quality. Inadequately fertilized trees result in a poorer fruit set, smaller fruit size, and increased susceptibility to pests and disease. Potassium and phosphorus requirements are relatively low in fruit crops, but calcium and trace elements are usually of particular importance to prevent disorders occurring in fruit, although the trees show no other symptoms.

Preharvest pests and disease In most fruit crops, pests (e.g., insects) and disease (e.g., fungi) are major problems. Many commercially bred varieties would be unlikely to survive in nature without human intervention, as they have been selected primarily on the basis of fruit quality and yield, rather than on pest and disease resistance. In most production regions, strict quarantine regulations are enforced to preclude entry of new pests and diseases.

There has been a widespread and general acceptance of the need to greatly minimize chemical pesticides by all sectors of the community, including growers, and recent progress in more environmentally friendly pest control has been quite remarkable. Integrated pest management (IPM), the established approach to controlling preharvest pests, is an integration of chemical, biological physical, and procedural methods. IPM fosters effective populations of the natural predators of the pest species, allowing a well-monitored balance between pest and predator species. If and when the balance is significantly disturbed, a minimum number of carefully applied and precisely timed applications of chemical sprays are applied to keep pests or disease within acceptable limits. The use of insect pheromones that are harmless to humans is now common in controling many pests. These are used either as lures on to treated surfaces containing insecticides or in traps for destruction or by disrupting mating behavior. There still remains much to be done in pest and disease control, and this work constitutes a currently active arena for researchers from many disciplines.

Climacteric and nonclimacteric fruits All fruit are living organs and as such continue to live and respire

after harvest. Fruits such as apples, pears, avocados, tomatoes, and bananas can be harvested slightly immature but 'green' (unripe) without significantly reducing the final eating quality when they subsequently ripen. During this ripening process, complex polysaccharides, such as starch or pectins, hydrolyze to sugar resulting in an increase in sweetness and palatability. All climacteric fruits fall into this category. The fruit are called '*climacteric*' fruit because, concomitantly, their respiration rate develops a climacteric (peak) as they ripen.

Some other fruits such as citrus, cherries, strawberries, grapes, pineapples, and some melons do not get better to eat *after harvest*. Although these fruit may change color, they do not get better to eat the way that a mature but unripe tomato or mango will become notably palatable as ripening proceeds. Concomitantly, these fruit do not have a climacteric peak of respiration, that is, they are '*nonclimacteric*.'

The postharvest ripening nature of major fruits is shown in Table 1.

Fruit Maturity

On the tree or bush, an attached fruit undergoes the natural sequence, whereby it grows (develops), matures, and commences to ripen. During ripening, the fruit becomes attractive to eat: softening, changing colour, losing unpalatable off-flavors such as tannins, increasing in sweetness, becoming less acid, and developing attractive flavors.

When a fruit is 'mature,' it has reached the most appropriate state of development and is now ready for the next stage of its progress, which may be storage, processing, marketing, or ripening for immediate consumption. 'Under-mature' or 'immature' means that the fruit has not yet reached the state of development most appropriate for a particular destiny, being too hard for processing or too unpalatable if consumed. 'Over mature' means that the fruit has developed past the most suitable state of development, for storage, processing, or marketing. Such fruit may be too soft, too colored, or too prone to breakdown during subsequent storage or marketing. A few fruits (e.g., pears and some bananas) do not reach maximum eating quality if left to ripen on the tree, and in that sense, the fresh fruit could become 'overmature' for human consumption.

Normally, the commercial fruit is harvested somewhat before the ripening has commenced to avoid damage during transport, but most climacteric fruit will improve in eating quality and reach an acceptable quality, even if picked substantially immature. Maturity is thus independent of ripeness. Fruits can be immature but unripe, immature and ripe, mature but unripe, mature and ripe.

Nonclimacteric fruits show a dramatic increase in eating quality during the last several days before natural ripeness begins, but this process halts at harvest, and no increase in palatability occurs (or very little). The exact cause for this different response has not been fully determined. If nonclimacteric fruits are harvested even only a few days too early, they most often lack a full-bodied flavor and palatability. However, if left too late, such fruits can suffer greatly increased rots and breakdown during marketing. Hence, the harvest maturity for nonclimacteric fruits is crucial and is often determined using a refractometer to measure the 'soluble solids' (mainly sugar) concentration in the juice of sample fruits. This measurement, either alone (pineapples, strawberries) or in conjunction with titratable acidity measurements (grapes, citrus), is then used to judge the 'maturity' of the fruits.

The maturity of the fruits is generally most important when judging to harvest the first fruit of a district for the season. For avocados, maturity is commonly judged using percentage dry matter.

The maturity indices mentioned (soluble solids; percentage dry matter) are destructive in that the sampled fruit is damaged and usually cannot be marketed. Considerable effort has been applied to develop nondestructive indices of fruit maturity, in particular NIR (near infra-red spectroscopy). This has been quite successfully used in some thin-skinned fruits (stonefruit) where a reflected infrared beam is automatically scanned and analyzed for sugar content. For other fruits such as citrus or pineapple, the thick skins currently pose an obstacle to accurate analysis using NIR. Methods of overcoming this and other problems for different fruits are currently being developed.

Harvesting, Handling, and Packaging

Harvesting constitutes a major production cost. Mechanical harvesting is increasingly used in developed countries, and often where suitable equipment is not currently applicable (e.g., pineapples, melons), research is in progress. Fruits destined for processing are often mechanically harvested because the fruit are processed rapidly before disease can develop from bruised fruits, and partially damaged fruits can be trimmed for processing.

Commercial fruit production in developed countries is often large scale and highly capital-intensive, with sophisticated and specialist equipment used for all processes, including unloading, washing, sorting, treating, size-grading, packing, cooling, handling,

and transporting. Computer tracking and monitoring are essential components.

Disinfestation and Phytosanitation

Insect pests are generally only of minor importance on fruit for domestic consumption but are a very serious issue on produce for export. Most importing countries have strict regulations (phytosanitary) for fresh fruit. Many previous chemical dips or fumigants for pests such as fruit fly have now been proscribed on human health or environmental grounds. In many instances, there are no acceptable treatments available. Nonresidual treatments have been intensively studied, with increasing success. Heat disinfestation (formerly termed vapor heat) is the controlled application of hot humidified air between 40 and 60 °C and between 80 and 100% RH to fruit in a chamber for a sufficient length of time to heat the innermost fruits and fruit core thoroughly to kill the pests without unacceptably damaging the fruit. The time–temperature 'window' for a treatment is very small before damage occurs, and many fruits, or fruits from some growing areas, are unacceptably injured by the disinfestation treatment. Recent research has revealed that 'preconditioning,' a pretreatment temperature regimen, is effective in ameliorating damage in otherwise susceptible fruit. Heat disinfestation is currently commercially used on papaya, lychees and mangoes, but current and ongoing research is very active, endeavoring to find suitable treatments for many other fruits. In some instances, it has been found that heat treatments can greatly reduce postharvest disease and thus improve the market quality.

Postharvest Aspects of Fresh-market Fruit

Fruits are highly perishable but can be marketed vast distances from the site of production with the application of sound postharvest techniques such as appropriate disease treatment; storage-temperature management, humidity control, controlled atmospheres, correct packaging and palletizing, ventilation, and transport carefulness and timely distribution. Small changes in preharvest conditions, harvest maturity, postharvest handling, storage conditions, new varieties, farm practices, or season can have dramatic affects on product quality. With large-scale handling methods, large-scale losses are a constant hazard to novice and experienced handler alike.

Storage temperature and humidity Correct temperature maintenance is the most important factor during marketing, as deterioration from both disease and ripening increases logarithmically with temperature. Fruits generally suffer from disorders if stored for too long or ripened at too low temperatures (the pear is a notable exception). Such disorders include off-flavors, breakdown, mealiness, flesh and skin browning, skin pitting, and increased susceptibility to disease. For example, peaches and nectarines suffer textural dryness (become 'woolly'), whereas avocados develop off-flavors if stored for too long below 13 °C. If tomatoes have been stored for too long at 10 °C or lower, they develop skin diseases from organisms that do not normally infect the fruit ('saprophytic' infections). For most fruits, the optimum ripening temperature is 20–22 °C. Conversely, some fruits can now be stored at lower temperatures than previously believed (and have a longer marketing life) provided that they are removed from cold storage before ripening commences. Recommended storage temperatures and maximum storage times are shown in Table 1.

Different cultivars, different production areas and different seasons can radically affect the tolerance to cold temperatures. Compared with tropical fruits, many temperate fruits can be held at much lower temperatures without any adverse affects, and a few can have relatively long storage lives. Apples can be stored for up to 12 months, citrus for up to 16 weeks, but stone fruit only 2–4 weeks and strawberries only 3–8 days.

Fruit Ripening and Respiration

Harvested fruits, being living tissue, respire during their postharvest life, taking up oxygen, 'burning' sugars, and giving out both carbon dioxide and heat at a rate directly proportional to the ambient temperature. When fruit is stacked, stored, or transported, sufficient refrigeration capacity is required to cope with any climacteric (peak) respiratory heat load that is autocatalytic. If not controlled, total breakdown can occur. Certain fruits (e.g., strawberries, peaches), have high rates of respiration and hence need special attention to cooling, but generally, all fruits destined for distant marketing need some refrigeration. Warm fruit that are not promptly cooled have a reduced market life, and runaway deterioration is a risk. In stacked produce, the cardboard cartons act as insulating containers, preventing cooling. Forcing air through such stacked trays or boxes ('forced-air cooling') is widely used in warm climates to rapidly remove field heat after harvest or prior to transport, reducing the respiration rate and consequently the rate of the heat production.

During ripening, many fruits produce ethylene gas, a potent plant hormone that initiates and catalyzes the commencement of ripening. Ethylene production in fruit follows a similar climacteric production to

respiration, but some fruit produce much higher ethylene levels than others. Table 1 shows the production rates for the different fruits. Ethylene from fruit can trigger senescent changes such as yellowing or withering in vegetables or flowers, or ripening in adjacent fruits. For this reason, during transport, fruits that produce substantial amounts of ethylene are sometimes isolated. Alternatively, ethylene in store room atmospheres is sometimes destroyed with ozone from special generators, or absorbed, using porous alumina beads impregnated with potassium permanganate and used as small disposable sachets in fruit cartons.

Effects of fertilizers on fruit quality and superior taste Whilst soil mineral composition and/or applied fertilizers have major affects on tree vigour and fruit yield, fruit quality is much less directly affected. The perceived 'sweetness' or 'flavor' of superior fruits depends on a three-way balance between the concentrations of sugar, acid, and flavor components. In an orchard, the concentration of sugar per fruit, generally an index of the superior taste, can vary from plant to plant or season to season. Sweetness usually decreases proportionally with increasing fruit mass per unit leaf area per plant. In general, for any particular variety, the flavor components depend on fruit maturity, the sugar concentration depends on ambient light intensity and leaf area, and acid concentration depends on ambient temperatures. The flesh color of some fruits at least (e.g., citrus) depends on day/night temperatures.

Deficiencies of some elements such as calcium, boron, and molybdenum affect shape, internal and external blemishes and storage disorders in some fruits more than others. A high calcium/potassium ratio in apples is used as an index of storage quality as it reduces softening during storage. In citrus fruits, applying extra potassium increases acidity, sometimes seen as a desirable factor. Applied nitrogen encourages leaf growth and photosynthetic efficiency, which can result in more sugars, thus giving sweeter fruit. In general, prevailing weather, applied water, pests, and diseases have a much greater influence on fruit quality than do mineral nutrition or applied fertilizer.

Globalization and the Future of Horticultural Research

Increased economic globalization over recent times has brought about a major decline of both economic viability and research support within horticulture in first-world countries. Third-world countries are becoming the heirs to the resources as their research institutions have often been fostered with using aid from first-world countries. During this same period, large numbers of horticultural research workers in first-world research systems have steadily been not replaced, while third world horticulture and horticultural research has dramatically expanded. The problem of the deinstitutionalization of the horticultural knowledge base in first world countries is now a serious challenge as career researchers are replaced with casual workers, and the institutional structure is eroded away. Concurrently, domestic horticultural production in first-world countries is being forced to compete with produce from third-world regions. The whole issue is contentious and politically challenging, and a situation that has steadily deteriorated for many years without any clear vision of resolution.

Fruits of the Ericacae

J F Hancock and R M Beaudry, Michigan State University, East Lansing, MI, USA
J J Luby, University of Minnesota, St. Paul, MN, USA

Global Distribution

The family Ericaceae is perhaps best known around the world for its showy garden members such as rhododendrons and heathers. However, some 13 genera contain species with fleshy berries, which are consumed locally in many parts of the world (Table 1). The fruits of these species are commonly eaten fresh or sometimes dried. Many are processed into preserves, juice, or wine.

Vaccinium is the most important genus in terms of fruit production. The majority of species inhabit open mountain slopes in the tropics, with the balance being distributed in subtropical, temperate, and boreal regions of the northern hemisphere. Plants of *Vaccinium* vary in form from epiphytes to trailing vines to trees, with the majority being terrestrial shrubs. Some form crowns, whereas others produce new aerial shoots from rhizomes. Flowers may be solitary or in racemes or clusters.

Commercial Importance

Commercial fruit production is mainly from species of section Cyanococcus (cluster-fruited blueberries), including cultivars of *V. corymbosum* L. (highbush blueberry) and *V. ashei* Reade (rabbiteye blueberry) and native stands of *V. angustifolium* Ait. and *V. myrtilloides* Michx. (lowbush blueberries). *Vaccinium macrocarpon* Ait. (large cranberry), a member of section Oxycoccus, is also an important domesticated fruit, although most of the cultivars were selected from the wild. *Vaccinium myrtillus* L. (bilberry, whortleberry), in section Myrtillus, is collected exclusively from the wild. *Vaccinium vitis-idaea* L. (lingonberry, mountain cranberry or cowberry), in section Vitis-idaea, is also collected predominantly from the wild, although it has recently been domesticated.

The highbush blueberry is by far the most important commercial crop, producing over 95 000 t of fruit annually on over 20 000 ha. Highbush production occurs in 36 states in the USA, in six Canadian provinces, and in Europe, Australia, and New Zealand. Highbush plants have recently been established in South American countries, especially Chile. The largest acreages are in Michigan, New Jersey, and North Carolina in the USA, and British Columbia in Canada. Interest is growing in California. Half-high types (*V. corymbosum* × *V. angustifolium*) have made an impact in Minnesota and regions too cold to successfully grow pure highbush.

The commercial production of rabbiteye blueberries is largely confined to southeastern USA, centered in Georgia, and extending from North Carolina to Texas. The estimated area in production in the USA is over 3000 ha with approximately half of this in Georgia. The total annual production is over 5500 t. There is also interest in growing rabbiteye blueberries in warm temperate and subtropical regions of the world, such as southern African and South American countries.
