specific foods and using these to calculate metabolizable energy intake. This method has the advantage that macronutrient digestibility is measured directly for specific foods and multiplied by the specific heats of combustion when available. In this method, the calculated digestible energies of the diets are close to the measured values for mixed diets since the final value reflects the sum of the individual components. This method has some problems. In the system of Merrill and Watt, the digestibility of carbohydrates was determined by difference, so accurate values for carbohydrate digestibility are lacking. This also means that a digestibility value for the fermentable food component portion of the carbohydrate fraction (as determined by difference) is lacking. It is, therefore, not possible to calculate the metabolic energy of a food of known composition since values for undigested and fermented components are not available. This limits the usefulness of this system to foods that have been measured. In addition to this problem, the NME value is appropriate for undigested and fermented food components, whereas the digestible energy value is not. Thus, this system does not allow any correction for energy lost when food components are resistant to digestion but fermented in the lower gut.

The second solution is to use an average digestibility value determined by examining typical mixed diets. This can be calculated by two separate methods: using a factorial approach or using an empirical model. Factorial models relate total protein, fat, carbohydrate, and dietary fiber intake to digestible energy through an equation of the type:

$$\begin{aligned}\text{ME (kca)} = {} & 4.0 \times \text{protein (g)} + 9.0 \times \text{fat (g)} + 3.75 \\ & \times \text{carbohydrate (g)} + \text{NME}_{\text{DF}} \\ & \times \text{dietary fiber (g)}. \end{aligned} \quad (19)$$

In the development of eqn (19), carbohydrate was determined directly (not determined by difference) and is expressed as monomeric units. Dietary fiber must also be measured directly through an approved, reproducible method that is not affected by food processing (*See* Dietary Fiber: Determination). The factors 4 (protein) and 9 (fat) are the general Atwater factors derived from mixed diets. The value of 3.75 for carbohydrate is slightly lower than the general Atwater factor of 4. This reflects the fact that the carbohydrate is expressed as the total monomeric weight.

The value of NME_{DF} (the NME for dietary fiber) comes from an analysis of the dietary fiber digestibility of mixed diets and the loss of energy to feces in mixed Western diets. This value is determined as follows. Firstly, the DE_{part} value for dietary fiber is obtained by comparing the digestible energies of mixed diets to the metabolizable energy calculated by eqn (19). The apparent digestible and metabolizable energies for carbohydrate and fat are identical since the macronutrient digestibilities were accounted for, and urine and gaseous losses of these components were negligible. Protein losses are corrected for urine nitrogen and protein digestibilities. The digestible energy for dietary fibre (DE dietary fiber) was estimated by:

$$\begin{aligned}\text{DE dietary fiber} &= \Delta H_{\text{c}} \times D_{\text{app}} \times (1 - a) \\ &= 4.1\ \text{kcal g}^{-1} \times 0.7 \times 0.7 \\ &= 2.0\ \text{kcal g}^{-1} (8.4\ \text{kJ g}^{-1}). \end{aligned} \quad (20)$$

The apparent digestibility of dietary fiber is around 0.7. The value of factor a in eqn (20) needs to be defined for dietary fiber. For sugar alcohols, the value is approximately 0.2 (see above). A value of 0.3 has been adopted for dietary fibers in humans. This value reflects the fact that the majority of energy loss estimates lie between 0.2 and 0.4 kcal per kcal of fermented energy. As already mentioned, a value of 0.2 was obtained when measuring lactitol energy utilization in human subjects. It has also been suggested that between 20 and 30% of the energy in undigested and fermented carbohydrates is utilized by bacteria in humans. A value of 0.2 kcal per kcal of fermented material has been measured in rats fed an α-amylase-resistant pea starch and a value of 0.4 kcal per kcal of fermented material has been measured in rats fed guar gum. In human diets with high intakes of dietary fiber, an increased fecal energy output of 0.3 and 0.39 kcal per kcal of energy fermented, respectively, has been measured. Overall, these data suggest that about 0.3 kcal of energy is lost to the feces per kcal of energy fermented. Thus, $1.0 - 0.3 = 0.7\ \text{kcal kcal}^{-1}$ is retained.

As indicated above, the digestible energy value does not give an accurate picture of the energy losses that occur during fermentation of undigested food components. Correction factors must be included for energy losses to the heat of fermentation (factor b), losses to fermentation gases (factor c), and the relative efficiency of utilization of short-chain fatty acids (factor d). Correcting the digestible energy for these values gives:

$$\begin{aligned}\text{NME}_{\text{DF}} = \Delta H_{\text{c}} \times D_{\text{app}} \times 0.54 &= 4.1\ \text{kcal g}^{-1} \\ \times 0.7 \times 0.54 &= 1.5\ \text{kcal g}^{-1}. \end{aligned} \quad (21)$$

Eqn (21) shows that the NME value for dietary fiber is approximately $1.5\ \text{kcal g}^{-1}$. Eqn (21) applies strictly to dietary fiber because the ΔH_{c} value and digestibilities were determined for dietary fiber. It is useful for

calculating the metabolic energy values of mixed diets because the digestibilities were determined for mixed diets. It is comparable, therefore, with the general Atwater factors of 4, 9, and 4 for carbohydrate, fat, and protein.

Empirical models represent another method for determining total energy intake. Empirical models are, in general, superior to the factorial models for a number of reasons, the most important being that the empirical models are much more robust to errors in carbohydrate, fat, and protein determinations as well as to the use of general Atwater factors. An example of an empirical equation is as follows:

$$\begin{aligned}\text{ME} = {} & 0.96 \times \text{total energy (kcal)} - 2.5\,\text{kcal g}^{-1} \\ & \times \text{dietary fiber (g)} - 12\,\text{kcal g}^{-1} \\ & \times \text{ingested nitrogen (g)}. \end{aligned} \quad (22)$$

Eqn (22) relates the metabolizable energy to total energy, protein, and dietary fiber only. The factor 0.96 represents the metabolizability of mixed diets in the absence of dietary fiber. The value of 2.5 kcal g^{-1} represents the NME energy loss associated with ingestion of dietary fiber. This value is, therefore the difference between the heat of combustion of dietary fiber and its NME_{DF} value (determined above):

$$\begin{aligned}2.5\,\text{kcal g}^{-1} = {} & \Delta H_{\text{c}} - \text{NME}_{\text{DF}} = 4.0\,\text{kcal g}^{-1} \\ & - 1.5\,\text{kcal g}^{-1}. \end{aligned} \quad (23)$$

A version of Eqn (22) was tested for bias and accuracy of prediction by comparison with 43 human diets containing varied intakes and sources of dietary fiber. The equation showed no bias over a wide range of dietary fibre intake (2–93 g daily). By necessity, this test was performed by comparing DE_{part} values because ME_{part} values cannot be measured directly for fermentable food components. This analysis provides further evidence for a general NME for dietary fiber of 1.5 kcal g^{-1}.

Overall Conclusion

Eating food components that are not digestible but that are fermentable lowers the amount of metabolizable and digestible energy available from food. This occurs because of two different processes. Fermentable food components, like dietary fiber, are not 100% fermentable, and so the NME for these components is lower than that of protein, carbohydrate, and fat. In addition, fermentation itself is associated with many different energy losses, including losses to increased bacterial mass, the heat of fermentation, fermentation gasses, as well as a lower efficiency of host utilization of short-chain fatty acids. Because the digestion of fermentable food components is so different from that of macronutrients, special equations are needed to determine the net metabolizable energy yield.

It is possible to utilize data from several sources to obtain an estimate of the relative losses that occur during fermentative digestion and back-correct to obtain an unbiased estimate of the energy value of dietary fiber. Taking into account all these energy losses, a NME value for dietary fiber of 1.5 kcal g^{-1} (6.3 kJ g^{-1}) has been calculated. This appears to accurately predict energy losses associated with mixed Western diets when analyzed using either factorial or empirical models. Thus, the NME of 1.5 kcal g^{-1} (6.3 kJ g^{-1}) can be used in a fashion similar to the general Atwater factors of 4, 9, and 4 for protein, fat, and carbohydrate to predict the metabolizable energy of mixed Western diets. Individually measured NME values for fiber in whole foods may differ from this value since dietary fiber is fermented to different extents and is intimately associated with the food matrix, which may limit macronutrient digestibility. Thus, individual measurements are needed for direct comparison and may be required for specific types of foods.

DIETARY REFERENCE VALUES

J Pollard, University of Leeds, Leeds, UK

Background to the Dietary Recommendations in the UK

The need to quantify aspects of the nations' diet has occupied scientists for many years. When one considers that an adult eats about one tonne of food each year, it is easy to see why nutrition has become such a public health issue. The food we eat should provide all the nutrients we need, yet in some countries, we have an excess of food and in others insufficient. In fact, it is only relatively recently in evolutionary terms that we have the variety of food in this country available today. For example, as recently as the 1930s, it was estimated that up to one-third of households in Britain could not afford an adequate diet. It is in this context that dietary recommendations were first developed, to ensure that people were able to consume an adequate diet. During the war years, recommendations were developed with the objective of providing enough food to enable a work force to achieve and maintain its productivity. However, as the science of nutrition has developed, and the publics' awareness and understanding has increased, the objectives have changed again towards one of maintaining health. The recommended dietary intakes (RDIs) were published in 1969 and were defined as 'the amount sufficient, or more than sufficient, for the nutritional needs of practically all healthy persons in a population.' These recommendations were subsequently replaced by the recommended daily amounts (RDAs). These were published in 1979, and were defined as 'the average amount of the nutrient, which should be provided per head in a group of people if the needs of practically all members of the group are to be met.' Both of these definitions attempt to make it clear that the standards are for use in population estimates only.

In other words, consumption of nutrients at the level set would be more than adequate for most people. The problem with both these sets of recommendations was that they were misused. People using the standards did not understand the proposed use, how they had been derived, or how accurate they were intended to be. People widely interpreted these standards as minimum amounts of nutrients that everyone had to consume, rather than amounts that would prove adequate for the majority. With this, then, comes the interpretation that more is better, leading to potential overdosing of some vitamins and minerals. Most of the confusion in using the standards lies in the difference between the terms 'recommendations' and 'requirements.' People who did not understand the previous standards used them to assess requirements. A requirement is the amount of a particular nutrient that an individual must consume in order to avoid deficiency. Deficiency may be defined by clinical, physiological, biochemical, or sociological criteria, and each of these may give different values at an individual level for nutrient intake needs. Requirements will differ from individual to individual. What the standards actually give us are recommendations, that is the amount of a nutrient judged to be the appropriate amount to maintain health in virtually all individuals in that group.

In 1987, the Committee on Medical Aspects of Food Policy (COMA) convened a Panel to review the 1979 RDAs. The result of this was the new recommendations, published in 1991, and entitled Dietary Reference Values for Food Energy and Nutrients for the United Kingdom. These new recommendations attempted to clarify the confusion in the usage of the previous recommendations and covered more nutrients, particularly the macronutrients, than the previous reports. The Report also took the objective of maintaining health one step further to try and provide an 'optimal diet'. An optimal diet can be defined as one which 'maximises health and longevity and therefore, prevents nutrient deficiencies, reduces risks of diet-related chronic diseases, and is composed of foods that are safe and palatable'.

Dietary Reference Values – Definition and Derivation

The term 'dietary reference values' (DRVs) refers to a number of different parameters that describe the distribution of the requirements for a particular nutrient found within a population. When one considers that people differ from one another in the amounts of nutrients they need, it would be impossible to represent these differences with just one value, as the previous standards attempted to do. Therefore, when COMA designed the DRVs, they came up with a range of values for each nutrient to represent the differing needs of the population.

The Panel used different criteria for the assessment of nutritional adequacy for individual nutrients, depending on what information was available and on the physiological effects of different nutrients. Evidence came from observational studies of healthy populations, clinical studies of deficiency symptoms, balance studies, or functional tests of a nutrient. The Panel identified a key functional parameter for each nutrient that was considered to be essential for healthy life. That functional parameter was then used to measure the range of needs for that nutrient within a community. Functional parameters used for each nutrient are shown in Table 1. The DRVs are derived from a statistical association describing the variation around the average seen when making measurements of a large number of people. As there is little evidence on the distribution of requirements in a population, the Panel made the assumption that they are normally distributed in almost all cases. Hence, the average requirement for each nutrient was calculated, and the upper and lower limits of its distribution could be estimated. The DRVs are based on this distribution, as shown in Figure 1.

The average amount of a nutrient required is called the estimated average requirement (EAR). The range of normal consumption is taken as the EAR plus or minus two notional standard deviations. The EAR plus two standard deviations is called the reference nutrient intake (RNI) and is defined as "an amount of a nutrient that is enough for almost every individual, even someone who has high needs." This is the equivalent of the old RDAs. The EAR minus two standard deviations is the lower reference nutrient intake (LRNI) and is defined as "the amount of a nutrient that is enough for only the small number of people with low needs." Statistically, we know that the RNI indicates the amount of a nutrient sufficient to meet the needs of up to 97.5% of the population. Similarly, we known that only about 2.5% of the population will have needs lower than the LRNI. So, the requirements of about 95% of the population will lie between the LRNI and the RNI. It should be pointed out that the EAR is not a recommended intake for an individual. It is the estimated average requirement of a nutrient throughout a large group of people: some will need more than this, and some will need less.

For some nutrients, a reference value called the 'safe intake' was assigned. This term was used if there was not enough information to ascertain requirements. This intake level was one that was judged by the COMA Panel to be adequate for almost everyone's needs but not so large as to cause undesirable effects.

Table 1 Functional parameters used by the COMA panel to assess DRVs

Nutrient	*Functional parameter*
Energy	Energy expenditure
Essential fatty acids	Prevention of essential fatty acid deficiency
Fat	Changes from current intakes that would be expected to result in specific changes in physiological and/or health outcomes, particularly in relation to coronary heart disease
Nonstarch Polysaccharides	Healthy bowel function and stool weight
Nonmilk extrinsic sugars	Effect on dental caries
Protein	Nitrogen balance
Vitamin A	Adequate body pool size, based on the amount of vitamin A in the liver
Vitamin B_1 (thiamin)	Urinary thiamin output, thiamin loading, glucose loading, and transketolase activation
Vitamin B_2 (riboflavin)	Measurement of urinary and red cell riboflavin; the determination of erythrocyte glutathione reductase activation coefficient – a measure of riboflavin tissue saturation and long-term riboflavin status
Niacin	Observational requirements to prevent or cure pellagra
Vitamin B_6	Estimates of body pool size and blood vitamin B_6 levels in depletion and repletion of adults on controlled diets
Vitamin B_{12}	Serum vitamin B_{12} levels
Folate	Serum levels, red cell folate, and liver reserves
Vitamin C	Plasma ascorbate levels and prevention of scurvy
Calcium	Growth, calcium retention, urinary excretion, and absorption
Magnesium	Magnesium balance
Phosphorus	1 mmol P: 1 mmol Ca
Sodium	Sodium balance and balance of risks and benefits that might practically be expected to occur, given the prevailing sociocultural environment
Potassium	Amount needed for growth plus losses (fecal, urinary, via skin and hair)
Iron	Estimated gut absorption and losses
Zinc	Systemic needs plus losses (fecal, urinary, skin, hair, semen, and menstruation) and absorption
Copper	Balance studies
Selenium	Glutathione peroxidase activity
Iodine	Prevention of deficiency symptoms of goiter

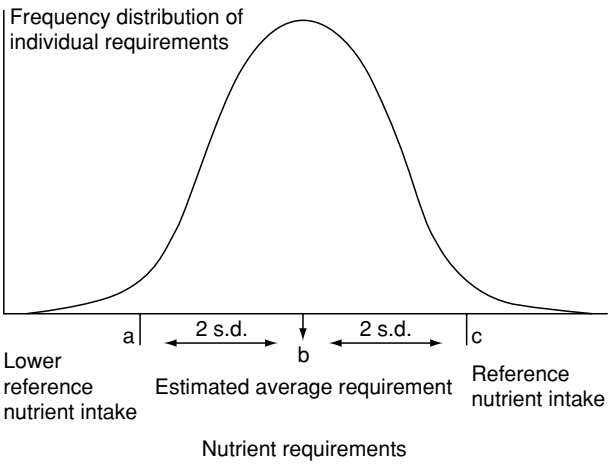

Figure 1 Dietary reference values – definition. From Department of Health (1991) *Report on Health and Social Subjects 41. Dietary Reference Values for Food Energy and Nutrients for the United Kingdom*. London: HMSO, with permission.

Energy, Protein, Vitamins, and Minerals

The RNI is designed to be adequate to meet the needs of most individuals in a population, even those with high needs. If a person with low needs consumed the RNI for most nutrients, this excess would not be harmful, but this is not the case with energy. If someone with low energy needs consumed excess, this would lead to an undesirable weight gain. Therefore, the Panel set energy standards at the average need, knowing that some people will need more and some will need less.

Safe intakes were set for pantothenic acid, biotin, vitamin E, vitamin K, molybdenum, manganese, chromium, and fluoride, as insufficient evidence was available for DRVs.

Fats, Carbohydrate and Nonstarch Polysaccharides (NSP)

As there are no specific deficiency signs or symptoms for fats and carbohydrates, and no absolute requirement for any of these individually, population averages have been derived from the likely effects that changes in their average consumption could be expected to have on certain health outcomes. These are given in the Report as percentages of the EAR for energy that they should, on average, provide. No ranges around the EAR are given.

The DRVs for NSP are based on an estimated desirable average intake, and the expected range of individual intakes around that figure.

Dietary Reference Values – Uses, Limitations, and Assumptions

The DRVs set out to reduce confusion over use, and in order to do this, they deliberately used the term 'reference' in the title to try and convey the message that these were not individual recommendations but a point of reference only. The main proposed uses of the DRVs were for food planners, health policy personnel, and the food industry, although many other people may wish to refer to the reference values.

Assessing the Diet of Individuals

DRVs, as with previous standards, are not designed for assessment of individual diets. It is not possible to know an individuals' requirement for a particular nutrient without measuring the functional parameter for that nutrient. However, the DRVs, unlike the previous standards, can tell us something about the likely adequacy of an individuals nutrient intake. If a person's consumption of a particular nutrient is somewhere between the LRNI and the RNI, it would not be possible for us to say whether or not that persons diet is adequate, as we do not know whether that person has a low, medium or high requirement. However, what we do know is that if an individual's consumption is above the RNI, they are likely to be meeting their needs, but the closer consumption gets to the LRNI, the more likely it is that that person is not meeting their needs. If a person is routinely consuming amounts of a nutrient less than the LRNI, they are likely to be deficient, but functional tests would be required to confirm this. DRVs can only give us an indication of nutritional adequacy in an individual, and great care needs to be taken when using them in this manner.

Assessing the Diet of Groups of People

When assessing the adequacy of diet in groups of people, the RNI should be used where possible to ensure that the risk of any deficiency in the group is small. When assessing the adequacy of the diet of a group of people, some assumptions have to be made. These are that the distribution of intakes in the group is identical to the distribution of requirements and that the people in the group with the highest requirements are generally those with the highest intakes, also that the measured diet is typical of habitual intake. Because of these assumptions, we are unable to say with certainty that intakes below the LRNI are inadequate, and, as with assessing the diets of individuals, measurement of functional parameters is required to identify deficiencies.

Planning Food Supplies

When planning food supplies, it is necessary to ensure that everyone (even those people with high requirements) obtains enough of every nutrient. Therefore, the RNI should be used as a reference point. Even though some people will be receiving in excess of their requirements, the risk of deficiency will be minimal.

Nutrition Labeling

The nutrition information appearing on a food label is used by individuals, and it would be inappropriate therefore to use the RNI as a reference level. If the RNI appeared on food packaging, many people might try and consume that level of the nutrient, even though they might have much lower requirements. Although this may not be harmful, it may be expensive and perhaps wasteful. Therefore, the EAR is used as a reference in nutrition labeling, and the amount of a nutrient in a product is expressed as a percentage of the EAR. However, this still needs some interpretation and is potentially misleading, as some people will still need more than the EAR and some less.

Identifying 'At Risk' Subgroups

By using the LRNI as a reference value, 'at risk' groups in the population may be identified. If people are routinely consuming less than the LRNI, they are likely to be 'at risk' of deficiency. These people then can be examined and their nutritional status assessed using the appropriate functional parameter.

There are numerous assumptions that have to be made, and therefore limitations to using DRVs. When deriving the DRVs, the COMA Panel emphasized that there was insufficient information to be able to set the RNI, EAR, and LRNI for most nutrients with any great confidence. The Panel stressed that some of the functional parameters used were far from ideal and emphasized the need for further research.

The DRVs only apply to healthy people and may not be appropriate for use with some clinical conditions or those with special requirements. DRVs are also not appropriate for use in planning nutritional requirements for intravenous therapy. It also needs to be taken into consideration that the requirement for a particular nutrient is dependent on the composition of the diet as a whole, as the presence or absence of other dietary constituents can affect the absorption and utilization of some nutrients. The DRVs for one particular nutrient therefore assume that DRVs are also being met for all other nutrients and energy.

Ultimately, the value of the DRVs when used as a frame of reference will also be affected by the quality of the intake data against which they are to be compared. The DRVs indicate how the amounts of

different nutrients should average out over time. It is not necessary for an individual to be consuming these amounts of every nutrient at every meal, or even on a daily basis. Therefore, when collecting dietary data for comparison with DRVs, the data should reflect long-term habitual intakes, whether in the individual or at the community level.

In conclusion, the DRVs are a major advance in the use of reference nutrient levels in the science of human nutrition. They build on the old methods whilst expanding the uses and relevance of recommendations. It is still necessary for people to be aware of the derivation and limitations of the DRVs, but they do go some way towards reducing the potential misuse and abuse of these values.

DIETARY REQUIREMENTS OF ADULTS

J Dwyer, Jean Mayer US Department of Agriculture, Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA

History and Current Status

Nutrients are substances that are not synthesized in the body in sufficient amounts to perform critical functions such as growth, reproduction, or health maintenance and therefore they are required from the diet.

Although humans have known since ancient times that they must eat to live, only recently has it been possible to specify the chemicals and amounts involved with certainty. The rise of this knowledge has led to the growth of nutrition as a science. In the nineteenth and early twentieth centuries, the concepts of energy metabolism and essential nutrients were formulated, and techniques for quantifying nutrient requirements were developed. Experimental and observational work determined the amounts of nutrients required to prevent frank dietary deficiency disease. During the middle and later twentieth century, attention turned to nutrient functions associated with chronic degenerative diseases and additional roles for nutrients. This chapter describes the recent work on dietary requirements as they have been formulated by the Health Canada/Food and Nutrition Board, National Academy of Sciences in the USA in the dietary reference intakes. These deliberations and parallel efforts by expert groups of the World Health Organization/Food and Agricultural Organization of the United Nations and many national or regional governments occupied most of the 1990s. They will conclude early in the twenty-first century.

The landmark Dietary Reference Intake project arose because much new work on nutrient needs, the balance and interactions between nutrients, and the development of chronic degenerative diseases had become available by the early 1990s. New techniques for evaluating the biological functions of nutrients were present. In addition, many nonnutrients in food with biological activities of health significance were being described. The need for upgrading data on the validity and reliability of existing dietary standards was evident. Moreover, new statistical techniques for adjusting nutrient intake data for assessment and planning purposes had recently become available, and these needed to be integrated into existing concepts. Finally, it had become apparent that, in the past, some uses of dietary requirements and nutrient standards had been inappropriate, and new guidance was needed.

Estimates of nutrient requirements are now well delineated for healthy adults, but they are still not so for special groups, such as very premature infants, the very old, and the ill. This remains a challenge for the future.

What Nutrients are Required?

All human beings require the energy-providing nutrients (amino acids, fatty acids and fat, glucose, and other carbohydrates), vitamins, minerals, and water. The specific essential nutrients include organic compounds such as nine essential amino acids (leucine, isoleucine, histidine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine). Cystine, which can replace some of the methionine requirement, and tyrosine, which can replace some of the phenylalanine requirement, are also sometimes considered to be essential. Taurine is thought to be essential in premature infants. There are two essential fatty acids (linoleic and arachadonic), four fat-soluble vitamins (A, D, E, and K), and 10 water-soluble vitamins (niacin, thiamin, riboflavin, folate, vitamin B_6, vitamin B_{12}, biotin, pantothenic acid, ascorbic acid, and choline). A source of glucose is also required, but this can be synthesized from glycerol and glycogenic of the amino acids if they are present in sufficient amounts. Among the inorganic substances, three minerals (calcium, phosphorus, and magnesium), nine trace mineral elements (iron, iodine, selenium, copper, zinc, manganese, fluoride, chromium, and molybdenum), three electrolytes (sodium, chlorine, and potassium), and water are required.

There are many other substances that are naturally present in foods and are known to be required in the diets of other species. For example, several ultratrace elements are essential in experimental animals and may also be essential in humans (arsenic, nickel, silicon, boron, cadmium, lead, lithium, tin, vanadium, and cobalt), but at present, evidence is lacking that they are. Dietary requirements, if any, for many other compounds, the so-called candidate nutrients, are also uncertain, and they are currently being explored. They include carnitine, myoinositol, cholesterol, the nonprovitamin A caratenoids, and dietary fibers. In addition to these substances that appear to be essential for some higher animals but not for humans, scores of other organic phytochemical and zoochemical compounds are present in foods that have various health effects, and some of them eventually may prove to be essential. These include growth factors and coenzymes such as dietary nucleotides, coenzyme Q, lipoic acid, and many others.

How Much is Required?

The amount of a nutrient required depends on the health criterion or indicator of adequacy that is used. For most nutrients, multiple possible criteria exist that are based on various health parameters. Levels of nutrients that are adequate to meet one of these criteria, such as prevention of night blindness, may not be so for reaching another, such as repletion of liver stores of vitamin A. The types of evidence and the criteria used to establish the quantitative requirements for a specific compound vary from nutrient to nutrient. They also vary from one age or physiological stage to another.

The amounts of nutrients that are needed, and sometimes the types of the essential nutrients that must be provided, differ depending on age and physiological state. For example, taurine is an amino acid that may be essential in premature infants but is not so in older infants or adults. Also, the forms in which nutrients occur in foods, fortified foods, and supplements affect their bioavailabiliy and thus their requirements.

How are Nutrient Requirements Expressed?

The quantitative recommendations for nutrient intakes used as reference values or standards for planning and evaluating the nutrient intakes of healthy people are collectively referred to as the dietary reference intakes, or DRIs. The DRIs include the estimated average requirement for nutrients (EAR) and three other reference values: the recommended dietary allowances, the adequate intake, and the tolerable upper level.

The process for establishing estimated average requirements and other dietary reference intakes used in the USA and Canada is summarized below. It is described in detail in monographs on groups of nutrients published by the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes of the Food and Nutrition Board, Institute of Medicine, National Academy of Sciences. They replace both the 1989 Recommended Dietary Allowances, the single reference values used in the USA, and previous reference data used by Canada in the past.

The DRI paradigm has now been used to develop current estimates of nutrient requirements for vitamins and minerals. Requirements for energy, macronutrients, water, and other compounds of possible health significance are now being considered, but as of this writing, no paradigm has been published for these dietary constituents.

Estimated Average Requirement

The estimated average requirement (EAR) is the amount of a nutrient that is estimated to meet the requirement for a specific criterion of adequacy of half of the healthy individuals of a specific age, sex, and life-stage. In setting the EAR, the evidence for

each possible criterion is considered, and the reason for selecting the criterion that is finally chosen is justified. The amount of the nutrient necessary to meet the appropriate criterion of adequacy varies from one individual to the next, but the data are usually distributed normally or can be transformed to achieve a normal distribution. The EAR is not useful as an estimate of nutrient adequacy in individuals, because it is a mean requirement for a group, and the variation around this number is considerable. At the EAR, 50% of the individuals in a group are below their requirement, and 50% are above it. Thus, a person whose usual intake is at the EAR has a 50% risk of an inadequate intake during the reporting period. An individual with an intake between the RDA and the EAR would have a risk of inadequacy between 50 and 2–3%. An individual with a usual intake below the EAR would have a risk of inadequacy between 50 and 100%. This is because the EAR is derived from a group estimate. The precise amount of a nutrient that will be adequate for any given individual is therefore unknown. It can be stated only in terms of probabilities, and thus it is rarely used in clinical practice. For healthy individuals whose usual nutrient intakes are accurately described, the EAR can be used to assess the approximate probability of inadequacy, although the range of error in the estimate is considerable.

Recommended Dietary Allowances

The recommended dietary allowance (RDA) is the average daily dietary intake level that suffices to meet the nutrient requirements of nearly all (97–98%) healthy persons of a specific sex, age, life stage, or physiological condition (such as pregnancy or lactation). The RDA is a nutrient intake goal for planning the diets of individuals.

To ensure that the needs of any given individual are met, a measure of variability around the EAR, usually the standard deviation or, if data are insufficient, an estimated coefficient of variation (CV) of 10 or 15%, is assumed. Then, an amount that covers this variation is calculated. The RDA is therefore defined statistically as two standard deviations above the EAR, assuming that the distribution of nutrient requirements is normal, as it may be for most nutrients that have been studied. That is, the RDA is the EAR + 2 SD. If the SD is not available, using a CV of 10%, the RDA is set at 1.2 times the EAR. If the CV is assumed to be 15%, the RDA is set at 1.3 times the EAR.

The risk, but not the certainty, of inadequacy increases as intakes fall further and further below the RDA. However, the RDA is an overly generous criterion for evaluating nutrient adequacy. By definition, the RDA exceeds the actual requirements of all but about 2–3% of the population. Therefore, many individuals who are below the RDA may still be getting enough of the nutrient in question to be above their requirement level.

The 1989 RDA consisted of a single reference point, with a focus on achieving sufficiency only, for individuals. However, the reference was often mistakenly applied as a standard for the evaluation of population nutrient intakes. In fact, the RDA is not appropriate for assessing the diets of individuals, or for assessing or planning the diets of groups.

Adequate Intake

For some nutrients, it is not possible to set RDA because data on the requirement (EAR) for the function of health significance that is judged to be the most important are not available. However, enough information is available to make some helpful statements about healthful nutrient intake levels. An adequate intake (AI) is set when experts believe that sufficient data on the requirement using the criterion that has been chosen to determine the requirement are still preliminary. More research is needed before an EAR and an RDA for that particular criterion or function can be determined. The AI is also an appropriate goal for the nutrient intake of individuals.

The AI is a value, based on observed or experimentally determined approximations of nutrient intakes by groups of healthy people, that is used when an EAR and an RDA cannot be determined. For infants, the AI is always based on the mean intakes of groups of healthy infants. For adults, in some instances, the AI is set as the mean of diets of healthy individuals in some reference groups. For other nutrients, the criteria are less precisely determined but always chosen to be generous enough for good health. In the DRIs that have been established to date, AIs rather than RDAs are proposed for all nutrients for infants up to age 1, and for calcium, vitamin D, fluoride, pantothenic acid, biotin, choline, vitamin K, chromium, and manganese) for persons of all ages. The AI is *not* a requirement, and it should not be interpreted as such. Rather, it is an average or median intake in a group of healthy people, all of whom are assumed to be meeting their nutrient requirements.

Tolerable Upper Intake Levels of Nutrients (UL)

Until recently, dietary requirements for nutrients were thought to consist solely of assuring adequacy. Now,

it is recognized that avoiding excess is also important. Intakes of nutrients that are far in excess of the RDA can disturb body functions and cause acute, progressive, or permanent disability. Some examples include fluorosis, hypervitaminosis A, and hypervitaminosis D. The DRIs now also address risks of possible excess of inadequate nutrient intakes. The tolerable upper intake level (UL) of a nutrient is the highest level of chronic, usual daily nutrient intake that is likely to pose no risk of adverse health effects to almost everyone in the population. Below the UL, individuals should be able to biologically tolerate this amount of the nutrient. Excesses of each nutrient may have many possible adverse effects. The UL is set for the effects that experts believe are most likely to be prejudicial for health and for which sufficient data are available. The UL is set using qualitative and quantitative evidence and inference-related judgments of experts in a logical process that assesses the associations between nutrient ingestion and the probability of adverse effects. The UL is set by determining the levels at which no observed adverse effects are noted, or the lowest level of intake associated with observed adverse effects. An uncertainty factor is then applied to insure that even very sensitive persons would not experience adverse effects at the UL dose chosen. For many nutrients, data on the adverse effects of large amounts of nutrients are simply unavailable, or they are so limited that a UL cannot be determined. The lack of a UL does *not* mean that the risk of adverse effects is nonexistent from high intakes; it simply means that data are not yet available, and the verdict is unknown. Therefore, caution is warranted in consuming high amounts of nutrients. The UL is *not* intended to be a recommended level of intake. There is no established benefit for healthy individuals of consuming nutrient levels above the RDA or AI. The amounts of individual foods that most people eat rarely reach levels that are likely to exceed the UL. In contrast, nutrient supplements provide more concentrated amounts of nutrients per dose, and thus the potential risk of excess is somewhat greater with them.

Current Estimates of Nutrient Requirements for Vitamins and Minerals

The EAR, RDA, AI, and UL all have specific uses in dietary assessment, for making nutritional recommendations and for dietary planning for individuals. The EARs for selected nutrients and age groups are provided in Table 1. Note that, for all of these nutrients, the estimated average requirements are based on oral intakes of nutrients. The appropriate use of the reference values is described in detail in the various publications of the Food and Nutrition Board.

Water

For adults under usual conditions, 1–1.5 ml of water per kcal energy expenditure is sufficient to allow for normal variations in physical activity levels, sweating, and solute loads of the diet. If renal function is normal, and solute intakes are adequate, the kidneys adjust to increased intakes of water by excreting the excess. If water intakes are inadequate to cover obligatory urine outputs, hydration status can be compromised. Obligatory water losses include 50–100 ml per day in the feces, 500–1000 ml by evaporation or exhalation, and, depending on the renal solute load, 1000 ml or more in the urine. If external losses increase, intakes must increase accordingly to avoid dehydration.

The stage of life and health influence water requirements. Pregnancy increases water needs by perhaps 30 ml per day, but during lactation, milk production increases requirements to at least 1 ml for each milliliter of milk produced or to 1 l per day or more, depending on milk production. In addition, water deficits may arise if disease causes increased losses, damages the kidneys, requires the use of diuretics, or, as in coma, makes it impossible for the individual to communicate their thirst. Fever increases water losses by approximately 200 ml per degree Celsius, and diarrhea losses vary but may be as great as 5 l per day in severe diarrhea. Vomiting and heavy sweating, especially in hot, dry climates and at altitude, also increase water losses substantially.

Energy

Recommendations on energy and the macronutrients are expected from the DRI process in 2002. Energy requirements or inputs must match energy outputs for weight to remain stable. The major sources of energy output are resting energy expenditure (REE) and physical activity. Minor sources include the energy cost of metabolizing food (thermic effect of food or specific dynamic action) and shivering thermogenesis (e.g., cold-induced thermogenesis). Because energy needs are so rarely measured directly, they are estimated in adults by assuming that if an individual is in energy balance and their body composition is not changing, they are in energy balance. To estimate the energy needs of an individual whose weight is stable, the formulas for estimating resting metabolism devised by Owen and colleagues are useful. First, an estimate of REE is obtained to provide a rough approximation of energy needs at rest in health: Male $\text{REE} = 900 + 10$ (weight in kg) or female $\text{REE} = 700 + 7$ (weight in kg). The result is then adjusted for physical activity level by multiplying it by 1.2 for the very sedentary, 1.4 for moderately active,

[a]This table presents estimated average requirements (EARs), which serve two purposes: for assessing adequacy of population intakes and as the basis for calculating recommended dietary allowances (RDAs) for individuals for those nutrients. EARs have not been established for vitamin D, vitamin K, pantothenic acid, biotin, choline, calcium, chromium, fluoride, manganese, or other nutrients not yet evaluated via the DRI process.

[b]As retinol activity equivalents (RAEs). 1 RAE = 1 μg of retinol, 12 μg of θ-carotene, 24 μg of l-carotene, or 24 μg θ-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A is the same as RE.

[c]As α-tocopherol. α-Tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2*R*-stereoisomeric forms of α-tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2*S*-stereoisomeric forms of α-tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*-α-tocopherol), also found in fortified foods and supplements.

[d]As niacin equivalents. 1 mg of niacin = 60 mg of tryptophan.

[e]As dietary folate equivalents (DFE). 1 DFE = 1 μg of food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

or 1.8 for very active individuals. More precise estimates of energy expended in physical activity may be used if they are available. Taken together, the product of REE times the activity factor provides an estimate of total caloric needs in a state of energy balance.

Energy needs decrease with declines in lean body mass, the major determinant of resting energy expenditure in health, and with physical activity. Because both actively metabolizing tissue and physical activity usually decline with age, energy needs in older persons, especially those over 70, are less than those of younger persons; in contrast, energy needs rise with pregnancy, because of the demands of fetal growth, in lactation, because of the energy lost required for milk production, and in growth and rehabilitation.

Macronutrients: Protein, Carbohydrate (Including Fiber), and Fat

Requirements for the macronutrients have been reviewed most recently in publications of the Food and Agricultural Organization/World Health Organization (FAO/WHO), and the update by the DRI Committee is expected shortly.

Factors Affecting Nutrient Requirements

Nutrient requirements are potentially affected by age, sex, rate of growth, pregnancy, lactation, and physical activity levels. They are also influenced by route of administration (e.g., by mouth or vein), composition of the diet with respect to nutrients and other constituents that may affect absorption, utilization or excretion, coexisting diseases, and drugs. The specific factors vary, and every nutrient must be assessed individually.

Assessing Dietary Adequacy Using Information on Nutrient Requirements

Dietary assessment determines whether intake is adequate while not being excessive. The first prerequisite for doing this is to obtain a representative estimate of usual dietary intake. Procedures for assessment of individuals and groups vary; a report on assessing dietary intakes is available. The Food and Nutrition Board is also completing a report on the uses of the DRI in planning for individuals and groups.

Measurement of Food Intake

M Nelson, King's College London, London, UK

Background

Measuring food consumption is a complex and difficult task. It may be carried out for a variety of reasons. For example:

- to determine the adequacy of food supply available to an entire country;
- to determine the adequacy of nutrient intake in a selected group of individuals;
- to establish levels of food self-sufficiency in the development of agricultural policy;
- to examine the relationship between diet and health in groups or individuals;
- as part of fundamental research on nutrient metabolism;

and for many other reasons.

It is fair to say that there is *no* method available that provides an entirely accurate measure of food consumption or nutrient intake, at whatever level the measurement is being made. It is impossible at the national or regional level to measure all food production completely, and to take into account all food and production losses and wastage; at the household level, people alter their purchasing or food-use habits while being observed; and at the individual level, people change their eating habits during a survey, or fail to describe their eating habits accurately. Awareness of the likely sources of error, however, allows for a sensible interpretation of results from studies of dietary assessment.

The type of measurement made, whether at the national, regional, household, or individual level, will be dictated by the purpose of the study being undertaken. This article identifies the points in the food chain at which measurements of food consumption can be usefully made, and highlights the strengths and weaknesses of the techniques available. It also considers the validity and reliability of these techniques when trying to relate diet and disease.

Methods for Measuring Food Consumption

Figure 1 shows the points in the food chain at which food consumption is commonly measured. Point I is at the level of domestic food production. In virtually all countries, a Department or Ministry of Agriculture requires food producers to report the amount of food produced. This information is useful in establishing levels of food self-sufficiency, but cannot be used alone to estimate the average consumption in the population.

Measurements at Point II are used by the Food and Agricultural Organization (FAO) of the United Nations to establish food-balance sheets. These measurements reflect domestic production, plus food imports and food taken from stocks, minus food exports, food moved into stocks, and food used for animal feed or non-food purposes (e.g., sugar used in the brewing industry). They can be used to show the average amount of food available per person in the population.

The next point of food measurement is the household (Point III). Typically, the weights and costs (or imputed value) of all food acquisitions (purchases, gifts, food from gardens and allotments, payments in kind, etc.) are recorded over a set period ranging from 1 week to 1 year. In addition, an inventory of the larder contents may be carried out at the beginning and end of the survey period in order to determine changes in food stocks, and allowances made for estimated food wastage, to yield an estimate of the amount of food available for consumption in the household (Point IV). Alternatively, respondents may be interviewed and asked to recall their purchases and food use over the previous week or two weeks, usually having been forewarned and asked to keep receipts and other informal records of food use and acquisition such as packaging and labels. Household surveys may include records of food purchased and eaten away from home, and household members' consumption of items not directly under the purview of the respondent, such as alcoholic beverages, sweets and soft drinks.

The final point of measurement (Point V) is at the level of the individual. Briefly, there are two

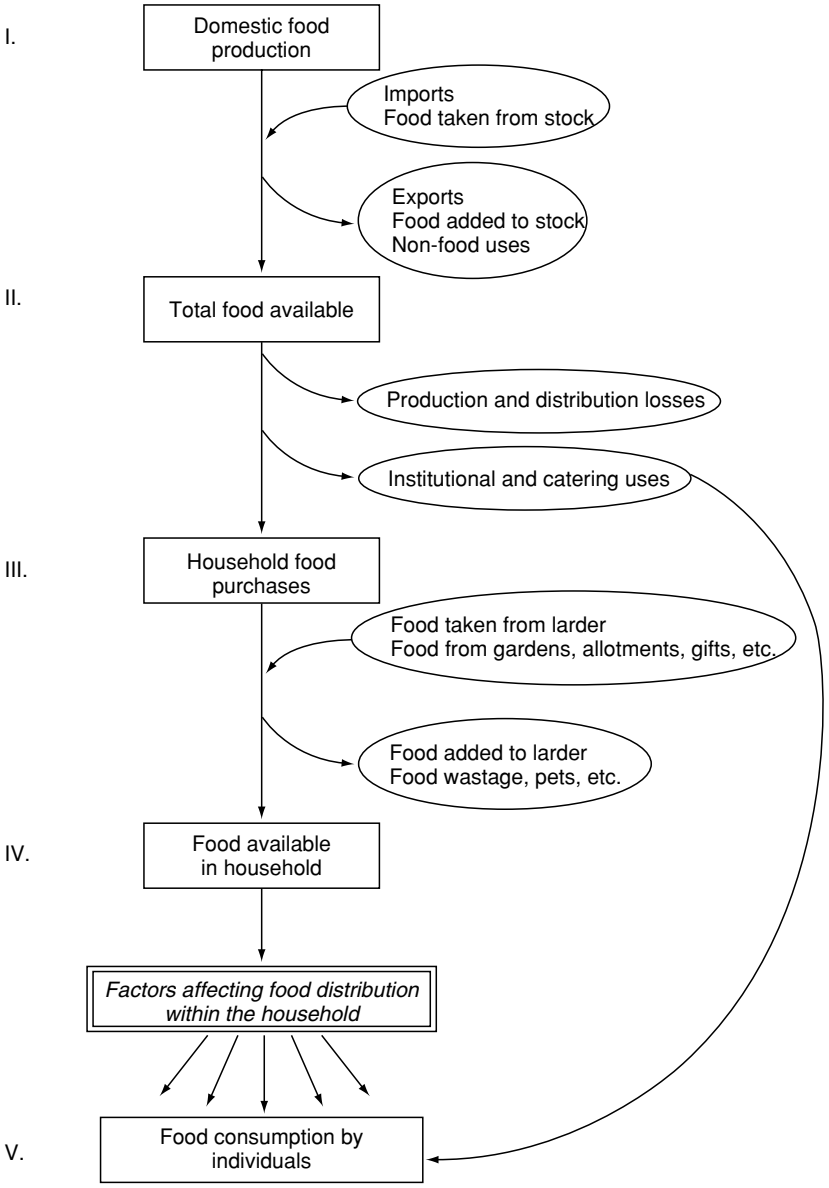

Figure 1 Points in the food supply chain at which it is convenient to measure food availability or consumption. Reproduced from Garrow J, James WPT and Ralph A (eds) *Human Nutrition and Dietetics*, 10th edn. London: Churchill Livingstone, wtih permission.

approaches, *prospective* and *retrospective*. Prospective methods include:

- *Duplicate diet*. The subject collects an exact duplicate or fixed aliquot (e.g., 10% by weight) of all food and drink actually consumed. The aliquot technique is especially well suited to households or institutions. A composite diet may be assembled in which representative local foods are combined into a single sample in proportion to the foods consumed (assessed using other techniques such as household food purchases or weighed inventories). The sample is then analyzed chemically for its nutrient content.
- *Weighed inventory or weighed record*. The subject records a detailed description and measured weight of all food and drink consumed.
- *Household measures*. The subject keeps a record of all food and drink consumed. Amounts are recorded in units of common household measures such as cups, spoons, bowls, etc.
- *Food check list*. The subject ticks a box on a preprinted list of food and drink to indicate each time a named item is consumed. Foods or drinks that do not appear on the list are recorded separately.

In general, the longer the period over which information on diet is collected, the greater will be the

[a]Includes other techniques of direct analysis (see text).
[b]Requires sample representative of population, institution or group, or analysis weighted to reflect balance of subgroups.
[c]Requires larder inventory. Short-term measures (e.g., 1 week) may not reflect usual diet in individual households.
[d]The need for data from all household members may distort usual household food consumption patterns.
[e]Semiweighed method (Nelson M and Nettleton PA (1980) Dietary survey methods. I. A semi-weighted technique for measuring dietary intake within families. *Journal of Human Nutrition* 34: 325–348.) reduces total respondent burden within household.
[f]Requires complex mathematical modeling of within-household food and nutrient distribution (Chesher A (1997) Diet revealed?: Semi-parametric estimation of nutrient intake age relationships. *Journal of the Royal Statistical Society, Series A – Statistics in Society* 160(3): 389–420.).
[g]Important to screen out individuals whose responses may not be valid (see text).
[h]Appropriate for ecological studies (see Hiller JE and McMichael AJ (1997) Ecological studies. In: Margetts BM and Nelson M (eds) *Design Concepts in Nutritional Epidemiology*, 2nd edn. Oxford: Oxford University Press.).
[i]See Margetts B and Nelson M (1997) *Design Concepts in Nutritional Epidemiology*, 2nd edn. Oxford: Oxford University. For a detailed discussion of use of dietary survey methods in epidemiological studies.
[j]Requires repeat 24-h recalls for valid classification of subjects according to levels of intake (see text).
[k]Useful only if range of foods is of limited variation in composition, allowing reliable use of food composition tables.
+++, very suitable; ++, moderately suitable; +, limited application; –, not suitable.

precision in the estimate of an individual's food or nutrient intake. However, the intake of some nutrients (like vitamin C) varies more from day to day than the intake of other nutrients (sugar, for example). The greater the day-to-day variation in intake, the longer the period of recording that will be needed to achieve a given level of precision.

Retrospective methods include:

- *Diet history*. The subject is asked by a trained interviewer about usual consumption habits in an extended interview lasting 1–2 h.
- *24-h recall*. A trained interviewer asks quantitatively about consumption of food and drink over the previous 24 h.
- *Food-frequency questionnaires (FFQ)*. These are completed either by the respondent or with the help of an interviewer. FFQs typically ask about the usual frequency and quantity of consumption of a wide range of food and drink. Alternatively, they may focus on the consumption of a limited range of items that are the main sources of intake of a particular nutrient. Some FFQs ask about frequency alone without assessing portion size.

Table 1 summarizes the principal applications of these different techniques. Food-balance sheets are appropriate for estimating national consumption levels, and are therefore of use in epidemiological studies comparing diets between countries. They cannot be used for assessing consumption at the regional, household, or individual level. Household surveys lend themselves to a wide variety of uses. If, for example, a nationally representative sample of households is used, it will be possible to estimate consumption levels nationally as well as in regional, socio-economic, and other subgroups within the population. Some household surveys include larder inventories at the beginning and end of the survey period, which allow estimates of consumption at the level of single households. Techniques are available to estimate the distribution of food and nutrient to individuals of similar age and sex within groups of households, and household surveys may therefore have application in some epidemiological surveys where a knowledge of the *pattern* of consumption to individuals, but not individual intakes *per se*, is required.

Duplicate diet techniques are most suitable for metabolic studies of individuals, where are a precise knowledge of nutrient intake is required. The

Table 2 Main attributes of the different dietary survey methods for measuring food consumption or nutrient intake in human populations

Type of survey	*Strengths*	*Weaknesses*[a]
Food-balance sheets	Determine national food consumption	National only
	Compare diets between countries	May overestimate food availability, especially in more affluent countries
Household budget surveys	Relatively cheap to obtain	Home food only
	Subgroupanalysis possible (by region, income, household composition, etc.)	Usually excludes meals eaten away from home, sweets, soft drinks, alcohol
	Useful where individual data hard to obtain	No individual data
	Time trends if collected annually	May be expenditure only, so weights of foods must be imputed
Without larder inventory	Lower respondent burden	Bias towards overpurchasing, especially in low income and elderly households
		Food acquisition, not consumption
With larder inventory	Consumption data	Distorts normal food purchasing pattern
		Higher respondent burden
Prospective surveys of individuals	Current diet	Labor-intensive
	Direct observation of diet	Requires literacy and numeracy skills
	Vary duration of survey according to needs	High motivation needed
		Distortion and/or omission due to 'health' issues
		Overweight subjects more likely to underreport true consumption levels
Duplicate diet	Direct analysis of nutrient content of diet (no food tables needed)	Very expensive
		Intensive supervision required
		Likely to distort usual diet
Weighed inventory	Widely used, facilitates comparisons between studies or groups	Loss of precision of estimate of nutrient intake compared with duplicate diet
Household measures	No scales needed	Loss of precision compared with weighed inventory
Retrospective surveys of individuals	Inexpensive	Bias: memory, conceptualization, interviewer
	Quick	Daily variation not usually assessed
	Low subject motivation needed	Depends on regular eating habits
	Good cooperation	
	Current or past diet	
Diet history	Assesses 'usual' diet	Tends to overestimate nutrient intake
24-h recall	Very quick	Tends to underestimate nutrient intake
	Repeat observations to obtain daily variation	Does not reflect individual intake unless repeated
Questionnaires	Suitable for very large number of subjects	Requires validation
	Can be posted	Literacy and numeracy skills needed if self-completed
	Focus on particular nutrients	

[a]With the exception of the duplicate diet technique, all methods rely on food composition tables for estimating nutrient intake.

composite diet technique is particularly suitable for estimating the nutrient content of foods eaten by a group of people where food composition tables (q.v.) are likely to be inadequate. The weighed inventory is suitable for assessment of individual food consumption or nutrient intake (using food-composition tables), and thus lends itself to a wide variety of uses, in that accurate estimates of dietary intake for groups of people can be built up from individual data. Where a limited range of foods of accurately known composition is being consumed, the weighed inventory may also be used in metabolic studies. Because the household-measures technique, like the weighed inventory, focuses on the individual as the unit of assessment, it can also be used in a wide variety of studies, but with some loss of precision in comparison with weighed inventories.

The retrospective techniques, because they rely on memory, are regarded as being less objective than the prospective techniques, but they may free the respondent of factors likely to distort the recording of diet (see Table 2). The diet history, particularly, may be used to assess the 'usual' diet of an individual more effectively than other techniques, in that seasonal variations in diet can be taken into account more readily. A single 24-h recall from one individual cannot be used to assess that individual's diet because of day-to-day variations in intake. Single 24-h recalls collected from a large number of subjects, however, may be useful for estimating the intake of a group.

Repeat 24-h recalls collected from an individual can provide an accurate assessment of that individual's diet. Questionnaires are of particular value in epidemiological studies, in that they can provide information economically from a large number of subjects.

Strengths and Weaknesses

Table 2 summarizes the main strengths and weaknesses of the methods available. When measuring diet, it is important that the method chosen is accurate enough to enable any hypothesis to be tested adequately. It is likely that many studies that fail to show a relationship between diet and disease do so, not because no relationship exists, but because the techniques used to assess diet were not appropriate, and measurement error (under-reporting actual intake, for example) was not taken into account. Equally important, if the aim of a study is to relate diet and health in groups of people, for example by comparing diet and health status between countries or regions, there is little point in spending resources on expensive and labor-intensive surveys that characterize the diets of individuals.

It must be decided at the beginning of a study whether measurements of food consumption, or nutrient intake, or both are required. The required precision (standard error) of the measurements will determine the number of subjects and the number of measurements per subject required, or the number of regions or countries to be included in a regression or correlation analysis. If ranking of subjects or groups will suffice, then a technique that has a systematic bias or nondifferential misclassification[1] may be acceptable, but if absolute measures of consumption or intake are required, techniques with a greater validity will be needed. Most prospective methods (apart from duplicate or composite diet techniques) and all retrospective methods rely on food composition tables (q.v.) for estimating nutrient intake, and the weaknesses associated with their use should be considered in any evaluation of findings. Measurements made will be affected by the time of year (summer/winter, wet season/dry season, holy days, festival days), the time of week (weekdays/weekends), and even the time of day (interview responses may differ before and after meals). Also, the precision and representativeness of the findings will be influenced by whether it is present or past diet that is being measured. Measurement of past diet is more difficult but may be important in relation to understanding the dietary origin of chronic diseases such as heart disease or some types of cancer.

In studies of individuals, different techniques require particular skills to complete records or recalls of diet satisfactorily. For example, very young or very old subjects may be unable to recall diet accurately; people with poor literacy and numeracy skills will be unable to keep adequate records.

Food-Balance Sheets (see 'Food Supply' database at http://apps.fao.org/)

These are eminently suitable for comparing diets between countries, and are readily available from the FAO, thereby reducing the cost of such studies. They do, however, show significant bias, in that the estimated availability of foods and nutrients may be considerably greater than the actual levels of consumption. In the UK, for example, food-balance sheet estimates of energy intake are 25% greater than the estimated energy requirement in the population (although some allowance needs to be made for waste and production losses). More important, this bias is probably not constant between countries. More affluent countries are more likely to overestimate consumption than poorer countries. This may be due in part to more efficient recording of food production in affluent countries, and in part to the presence in poorer countries of many small holdings and subsistence farms whose production is underrecorded.

Household Budget Surveys

Household budget surveys of nationally representative samples are regularly conducted by many governments. The results provide a ready-made database for analysis of food trends across time, and between regions or subgroups within the population. Where it is difficult to obtain individual data (such as in cultures where families eat communally from large serving vessels), household surveys may provide a valuable way of characterizing diet.

Their principal disadvantage is that foods eaten away from home are rarely recorded. These usually include a high proportion of sweets, soft drinks, alcoholic beverages, and snack foods. Also, individual intakes cannot be estimated, which may be a particular disadvantage in epidemiological studies, where it is important to relate disease outcome in individuals to diet.

Some household surveys are conducted without a larder inventory, so as to reduce the respondent burden. The assumption is that over a sufficient number of households (say 20), the differences within individual households between purchases and actual consumption will balance out, giving an overall

[1] In nondifferential misclassification, measurement errors that are present affect all subjects equally or proportionately. In differential misclassification, errors in reporting are greater in some groups (for example, overweight or elderly people) than in others. Consequently, comparison between groups is difficult to interpret. Differential measurement errors may undermine attempts to establish diet–disease relationships.

estimate of consumption close to the true level. In practice, it has been observed that surveys of food purchases in developed countries tend, on average, to stimulate purchasing in excess of actual consumption by as much as 15%. This bias is greater in households with respondents over 60 years of age and in respondents from lower income households. As lower income group consumption levels are generally lower, comparisons of the food purchases or estimated nutrient intakes are likely to underestimate the true differences between income groups except where very major differences occur (in fruit consumption, for example). Comparison of food or nutrient *profiles* (per cent of income spent on certain foodstuffs, or nutrient intakes per MJ) may be more reliable. This problem is less pronounced in surveys where the variety of food purchases is limited (as in many developing countries), or where purchases are reported retrospectively rather than prospectively. Reported household food purchases may be supplemented by records from individual household members of consumption of foods eaten outside the home, but are often subject to errors of omission.

Household surveys conducted with larder inventories give a more precise estimate of levels of food consumption and nutrient intake, but they tend to distort usual purchasing patterns when respondents' attention may be drawn to the larder contents. They also have a higher respondent burden. Some household budget surveys include expenditure only. It is then necessary to impute purchase quantities from expenditure. These are likely to be less reliable than surveys that record amounts of food purchased as well as expenditure.

Prospective Surveys of Individuals

These have the advantage of direct observation of current diet. They can be varied in duration to improved the accuracy of classification of individuals' nutrient intakes, i.e., the greater the number of days of information recorded, the more likely it is to reflect the true intake of the individual. For example, carbohydrate intake may be estimated within a few days, whereas energy intake may require a week, and fatty acid intake 2 weeks. Where a large number of days is needed, problems of respondent fatigue can be overcome by having a series of shorter periods (four 4-day periods, for example).

The principal disadvantage of prospective techniques is the level of literacy and numeracy skills required to complete the surveys. This can be overcome to some extent by having an interviewer do the recording and measuring, but this is very invasive for the subject and expensive in terms of staff time. Prospective methods may also encourage distortion of diet and avoidance of foods regarded as unhealthy, particularly sweets and alcoholic beverages, or there may be simple omission of items owing to poor recording techniques. A particular problem that has come to light with the advent of the (very accurate) doubly labelled water method for estimating energy expenditure is that overweight subjects are more likely to underrecord their intake than normal weight subjects. This has important implications when trying to establish links between diet and disease where being overweight may itself be a risk factor (heart disease, for example).

The *duplicate diet technique* is appropriate mainly for metabolic studies, as it is very expensive and time-consuming. Its use in free-living populations requires exceptionally close supervision to ensure that the food samples collected are truly representative of the foods that have been eaten. It has been used in epidemiological studies where a single day's duplicate has been collected from a number of subjects in order to characterize the group diet rather than individual diets. The composite diet technique is easier to use for assessing group diet characteristics by chemical analysis. It is very good for estimating average levels of additives or contaminants present in the diet. It has the disadvantage of relying on food intake or purchasing records or dietary recall.

The *weighed inventory* has been used very widely, and for this reason, there are many values in the literature against which new data can be compared. It is less demanding of both respondent and interviewer than the duplicate diet technique, but because it relies on food composition tables, there is a loss of precision in estimating nutrient intake. The household measures technique is useful where subjects are unused to using scales, or resources are limited, and requires a lower level of numeracy than the weighed inventory, but there is a loss of validity owing to a variation in portion sizes not reflected in their descriptions.

Retrospective Surveys of Individuals

In comparison with prospective techniques, retrospective techniques are relatively inexpensive, demanding less time of both respondent and interviewer. They therefore tend to have slightly higher cooperation rates. For foods that are consumed only occasionally (like liver) or about which there may be some stigma (like sweets or alcoholic beverages) in some countries, and for assessing the intake of nutrients (such as carotene or vitamin B_{12}) that would require many days of recording, there are advantages in using retrospective techniques that ask about the usual frequency of consumption of foods. Retrospective techniques also have the unique advantage of allowing assessment of past diet, although, in

practice, estimates of past diet may be heavily influenced by present diet. Most recalls of diet in the distant past (2 or more years prior to the interview) correlate as strongly with current diet as with the past diet assessed at the time.

Results from retrospective methods, like those from prospective methods, are subject to differential misclassification, but for different reasons. Memory and conceptualization skills (the ability to describe quantitatively what was actually eaten) differ in an unsystematic way between individuals. The very young (under 12) and the very old (over 70) are less likely to be able to recall their diets correctly. The number of food items recalled has been shown to correlate with the estimated energy intake, independent of the true level of intake. Apart from the use of repeat 24-h recalls, retrospective methods provide little or no information on day-to-day variation in diet. Such measures of variation can be useful in determining the likely accuracy of ranking of individuals according to nutrient intake. For the diet history and questionnaires, especially, subjects who do not have regular eating habits will have difficulty in describing the 'usual' frequency of consumption or portion size.

The *diet history* is especially valuable for assessing the 'usual' diet, but the nature of the interview may encourage overreporting, and the results from diet history assessments usually exceed those from weighed inventories, which, in normal-weight individuals, are probably a good reflection of 'usual' intake.

The *24-h recall* is relatively quick, demanding little of respondents' time, but cannot be used to characterize individuals' diets unless it is repeated over a number of days. In general, because of the absence of a 'training effect,' respondents are more likely to omit items than in methods that extend over several days. Estimates of nutrient intake using 24-h recalls therefore tend to be low in comparison with other techniques (whether prospective or retrospective). A new 'triple pass' 24-h recall technique (in which respondents are given two further opportunities in the same interview to recall other items consumed) has resulted in higher estimates of intake.

Questionnaires are suitable for obtaining information from very large numbers of subjects. Their administration can be more readily standardized than other types of dietary assessment (for example, administered by computer or sent by post for self-completion by respondents). Where the hypothesis to be tested relates to specific foods (e.g., vegetables) or nutrients (e.g., calcium), they can be of limited length pertaining to relatively few foods. They can thus have the advantage of brevity while still being able to rank subjects with a known degree of validity. Because of the uncertainty regarding the successful completion and validity of assessment of newly designed questionnaires, it is essential that they are properly evaluated against a dietary survey method in which the errors of assessment can be estimated. If they are to be self-completed after being posted to subjects, literacy and numeracy skills will be needed, and differential misclassification may affect interpretation.

Use of Computers

Computers are used universally to calculate the nutrient content of diets for which no direct chemical analysis is made, but they can also be used directly in the dietary assessment of individuals. Data-entry programs such as UNIDAP (Unilever) have been tailored to allow interviewers to enter patterned food consumption data, thus effectively providing the facility for an interactive diet history. Branching interactive programmes (such as EPICSOFT) allow for 24-h recall data to be entered directly at interview. Short, structured questionnaires (e.g., CALQUEST for measuring habitual calcium intake) have also been devised for interactive use. In Integrated Dietary Analysis (IDA), respondents use a hand-held computer linked with digital electronic weighing scales to collect weighed inventory data without the need for written recording or subsequent computer entry of data. Scales have also been linked to computers with special keypads with symbols instead of letters (FRED and FREDA), allowing respondents to use pictures to indicate the food being consumed; again, weights and codes are recorded automatically. A tape recorder has also been linked to scales (PETRA), allowing subjects to describe foods orally rather than in writing, a weight being recorded automatically on the tape in association with each item described. With the exception of interactive recalls, the use of computers for data collection has been disappointing because of high costs or laborious transcription of data.

Use of Biological Markers

Given the errors that are inherent in any reporting of diet, it is important to have objective measures that reflect usual food consumption or nutrient intake. Biochemical measurements of nutrients or related metabolites in blood or urine have long been used to identify nutrient deficiencies or irregularities. Markers of diet that span the whole range of intake are less common. Collection and storage of appropriate sample material may be a problem in itself (e.g., ensuring completeness of collection of 24-h urine samples). Biological markers do, however, provide important tools for evaluation of the validity of

dietary assessment and for characterization of nutritional status in population studies. For a fuller discussion of the use of biological markers, readers are referred to Margetts and Nelson (1997).

Surveys of National Food Intake

J A T Pennington, Division of Nutrition Research Coordination, Bethesda, MD, USA

Purpose/Objectives of National Food Intake Surveys

National food intake (consumption) surveys are usually undertaken by government agencies responsible for the health and/or food supplies of a population. Such agencies may include departments or ministries of health, departments of agriculture, or food administrations.

National food intake surveys may be carried out to assess and monitor the dietary status of the population. Other objectives for food intake surveys are to determine the adequacy and safety of the national food supply, to determine the effects of dietary patterns on nutrient intake and health status, to assess changes in dietary patterns and their affects on nutrient intake, and to identify needs for changes in national food policies or regulations.

The dietary status of the population can be monitored by comparing food and nutrient intakes with recommended intake standards set by government, academic, or private agencies. For example, the average number of servings of fruits, vegetables, dairy products, grain products, and meats or meat substitutes may be compared with the recommended standards, and the average daily intake of nutrients (e.g., protein, fat, carbohydrate, vitamins, and minerals) may be compared with recommended dietary allowances for these nutrients. The dietary status of a nation can also be compared with measures of disease incidence to determine potential relationships between nutrient intakes and dietary deficiency diseases or chronic diseases such as obesity, heart disease, diabetes, stroke, alcoholism, and various types of cancer.

Results from food intake surveys help determine the adequacy of the national food supply and identify populations without adequate food that are underserved by current food relief efforts. Assessments of food and nutrient intake help determine the extent of physical, mental, and emotional problems relating to food insecurity (i.e., inadequate food intake). Dietary surveys help determine which population subgroups as defined by age, sex, race, ethnicity, income, urbanization, or education are at risk for energy and nutrient deficiencies. Food intake surveys should include questions about the use of public food assistance, food banks, and community feeding programs because the responses to these questions may assist government agencies in making decisions about the need for continued or increased support of such programs. Information from the survey may help determine the effectiveness of public health policies regarding food fortification, food stamps, and feeding programs for children, the elderly, institutionalized persons, and those below the poverty level. Survey results may assist governments in revising current food-related policies or developing new policies.

Results from food intake surveys also help determine the safety of the food supply. In addition to providing estimates of nutrient intake, the information from national food intake surveys may help provide dietary exposure estimates for pesticide residues, food contaminants, and food toxins. Concentration data on the levels of pesticide residues, contaminants, and toxins in foods may be merged with the food consumption data from the surveys to provide such exposure estimates. Information on dietary exposure to potentially harmful constituents in foods may be useful for modifying or revising policies concerning agricultural and food manufacturing practices.

Results from food intake surveys help determine the effects of dietary patterns on nutrient intake and on health status. Families perpetuate the dietary patterns learned from their parents and other relatives, and families within communities and larger geographic areas (e.g., countries) tend to have similar dietary patterns. These learned dietary patterns may be modified or changed with exposure to the foods and eating patterns of other cultures via travel, immigration, migration, or the presence of visitors. Media food advertising and the offering of new and different foods from grocery stores and restaurants may also affect dietary patterns. Dietary surveys should include questions about cultural and ethnic dietary patterns so that the relationships of cultural and ethnic factors to food and nutrient intake can be identified. This may allow for the identification of relationships between culturally or ethnically defined dietary patterns on dietary and health status.

Food intake surveys are useful for following changes in dietary patterns, their effects on nutrient intake, and potential implications for health. For this purpose, the surveys are most useful if they are done routinely (e.g., yearly or biennially) using the same or similar methodology so that changes and trends in food and nutrient intake can be identified. Changes in food intake may reflect the impact of the availability of ready-to-eat products from grocery stores, fast food restaurants, and other food vendors. Changes in agricultural and manufacturing practices may result in changes in the composition of foods (e.g., the type of fats and oils in baked products and the type of sweeteners in soft drinks and desserts) so that nutrient intake changes even without changes in food patterns. It is important to have ongoing monitoring of food and nutrient intake as well as monitoring of disease incidence so that cause and effect might be investigated.

Food intake surveys are useful for identifying issues that might require changes in policies or regulations concerning food safety, food labeling, food fortification, food additives, agriculture practices, or manufacturer practices. Ultimately, the food policies and regulations developed by government agencies should serve to maintain and improve the health of its citizens. Food intake surveys may be done in conjunction with health examination surveys that include physical exams, health histories, clinical measures, and/or the collection of biological samples (urine, blood, or other tissue) that are analyzed to assess nutritional or health status. When surveys of food intake and health measures are done concurrently on the same population, there are opportunities to relate food and nutrient intake to health status measures such as blood pressure, body weight, and blood levels of cholesterol, triglycerides, and various nutrients. Changes in the health status of people within a country could be the result of many factors (diet being one of them). Dietary status data derived from food intake surveys could be an important factor when assessing the health of a population. Other factors (physical activity patterns, environmental health, economics, epidemics, etc.) are also very important with regard to the health of a population. Dietary surveys provide an important piece of information that will help governments in making policy and regulatory decisions concerning foods and agriculture.

Sample Population

A food intake survey should include survey participants that are representative of the population in terms of the demographic features of interest to the investigators. Usually, the demographic factors include sex, age, region, urbanization, income, education, race, and ethnicity. There may be other important considerations with respect to population sampling for a national survey. For example, a government agency may wish to oversample at-risk populations or minority populations for whom few dietary data are currently available.

Obtaining a representative sample population for a food intake survey requires the expertise of statisticians who are knowledgeable of the population and its dynamics. The statisticians can assess the currently available population databases (e.g., census database, voters registration database) and determine whether they might be useful to develop a sample population for the dietary intake survey.

The agency responsible for the food intake survey must consult with the statisticians and survey designers regarding important facts such as:

- If individuals in institutions (hospitals, prisons, rest homes, retirement communities, convents, monasteries, etc), individuals without permanent resident status (immigrants, aliens), and individuals without homes are to be included in the survey. Survey participants generally need to have a home address, a telephone or other means of contact so they can be requested to participate in a survey.
- Which demographic features (age, sex, race/ethnic group, income, region, urbanization, education) are of importance to the survey results and how many individuals with the demographic features must be in the survey so that representative dietary intakes can be calculated for them.
- If minority or at-risk groups should be oversampled if they will not be present in sufficient numbers in the overall sample.

- If the survey should be designed to correct for sample bias (e.g., nonresponse rate, oversampling). One method to correct for sample bias is to develop weighting factors for each individual in the survey that pertains to his/her demographic characteristics.
- How to obtain dietary information for those not able to respond for themselves (e.g., young children, ill, elderly, at work, traveling, illiterate, etc.).
- How to maximize survey participation of the selected participants, e.g., by sending a letter of intent, following up with a phone call, minimizing respondent burden, and providing remuneration (if possible) for the subjects' time and effort.
- How to recontact people if necessary (e.g., to clarify information) without violating privacy issues.

Methods Used for National Food Intake

Information about the foods consumed by a nation can be obtained using a variety of methods such as food disappearance (per capita intake), food balance sheets, household inventories, 24-h dietary recalls with a professional interviewer or computer assistance, food diaries (records) kept by survey participants, weighed food intakes, diet histories, duplicate portions, and food frequency questionnaires. There are various advantages and disadvantages of each method with regard to costs, respondent burden, and accuracy and reliability of the information obtained. Costs include the staff time, field survey transport and housing, materials, data processing, and participant renumeration. Respondent burden refers to the time and effort required by the survey participant to provide information. (*See* **Dietary Surveys**: Measurement of Food Intake.)

The preferred methods for national food intake surveys are 24-h dietary recalls or food diaries, and it is most useful if there are two or more days of dietary information for each survey participant. The methods of food disappearance, food balance sheets, and household inventories are less accurate, tending to overestimate food intake, and do not provide specific information based on the age and sex of participants. Weighed food intakes, diet histories, and duplicate portions take much interviewer and participant time and are expensive (i.e., the cost per person is high for the large sample population needed for national data). The weighed intakes and duplicate portion technique also tend to alter usual eating patterns, usually by decreasing total food intake. Food frequency questionnaires may provide useful information but are generally not quantitative and are not specific enough because they include a limited number of foods (as low as 50).

Although the 24-h dietary recalls and food diaries are likely the methods of choice for national surveys, they too have disadvantages. The 24-h dietary recall requires accurate memory and honesty of the survey participant as well as knowledge of food names, descriptions, and serving sizes. Food diaries have the effect of altering usual food intake and are also subject to the honesty of the survey participant. The act of writing down consumed foods in a diary tends to decrease total food intake and may result in 'healthier' food choices that are not typical or usual in countries where obesity prevalence is high. The main problem with dietary recalls and diaries appears to be underestimation of total food intake. Recent studies, using the doubly labeled water technique, have estimated that dietary recalls and diaries may be underestimated by about 20% of energy. It is not known if the underestimation applies equally to all foods or if there is selective underestimation as for example with alcoholic beverages, snack foods, or desserts.

The information derived from dietary surveys is particularly useful to identify potential health problems related to food and nutrient intake. The potential problems can be investigated more fully by collecting and evaluating information obtained from clinical and biochemical measures of nutritional status. Because of the difficulty of obtaining accurate, valid, and reliably dietary information from survey participants, dietary data are usually not considered sufficient for making changes in nutrition policy, i.e., the dietary results need to be verified with clinical and biochemical results. Otherwise the benefits of policy changes (which can be expensive and burdensome on the food industry) may not be forthcoming.

Considerations with Dietary Recalls and Records

The food intake survey should be designed with considerations for the number of days of recalls or records, the days of the week and seasons of the year, memory cues and probes, the interviewing situation and interviewing techniques, the food composition database, default food codes, dietary supplements, cultural sensitivity of the dietary tool, specific food use questions, and the use of biochemical markers to assess the validity of the dietary method.

1. For most nutrients, as many as 7–14 days of dietary information may be necessary to characterize usual intake for an individual. However, for population distributions of nutrient intake, 2 days of food recalls or diaries are usually sufficient. Collecting and processing additional days (beyond

two) of dietary information result in increased financial costs as well as reduced response rates as individuals tire of participating.

2. Because people tend to eat differently on work days and days off work, it is important to factor days of the week into the sample design for food recalls and diaries. Eating patterns are affected by the seasonality of some foods (e.g., watermelon, strawberries, plums, grapes, corn, spring lamb, oysters, and crabs). The seasonality of outside temperatures may affect food preferences and eating patterns. People often prefer hot and hearty soups and meals on cold days and salads or lighter meals on hot days. Feasting and fasting patterns around religious and national holidays are often different than other days. It may be best to avoid collecting data for such days or to factor these days into the sampling design so that the overall results will be representative.
3. Cues and probes provided by the dietary interviewer or the computer-assisted interview help survey participants remember the details about the foods they eat. Questions about snacks and about added ingredients (sugar and cream in coffee, catsup, salad dressing, sauces) are important to obtain complete food recalls and diaries. The use of food models and food pictures also helps to clearly identify foods and to improve the accuracy of serving size estimates.
4. The manner in which food-related questions are asked affects responses. Certain characteristics of the interviewing situation may affect responses about foods that might be depicted as 'good foods' or 'bad foods' by the survey participants. For example, the presence of other family members during the dietary interview may lead to underestimation of the intake of alcoholic beverages, snacks, and dessert items (especially for parents and teenagers). An interview in a health setting such as a clinic may elicit responses with underestimated amounts of fat and overestimated amounts of foods with higher nutrient content (e.g., fruits and vegetables). Interviewers should attempt individual interviews, if possible, refrain from either positive of negative feedback about food choices, and encourage subjects to accurately report all foods. Interviewers can emphasize the confidentiality of the recall or diary and indicate that only grouped results will be reported unless sent in advance via mail to the participants.
5. Dietary interviews have traditionally been done as in-person (one-on-one or in family interviews), but are now also done by computer and by telephone. The computer-assisted interview helps standardize the questions and probes because some potential human errors are removed. Computers do not get tired, sick, forgetful, or irritable, and computers do not require training, quality control checks, or intrainterviewer compatibility checks. Telephone interviews are less expensive than in-person interviews as they do not require an examination site or the travel costs of survey participants. However, telephone interviews have the disadvantage of not permitting the use of food pictures or models of serving portions.
6. To derive accurate and reliable information from the dietary interview, the food consumption data must be merged with a food composition database that contains accurate and relevant data on the nutrient content of the foods consumed by the population. The database should contain both the generic and brand name products typically eaten. To ensure accuracy, the nutrient information on brand name products in the database should be obtained from the manufacturers or from a qualified laboratory. The foods in the database should contain the current levels of nutrient fortification for products usually fortified such as wheat flour, white rice, cornmeal, ready-to-eat breakfast cereals, milk, salt, etc. The database should include foods from fast food and other restaurants as well as manufactured and homemade mixed dishes, ethnic foods, and desserts.
7. Survey participants often have difficulty identifying foods, remembering (or knowing) the ingredients in mixed dishes, and properly identifying serving portions. Food models, pictures, and computer graphics may help participants identify foods and serving sizes. However, default food codes will be necessary when detailed information cannot be elicited from the participants. Default food codes are needed for mixed dishes, especially homemade and restaurant where exact recipes and ingredients are not known. The database can carry mixed dishes with traditional ingredients (from cookbooks) and calculated nutrient values as defaults. Defaults may also be necessary for sandwiches, soups, pizza, pie, cake, cereal, salad, and many other general food categories where more detail cannot be elicited.
8. Information about the intake of dietary supplements is important because supplements can be very potent sources of nutrients and far outweigh the concentration of nutrients obtained from foods. However, it is usually best to maintain information about supplement intake separately from food intake so that survey results can be presented both ways (i.e., as nutrient intakes excluding supplements and intakes with supplements for those individuals who consume them).

Of primary interest is the type of supplement taken (the nutrients included and the brand name), the potency for each nutrient, the frequency of use of the supplement, and the duration of use. There are thousands of supplement products available both over-the-counter and by prescription. Information about supplement intake is difficult to capture and code. A particular complexity in assessing supplement use is that many individuals take supplements inconsistently or in patterns that are difficult to characterize (e.g., when they do not feel good, on certain days of the week, until the bottle is empty, when they feel tired). If possible, the survey participants should be asked to bring their supplement bottles to the interview so that the interviewer can account for the types and amounts taken. If supplement intake data are to be collected during the survey, a supplement database will be needed to convert the supplement intake data into nutrient intake data.

9. The dietary tool developed for a food intake survey may not work equally well for all groups within a population. The method may not retrieve the same level and quality of information from minority populations or population subgroups that differ by culture, urbanization, income, education, or living situation. (In fact, men and women may respond differently to the same tool, and children may respond differently than teenagers or adults.) The food intake tools should be culturally competent, or there should be different tools for different cultures. Infants, children, adolescents, and elderly persons may require surrogate reports or confirmation of dietary intakes from parents or caretakers. People who are institutionalized (i.e., in hospitals, rest homes, retirement homes, prisons, or psychiatric institutions) may require surrogate dietary intake reports from their caretakers.
10. It may be necessary to include specific food use questions in the survey to meet the identified objectives of the agency conducting the survey. For example, there may be questions about the type of cooking and table fat typically used (butter, margarine, lard, suet, shortening), the use of discretionary salt during cooking and at the table, whether the salt is iodized or not, the use of a microwave oven, typical methods of food preparation (frying, baking, grilling), the use of artificial sweeteners, the use of foods with fat or sugar replacers, the use of medical foods, if fat is trimmed from meat cuts, if skin is removed from poultry, or the use of low calorie products (e.g., salad dressings, soft drinks).
11. Dietary surveys are much less expensive than physical exams with clinical and biochemical measurements to assess the nutritional status of a population. However, as noted, the results of dietary surveys are not completely accurate. It would help to validate (or invalidate) the results of dietary surveys by using a short-term biochemical marker, if resources permit. Short-term biochemical markers that have been used to attempt to validate the previous day's nutrient intake include urinary nitrogen, potassium, sodium, and carotenoids for dietary protein, potassium, sodium, and carotene as well as the doubly labeled water technique for energy intake.

Summarizing Data and Data Availability

The information collected during dietary surveys must be stored, reviewed, aggregated, and evaluated with special attention to weighting factors and to the sample number when data are reported by demographic characteristics. Nutrient intakes may be reported as means with standard deviations, medians, and percentile distributions. The data derived from a national food intake survey are generally valid for the population as a whole and for population subgroups for which the sample size is sufficient. Government agencies should make the results of their food intake surveys widely available through publications and on the internet to assist other government agencies that are attempting to undertake food intake surveys for the first time or that wish to improve upon the methods used in their previous surveys. Government agencies should summarize the results of their food intake surveys and explain and justify their conclusions regarding the dietary status of their population. They may also attempt to relate the dietary status of the population or population subgroups to the reported incidence of diet-related diseases in the population or in population subgroups.

Surveys of Food Intakes in Groups and Individuals

G H Beaton, GHB Consulting, Willowdale, Ontario, Canada

Background

Studies of food intake by individuals or groups are usually undertaken for a narrowly defined purpose. This must influence both the choice of dietary methodology and approach to analysis and interpretation. In the case of individuals, intake assessments are undertaken most often in connection with dietary counseling, monitoring compliance, and, sometimes, as part of a risk-assessment program. Since counseling usually relates to foods, not nutrients and even more often to patterns of food use, qualitative assessment of food use may be all that is needed. When compliance to a strict metabolic regimen is to be assessed, quantitative methodologies and computation of nutrient intakes are likely necessary. The methodological demands are very different, depending upon the intended application. The potential purposes for group surveys are more diverse. The intake data collection might be a part of a national health and nutrition survey; here, primary interest often spans both nutrient intake and food usage, but the important focus is on the distribution of usual intakes among individuals in the target population. Quantitative estimates of intake are needed. More often, group surveys may be undertaken either as part of the evaluation of a program or in the assessment of possible need for an intervention in a subpopulation. Here, the precise measures of interest will depend on the defined evaluation, but usually, quantitative assessments are needed. A different demand emerges when data collection is a part of a specific epidemiological study. The primary objective may be to rank individuals along a continuum of intakes with less concern about absolute levels of intake. Depending on the nutrient(s) or food(s) of interest in the planned epidemiological study, a semiquantitative methodology may suffice and may be more cost-effective. While it is possible to design simplified assessment tools for nutrients such as vitamin A or calcium, caution must be taken to avoid using the data collected for other purposes. The more broadly the data are to be used, the greater demand there is for quantitative methodology. A recent report by the European Food Consumption Survey Method group concluded that repeated 24-h recalls were the preferred method for planned health and nutrition monitoring. This is consistent with earlier decisions relating to the design of the two large US national surveys.

The impact of error terms in dietary data, and the availability of statistical methodology to diminish their impact in analyses, is vastly different between the assessment of individuals and groups.

Group Studies

Epidemiological Studies

Although it is clear that epidemiologists can and do use quantitative food intake data, it is also clear that many such studies collect data with food-frequency or diet-history techniques, most often classified as qualitative or semiquantitative methods. Large epidemiological studies differ in purpose and design from national surveys. They are often designed to examine groups defined by specific characteristics of interest to the investigator rather than representing the population as a whole. They may be concerned with a particular aspect of diet and hence can optimize data collection for this variable. Rather than being primarily interested in the distribution of intakes in a national survey, the epidemiology study usually wants to test the association between the intake variable and a defined outcome. This places emphasis on the ranking of intakes of individuals rather than the distributional characteristics.

Many epidemiologists select food-frequency or diet-history methodologies, sometimes selectively abbreviated, rather than the quantitative methods recommended for national surveys. There are at least two apparent reasons for this choice, one theoretical and one logistical: (1) the frequency questionnaire may be assumed to circumvent the problems of day-to-day variation in intake by asking about usual eating practices (see discussion of this under individuals, below); (2) a frequency questionnaire is more easily administered than a record, one day recall or diet history. Frequency questionnaires may be designed for self-reporting and may be distributed to participants by

mail. Food-frequency data are generally believed to provide less precise quantitative information than expected with daily recalls or records of foods consumed. There may be a trade-off between errors involved and feasibility in the selection of methodologies.

It is almost certain that, in common with all other dietary methodologies, there is an error term attached to the data collected with food-frequency methods. This may be the equivalent of the 'random error' in records and recalls, although potentially of smaller magnitude. However, since the investigator has only a single estimate for each individual, there is no simple approach estimate this error. Approaches have been developed and are still evolving to use highly standardized 24-h recall intake data in the calibration of food-frequency data across multiple studies.

Drawing on the theory of errors in measurement, numerous statistical approaches that offer the possibility of adjusting analyses, or at least assessing the impact of random error on analytical outcome, have been proposed. These require the estimation of the error term in the dietary data. Therein lies a key limitation of the food-frequency instruments; the error term is essentially inestimable.

For large epidemiological studies, involving geographically dispersed subjects, logistical feasibility becomes an overwhelming consideration. The food-frequency method often carries overwhelming logistical advantages for epidemiological studies – advantages that far outweigh the potential or real disadvantages mentioned above.

Evaluation and Monitoring of Interventions

When the objective of a special-purpose survey is to evaluate or monitor an intervention program, there could be interest in a specific dimension of food intake, allowing adoption of specifically designed and targeted food-intake methodology. Often, the investigator may wish to estimate intakes of many foods, patterns of food use, or multiple nutrient intakes. If so, the preferred methodology may be repeated one-day recalls or records. Depending upon planned analyses, the investigator may be more interested in group behavior than in individual response. This too will affect the choice of methodology.

General Comment and Conclusion about Group Assessments

When the research question to be posed concerns the 'population risk' or prevalence of apparently inadequate intakes, the past 20 years have seen major forward strides. Now available are statistical approaches and software that can estimate the distribution of usual intakes with a single day of data on all subjects and a sample of replicates, or preferably, two independent days of data for all subjects (Hoffman *et al.*, 2002; Institute of Medicine, 2000). It has also been demonstrated that the prevalence of apparently inadequate intakes can be approximated by estimating the proportion of individual with usual intakes below the median nutrient requirement for the specific class of person (Institute of Medicine, 2000). Two major difficulties have been resolved. A remaining serious problem is that of alleged underreporting bias (see discussion below). Although many group assessments are undertaken for very specific purposes that allow adoption of specialized and targeted methodologies, there is danger in *post-hoc* analyses of the data base for other purposes.

Studies of Food Intake in Individuals

Although the unit of observation in groups is the individual, the unit of interest is the group. In this section, we address the situation when the unit of observation and of interest are both the individual. While this may seem 'academic,' it will be seen that there are extremely important differences between collecting and analyzing data for individuals as part of a group and for individuals as individuals.

The worst-case scenario arises when the goal of investigation is to evaluate the apparent adequacy of dietary intake for the particular individual (without assessment of the health condition of the individual). This involves an estimation of the individual's *usual* intake of one or more nutrients and comparison of this with their requirement of the nutrient(s). In this situation, three very serious issues must be addressed.

The most obvious problem is that associated with day-to-day variation in reported intake. For most nutrients, the within-person coefficient of variation (CV) falls between 15 and 30%. Vitamin A, vitamin B_{12}, dietary cholesterol, and fatty acid ratios have a notoriously higher day-to-day variation. Consider the very conservative estimate of a CV of 15%. For a single day's intake, this translates to mean that the individual's true usual intake lies within $\pm$ 30% of the estimate (95% confidence interval assuming a normal distribution). With an average of seven independent days of data, the confidence interval might fall to about $\pm$ 11–12%, and with 14 days of data, the interval might be $\pm$ 8%. It has been suggested that for dietary cholesterol, 4 weeks or more of dietary data might be needed to bring the confidence bounds to $\pm$ 10%. To make matters worse, it is generally assumed that the day-to-day variation in intake is random and that its magnitude across individuals is comparable. Both of these assumptions have been shown to be wrong. The magnitude of day-to-day variation is a characteristic of the individual. The

confidence bounds on an estimate of intake for a fixed number of days vary between individuals. Furthermore, a part of the variation is not random. It has been recognized that day of the week and other social patterns exert effects on food intakes of individuals. In addition, many individuals exhibit long-term patterns within their day-to-day variation. The reported energy intakes of one such individual collected across 365 consecutive days) are portrayed in Figure 1. One implication of these longer time trends is that to sample days correctly, one must define the time dimension of 'usual' and sample across that time frame rather than just worrying about the number of days needed for a defined confidence bound. It is seldom possible to collect many days of data for an individual and rarely possible to sample time correctly. Instead, it must be accepted that there are residual errors, often very substantial, in the feasible estimates of the usual intake of the particular individual. It is not clear whether diet-history methods can overcome these problems, and no easy way to address this question has been forthcoming. Compare this with the availability of statistical methods to estimate the distribution of usual intakes with only 2 days of data in the examination of large groups.

A second issue in the assessment of nutrient intake of a particular individual is that, for nutrients such as iron and zinc, we must recognize the potential effect of absorption enhancers and inhibitors concurrently consumed *in the same meal*. With folic acid, it is now suggested that folic acid taken as supplements or added to foods in fortification is absorbed more efficiently than the folate indigenous to foods. While our understanding of effects such as these is improving and algorithms to adjust estimated intake (e.g., to folate equivalents) are appearing, it must be accepted that we face appreciable errors from this source, irrespective of the choice of food-intake methodology. If these become essentially random errors, in population analyses the effects are addressed along with other random errors, but not in examination of the particular individual.

The third issue, this time relating to data analysis and interpretation, arises in the comparison of intake with requirement. Individuals have specific requirements for nutrients, but these differ among seemingly similar individuals categorized by age, gender, body size and composition, physical activity, etc. At best, we can describe the estimated distribution of requirements among individuals like the specific subject. There can never be a way of classifying the intake of a subject as 'adequate' or 'inadequate' unless their usual intake lies well above or well below the range of requirements. If the usual intake falls within the range, in theory one can assign a probability of adequacy. Any probability statement is based on the cumulative distribution of requirements. This is illustrated, for protein (FAO/WHO/UNU 1985 requirement estimates) in Figure 2. If the estimated usual intake of protein were estimated to be $0.1\,g\,kg^{-1}\,day^{-1}$, it would almost certainly be inadequate. Very few people would be expected to have a requirement that low. If the intake were $1.5\,g\,kg^{-1}\,day^{-1}$, one could assert confidently that intake is almost certainly adequate. Very few individuals would be expected to have a requirement that high. If the intake were $0.6\,g\,kg^{-1}\,day^{-1}$ (the median requirement), there

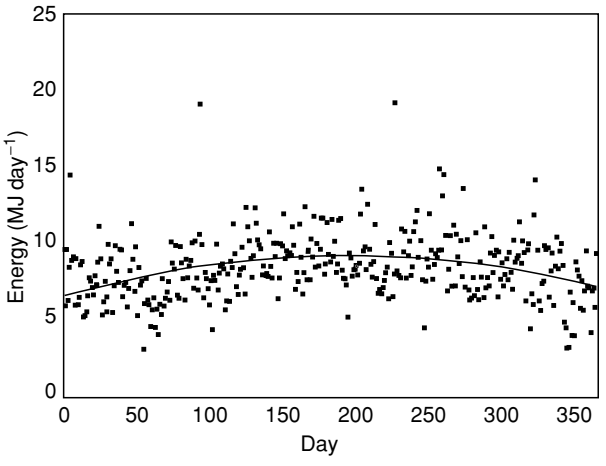

Figure 1 Long-term pattern within the day-to-day variation of energy intake in a single subject who reported intake for 365 consecutive days. From Beaton and Tarasuk (1991), with permission. Data from the Beltsville One Year Study of Dietary Intake.

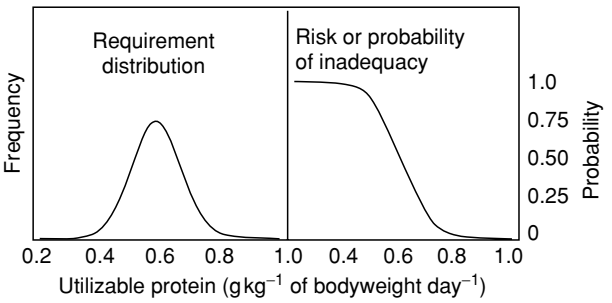

Figure 2 Probability approach to assessment of observed intake. The estimated distribution of protein requirements of young adult men is portrayed on the left (based on FAO/WHO/UNU (1985) *Energy and Protein Requirements: Report of a Joint FAO/WHO/UNU Expert Consultation. World Health Organization Technical Report Series 724*. Geneva: World Health Organization). The probability or risk curve, portraying the likelihood that a particular level of usual intake is inadequate to meet the actual requirement of a randomly selected individual, is shown on the right. Reproduced from Dietary Surveys: Surveys of Food Intakes in Groups and Individuals, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

would be a 50:50 chance that intake is inadequate: half of the individuals would be expected to have a higher requirement, and half would be expected to have a lower requirement. The approach can be formalized by the development of a risk curve, as portrayed in Figure 2.

The description of the probability approach described above assumes that the individual's usual intake is known without error. This is an incorrect assumption, as indicated above. Indeed, the error associated with the estimated usual intake may equal, or exceed, the estimated variability of requirement. This issue was addressed, without satisfying resolution, by the Institute of Medicine in 2000.

The final position we must accept is that, in spite of a sound theory based on probability, in fact we do not have, as yet, any practical tools that allow valid assessment of apparent adequacy of intake in a particular individual. We are deceiving ourselves if we think such assessment can be made, except in the situation of estimated usual intakes greatly higher or lower than the range of requirements (technically, at least two standard deviations of estimated usual intake above or below the tails of the requirement distribution).

What may be very hard to understand is that, while these issues may seem insurmountable in investigating of a particular individual, they become much less important in groups and, more particularly, population assessments. Many of the errors discussed above behave like random error terms. Some cancel out, but all can be addressed using currently available statistical tools. The existence of bias in reporting food intake (systematic under- or overreporting) cannot be corrected by any presently accepted procedure and remains an important issue for both individual and group assessment. The probability assessment of observed intake has established merit when applied to large groups and can even be greatly simplified in many situations.

Summary Comment – Individual Assessment

From the above, it follows logically that if evaluation of nutrient intake in the particular individual is very problematic, one must ask whether or not it is worth attempting. A much simpler dietary methodology can suffice to provide general descriptions of current food-use patterns, even though these may be more qualitative. For many counseling applications, or for monitoring compliance with a prescribed dietary regime, these may suffice and are almost certainly more acceptable to the client. The professional must judge what level of error is acceptable for the purpose at hand. If a high degree of precision is needed in such assessment, the other approaches not involving dietary data should be considered.

Bias in Reporting and Recording Food Intake or Computing Nutrient Intake

Bias in estimated nutrient intake can result from intentional or unintentional (erroneous memory) reporting by the individual; from errors associated with the instrument and/or interviewer involved in recoding the reported intake; or from food coding and the food-composition database. A specific example of the last of these might be the estimation of selenium intake without identification and coding of wheat sources in a country that imports wheat from more than one region. Instrument and interviewer errors have been documented in a number of studies. These sources of error are being addressed through a periodic comparison of chemically measured and calculated composition of composite meals and by careful training of interviewers together with a greater reliance on new computerized interview techniques that incorporate probes and quality checks. The most difficult source of bias to detect and control is that arising from the subject themselves, be it intentional under- or overreporting, or the consequence of imperfect memory. Interview probes may help avoid the latter.

The most widely described bias in estimated intake is with reference to energy. A few early studies demonstrated that obese subjects fed what they reported consuming showed weight changes very different from those seen when intake was being reported (inference was underreporting). When algorithms for predicting basal metabolic rate and total energy needs became available, these were applied to large group databases, and the discrepancies between reported intake and computed need in apparently weight-stable people were cited as evidence of bias in reporting. With the introduction of doubly labeled water techniques for indirect estimation of total energy expenditure, we have seen a new wave of reported bias in estimated energy intakes. Information pertaining to nutrients is sparse, since we seldom have an accepted gold standard for independent estimation of intake.

There can be no question that bias in estimating nutrient intake exists. The theoretical impact is clear. Consider, for example, the impact of underestimating protein intake by 10%. If true intake is well above the range of requirements, the assessed risk of inadequacy would remain 0 and present no problem. If true intake were perhaps $0.8\,g\,kg^{-1}\,day^{-1}$, the assessed probability of inadequacy could increase from

2–3% to about 30%. In groups, the bias likely varies from person to person. For assessments of the type just portrayed, there remains a problem. For epidemiological studies in large groups, 'random' bias does not necessarily hide true associations between intake and some health outcome; it increases 'noise' in the data and decreases statistical power. Conversely, while the presence of an association may be detected, the description of that association involving actual levels of intake is affected. If the bias moves with the outcome of interest (e.g., alleged underreporting of intake by overweight subjects), extremely serious confounding of analyses can result.

To date, no generally accepted method of 'adjusting' nutrient intakes for the probable bias has been developed. Many approaches have been suggested, but each presents serious limitations, at least for some applications. Two general approaches in varying forms have appeared and are mentioned here to illustrate the type of issues that arise. One approach would predict energy need and then adjust nutrient data by a factor (estimated energy requirement)/(estimated energy intake). The second would also predict energy requirement, establish limits based on expected errors in that estimate, then reject subjects with estimated intakes outside those limits. When these approaches are applied to nutrients, they both assume that misreporting of nutrients is exactly proportional to energy (i.e., the nutrient:energy ratio is valid). We lack sound evidence for this assumption. When outliers are excluded, one is likely to generate yet another bias – erroneous reporting that moves a subject into the acceptable range will be missed. Further, if rejection rates are substantial, one must question whether the data continue to represent the target population. A final issue is the simple observation that, at present, we are unlikely to be able to predict the energy requirement of a particular free-living subject with any better precision than we can estimate their energy intake. One must question approaches that attempt to address measurement error by using an erroneous reference.

Bias in estimated nutrient intake is a continuing problem without, at present, a satisfactory solution. Analysts and users of nutritional analyses must be cognizant and cautious in their interpretations.

Conclusion

There are serious limitations associated with the estimation of food and nutrient intakes in individuals. As one moves to larger groups, some of these limitations diminish in importance. Certainly, existing limitations have not prevented major advances in establishing associations between diet and disease. However, at the level of the particular individual, the recognized limitations call into question the merit of attempting detailed dietary assessments. Limitations of data collected in studies of individuals or groups must be weighed up in terms of the defined purpose of the study and planned analytical methodology. When there is a mismatch between purpose and methodology (of collection and analysis), quality declines, and limitations on interpretation are likely to increase.

DIETETICS

P A Judd, University of Central Lancashire, Preston, Lancashire, UK

Introduction

This article briefly relates the history of the development of dietetics and the role of the dietitian and describes the current roles of dietitians in some general and specialist areas of practice. The increasingly important roles of the dietitian in research and education are also discussed.

Definition and History of Dietetics

Dietetics is defined as 'the application of the science of nutrition to the human being in health and disease.' However, the term 'dietitian,' used to describe a practitioner of dietetics, was in use long before the science of nutrition had become an accepted discipline. Although Florence Nightingale has been described as the first dietitian because of her insistence, during the Crimean war, that the sick men in her charge would not recover if not well fed, the first use of the title of dietitian was recorded in 1899 in the USA. The dietitian was then described as a person working in a hospital who provided nutritious meals to patients and the earliest dietitians were primarily home economists. The role of the dietitian expanded greatly during the 20th century and is no longer seen simply as the provision of food. The dietitian is seen as the expert in the planning and evaluation of nutritional care for patients requiring therapeutic dietary regimens as well as for the population in general and this is reflected in the breadth of knowledge and skills required for qualification and registration as a dietitian.

The profession of dietetics is a relatively young one, first formalized in the USA in 1917 when the American Dietetic Association (ADA) was founded. In the UK the first dietitians were nurses and the first dietetic department was started in the Edinburgh Royal Infirmary in 1924. Several of the pioneers of British dietetics were able to visit the USA in the 1920s to study the work of established dietetic departments there and after several abortive attempts the British Dietetic Association (BDA) was established in 1936. Other countries followed and in 2000 there were more than 30 dietetic associations throughout the world registered with the International Committee of Dietetic Associations (ICDA).

Dietetics Qualifications

It is now accepted that the practice of dietetics requires a wide range of knowledge and skills. As the scope of dietetic practice has expanded over the years, training programs have continually adapted to insure that the practitioner has the current knowledge and skills required. The education and training of a dietitian usually comprises a degree program (either BSc or MSc), based in a university, including or followed by a period of practical training based in a recognized hospital dietetic department.

Preregistration programs include coverage of basic and applied sciences (chemistry, biochemistry, physiology, nutrition, microbiology) as well as social sciences (psychology and sociology). In addition, as dietetics is concerned with feeding people, a knowledge of the food habits of populations together with detailed knowledge of food composition and food preparation is essential. To this basic foundation is added knowledge of medicine, pathology, and the therapeutic uses of dietary treatment. Increasingly the development of skills required to communicate with all types of people is emphasized, whether counseling individuals or teaching groups.

During the practical training or internship the student dietitian learns to apply the theory learned at university with individuals or groups of people. The training covers all aspects of dietetic practice and the students spend time in different settings, including community care and, in some countries, in large-scale catering establishments. In order to become a registered practitioner students must demonstrate that they have both good theoretical knowledge and are competent practically.

In the USA, UK, Canada, Australia, New Zealand, South Africa, The Netherlands, and many other countries, training programs are regulated by bodies external to the educational establishments and successful completion of such a regulated training allows registration as a dietitian. In the USA regulation of courses and training programs is carried out by the ADA. In the UK, the former Dietitian's Board of the Council for Professions Supplementary to Medicine (CPSM) has been replaced by the Health Professions Council, set up to regulate the 12 professions previously overseen by the Boards of the CPSM. In the UK only state-registered dietitians may be employed in the National Health Service. The registration body, in each case,

produces a statement of conduct which describes the role and responsibilities of the registered dietitian and failure to work within this statement of conduct may result in disciplinary action and removal from the register. Registration in one country does not automatically mean that a dietitian can work elsewhere in the world as levels of education and training are not always comparable from country to country. Each registering body will therefore consider applications from dietitians from other countries and suggest further training if appropriate.

Continuing education and demonstration of continuing competence to practice is increasingly being seen as vital in this rapidly changing profession; in the USA there has long been a requirement to demonstrate continuing education and continuing registration is dependent on this. In the UK it is not yet a registration requirement to demonstrate continued competence to practice, although this was considered as part of the recent review of the Act of parliament defining Professions Supplementary to Medicine and is likely to become mandatory now that the Health Professions Council has succeeded the CPSM. However, the BDA, the professional association for dietitians, has recently introduced a Diploma in Advanced Dietetic Practice, which has as part of its remit the recognition of continuing education.

The Role of the Dietitian

The first dietitians (with the exception of those concerned mainly with food service provision) worked mainly in hospitals. Clinical dietetics and the acute hospital service still claim a large proportion of the graduates from dietetics training but other areas of work are increasingly becoming more important. In the UK changes in the emphasis of health care, particularly the change of emphasis from acute (hospital) care to care in the primary health care setting, has resulted in a marked increase in the number of 'community-based' dietitians and the Community Nutrition Group of the BDA has been the fastest-growing specialist group in recent years.

Dietitians also have many other roles outside the health services. In industry they may work as advisors to food companies, wholesale and retail suppliers of food, and companies producing specialized dietary products. They also work with government agencies, e.g., in dietary surveys of the population, in evaluation of intervention programs, and advising on the practical application of policy. In addition dietitians are increasingly working independently as consultants, e.g., in private practice, journalism, and sports nutrition. Whatever aspect of work a dietitian chooses, one of the primary roles will be that of an educator, whether in assisting individuals to understand and apply a therapeutic regimen, teaching doctors, nurses, or other health professionals about nutrition and dietetics to help them carry out their functions, teaching groups of people about aspects of preventive nutrition, or writing an article for the scientific or lay press. The ability to communicate is therefore central to every dietitian's role.

The Dietitian's Role in Food Service

In the USA and countries which follow the US model, hospital dietitians work in either administrative or clinical (therapeutic) areas. Administrative dietitians manage the provision of food services for all patients and staff. They are responsible for food production and quality control in the delivery of the hospital meal service as well as insuring their nutritional adequacy. They are also often responsible for budgeting and staffing of the dietary departments and usually relate to other administrators and managers, having little or no direct contact with patients or medical staff. The clinical dietitian is the person who has direct contact with patients and the medical and paramedical staff involved in their care.

In the UK the practice of dietetics has evolved along a different route and dietitians do not usually have overall responsibility for food service. However, there is usually close liaison between dietitians and the catering manager to insure the provision of nutritionally sound selective menus. The dietetic manager will also be consulted on matters of policy such as the implications of changes in food preparation systems or the introduction of healthy eating policies. It is acknowledged now that many patients (especially elderly people) are malnourished when they enter hospital and that this often becomes worse during their stay. Dietitians are therefore very much involved in attempts to insure that every patient has a nutritionally adequate diet.

Clinical or Therapeutic Dietetics

The term 'therapeutic dietetics' is used to describe the work of the dietitian in his or her direct dealings with patients who require special diets, for various reasons, as outlined in Tables 1 and 2. The role of the clinical dietitian has broadened in the last decade, both with respect to the range of conditions which are encountered and the setting in which the work is done. In the past the role of the therapeutic dietitian was to calculate, teach, and facilitate compliance to a range of dietary regimens prescribed by medical or surgical practitioners for specific disorders. These functions are still important and, indeed, are

Table 1 Examples of the use of therapeutic diets to alleviate symptoms of disease

Symptoms	*Condition*	*Therapeutic diet*
Dysphagia	Disease of mouth or esophagus	Semisolid diet, with thickeners
Weight loss	Trauma, surgery, carcinoma, severe burns	High-energy
Constipation	Diverticular disease, irritable bowel syndrome.	High-fiber
Diarrhea	Pancreatic insufficiency	Low-fat
	Lactose intolerance	Lactose-free
Polyuria, polydipsia	Diabetes	Controlled energy; high-complex-carbohydrate and low-fat

Table 2 Examples of therapeutic diets used to correct disturbances in physiological or metabolic function

Condition	*Cause*	*Therapeutic diet*
Uremia	Renal failure	Moderate-protein, high-energy, low-phosphate
Edema	Liver or renal diseases	Salt restriction
Malabsorption	Pancreatic disease	Low-fat plus MCT
	Cows' milk protein intolerance	Exclude milk and dairy products
Eczema	Food allergy	Remove identified foods, e.g., cows' milk, eggs
Villous atrophy	Celiac disease	Gluten-free
High blood phenylalanine	Phenylketonuria	Controlled phenylalanine intake plus amino acid supplements

extending as improvements in medicine enable patients who would previously have died in childhood to survive to adulthood with continuing needs for nutritional care. For example, patients with cystic fibrosis require nutritional support as their lungs deteriorate and women with hyperphenylalaninemia need dietary advice in order to help them achieve successful pregnancies.

In addition to these roles, however, dietitians are increasingly involved in the assessment and support of patients not traditionally seen as requiring a therapeutic diet. Planning and implementing feeding for patients who are nutritionally compromised as a result of trauma, surgery, or chronic illnesses such as cancer or acquired immunodeficiency syndrome (AIDS) has become an important part of the workload of the dietitian working in both acute and community settings.

Clinical dietitians are increasingly involved in decisions about the appropriateness of particular dietary regimens or the type of nutritional support required and in many institutions are responsible for prescribing the patient's diet in consultation with the physician or surgeon, who recognizes the dietitian as the expert. In acute care a dietitian is an important member of the nutrition support team, working alongside nurses, pharmacists, and medical staff to advise on the feeding of all patients who need nutritional support. (However, in the UK at least, the medical practitioner is ultimately responsible for the patient and any therapeutic regimen, including dietary treatment.)

As new advances occur in clinical practice, the dietitian must be aware of these, and many dietitians are now involved both in research into the development of new treatments and in evaluating current practice. There has been a rapid increase in the numbers of dietetic practitioners with research qualifications and dietitians are increasingly initiating their own projects, working alongside experienced investigators rather than acting as technicians in other people's projects, as sometimes happened in the past. These advances are contributing in some part to a reevaluation of dietetic practice and result in a need for dietitians to justify the evidence-base for therapies and to set priorities in their work. As dietetics has developed it has become more specialized and this has resulted in the formation of practice groups within the dietetic associations. These groups have become a forum where advances in practice in particular areas can be shared and are often a focus for continuing education, both formally (by running courses) and informally. Some of the more specialized roles in which dietitians are working are described below.

Pediatric Dietetics

The pediatric dietitian has a unique role in that he or she has to combine the metabolic requirements of the disease process or condition with the normal requirements for growth and development. With the advances in early diagnosis of many complex metabolic conditions, children may require complicated diets which are very different from the rest of their family and peers, which need constant modification as the child grows and which may be lifelong. The dietitian is responsible for modifying the diet as necessary to take account of the patient's metabolic

requirements, any feeding difficulties, whether mechanical or physiological, and the patient's food preferences and dislikes as he or she grows. The dietitian is an essential part of the support system for children with inborn errors of metabolism such as phenylketonuria and cystic fibrosis, conditions such as renal or heart disease, food allergies, diabetes, and many others, being able to tailor the diet to the patient's specific needs and having access to the information about special foods and products of which the carer might be unaware or have difficulty in locating.

The pediatric dietitian also has an important role as an educator, often teaching the child's parents initially and later the child him-/herself how to cope with the constraints of a special diet, both at home and in school. As is the case with adult patients, the dietitian will often be able to put the child and family in contact with support groups where newly diagnosed patients or parents will be helped by others with first-hand experience of the disease and its treatment.

Renal Dietetics

Renal dietitians are usually attached to specialized renal units and are an integral part of the team involved in the treatment of people suffering from varying degrees of renal impairment, whether acute or chronic. In the USA there is a legal requirement related to funding of patient care which states that a qualified dietitian must be part of the professional team which develops long- and short-term care plans for renal patients. The dietitian, together with the nephrologist, has responsibility for nutritional assessment, the diet prescription, and for monitoring responses to treatment. In addition, he or she must be able to devise appropriate individualized dietary plans, taking into account any other ongoing disease processes or conditions (e.g., diabetes mellitus) and will teach the patient and family how to manipulate the diet. The dietitian will also monitor dietary compliance. A thorough knowledge of physiology and the pathological processes involved in the various kidney diseases and an ability to interpret the patient's biochemical data are therefore essential for the renal dietitian.

Some disorders may resolve with treatment but others may become chronic and result in permanent kidney failure. In progressive renal disease, patients may initially be managed using diet and drugs alone but as the kidneys fail they will require replacement therapy such as peritoneal dialysis, hemodialysis, or transplantation. Each of these stages requires different dietary treatment. The dietitian will deal with a variety of patients with different types of disease and at different stages of progression, with different needs with respect to diet and will also have to teach the patient how to cope with changes in diet which follow as he or she changes from one treatment to another.

Nutritional Support

Nutritional support of patients who are unable to feed themselves adequately by the normal oral route is now an important area practice. The dietitian's involvement here ranges from simply advising on and providing supplements for the patient who cannot eat enough to designing and advising on complete parenteral nutrition regimens for the unconscious patient in intensive care. Between these two extremes will be patients who need enteral feeds to provide complete or supplementary nutrition for a variety of reasons and for periods varying from a few days to a lifetime.

Patients requiring nutritional support may be acutely ill or may require long-term feeding, sometimes at home. The dietitian must be able to assess the nutritional requirements of each individual and design appropriate feeding regimens under all circumstances. Many patients will be sent home whilst still being tube-fed, either enterally or parenterally, and the community dietitian as well as the dietitian in the acute hospital will both be closely involved in the patient's care and in monitoring progress.

Diabetes Care and Education

Traditionally the dietitian always had an important role in the treatment of patients with diabetes mellitus, and the radical changes in dietary treatment over the last 15–20 years have emphasized this role. Since the early 1980s there has been a move away from diets low in carbohydrate and the basis for the treatment of all people with diabetes mellitus, whether young and insulin-dependent, or older and treated by diet alone or diet and hypoglycemic drugs, is now the supply of an appropriate amount of energy as a low-fat diet with at least 50% of energy from foods rich in complex carbohydrates and nonstarch polysaccharides. In addition, the recognition that similar amounts of carbohydrate from different foods have different effects on blood glucose levels has led to less stress on absolute intakes of carbohydrate and a move towards a qualitative approach to the diet.

Many established diabetics found the change in dietary treatment confusing and have needed help in switching to the new regimen. Newly diagnosed patients also need help in learning to manipulate and control this lifelong disorder. Many dietitians have also been involved in the research which has underpinned the progression of dietary treatment and are now evaluating its effects.

HIV and AIDS

The dietetic care of patients with human immunodeficiency virus (HIV) and AIDS has become increasingly important in the last decade. Dietitians may work with people who are HIV-positive to help them optimize their nutritional status and resist the opportunist infections which eventually cause death in the patient with frank AIDS. Once the person develops AIDS, the dietitian's role becomes both therapeutic and palliative, devising and implementing with the patient regimens to satisfy nutritional requirements when, for example, disease of the gastrointestinal tract results in multiple malabsorption or cancer results in weight loss and anorexia. The advent of new multidrug regimens which require careful planning of meals to match their absorption characteristics and which have side-effects affecting nutritional status has made the dietitian's role even more important.

Other Areas of Specialization

There are many other areas of clinical dietetics in which individuals may specialize, including oncology, liver disease, gastroenterology, eating disorders, gerontology, and care of the mentally ill or mentally handicapped. Many of the activities in these areas and those described in the sections above are not confined to the hospital but require input from the dietitian in the community.

Dietetics in the Community

Community dietitians fulfill a variety of roles which may range from working mainly in clinical dietetics in the community setting, e.g., advising a variety of patients in a general practitioner's clinic, to that of public health nutritionist advising the local health or social services on aspects of food policy. In recent years, due to the changing emphasis in health care, the numbers of community dietitians in the UK have increased markedly. The main increase has been in supplying clinical (therapeutic) care to the primary health care setting and about 21% of UK community dietitians surveyed in 1997 stated that this was their only role. About half of the respondents to the survey were involved in health promotion activity as well as clinical work but only 9% worked solely in health promotion.

Many of the dietitians working in health promotion achieve their objectives by educating other professional groups, such as doctors, nurses, health visitors, and midwives, who will then pass the specific knowledge on to the individual or groups of patients. Prevention of diseases which may be diet-related has recently become a much more important issue, and dietitians are working with schools, health education departments and industry to try to educate the public towards consuming a healthier diet. Dietitians also work as advisors in government departments and are therefore involved in planning nutrition policies for the country as a whole.

Dietitians in Research and Education

The advances in all areas of nutritional knowledge, both in terms of achieving optimal health and prevention of disease as well as in therapeutic nutrition, have led to an increasing number of dietitians working in research. The combination of nutritional and medical knowledge and the ability to translate these into terms of foods eaten means that the dietitian has a unique role to play. Dietitians often approach research from a deductive perspective in order to understand or solve difficulties observed in practice, and the results of this research will often have practical significance and can be incorporated into treatments. Evaluation of practice can also be considered as part of this deductive process and is essential in the current health care climate when increasing reliance is put on measuring effectiveness and the use of evidence-based medicine. In addition, dietitians are increasingly involved in basic experimental and analytical scientific research which is essential for nutrition and dietetics to advance in both clinical and nonclinical areas. Involvement in research has led to registration for higher degrees and the number of dietitians with masters' degrees or doctorates is now considerable in countries such as the USA, UK, Canada, and Australia.

Research is also seen as an important part of the role of those dietitians employed in universities and colleges to teach dietetic and other students. In the UK and other countries, there is a requirement that each dietetic training course has registered dietitians on the staff and in many cases these people also work in the National Health Service in order to keep up to date with current practice. Dietitians are also involved in the education of many other professional groups, including nurses, midwives, and pharmacists. Recently, advances have been made in convincing those in charge of medical education at undergraduate and postgraduate level of the importance of nutrition in medical education and this is also seen as an important area where dietitians should be involved.

DRESSINGS AND MAYONNAISE

Contents

The Products and Their Manufacture

S C Yang and L S Lal, Providence University, Taiwan, Republic of China

Introduction

Salad dressings are liquid or semiliquid products used to flavor, moisturize, and enrich salads. In addition, they may be used as spreads for sandwiches or as ingredients in a variety of cold and hot recipes.

A two-phase emulsion may consist of oil droplets in water phase (i.e. oil-in-water emulsion) or water droplets in oil phase (water-in-oil emulsion), as shown in Figure 1. Traditional salad dressings are oil-in-water emulsions. Droplets of oil, the dispersed phase, are suspended in a continuous aqueous acidic phase such as vinegar or lemon juice. Other ingredients are added to modify the flavor or texture. Normally oil and water do not combine well, but separate into layers. However, the two phases must remain evenly dispersed in an acceptable salad dressing. (*See* **Colloids and Emulsions**.)

Salad dressings can be divided into four categories on the basis of their formulations and stability:

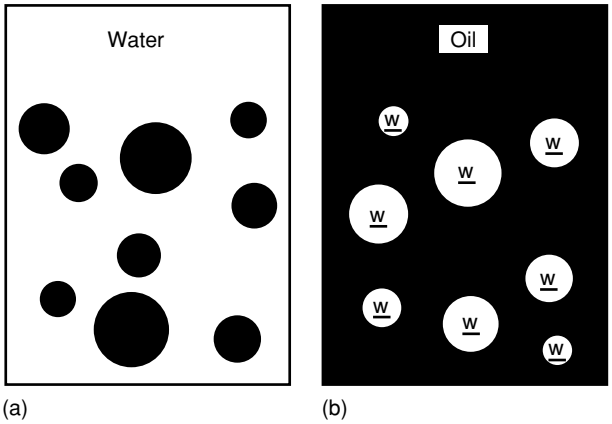

Figure 1 A two-phase emulsion may consist of (a) oil droplets in water (o/w) or (b) water droplets in oil (w/o).

1. oil and vinegar dressings (most are temporary emulsions);
2. emulsified dressings (most are permanent emulsions);
3. cooked salad dressings (most are emulsions containing a starch thickener);
4. low-fat/diet products (most are emulsions containing hydrocolloids for viscosity and texture characteristics).

Each type of salad dressing must conform to certain specifications; in the USA each has a standard of identity established by the Food and Drug Administration (FDA).

Typical Examples and Their Uses

Oil and Vinegar Dressings

Basic French dressing and variations such as mustard French, herbed French, Italian, piquante, chiffonade, and avocado dressings are examples of temporary oil and vinegar emulsions. The ingredients include vinegar, oil, and various dry ingredients. In these products the liquid phase separates after mixing, although dry ingredients, such as mustard and paprika, collect at the oil–water interface to give limited stability to the emulsion. These dressings should be mixed thoroughly immediately before they are used. The harder the mixture is beaten or shaken, the longer it takes for it to separate again.

Emulsified Dressings

The classic example of an emulsified dressing is mayonnaise, a permanent oil-in-water emulsion. Mayonnaise is made from a vegetable oil, vinegar and/or lemon juice, and whole egg or egg yolk. Additional seasonings such as mustard, paprika, and salt are usually added. By legal definition in many countries (e.g., the USA), commercial mayonnaise must contain either egg yolk or whole egg and must have an oil content of not less than 65% by weight. Whole egg or egg yolk functions as an effective emulsifier and creates a permanent emulsion. The rather high percentage of oil contributes significantly to the viscosity of the dressing. The viscous nature of permanent

emulsions makes it difficult for the oil drops to come into direct contact and coalesce. (*See* **Emulsifiers**: Organic Emulsifiers.)

Emulsified French dressing is similar to basic French dressing, except that egg yolk is added to prevent the oil and vinegar from separating. Its preparation is similar to that of mayonnaise. Mayonnaise is sometimes used by itself as a salad dressing but more often serves as the base for a variety of other dressings. Thousand Island, Lousis, Russian, Chantilly, and blue cheese dressings are all mayonnaise-based. These dressings are generally thick and creamy, and many of them contain sour cream.

Cooked Salad Dressings

Cooked salad dressings resemble mayonnaise in appearance but differ in some of the ingredients and in the method of preparation. The basic ingredients are vegetable oil, vinegar or lemon juice, whole egg or egg yolk, milk or water, and a cooked starch paste. Homemade cooked salad dressings are usually thickened with starch and/or egg. Very little, if any, oil is used in these dressings. However, a commercial salad dressing, labeled as such, must meet the standard of identity of the FDA and contain by weight no less than 30% vegetable oil and no less than 4% liquid egg yolk or the equivalent. Although these dressings are often very similar in appearance to mayonnaise, they cannot be labeled mayonnaise because of the lower oil and egg yolk content, plus the fact that they may contain cooked starch. The reduced oil content has the advantage of making this product lower in calories than mayonnaise.

Low-Fat/Diet Products

The recent change in dietary consciousness has affected the type of food consumers select at supermarkets and in restaurants. In 1985, the size of reduced-fat or reduced-calorie sauces and dressings grew faster than the total market. In 1986, this category of food grew at an annual rate of 6% but reduced-calorie products achieved 23% growth. The driving forces were the increased interest in nutritious foods and dietary fiber, less consumption of cholesterol, and a marked increase in vegetarianism.

By moving low-calorie/reduced-fat out of the diet section of supermarkets and repositioning them with regular, standard products, producers improved the image of these products. The low-calorie/reduced-fat products are now recognized by consumers not as diet foods but as nutritious, lower-calorie counterparts to the standard products, with good sensory properties.

Reduced-fat dressings and mayonnaise require processing similar to traditional products and a one-third reduction of oil content. The oils are the same as for the full-fat products. Generally, soya bean oil is used. Gums, particularly xanthum and alginates, are incorporated to stabilize the formula, and water replaces the fat removed. These products rely totally on hydrocolloids for viscosity and texture characteristics.

Food technologists have developed ingredients that can be used to replace or lower the fat content of food products. One such ingredient is Simplesse, a physically modified combination of milk and egg-white proteins processed by an internationally patented heating and blending procedure called microparticulation. Simplesse possesses fat-like characteristics while providing significantly fewer calories than fat for such items as mayonnaise and salad dressings. Other recently developed fat substitutes include Olestra, a sucrose polyester, and Veri-Lo, a creamy white emulsion containing milk fat. All substances must undergo review and gain official approval before they can be used. (*See* **Fats**: Fat Replacers.)

Reduced-sodium mayonnaise and salad dressings are also of interest to health-conscious consumers. The market has grown steadily since 1980, and is expected to make up 23% of the total sauces and dressings market by 1995. Reduced-sodium mayonnaise is made with salted egg yolk containing potassium chloride rather than sodium chloride. Frozen salted egg yolk made with potassium chloride is less viscous than that containing sodium chloride. However, viscosity and stability of mayonnaise made from 10% salted (potassium chloride) egg yolk are acceptable. (*See* **Hypertension**: Hypertension and Diet; **Sodium**: Physiology.)

Continued growth in the area of low-calorie, reduced-fat and reduced-sodium mayonnaise and salad dressings is anticipated. The aging population, combined with increased nutritional awareness, will create a market for such modified products.

Formulations

Oil and Vinegar Dressings

French dressing is prepared from edible vegetable oil and the following acidifying and flavoring ingredients:

1. salt;
2. nutritive carbohydrate sweeteners, such as sucrose, dextrose, corn syrup, glucose syrup, or honey;
3. mustard, paprika or other spices, spice oils or spice extracts;
4. any suitable, harmless food seasoning or flavoring (other than imitation);
5. tomato paste, tomato purée, catsup, sherry wine;
6. any vinegar or vinegar diluted with water to an acidity of not less than 2.5% by weight calculated

as acetic acid, or any such vinegar or diluted vinegar mixed with an additional optional acidifying ingredient such as citric acid, weighing no more than 25% of the weight of the acids of the vinegar or diluted vinegar calculated as acetic acid (lemon juice is another acidifying ingredient which may be used in place of vinegar).

French dressing contains not less than 35% by weight of vegetable oil. The ratio of oil to vinegar in basic French dressing is 3:1. Some chefs prefer a 2:1 ratio. Less oil makes the dressing more tart, while more oil makes it milder in flavor and oilier. For emulsified French dressing, eggs or other emulsifiers (vegetable gum, propylene glycol esters of alginic acid, methyl cellulose, pectin, xanthan gum, etc.) may be added, the total content being no more than 0.75% by weight. Eggs used for French dressing can be fresh, frozen, or dried.

Formulae for commercially prepared dressings and mayonnaise vary according to the specific plant and equipment employed. Also, taste preference is different from region to region. Herein, typical formulae for certain commercial products are presented.

A typical commercial French dressing formula may contain:

Water	12.0%
Vinegar (cider) 5%	22.0%
Sugar	8.8%
Salt	3.5%
Worcestershire sauce	3.5%
Paprika	4.5%
Mustard, garlic, onion	4.7%
White pepper	0.3%
Vegetable oil	40.0%
Gum tragacanth	0.4%
Dried egg-yolk solids	0.3%

In this formula, the total solids of commercial liquid egg yolk is about 44%. Dried egg yolk may be substituted for commercial liquid egg yolk on a total solids basis. French dressing may be mixed and packed in an inert atmosphere in which air is replaced totally or in part by carbon dioxide or nitrogen.

Emulsified Dressings

Mayonnaise and mayonnaise dressing are emulsified semisolid food products prepared from edible vegetable oil, egg yolk-containing ingredients and the following acidifying and flavoring ingredients:

1. salt;
2. nutritive carbohydrate sweeteners, such as sucrose, dextrose, corn syrup, glucose syrup, or honey;
3. mustard, paprika or other spices, spice oils or spice extracts, except turmeric or saffron, and no spice oil or spice extract which imparts to the mayonnaise a color simulating that imparted by egg yolk;
4. any suitable, harmless food seasoning or flavoring (other than imitations), provided it does not impart to the mayonnaise a color simulating that imparted by egg yolk;
5. monosodium glutamate;
6. acidifying ingredients, which may be any vinegar of not less than 2.5% acetic acid, or frozen, canned, concentrated or dried lemon or lime juice with a total acidity of no less than 2.5% calculated as acetic acid; citric or malic acid may be used in a proportion not to exceed 2.5% of the acid of the vinegar calculated as acetic acid.

A typical commercial mayonnaise formula may contain:

Vegetable oil	78.5%
Vinegar, white (10%)	3.8%
Water	11.6%
Sugar	1.8%
Salt	1.2%
Spices (mustard, onion, etc.)	0.3%
Dried egg yolk solids	2.8%

This formula provides a mayonnaise with medium viscosity. For a heavier viscosity, vegetable oil may be increased to 80.5% and water decreased to 9.6%. Mayonnaise may be mixed and packed in an inert atmosphere in which air is replaced totally or in part by carbon dioxide or nitrogen. Dried egg-yolk solids may be substituted for liquid egg yolk on a total solids basis.

Cooked Salad Dressings

Salad dressing is the emulsified semisolid product prepared from ingredients such as those of mayonnaise plus cooked (or partially cooked) starch paste prepared with a food starch, tapioca, wheat or rye flour, or any two or more of these. Salad dressing under the FDA standards of identity resembles mayonnaise in that it is an emulsion of oil in vinegar with egg as an emulsifier. It differs from mayonnaise in that it also contains starch paste as a thickener. Salad dressing may be flavored with one or more of the following ingredients:

1. salt;
2. nutritive carbohydrate sweeteners;
3. mustard, paprika or other spices, spice oils or any suitable harmless food seasoning or flavoring ingredient providing they do not impart a color simulating that imparted by egg yolk;
4. monosodium glutamate.

Salad dressing contains not less than 30% by weight of vegetable oil and no less egg yolk-containing ingredient than is equivalent to 4% by weight of the yolk solids of liquid egg yolk. Salad dressing may also contain not more than 0.75% by weight of any of several polysaccharide gums or their cellulose derivatives, methylcellulose and sodium carboxymethylcellulose; gums are not permitted in mayonnaise. The acidifying ingredients may be any vinegar or frozen, canned concentrated or dried lemon juice. Citric or malic acid may be used in a proportion not to exceed 25% of the total acid of the vinegar calculated as acetic acid. A typical commercial salad dressing formula may contain:

Vegetable oil	30.0%
Starch paste mixture	68.2%
Dried egg-yolk solids	1.8%

Dried egg-yolk solids may be substituted for liquid egg yolk on a total solids basis.

The starch paste is made by cooking and cooling a combination of ingredients in the following proportions:

Vinegar (10%)	17.2%
Salt	4.0%
Starches	7.7%
Sugar	15.0%
Spices (mustard, celery, etc.)	1.1%
Water	55.0%

The starch may be a food starch, modified food starch, tapioca, wheat, rye flour, or any two or more of these. Water may be added in the preparation of the paste. Salad dressing may be mixed and packed in an inert atmosphere in which air is replaced in total or in part by carbon dioxide or nitrogen.

Low-Fat/Diet Products

The Nutrition Labeling and Educational Act (NLEA) of 1990 standardized the nutrient content claims on food labels in the USA. Additionally, the NLEA standardized the serving sizes for each product. The US regulations for foods are published in Code of Food Regulations 21 CFR Part 101 each year. The three claims of particular interest here are 'reduced,' 'low,' and 'free' as applied to calories, sodium, fat, saturated fat, and cholesterol. In the USA, the term 'reduced' refers to a nutritionally altered product that contains at least 25% less of a nutrient or 25% fewer calories than a reference food. The term 'low' refers to a reference amount (or 50 g of food, if the reference amount is small) that contains ≤ 40 calories, ≤ 140 mg sodium, ≤ 3 g fat, ≤ 1 g saturated fat, and $\leq 15\%$ of calories from saturated fat, or ≤ 20 mg of cholesterol. The term 'free' refers to a serving and the reference amount contains no or physiologically inconsequential amount, specifically, < 5 cal, < 5 mg sodium, < 0.5 g fat, < 0.5 g saturated fat and < 0.5 g *trans* fatty acids, < 2 mg cholesterol, or < 0.5 g sugars. Standards may vary by country.

Various fat-replacers, including starch-derived fat mimetics, fiber-based fat mimetics, microparticulated proteins, hydrocolloid gums, and synthetic fat mimetics, have been successfully applied to reduced-fat, low-fat, and fat-free salad dressings. Formulation of a low-fat salad dressing containing 5% oil may contain:

Microcrystalline cellulose	3.2%
Vegetable oil	4.3%
Xanthan gum	0.3%
Modified starch	3.6%
Sugar	5.8%
Egg yolk	4.0%
Vinegar	4.5%
Lemon juice	0.5%
Salt	1.8%
Water	72.0%

The reduced-fat, low-fat, and fat-free salad dressing formulations are generally designed to impart a full-fat organoleptic profile, including texture, appearance, mouth feel, and body.

Major Ingredients in the Formulae

Vegetable oil Oil is the major ingredient contributing to the viscosity and body of mayonnaise. The rigidity of the emulsion depends partly on the size of the oil droplets and partly on how tightly they are packed. The more oil that is dispersed in the emulsion, the stiffer it will be. The choice of oil is governed by quality and local preference. It should be bland. Strongly flavored oils can make excellent dressings but are not appropriate with every food. Today, soya bean, cottonseed, sunflower, and corn oils are used commercially. They may be used singly or in combination. Deodorized, winterized oil should be used with dressings that are to be refrigerated. (*See* **Soy (Soya) Beans**: The Crop.)

Vinegar The functions of vinegar are as a preservative and a flavoring. Acid is the main preservative against microbial spoilage in mayonnaise. The industry makes use primarily of two types of vinegar, namely cider vinegar and distilled vinegar. The ideal vinegar for salad dressing and mayonnaise is one which is mild in odor and taste. Vinegar strength is measured by 'grain', 100 g equalling 10% acetic acid. Most salad vinegars range from 3 to 5% and should be standardized by dilution with water before measuring out for a recipe. (*See* **Vinegar.**)

Cider, malt and wine vinegars are more costly than distilled vinegar, but have unique flavors which contribute character to mayonnaise. Distilled vinegar is used when a neutral flavor is desired. Lemon juice may be used in place of, or in addition to, vinegar when its flavor is desired.

Egg Egg yolk is the emulsifying agent most often used in the home for preparing emulsions requiring stability. The fact that egg yolk is itself an emulsion explains, at least in part, why it is such an effective agent. (*See* **Stabilizers**: Types and Function.)

Eggs for mayonnaise may be fresh, frozen, or dried. Fresh broken eggs usually make a weak-bodied mayonnaise, although the product may stiffen somewhat during storage. Upon freezing and storing raw egg yolk below $-6\,^{\circ}C$, its viscosity increases and gelation occurs. This irreversible gelation of egg yolk makes it useless for mayonnaise production. The addition of 10% salt (sodium chloride) or 10% sugar will partially inhibit the gelation. Mayonnaise made from frozen salted egg yolk is thick and creamy. Dried yolk disperses readily in the aqueous phase of mayonnaise, and results in a thicker product than that obtained from frozen egg when prepared with the same total egg solids content.

Egg yolk is the primary source of color in mayonnaise. The intensity and tone of the yellow color of the yolk determine the color of the finished product, because no other coloring matter is permitted. In mayonnaise formulation, sequestrants, including but not limited to calcium disodium ethylenediaminetetra-acetate (EDTA) and/or disodium EDTA, may be used to preserve color.

Pasteurization of egg products in the USA became mandatory on 1 June 1966 in order to eliminate problems with salmonella. Eggs used for dressings and mayonnaise must meet this requirement.

Biopolymer Proteins and polysaccharides, such as soy protein isolate, whey protein concentrate, xanthan gum, sodium alginate, propylene glycol alginate, locust bean gum, guar gum, gum arabic, gum acacia, starch, modified starch and microcrystalline cellulose, are the two most important types of biopolymers used as ingredients in mayonnaise and salad dressings to enhance the texture, replace part or all of the fat, and enhance the stability of emulsions.

Proteins can form a film around the surface of fat droplets through three stages: (1) native protein molecules diffuse to the interface; (2) protein penetrates the interface; and (3) molecules rearrange to achieve minimum energy. Such actions not only reduce the interfacial tension, but also form a physical barrier to reduce the possibilities of flocculation and coalescence of fat droplets. Gums and/or starches are added to dressings possibly due to their thickening and/or surface-active effect. Gums and/or starches may improve the emulsion stability of the dressings by making the continuous phase more viscous, reducing the possibilities of fat droplets encountering each other, and creating a yield stress which increases emulsion stability by minimizing or eliminating creaming of the fat droplets under gravity force.

Mustard Mustard flour is probably used in more dressing formulae than any other spice. It is used chiefly for flavor but contributes slightly to emulsification. Oil of mustard can be used in place of mustard flour without affecting the emulsion strength. Oil of mustard must be obtained from mustard seed. Synthetic allyl isothiocyanate is not permitted. (*See* **Mustard and Condiment Products**.)

Procedures for Manufacture

Mayonnaise is prepared commercially by both batch and continuous methods, and there are many variations with respect to order and rate of ingredient additions. All equipment should be fabricated from stainless steel since vinegar will corrode ordinary steel and aluminum. Two-stage mixing is commonly employed with high-speed turbine blades in the first stage followed by more severe shearing of the oil into fine droplets in the second stage. The second-stage mixer may possess close-clearance whirling teeth as in a colloid mill.

The Dixie–Charlotte system is probably the one most widely used for the production of mayonnaise and salad dressings. The system consists of two Dixie mixers and a Charlotte colloid mill connected by appropriate piping, valves, and a rotary positive displacement pump. It is arranged so that one mixer feeds premix to the mill while another batch of premix is being prepared in the other mixer. The Dixie mixer is a deep circular tank fitted with three turbine mixers mounted side-by-side on a horizontal shaft close to the tank bottom. The shaft is turned by a variable-speed motor. This mixer can prepare mayonnaise requiring no further processing. The emulsion will be similar to one made with a Hobart mixer. The creamy texture of modern mayonnaise is obtained by pumping this relatively soft, coarse emulsion through the Charlotte mill. This equipment is available in a number of sizes with capacities ranging from 60 to 760 l per batch and yielding 230–4540 l of finished mayonnaise per hour. The system is arranged on a continuous-batch basis and can be modified to be operated as a truly continuous system.

Preparation of mayonnaise premix in the Dixie mixer is started by adding mayonnaise from a previous run to a level which will reach the mixer shaft. This gives the turbine blades a heavy material to work against while shearing the oil into fine droplets. Egg and dry ingredients are then added to the mixer with low-speed agitation. Oil and vinegar are then pumped or fed by gravity from supply tanks into the mixer. Agitation speed is usually increased periodically as the level of the premix rises. If the oil is added too slowly the premix will be thick and only partially emulsified. The subsequent passage through the colloid mill causes an overemulsification, resulting in a less viscous and stable mayonnaise. If the oil is added too quickly, in relation to agitator speed, the premix will develop an oily and curdled appearance; and, if the rate is not reduced, the emulsion will reverse to the water-in-oil type.

The premix is pumped through the Charlotte mill as soon as it is made. Timing should be such that the alternate premix tank should have just finished emptying. This is critical with many mayonnaise formulations as the premix can gel in the dixie mixer. The longer the premix is held in the mix tank prior to milling, the softer the final product will be.

Since salad dressings are similar to mayonnaise except for the lower oil content and the added starch paste, the ingredients function as in mayonnaise, and principles with respect to mixing and emulsion stability are similar. Special care must be given to starch cooking to develop the desired degree of thickening.

Raw starch is not water-soluble, but can be dispersed in cold water. It requires cooking to form a thickened suspension or paste. The sugar, salt, and vinegar are also part of the paste. The process calls for cooking and cooling the paste before combining it with the egg and oil emulsion. In batch processing, some of the paste is usually added to the egg before any oil is incorporated. This weakens the egg. The oil is thereby prevented from forming too tight an emulsion. The oil is not whipped in as vigorously as with mayonnaise. When the balance of the starch paste is mixed in after the oil is added, the entire mass must be fairly soft so that it can be pumped. The colloid mill yields a salad dressing with high viscosity and smooth texture. If the premix is too stiff, it will break down in the mill.

A batch-type starch paste cooker is essentially a jacketed vertical stainless-steel tank equipped with single- or double-acting agitators having side-scraping blades. A similar vessel is used for cooling the paste in which cold water or brine solution is used as the cooling medium. The most modern method for processing starch paste is a continuous one employing the concept of energy regeneration resulting from the use of a plate heat exchanger.

No matter what process is employed, starch paste should be used as soon as possible after preparation. The longer it stands after cooling, the more readily it will break down on being worked into the dressing. This is especially true with high-amylose starches. Cooking starch in vinegar solution tends to degrade or hydrolyze the starch to some extent. Modified starches are usually more resistant to breakdown than unmodified types. Where feasible, it is best to cook the starch with a minimum amount of vinegar in the water solution. (*See* **Starch**: Modified Starches.)

The continuous method employed in the manufacture of mayonnaise and salad dressing provides continuous automatic control so that one worker can process up to 75701 of mayonnaise, salad dressing, and pourable dressings per hour. One operator can monitor the entire system. Manual operation is almost nonexistent now.

Formulae are monitored from a control center. In the case of salad dressings, the system includes four probe-controlled surge tanks: one for oil, one for starch, one for egg, and one for the brine additive. Each of the surge tanks is probed at a high and low level so that, when a low level is reached, a signal is sent to a pump, and the tank will be resupplied with oil, starch, or egg until it reaches the high point. This maintains a constant supply of ingredients. Should any one of the tanks become empty, the entire system halts. Each controlled surge tank leads to a metering pump. Each pump is monitored from the control center so that it delivers the desired volume within 0.5%.

By setting the predetermined speed of each pump, the egg, brine, oil, and starch are metered accurately at the proper flow rate ratio to the inline mixer or preemulsifier where the ingredients are thoroughly mixed and a preemulsion is created. The preemulsion is then pumped with a sanitary pump to a colloid mill, where an extremely fine globule emulsion is created, and then on to the filler. Using this system, up to 25 different varieties of dressing can be made, all within the accuracy of 0.5% in the formulation.

Chemistry of the Products

S C Yang and L S Lal, Providence University, Taiwan, Republic of China

Introduction

Food emulsions, such as mayonnaise and salad dressings, are two-phase systems of immiscible liquids with limited stability. One phase is in the form of finely divided droplets of diameters generally larger than 0.1 μm. This dispersed, internal, or discontinuous phase is suspended in the continuous or external phase. Emulsion systems can be divided into two categories: (1) those consisting of droplets of oil dispersed throughout an aqueous medium, which are usually referred to as oil-in-water emulsions; (2) those in which droplets of water are dispersed throughout an oil or fat medium, which are termed water-in-oil emulsions. Most food emulsions are of the oil-in-water type. Emulsion properties generally depend on the nature of the continuous phase and the proportion of this phase to the dispersed phase. (*See* **Colloids and Emulsions**.)

Standards of identity, in the USA, for mayonnaise define the product as a semisolid emulsion made of egg yolk, edible vegetable oil, and acetic or citric acid. It may also contain salt, spices or spices oils, natural sweeteners and various natural flavoring ingredients. The oil content must be not less than 65% by weight, and the product must contain at least 2.5% acetic acid by weight. Citric acid in the form of lemon or lime juice may replace the acetic acid at a minimum level of 2.5%. The egg yolk may be in liquid, frozen, and/or dried forms. This ingredient provides emulsifying properties and gives the mayonnaise a pale yellow color, which must not be intensified by any other ingredient. Salad dressings are also oil-in-water emulsions, but the concentration of oil is only about 30–45% as compared to 65–82% in mayonnaise. In addition to yolk, stabilizers are permitted in this product. Commercial products of reduced-fat mayonnaise and salad dressings usually contain less than half fat content as compared to regular product. Fat-free products should contain no or physiologically inconsequential amount of fat (< 0.5 g fat) per serving. All reduced/low-fat or fat-free products generally rely heavily on hydrocolloids for viscosity and texture characteristics. **Table 1** shows the composition of selected types of dressings and mayonnaise. Many variations in formulations exist within each type of product. (*See* **Emulsifiers**: Organic Emulsifiers; Uses in Processed Foods; **Stabilizers**: Types and Function; Applications.)

Physical Structure and Rheology

Reduction of interfacial tension is probably the first step in the formation of an emulsion. Surface-active agents form a film around the oil globules and prevent their coalescence. In surrounding the oil droplets, the lipophilic (oil-loving) portion orients itself in the aqueous phase, forming a shell around the droplets of the dispersed phase. By collecting itself at the interface, the emulsifier prevents the dispersed particles from coalescing and separating out, thereby increasing the emulsion's stability.

The microstructure of mayonnaise, as revealed by the scanning electron microscope, contains fat globules of various sizes (**Figure 1a**). Both the dispersed fat and continuous phase are evident. The continuous phase binds tightly to the fat globules (**Figure 1b**). Several very small fat globules can be seen adhering to the large globules. Under the high magnification of

transmission electron microscopy, part of the interfacial film is visible surrounding the lipid droplets of diluted mayonnaise (Figure 2). The electron-dense material at the interface is the emulsifying material from egg yolk. This material, which acts as a surface-active agent, consists of complexes of egg yolk protein fractions such as lipovitellin, livetin, and lipovitellenin. (*See* **Eggs**: Structure and Composition.)

In addition to functioning as an emulsifying agent, egg yolk contributes viscosity to mayonnaise. Increasing the amount of egg yolk from 5 to 12% increases the thickness of the product. Viscous emulsions tend to be more stable. However, amounts of yolk in excess of 12% are not associated with a change in consistency of the mayonnaise. It is essential that there is a sufficient amount of aqueous phase (usually vinegar) to surround oil droplets as they become smaller and expose more surface during emulsification. However, an excess of aqueous phase is not conducive to a good emulsion.

Since salad dressing contains less oil than mayonnaise, there are fewer lipid droplets, and a higher concentration of amorphous material between droplets. The amorphous material is assumed to be cooked starch paste, a stabilizing ingredient added to salad dressing but not to mayonnaise. Starch paste also reduces the rate of lipid droplet coalescence in salad dressing. (*See* **Starch**: Modified Starches.)

Sensory attributes of dressing emulsions, such as creaminess, thickness, smoothness, spreadability, and pourability, are related to their rheological properties. The shelf-life of dressing emulsions also depends on their rheological characteristics. Viscosities of dressing emulsions depend on the shear rate applied. Pseudoplastic flow is the most common type. It manifests itself as a decrease in the apparent viscosity as the shear rate is increased and is therefore often referred to as shear thinning. Viscosities of dressing emulsions also depend on the shear time. Thixotropic behavior is the most common type, in which the apparent viscosity decreases with time when subjected to a constant shear rate. Dressing emulsions that exhibit this type of behavior often contain droplets aggregated by weak forces. Shearing of the material causes the aggregated droplets to be progressively deformed and disrupted, which decreases the resistance to flow and therefore causes a reduction in viscosity over time. For example, pourable salad dressings, such as French varieties, Thousand Island, and Creamy Italian, are primarily viscous in their flow behavior, but exhibit varying degrees of thixotropy and often a measurable yield stress as well.

Some dressing emulsions are not purely viscous or elastic, but instead partly viscous and partly elastic. For example, mayonnaise and spoonable salad dressings show viscoelastic rheological behavior and also possess a yield stress. The viscoelastic behavior

could be characterized through creep tests or dynamic tests. Creep test consists of the application of a constant stress and ensuing study of the time-dependent behavior of the strain. Dynamic experiment consists of the application of a sinusoidal stress and the resulting sinusoidal strain is measured or vice versa. The amplitude of the applied stress or strain used in this type of test is usually so small that the material is in the linear viscoelastic region, and the rest state of the material can therefore be successfully studied.

The rheological properties of dressing emulsions are a function of the continuous-phase viscosity, the phase volume fraction of the dispersed phase, the droplet size, and the nature of the colloidal interactions. In general, the viscosity of an emulsion increases as the continuous-phase viscosity increases. Typically, gums and stabilizers that have non-Newtonian rheology are added to pourable salad dressings to impart the non-Newtonian character to emulsions and increase the viscosity of the continuous phase and hence the viscosity of emulsions. The emulsion viscosity generally increases with the phase volume fraction of the dispersed phase in a nonlinear manner, and decreases with increasing droplet size. Rheological properties of an emulsion also depend on the relative magnitude of the attractive and repulsive

interactions between the droplets. Viscosities of emulsions can be increased by adding biopolymers to increase the depletion attraction or bridging flocculation, by altering the pH or ionic strength to reduce electrostatic repulsion, and by heating protein-stabilized emulsion to increase hydrophobic attraction. Aggregation may increase the emulsion viscosity. The aggregation state of an emulsion is clearly dependent on the shear rate, and for thixotropic (time-dependent) systems, on shear history.

Factors Affecting Physical Stability

Emulsion Stability

The term 'emulsion stability' refers to the ability of an emulsion to resist changes in its properties over time. The more stable the emulsion, the more slowly its properties change. All emulsions are thermodynamically unstable and, given enough time, undergo phase separation. However, in a kinetic sense, the dressing emulsions can be made stable over shelf-life, maintaining appearance, texture, and flavor that are desirable to the consumer. The stability of dressing emulsions may range from seconds for a product like separating Italian dressing, to years for a product like mayonnaise. Semisolid dressings, such as mayonnaise and spoonable salad dressings, are very viscous emulsions. Due to the high oil content of the mayonnaise emulsion, the oil droplets are forced close together. This close proximity precludes concern for flocculation, and emulsion stability must instead be concerned with preventing coalescence, which can be delayed by employing tough, pliable membranes that are formed from the protein and polar lipid components of egg yolk around the oil droplets. Pourable dressings are much less viscous than semisolid dressings, and are susceptible to creaming. Since the oil droplets are spaced apart from each other, flocculation that could lead to coalescence is also of concern. For low-fat and fat-free dressings, emulsion stability is normally not a major problem due to the low amount of oils. Special considerations have to be given to impart a full-fat flavor and texture for these products.

The emulsion stability is influenced by a number of factors, including the egg yolk, the emulsifying effect of mustard, method of mixing, and storage conditions. The stability of mayonnaise may be evaluated by simply storing samples at room temperature until visible separation occurs. Centrifugation of emulsions hastens the formation of separate layers and is also a useful test of stability. The stability index for mayonnaise is calculated as the percentage of the sample remaining emulsified after being centrifuged at 5000 rpm for 30 min and then allowed to stand for a period of time.

Egg yolk

Egg yolk is itself an emulsion, and it functions as an efficient emulsifying agent. Three types of egg yolk are currently used in dressings and mayonnaise: liquid egg yolk, frozen salted egg yolk, and dried egg yolk.

Liquid egg yolk The emulsifying ability of egg yolk is affected by the age and genetic factors of the bird from which the eggs were obtained. Decreased emulsifying ability is associated with eggs from older birds. Also, low social dominant strains of the White Leghorn breed were found to produce eggs with greater emulsifying ability than eggs from high social dominant strains. The emulsification capacity of liquid yolk decreases as dilution with albumen increases. This is due to the lower solids content and to interactions between albumen proteins and yolk fractions.

Pasteurization does not significantly affect the emulsification capacity of commercial fresh yolk containing 48–49% solids. Heating albumen-free yolk to 61 °C causes no significant change in emulsion stability, but emulsification capacity is significantly increased by heating the yolk to 63 °C. Pasteurization temperatures above 63 °C cause a considerable increase in egg yolk viscosity. However, salted (10% sodium chloride) liquid egg yolk can be pasteurized at 62–78 °C for 5 min without damage to emulsifying properties. In the manufacture of oil-in-water salad dressings, the addition of egg yolk and salt results not only in an increase of emulsion viscosity, but also in a reduction of oil droplet size. (*See* **Pasteurization**: Principles.)

Frozen salted egg yolk Viscosity increases and gelation occurs in raw egg yolk subjected to freezing and storage below −6 °C. The addition of salt reduces gelation and inhibits microbial growth during thawing. Frozen yolk containing 10% sodium chloride is the most common form used in the dressings and mayonnaise industry. Frozen salted egg yolk produces mayonnaise that is stiffer than that made with fresh yolk. Freezing at −29 °C and storage at −23 °C for 1–4 months is detrimental to both pasteurized and unpasteurized salted egg yolk. Acidification in combination with pasteurization, followed by freezing and storage, also damages the emulsification ability of salted egg yolk.

Dried egg yolk The advantages of using dried egg yolk are threefold:

1. less storage space and transportation cost than liquid or frozen egg yolk;
2. not susceptible to bacterial growth during storage;

3. good uniformity, easy to handle in a sanitary manner.

Compared to frozen and to freeze-dried egg yolk, spray-dried egg yolk produces the least stable emulsions. This detrimental effect of spray-drying on yolk is due to the rapid increase in extractability of the free lipids.

Mustard

Mustard has a slight stabilizing effect on emulsions. This effect depends not only on the chemical and physical properties of mustard, but also on the method of incorporating mustard into the mayonnaise. In general, mustard collects at the oil–water interface and tends to prevent droplets of oil from coalescing. (*See* **Mustard and Condiment Products**.)

Method of Mixing

Introduction of oil beneath the emulsion surface provides mayonnaise with improved stability, consistency, and homogeneity. Using this method, the best mayonnaise can be produced when a small amount of oil is first added to the emulsifying agent, followed by the addition of acid, and then the addition of the remainder of the oil.

The appearance of the dispersed and continuous phases in laboratory and commercially made mayonnaises is different. This is due to the difference in the degree of agitation. A colloidal mill is used to prepare the emulsion of commercial products, whereas a catering-type food mixer is used in the laboratory. The colloidal mill results in uniformity in the size and shape of fat globules and a continuous phase with no separation from the fat globules. In mayonnaise prepared in a food mixer, the fat globules are irregular in both size and shape, and some globules seem to join together to form a continuous mass. Other mixing factors that affect consistency of mayonnaise include the amount and composition of the aqueous phase added during the first stage of mixing, the duration of beating and resting periods, and the addition of vinegar at various stages in the process.

Storage Conditions

Mayonnaise and salad dressing become increasingly unstable when stored at 55 °C for 3 days. The rate of droplet coalescence in salad dressing may not be as high as in mayonnaise due to the stabilizing effect of the starch ingredients.

Freezing usually causes the dispersed phase of emulsions to coalesce. Thus, freezing and thawing of mayonnaise result in collapse of the emulsion structure. The emulsion may separate into two layers, the upper layer of oil and the lower layer probably containing water, proteins, sugar, salt, and mustard (Figure 3). The damage to emulsions that are broken by freezing is related to the influence of freezing on the emulsifying agent. (*See* **Freeze-drying**: Structural and Flavor (Flavour) Changes.)

Salad dressing may be stable to frozen storage when the oil does not crystallize, or crystallizes slowly. Other conditions favoring stability include use of a thickening agent such as waxy rice flour and freshly salted unfrozen egg yolk, at a level of 5.3–8%, along with a decrease in oil. At storage temperatures above −18 °C, this combination was stable for 6 months. Other factors affecting emulsion stability include:

1. fermentation of the egg yolk with pancreatic phospholipase A_2;
2. acetylation and succinylation of egg yolk lipoproteins;
3. addition of 0.05% sodium 2-lactylate to egg yolk.

Storage and Shelf-Life

Most dressings and mayonnaise held at room temperature have a shelf-life of approximately 7 months. These products are preserved against microbial spoilage by their acid and sodium chloride content, but they are very sensitive to oxidative deterioration in flavor and should be refrigerated after their containers are opened. (*See* **Storage Stability**: Mechanisms of Degradation.)

The acid and sodium chloride content protects against spoilage by microorganisms such as *Salmonella* and *Staphylococcus* species. Some lactic acid bacteria and yeast may survive at the low pH (pH 4.0) of mayonnaise, but they are destroyed by pasteurization at 60–63 °C for 3–5 min. Care should be taken when mixing dressing with mayonnaise to avoid growth of microorganisms which might occur at the higher pH of the mixture. (*See* **Lactic Acid Bacteria**; **Spoilage**: Yeasts in Spoilage; ***Staphylococcus***: Properties and Occurrence.)

Oxidative rancidity is one of the major problems in relation to the use of vegetable oils. Even a hint of a rancid flavor can ruin an entire batch of salad dressing or mayonnaise. A thin film of oil, such as might be left on containers through inadequate washing, can become rancid very quickly. Thus, all dressing containers must be cleaned thoroughly, and a fresh batch should never be poured into a container containing older dressing.

Time, temperature, light, air, surface exposure, moisture, nitrogenous organic material, and traces of metals are factors responsible for the rancidity of dressings and mayonnaise. In salad dressing and mayonnaise products, the oil is subjected simultaneously to most or all of these adverse conditions:

- The emulsification process increases the exposed surface area of the oil.
- On average, mayonnaise contains 10–12% air by volume, although an inert gas such as nitrogen may replace some of the air.
- Moisture is present.
- Nitrogenous organic material is dispersed in films surrounding the oil globules.
- The products are packed in glass jars that are exposed to light.
- In some production areas traces of metals may be dissolved out of the equipment by the vinegar, although the use of stainless-steel equipment minimizes this.
- The temperature at which salad dressing and mayonnaise are kept may be as high as 38 °C or higher.
- It may be 3–6 months before these products are consumed.

For these reasons, the oil used by the salad dressing industry must be of high quality. Commercial salad dressings are presently made with both unhydrogenated and hydrogenated soya bean oil. Whether or not hydrogenation is necessary to prepare oxidatively stable salad dressing is a controversial issue in the industry. Hydrogenation of soya bean oil with copper and nickel catalysts effectively increases the storage stability of salad dressing at 21 °C but not at 32 °C. The use of butylated hydroxytoluene (BHT) as an antioxidant in the oil, and ethylenediaminetetraacetic acid (EDTA) as a metal scavenger in the starch base, as well as nitrogen packaging, are effective in prolonging the storage stability of salad dressing made with unhydrogenated soya bean oil. Therefore, these additives or nitrogen packaging may provide economic substitutes for hydrogenation of soya bean oil used in salad dressing. (*See* **Antioxidants:** Synthetic Antioxidants; **Soy (Soya) Beans:** The Crop; **Vegetable Oils:** Oil Production and Processing.)

Separation of mayonnaise may occur as a result of long storage, warm temperature, freezing, or considerable shaking or agitation during shipping. This problem is controlled commercially by fine division of the oil droplets, use of an effective stabilizer, cool storage temperatures (0–5 °C), and protection from air and light during storage.

DRUG–NUTRIENT INTERACTIONS

B Caballero and K G Conner, Johns Hopkins University, Baltimore, MD, USA

Background

Understanding the interactions between dietary constituents and pharmacological compounds is essential to monitor drug therapy correctly as well as to assess the potential nutritional impact of medications. Most therapeutic agents exhibit some form of interaction that ultimately affects the nutritional status of the host, by altering absorption or utilization of nutrients. Frequently, these changes are not readily identified or may be obscured by the underlying disease.

The interactions between therapeutic agents and nutrients are part of the large number of interactions occurring between nutritional and nonnutritional constituents of the human diet. These include all substances added to the food chain – incidentally or deliberately – during harvesting, processing, packaging, distribution, and preparation of foods. Some examples of this broad category would include pesticides, food additives, antibiotics, hormones, and environmental toxins.

Drug–nutrient interactions operate in both ways: drugs can have a significant impact on nutrient absorption and utilization. Also, the nutritional status of the host certainly affects the ability of drugs to be absorbed and transported, and to exert an effect at the target tissues.

Drug–nutrient interactions can be broadly classified in two categories: direct physicochemical interaction and physiological or functional interaction. Drug–nutrient interactions can also be classified according to the site of their occurrence: within the food matrix, in the gastrointestinal tract, or during transport, metabolism, and excretion. The mechanisms and sites of drug–nutrient interactions are listed in Table 1.

Physicochemical Interactions

These usually involve some form of molecular interaction between the drug and a nutrient, and occur primarily during digestion and absorption. The usual consequence of this interaction is a reduction in the bioavailability of the drug and/or the nutrient. A well-known example of this mechanism is the binding of metals by the antibiotic tetracycline.

Functional Interactions

Functional Interactions at the Gastrointestinal Tract

These acquire particular significance because alterations in gastrointestinal (GI) function are likely to affect the digestion and absorption both of the drug causing it and of a number of nutrients. The most common GI functional effects altering those functions are as follows.

Changes in GI motility A reduction in transit time may lead to a decreased absorption. A large number of drugs have an effect on gut motility, whether this is their primary therapeutic effect or not. Conversely, food composition affects motility as well. Dietary fiber not only increases motility but also may trap other nutrients and drugs and reduce their availability for absorption.

Table 1 Mechanisms and sites of drug–nutrient interactions

Site	*Mechanism*	*Effect*
Food matrix	Binding and chelation	Decreases bioavailability
Gastrointestinal (GI) tract	Changes in GI motility	Increase in transit time reduces absorption
	Binding and chelation	Decreases bioavailability
	Change in bile acid concentration	Reduces absorption of fat-soluble nutrients
	Gastric pH	Affects absorption of iron, vitamin B_{12}, and others
Circulation	Albumin concentration	Decreases transport of bound substances
	Competitors for albumin binding	Displaces albumin-bound nutrients (fatty acids, tryptophan, etc.)
Target tissues	Antagonistic effects	May increase requirements for antagonized nutrient
	Enzyme activities	Reduces concentration of enzyme product
Excretion	Renal function	Increased excretion may lower nutrient levels, increase requirements
	Sequestration	Same as above

Changes in gastric acid output A reduced chloride production with a subsequent increase in gastric pH retards gastric emptying and may alter the balance between ionized and nonionized forms of therapeutic agents.

Reduction in the concentration of bile acids This affects the absorption of most fat-soluble compounds. Lower bile acid concentration may result from increased binding and excretion or decreased production. For example, the antibiotic neomycin binds to bile acids and increases their fecal excretion, thus reducing their luminal concentration, and in so doing decreasing the absorption of fat-soluble vitamins. This interaction, like many others, can be used therapeutically to reduce bile acid turnover in certain liver diseases, and to lower cholesterol levels by reducing their reabsorption.

Alterations in the GI microflora This may affect the availability of nutrients produced by the normal gut flora, such as vitamin B_{12}. Since many drugs are susceptible to bacterial metabolism, changes in the gut flora may also affect drug bioavailability. In certain cases, drug cleavage by intestinal microorganisms is an expected and necessary step for adequate drug action. For example, the antiinflammatory agent 5-aminosalicylic acid is given as its precursor sulfasalazine, which is converted to the active compound by colonic bacteria. An altered colonic flora affects the production of the active compound. Drugs can also inhibit nutrient absorption by directly affecting protein synthesis in the enterocyte. Since most transport systems require active protein synthesis and turnover, such inhibition would result in a decreased rate of nutrient absorption. Furthermore, certain drugs undergo initial metabolism in the enterocyte, before reaching the bloodstream. Alterations in protein synthesis at the enterocyte, or an impaired turnover of the intestinal epithelia, also affect this process.

Interactions Affecting Transport, Metabolism and Excretion

Functional Synergism or Antagonism

The biological actions of nutrients and drugs can be synergistic or antagonistic, occur in different time periods after exposure, and affect a variety of target tissues. Some of the most common mechanisms are as follows.

Alterations in drug transport Drugs circulate in the bloodstream as free compounds or bound to other blood constituents, usually proteins. Drugs vary greatly in their propensity to bind to circulating proteins, virtually covering the entire spectrum from zero to 100%. For a given drug, the bound fraction tends to be relatively constant under physiological conditions, but responds to changes in pH, electrolyte balance, and the presence of competing molecules. The major transport protein in plasma is albumin, and its concentration and the presence of other compounds with affinity for albumin binding affect the amount of drug that ultimately will be transported by this protein.

Increase in nutrient catabolism Certain drugs stimulate detoxifying systems such as the cytochrome P-450 pathway. Activation of this system may result in an increased catabolism of certain nutrients. In other cases, drugs have a direct action on nutrient catabolism, as in the case of anticonvulsant drugs, which stimulate vitamin D catabolism in the liver.

Biological antagonism This occurs when a drug and nutrient have opposite biological actions, as is the case, for example, of vitamin K and salicylates in the coagulation process.

Increased nutrient losses Many drugs enhance directly or indirectly the urinary excretion of nutrients. Examples include the increased urinary losses of electrolytes caused by aminoglycoside antibiotics, and the increase in urinary ascorbic acid excretion induced by barbiturates.

Host-related Functional Interactions

Nutrients and nutritional status can conversely also affect drug action and disposition. Perhaps the most significant host-related factor affecting drug disposition is protein synthesis. An altered protein synthesis, usually resulting from deficient dietary protein intake or severe diseases, will affect absorption, transport, metabolism, and excretion, all protein-dependent processes. The role of plasma albumin in drug transport was discussed above, and is certainly affected by impaired albumin synthesis and/or sequestration in the extravascular space, as seen in protein–energy malnutrition. It should be noted, however, that malnutrition affects many aspects of drug metabolism, not all in the same direction. For example, drug delivery may be reduced by impaired albumin concentration, but drug concentration in the bloodstream may be increased, owing to impaired clearance, which is also affected by malnutrition.

The plasma amino acid profile may affect the efficacy of drug entry into the central nervous system. At the blood–brain barrier, certain drugs are transported

Table 2 Major drug–nutrient interactions of clinical relevance

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Acarbose	Antidiabetic	Food	Delays carbohydrate breakdown: delays glucose absorption
		Iron	Decreased iron absorption
Acetaminophen	Analgesic	Food	May delay extended release; high-pectin food delays absorption
		Alcohol	Increased risk of hepatotoxicity
Acetohexadmide	Antidiabetic	Glucose	Hypoglycemia
		Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
		Sodium	Hyponatremia, SIADH
Acyclovir	Antiviral	Food	No effect; may take with meals
Aluminum hydroxide	Antacid	Thiamin	Affects bioavailability, because of pH
		Iron	Decreased iron absorption
		Phosphorus	Inhibits phosphorus absorption
		Vitamin A	Inhibits vitamin A absorption
Amikacin	Antibiotic	Calcium, potassium, magnesium	Causes renal wasting of these nutrients
Amoxicillin	Antibiotic	Food	Decreased absorption by delayed gastric emptying
Amphotericin B	Antifungal	Potassium, magnesium	Causes renal wasting of potassium and magnesium
Ampicillin	Antibiotic	Food	Decreased absorption by delayed gastric emptying
		Potassium	High doses increase urinary potassium losses
Antipyrine		Green vegetables, beef protein	Decreased absorption
Aspirin	Analgesic	Food	Decreased rate of absorption
		Folic acid	Increased excretion of folate
		Amino acids	Decreased intestinal absorption of amino acids, increased urinary excretion of tryptophan
		Iron	Chronic high dose 3–4 g day^{-1}, iron deficiency possible
		Alcohol	Gastric irritation, leading to possible gastric bleeding
		Curry powder, licorice, teas, raisins, paprika	Potential salicylate accumulation
		Ascorbic acid, vitamin C, fresh fruits, high vitamin C	Increased urinary excretion; decreased concentration in serum and platelets
Astemizole	Antihistamine	Food	Decreased bioavailability
Atenolol	Antihypertensive	Food	Delayed absorption
Atovaquone	Antibiotic	Food	Bioavailability increased, especially high-fat foods
Atropine	Anticholinergic	Iron	Delayed absorption
Azithromycin	Antibiotic	Food	Decreased rate and delayed absorption
Bacampicillin	Antibiotic (penicillins)	Food	Decreased absorption
Barbiturates	Anticonvulsant	Alcohol	Enhanced CNS depression
		Calcium, vitamin D	Increased vitamin D requirements, owing to increased metabolism
		Cyanocobalamin	Increased bone resorption
		Folic acid	Decreased serum levels, leading to megaloblastic anemia
		Serum lipids	Decreased CSF folate and erythrocyte concentration; may increase cholesterol, HDL triacylglycerols
Benzodiazepines	Anticonvulsant	Nutrient	Enhanced CNS depression
Clonazedam		Calcium	Increased vitamin D requirements, secondary to increased metabolism
Clorazepate dipotassium		Vitamin D	Increased bone resorption
Lopazepam		Cyanocobalamin	Decreased serum levels, leading to megaloblastic anemia
Oxazepam		Folic acid	Decreased CSF folate and erythrocyte concentration
		Serum lipids	May increase cholesterol, HDL triacylglycerols
Buprenorphone HCL	Analgesic Narcotic Agonist–antagonist	Alcohol	Enhanced CNS depression

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Butorphanol tartate	Analgesic Narcotic Agonist–antagonist	Alcohol	Enhanced CNS depression
Calcium carbonate	Antacid	Iron	Decreased iron absorption
		Fats	May cause steatorrhea
Captopril	Antihypertensive angiotensin-converting enzyme inhibitor	Food	Reduced absorption
Carbamazpine	Anticonvulsant	Sodium	SIADH
		Food	Enhanced absorption, increased bile production
Carbenicillin iandanyl sodium	Antibiotic	Food	Decreased rate of absorption
Cephalosporins	Antibiotic	General alcohol	Flushing, headache, nausea, vomiting, tachycardia
Cefachlor		Food	Decreased rate of absorption
Cefadroxil		Food	No effect (may take food)
Cefamandole		Vitamin K	Decreased vitamin K hypoprothrombinemia
Cefixime		Food	Decreased rate of absorption
Cefoperazone		Vitamin K	Decreased vitamin K hypoprothrombinemia
Cefotetan		Vitamin K	Decreased vitamin K hypoprothrombinemia
Cefpodoxime proxetil		Food	Bioavailability increased with food
Ceftibuten		Food	Decreased absorption
Cefuroxim axetil		Food	Bioavailability increased with food
Cephalexin		Food	Absorption reduced for suspension; delayed for capsules
Cephradine		Food	Rate of absorption delayed
Cetrizine	Antihistamine	Food	Delays time to serum peak; no effect on overall absorption
Chlorambucil	Antineoplastic	Food	Reduced absorption
Chloramphenicol	Antibiotic	Iron	Increased serum level iron; increased total iron-binding capacity
		Folic acid	Antagonist to physiological action; increased requirements of folic acid
		Vitamin B_{12}	Increased requirements of vitamin B_{12} can cause peripheral neuropathy
Chloroquine	Antimalarial	Food	Increased bioavailability
Chlorothiazide	Diuretic	Food	Increased drug absorption owing to delayed gastric emptying
Chlorpromazine	Antiemetic	Food	Decreased absorption owing to delayed gastric emptying
Chlorpropamide	Antidiabetic	Glucose	Decreased blood glucose concentration
		Sodium	Hyponatremia, SIADH
		Alcohol	Flushing, headache, nausea, vomiting, tachycardia
Cholchicine	Antigout	Cyanocobalamin	Decreased absorption of cyanocobalamin
Cimetidine	Histamine 2 antagonist	Food	Delays absorption
Ciprofloxacin	Antibiotic (quinolone)	Caffeine	Decreased rate of absorption
		Food	Cipro decreased elimination of caffeine
		Calcium	Calcium can bind quinolones
		Mineral supplement	Absorption of divalent cations and trivalent cations decreased by binding to quinolones
Clarithromycin	Antibiotic (macrolide)	Food	Decreased onset of absorption; no change in total amount absorbed
Clonazepam	Anticonvulsants (benzodiazepine)	Nutrient	Enhanced CNS depression
Clorazepate dipotassium		Calcium	Increased vitamin D requirements, owing to increased metabolism
		Vitamin D	Increased bone resorption
		Cyanocobalamin	Decreased serum levels, leading to megaloblastic anemia
		Folic acid	Decreased CSF folate and erythrocyte concentration
		Serum lipis	May increase cholesterol, HDL triacyclglycerols
Cloxacillin	Antibiotic (penicillin)	Food	Decreased rate of absorption

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Codeine	Narcotic agonist, analgesic	Alcohol	Enhanced CNS effect
		Glucose	Can cause hyperglycemia
Corticosteroids	Steroid	Calcium, phosphorus, vitamin D	Decreased absorption of Ca, P; increased urinary excretion; chronic high dose can cause osteomalacia
Dexamethazone Hydrocortisone Methylprednisolone (Prednisone, Prednisolone)			
Corticosteroids	Steroid	Nitrogen	Increased urinary nitrogen losses
		Zinc	Increased urinary excretion and decreased serum levels
		Glucose	Impairs glucose tolerance; increases plasma levels
		Triacylglycerols, cholesterol	Increased serum levels
Co-trimaxazole	Antibiotic	Potassium	Decreased excretion hyperkalemia
		Sodium	Increased excretion hyponatremia
		Folic acid	Potential for folate deficiency
Cyclosporine	Antirejection	Milk, fat, pineapple juice	Increased absorption
Demeclocycline	Antibiotic	Food, calcium, iron	Decreased absorption of dairy products and divalent and trivalent cations
Diazepam	Anticonvulsant	Food	Increased absorption with high-fat meals and delayed gastric emptying
Clonazedam Clorazepate dipotassium Lopazepam Oxazepam			
Dicumarol	Anticoagulant	Food	Increased absorption with high-fat meals and delayed gastric emptying
Didanosine Tab	Antiviral	Food	Decreased rate and extent of absorption
Oral suspension		Fruit juice or acid liquid	Didanosine unstable in acid pH
Digoxin	Cardiac	Food	Delay absorption; adsorbent to high-fiber, high-pectin foods
Dirithromycin	Antibiotic (macrocide)	Food	Slightly increased absorption
Divalproex	Anticonvulsant	Food	Decreased rate of absorption; extent of absorption not affected
Doxycycline	Antibiotic	Food	Decreased absorption of food and milk
Erythromycin	Antibiotic (macrocide)	Food	Increased absorption by delayed gastric emptying
Erythromycin stearate		Food	Reduced absorption by delayed gastric emptying
Ethionamide	Antituberculosis	Pyridoxins	Reports of peripheral neuritis and paresthesia
Etodolac	Nonsteroidal antiinflammatory drug (NSAID)	Food (milk)	Decreased total bioavailability of tolmetin; decreased absorption of ibuprofen
		Sodium	Hyponatremia (indomethacin/ketorolac)
		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food	Increased rate of absorption
Felbamate	Anticonvulsant	Glucose	Hypoglycemia
		Magnesium	Hypomagnesemia
		Phosphorus	Hypophosphatemia
		Potassium	Hypokalemia
		Sodium	Hyponatremia
Fenoprofen	NSAID	Food (milk)	Decreased total bioavailability of tolmetin
Fenoprofen calcium		Sodium	Hyponatremia (indomethacin/ketorolac)
		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food (milk)	Decreased bioavailability of tolmetin; decreased absorption of ibuprofen
		Food	Increased rate of absorption
Fluconazole	Antifungal	Potassium	Hypokalemia
Flucytosine	Antifungal	Food	Decreased rate of absorption; no change in extent of absorption

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Foscarnet	Antiviral	Calcium	Hypocalcemia; drug chelates; divalent metal ions
		Magnesium	Hypomagnesemia
		Phosphorus	Hypo- and hyperphosphatemia
		Potassium	Hypokalemia
Furazolidone	Antiinfective	Tyramine-rich foods (avocados, canned figs, aged cheese, cola beverages, coffee, chocolate, wines, soy sauces, fermented meats, yeast preparation, yogurts)	Prolonged large doses result in increased risk for hypertensive crisis
		Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
Furosemide	Diuretic	Food	Delayed absorption
Ganciclovir	Antiviral	Food	Increased area under curve plasma concentration
Glipizide	Antidiabetic	Food	Delayed absorption
		Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
		Sodium	Hyponatremia, SIADH
Griseofluvin	Antifungal	Alcohol	Can increase alcohol effect, flushing, tachycardia
		High-fat food	Increased drug absorption rate
Hydralazine	Diuretic	Food	Increased absorption
Hydrochlorothiazide	Diuretic	Food	Increased absorption by delayed gastric emptying
Ibuprofen	NSAID	Food (milk)	Decreased total bioavailability of tolmetin; decreased absorption of ibuprofen
		Sodium	Hyponatremia (indomethacin/ketorolac)
		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food	Increased rate of absorption
Indinavir	Antiviral	Food	Decreased absorption of high-calorie, high-fat, and protein
		Grapefruit juice	Decreased area under curve concentration
Indomethicin	NSAID	Food (milk)	Decreased total bioavailability of tolmetin; decreased absorption of ibuprofen
		Sodium	Hyponatremia (indomethacin/ketorolac)
		Potassium	Hyperkalemia (indomethacin/ketorolac)
		Food	Increased rate of absorption
Iron	Mineral	Ascorbic acid	Increased absorption
		Amino acids	Increased absorption
		Calcium phosphate	Decreased absorption
		Zinc	Inhibits absorption
		Vitamin A	Vitamin A deficiency inhibits iron utilization and accelerates development of anemia
		Tea/coffee	Decreased absorption owing to formation of iron tannate
		Vegetable polyphenols	Binds and insolubilizes iron
Isoniazid	Antituberculosis	Food	Decreased intestinal absorption
		Pyridoxine	Decreased metabolism, antagonism
		Food and histamine, tuna, liver, aubergine, parmesan cheese, tomato, spinach, tyramine-containing foods	Headache, redness, itching of eyes and face, chills, diarrhea, palpitation
			Potential hypertensive crisis owing to monoamine oxidase inhibitor activity

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Itraconazole	Antifungal	Food	Increased absorption, increased triacylglycerols
		Potassium	Hypokalemia
Ketoconazole	Antifungal	Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
Labetalol	Antihypertensive	Food	Increased absorption
Lamivudone (3TC)	Antiviral	Food	Decreased rate of absorption
Levodopa	Anti-Parkinson	Food	Decreased absorption; with high-protein meals amino acids compete for absorption
Lithium	Antimanic	Low-sodium diet	Increased lithium concentrations
		High-sodium diet	Increased lithium clearance
		Food	Increased absorption
Lomefloxacin	Antibiotic (quinolone)	Food	Decreased rate and extent of absorption
Loracarbef	Antibiotic	Food	Increased rate of absorption
Lovastatin	Antihyperlipidemia	Food	Increased absorption
Mebendazole	Anthelmintic	Food	Increased absorption
Meclofenamate	NSAID	Alcohol	Additive CNS effects; increased prothrombin time
		Food	Decreased bioavailability
Melphalan	Antineoplastic	Food	Reduced absorption
Mercaptopurine	Antineoplastic	Food	Reduced absorption
Methacycline	Antibiotic	Food, calcium, iron	Decreased absorption of dairy products, cereals, divalent and trivalent cations
Methenamine mandelate	Urinary antiinfective	Milk products, citrus fruits	Excessive amounts inhibits drug conversion
Methosuximide	Anticonvulsant	Alcohol, calcium	Additive CNS effects; hypocalcemia
Methotreate	Antineoplastic	Food	Increased absorption
Methyldopa	Antihypertensive	Vitamin B_{12}, folate	In high doses methyldopa can increase vitamin B_{12} and folate losses
		Food	High-protein meals compete for absorption
Metoprolol	Antihypertensive	Food	Increased absorption
Metronidazole	Antibiotic	Alcohol	Flushing, headache, nausea, vomiting, sweating, tachycardia
		Food	Decreased peak serum concentration but total amount of drug absorbed not affected
Minocycline	Antibiotic	Food, calcium	Decreased absorption
Nafcillin	Antibiotic	Food	Decreased absorption; decreased serum levels owing to altered gastric pH
		Potassium	High doses can cause hypokalemia owing to increased urinary losses
Nifedepine	Antihypertensive calcium channel blocker	Grapefruit juice	Increased serum level of nifedepine flavonoids inhibits cytochrome P-450
		Food	Decreased bioavailability, formulation dependent
Nitrofurantoin	Antibiotic	Food	Increased absorption by delayed gastric emptying
NSAIDs	NSAID	Food (milk)	Decreased bioavailability of tolmetin
Diclofenal Etodolac		Sodium	Hyponatremia (indomethacin/ketorolac)
Fenoprofen Ca Ibuprofen		Potassium	Hyperkalemia (indomethacin/ketorolac)
Ketoprofen Ketorolac Naproxen Oxaproxin Piroxican Sulindac		Food	Decreased absorption of ibuprofen
Tolmetin NA		Food	Increased rate of absorption
Norfloxacin	Antibiotic (quinolone)	Food, dairy products	Decreased rate of absorption
		Multivitamin and mineral supplements	Decreased absorption owing to formation of divalent/trivalent cation complexes with quinolones
Oflaxacine	Antibiotic (quinolone)	Dairy products and mineral supplements	Decreased absorption by polyvalent cations

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Ondansetron	Antiemetic	Food	Increased extent of absorption
		Potassium	Hypokalemia
Oral contraceptives		Ascorbic acid	Decreased ascorbic acid concentration in plasma, platelets, leucocytes
		Vitamin C, folic acid	Decrease in their serum levels
		Vitamin B_{12}	Impairs tryptophan metabolism
		Amino acids, vitamin A, vitamin E, copper	Increase in their serum levels
Oxacillin	Antibiotic	Food	Decreased absorption and decreased serum concentration
		Fats	Oxacillin can cause steatorrhea
Paromomycin	Amoebicide	Food	Increased absorption by delayed gastric emptying
		Vitamins A, D, E, K	Malabsorption of fat-soluble vitamins owing to hypocholesterolemia
Penicillamine	Antidote (chelating agent)	Food	Decreased absorption
		Iron/zinc	Decreased absorption 30–70% of increased zinc absorption; decreased penicillamine absorption
Penicillin G & VK	Antibiotic	Food	Decreased absorption by delayed gastric emptying
		Glucose	Hyperglycemia
Pentamidine	Antibiotic	Calcium, magnesium	Hypomagmanesemia, hypocalemia
		Potassium	Hyperkalemia due to nephrotoxicity
Phenacemide	Anticonvulsant	Fresh fruits and vitamin C	Increased urinary excretion of phenacemide
Phenobarbital	Anticonvulsant (see *Barbiturates*)	Food	Decreased absorption owing to protein binding
		Protein	Low-protein diet increases duration of action of phenobarbitol
		Vitamin D, calcium	Decreased serum vitamin D by cytochrome P-450 hypocalcemia
		Fresh fruits and vitamin C	Increased urinary excretion of phenobarbitol
Phensuximide	Anticonvulsant (succinimides)	Calcium, vitamin D	Decreased serum vitamin D by P-450 cytochrome hypocalcemia
		Vitamin B_{12}, folic acid	Decreased absorption and serum levels of folates; inhibits vitamin B_{12} transport
		Copper	Increased serum levels
Phenytoin	Anticonvulsant (hydantoins)	Fresh fruits and vitamin C	Increased urinary excretion
		Vitamin D, calcium	Decreased serum vitamin D by cytochrome P-450 hypocalcemia
		Enteral feeds	Decreased absorption
		Food	Increased absorption by delayed gastric emptying
Piroxicam		Food	Delayed absorption
Praziquantel	Anthelmintic	Food	Decreased rate and extent of absorption
Primidone	Anticonvulsant	Fresh fruits and vitamin C	Increased urinary excretion of primidone
		Protein	Low-protein diet increases duration of action of primidone
Propranolol	Antihypertensive	High-protein foods	Increased absorption
Propantheline		Food	Decreased absorption
Proxyphene	Analgesic	Food	Increased absorption by delayed gastric emptying
Pyrimethamine	Antimalarial	Folic acid	Decreased serum folate concentrations
Quinidine	Antiarrhythmic	Food	Delayed absorption owing to protein binding
Riboflavin	Vitamin	Food	Increased absorption by delayed gastric emptying
Rifampin	Antibiotic	Food	Decreased absorption
Ritonavir	Antiviral	Vitamins	Can cause vitamin deficiency
		Potassium	Hyper- and hypokalemia
		Cholesterol	Hypercholesterolemia
		Triacylglycerols	Hypertriacylglycerolemia
		Food	Delayed absorption
Oral solution capsules		Food	Increased extent of absorption

Continued

Table 2 Continued

Drug	*Class*	*Food/nutrient*	*Effect/mechanism*
Salicylates	Analgesic	Iron	Long-term chronic use decreases serum iron
Magnesium salicylate			
Choline salicylate		Vitamin C	Decreases concentration in serum and platelets
Sodium salicylate		Amino acids	Decreases their intestinal absorption and increases urinary secretion
Saquinavir mesylate	Antiviral	Food	Increased absorption of high-calorie, high-fat foods
		Calcium	Hypercalemia
		Glucose	Hyper- and hypoglycemia
		Phosphorus	Changes in serum phosphorus
		Potassium	Hyper- and hypokalemia
Spironolactone	Diuretic	Food	Increased absorption by delayed gastric emptying
Sulfonamides	Antibiotic	Food	Delayed with no effect on extent of absorption
Sulfdiazine			
Sulfisoxazole		Folic acid	Decreased intestinal synthesis, absorption and serum levels
Sulfamethoxazole			
Tetracycline	Antibiotic	Food	Decreased absorption
		Minerals	Inhibits absorption of iron, calcium, zinc and magnesium; chelation by polyvalent cations
		Fats	Decreases their absorption
		Vitamin K	Decreases bioavailability
		Vitamin C	Increase urinary losses; decreases plasma and leucocytes and levels
Theophylline	Broncodilator	Charbroiled beef	Increased metabolism of theophylline
		High-fat meals	Increased absorption dependent on formulation
Tolazamide	Antidiabetic	Sodium	Hyponatremia and SIADH
Tolbutamide			
Trimethoprim	Antibiotic	Folic acid	Decreased serum folate levels
Valproic acid	Anticonvulsant	Milk, food, carbonated drinks	Delayed absorption but no effect on extent of absorption
Divalproex sodium			
Valproate sodium			
Oral solution			
Warfarin	Anticoagulant	Alcohol	Inhibits warfarin metabolism
		Vitamin K	Beef liver, pork liver, green tea, leafy green vegetables high in vitamin K inhibit anticoagulant effect
		Vitamin E	Can increase warfarin response
Zalcitabine	Antiviral	Food	Decreased rate and extent of absorption
Zidovudine	Antiviral	Food	Decreased rate of absorption

CSF, cerebrospinal fluid; NSAID, nonsteroidal antiinflammatory drug; SIADH, Syndrome of Inappropriate Antidiuretic Hormone excretion.

into the brain by the same transport system as the large neutral amino acids, and thus must compete with them for use of the carrier binding sites. Diet composition, by affecting the postprandial amino acid profile, may change significantly the clinical efficacy of drugs such as L-dopa, used in the treatment of Parkinson's disease.

Body composition is also a relevant determinant of drug disposition and action. Although most drug dosages are calculated by total body weight, most drugs only act in the fat-free body mass. Thus, at a given body weight, individuals with more body fat will tend to receive a higher effective dose than those with lower body fat. The size of the body fat mass is also important for drugs that are stored in adipose tissue.

Major Drug–Nutrient Interactions of Clinical Relevance

Table 2 provides information on the major drug–nutrient interactions of clinical relevance. The list reflects well-known interactions of drugs that have been in the market for some time. The US Food and Drug Administration (FDA) maintains an on-line database of recently reported interactions and those of new drugs. The database can be assessed at www.fda.gov.

DRYING

Contents

Theory of Air-drying

J G Brennan, The University of Reading, Reading, UK

Background

Drying, or dehydration, is the oldest method of food preservation practiced by man, and today it is a major contributor to the convenience food market. The main objective of drying food is to prolong its shelf-life beyond that of the fresh material, while at the same time minimizing undesirable changes in appearance, texture, flavor, and nutritional value during the drying process. In addition to the preservation of the product, drying can bring about savings in storage and transport of foods owing to the reduction in weight and bulk that occurs during most methods of drying.

Water in Foods

Water is an important contributor to the sensory quality of foods and a loss or gain of moisture from a product can adversely affect its acceptability. However, a certain amount of moisture in foods enables undesirable changes to occur as a result of the activity of microorganisms and enzymes or through nonenzymic chemical reactions. (*See* **Drying:** Chemical Changes.) Thus, removing moisture from a food, or making it less available, is one way of extending its shelf-life.

The *moisture content* of a wet material may be expressed on a *wet-weight basis* (wwb), i.e., the mass of water per unit mass of the wet material, or on a

dry-weight basis (dwb), i.e., the mass of water per unit mass of dry solids. The latter way of expressing moisture content is usually used in drying formulae and calculations; see section Theory of Air Drying.

However, when the influence of moisture on the stability of foods is being studied, it is not only the total moisture content that is of importance but also how much of that moisture is available to support the activity of microorganisms and enzymes and enable chemical changes to occur. It is now widely accepted that a fraction of the total moisture in food is strongly bound to individual sites on the solid components and is not available to support these activities. An additional amount of moisture is less firmly bound but is still not readily available as a solvent for soluble components of the food. Such 'bound' moisture exerts a vapor pressure less than the vapor pressure of pure water at the prevailing temperature. A property known as water activity (a_w) is used to represent the availability of moisture in foods thus:

$$a_w = \frac{p_v}{p_w} \qquad (1)$$

where p_v is the water vapor pressure exerted by a solution or wet solid, and p_w is the vapor pressure of pure water at the same temperature. This expression also represents the relative humidity of an air–water vapor mixture ($\times 100$ to give the percentage relative humidity). A graph of moisture content as a function of water activity, with which it is in equilibrium, is known as a *sorption isotherm*. Such plots may be constructed by adsorption or desorption, which, in the case of many foods, results in two different curves, exhibiting hysterisis (Figure 1). Food isotherms may be considered to be made up of three regions. In region A, water is strongly bound to specific sites on the solid components, is not available as a solvent, and so does not support, microbiological, enzymic or chemical activity. The amount of moisture held in this way is known as the monolayer or monomolecular moisture content. This type of moisture usually exits below a_w 0.35, corresponding to a moisture content range 0.05–0.11 (dwb). Above region A, water is less strongly bound to the solids but still does not exert its full vapor pressure. In some publications, region B (Figure 1), is said to contain moisture that is bound in multilayers to the solid, and in region C, structural and solution effects lower the water vapor pressure. However, it is more likely that all these effects have an influence over the whole isotherm. At moisture contents of 1.0 (dwb) and above, most foods exert vapor pressures equal to that of pure water. Temperature affects the sorption behavior of foods according to the expression:

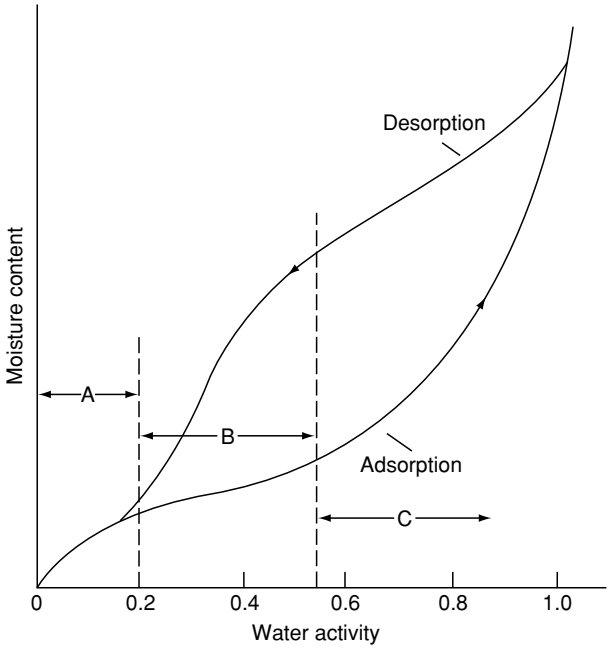

Figure 1 Adsorption and desorption isotherms showing hysteresis. From Brennan JG, Butters JR, Cowell ND and Lilly AEV (1990) *Food Engineering Operations*, 3rd edn. London: Elsevier Applied Science, with permission.

$$\frac{d(\ln a_w)}{d\left(\frac{1}{T}\right)} = -\frac{Q_s}{R}, \qquad (2)$$

where T is the absolute temperature, Q_s is the heat of adsorption, and R is the gas constant. The amount of adsorbed water at any given value of a_w decreases as the temperature increases.

Numerous mathematical models have been proposed to represent sorption isotherms of foods. One of the earliest was the Brunauer–Emmet–Teller isotherm:

$$\frac{a_w}{(1-a_w)W} = \frac{1}{W_m C} + \frac{a_w(C-1)}{W_m C}, \qquad (3)$$

where W is the total moisture content (dwb), W_m is the monolayer moisture content (dwb), and C is constant. This model is said to apply over the a_w range 0.05–0.45. An extended version of eqn (3), which takes into account multilayer adsorption and is said to be applicable up to a_w 0.90, is the Guggenheim–Anderson–DeBoer model:

$$\frac{W}{W_m} = \frac{Cka_w}{(1-ka_w)(1-ka_w+Cka_w)}, \qquad (4)$$

where C is known as the 'Guggenheim' constant, and k is a factor correcting properties of the multilayer molecules with respect to the bulk liquid.

A knowledge of the sorption characteristics of foods is useful in the prediction of drying times and energy requirements for drying processes. When

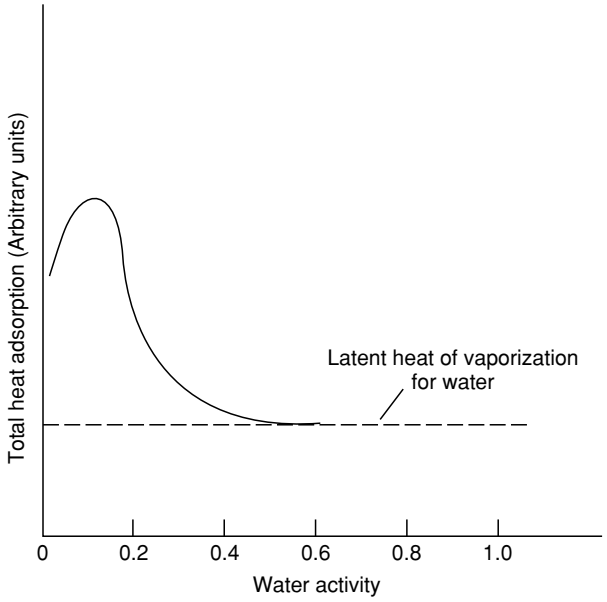

Figure 2 Dependence of the total heat of adsorption (latent heat plus heat of adsorption) on water activity. Adapted from Karel M (1974) Fundamentals of drying processes. In: Spicer A (ed.) *Advances in Pre-concentration and Dehydration of Foods*, pp. 45–94. London: Applied Science.

drying to very low moisture contents, extra energy is required to overcome the bonding of the water to the solids (Figure 2). The influence of a_w on the stability and shelf-life of foods is covered in **Drying:** Chemical Changes. The most common method of drying foods is air drying.

Theory of Air Drying

When a wet material is placed in a current of heated air, the air performs two main functions: it supplies the sensible and latent heat to bring about the evaporation of the moisture, and it acts as a carrier to move the water vapor formed away from the drying surface, thus enabling further evaporation to take place. Consider a wet solid composed of pure water and inert solids, in the form of a thin slab, which is placed in a current of heated air. If it is assumed that drying takes place from one large face only, that the temperature, humidity, and velocity of the air remain constant, and that all the heat is transferred from the air by convection, the drying curve should have the familiar shape shown in Figure 3. It comprises a number of stages or periods.

Period A–B is an *equilibration period* during which equilibrium is attained between the wet solid and the drying air. This period usually takes up a relatively small part of the drying curve.

Period B–C is known as the *constant rate period*, as the rate of drying remains constant during the period.

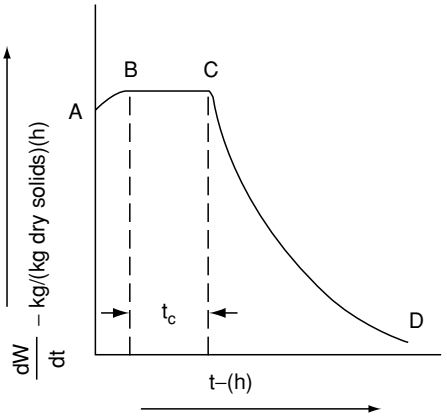

Figure 3 Model drying curve for a slab-shaped wet solid in air at constant temperature, humidity, and velocity. Adapted from Brennan JG, Butters JR, Cowell ND and Lilly AEV (1990) *Food Engineering Operations*, 3rd edn. London: Elsevier Applied Science, with permission.

Throughout this period, the surface of the solid is fully saturated with water. The movement of water from within the solid is sufficient to maintain saturated conditions at the surface. A state of equilibrium exists at the surface as the heat transfer to the surface from the air balances the rate of evaporation from the surface. The temperature at the surface of the solid remains constant at a value that corresponds to the wet-bulb temperature of the air. The driving force that causes water to evaporate into the air is the difference in water vapor pressure at the surface from that in the main air stream. The rate of drying, i.e., rate of change of weight $(-dw/dt)$, may be represented by the expression:

$$\frac{dw}{dt} = -K_g A(p_s - p_a), \qquad (5)$$

where K_g is the mass transfer coefficient, A is the drying area, p_s is the water vapor pressure at the surface of the solid, and p_a is the water vapor pressure in the main stream of the air. Eqn (5) may also be written as:

$$\frac{dw}{dt} = -K'_g A(H_s - H_a), \qquad (6)$$

where K'_g is the mass transfer coefficient, H_s is the absolute humidity at the surface of the solid, and H_a is the absolute humidity in the main air stream.

The rate of heat transfer from the air to the drying surface (dQ/dt) may be represented by the expression:

$$\frac{dQ}{dt} = h_c A(\vartheta_a - \vartheta_s), \qquad (7)$$

where h_c is the convection heat transfer coefficient, ϑ_a is the dry-bulb temperature of the air, and ϑ_s is the wet-bulb temperature of the air (temperature at

the drying surface). If sensible heat changes are neglected, the equilibrium between heat and mass transfer at the drying surface may be represented by:

$$\frac{dw}{dt}L_s = -\frac{dQ}{dt}, \tag{8}$$

where L_s is the latent heat at ϑ_s. Therefore, the rate of drying may be represented by the expression:

$$\frac{dw}{dt} = -\frac{h_c A}{L_s}\ (\vartheta_a - \vartheta_s). \tag{9}$$

The drying rate may be expressed in terms of the rate of change of moisture content ($-dW/dt$):

$$\frac{dW}{dt} = -\frac{h_c A'}{L_s}\ (\vartheta_a - \vartheta_s), \tag{10}$$

where W is the moisture content (dwb), and A' is the drying surface associated with the unit mass of dry solids. If the thickness of the slab is l, and the bulk density of the solids is ρ_s, the rate of drying may be expressed as:

$$\frac{dW}{dt} = -\frac{h_c}{\rho_s L_s l}(\vartheta_a - \vartheta_s), \tag{11}$$

If W_0 is the moisture content (dwb) of the wet material at the beginning of the constant rate period, and W_c is the moisture content (dwb) at the end of that period, the duration of the constant rate period (t_c) may be expressed as:

$$t_c = \frac{(W_0 - W_c)\rho_s L_s l}{h_c(\vartheta_a - \vartheta_s)}. \tag{12}$$

From the equations above, it can be seen that the higher the temperature and the lower the humidity of the air, the higher the rate of drying during the constant rate period. The velocity of the air also influences the drying rate during this period by affecting the heat transfer coefficient thus:

$$h_c = \frac{aG^n}{D_c^m}, \tag{13}$$

where G is the mass velocity of the air, D_c is the characteristic dimension of the system, and a, n, and m are constants. D_c has been represented by the equivalent diameter of the flow channel (cross-sectional area $\times$ 4%perimeter) or the length of the drying surface parallel to the direction of flow of the air. For most tray-drying calculations, the equivalent diameter is used. Values of n reported in the literature range from 0.35 to 0.80. Where no specific values are available, 0.80 is usually used in calculations. For situations where the air does not flow parallel to the drying surface, alternative expressions for h_c are available. When some of the heat is transferred to the drying surface by conduction or radiation, an overall heat transfer coefficient taking these sources of heat into account must be used.

Many solid foods do not exhibit a constant rate period. Others do, but it is usually quite short. Some recent work suggests that, if changes in dimensions of the solid pieces during drying are taken into account, more foods would exhibit a constant rate period.

As drying proceeds, a point is reached, C in Figure 3,when the movement of moisture to the surface is no longer fast enough to maintain the surface in a saturated condition. Beyond this point, the drying rate starts to fall and continues to do so throughout the rest of the drying cycle. Point C is known as the critical point and the moisture content at that point, W_c, the critical moisture content. The characteristics of the material being dried and the drying conditions influence the value of W_c. Period C–D (Figure 1), is known as the *falling rate period*. Many publications have reported the existence of two or more falling rate periods (see below).

During the falling rate period, the external conditions, in particular the velocity of the air, have less influence on the drying rate. This is determined by the factors that affect the movement of water from the interior of the solid to the surface. Numerous mathematical models have been proposed to represent the falling rate period of drying. Many are based on the mechanism whereby the moisture is assumed to move to the surface. Several mechanisms have been proposed, but the mechanism that has been most widely accepted is that in which the moisture moves by diffusion as a result of the concentration gradient between the surface and the interior of the wet solid. This type of movement may be represented by Fick's second law:

$$\frac{dW}{dt} = D\frac{d^2W}{dl^2}, \tag{14}$$

where W is the moisture content (dwb), t is the time, l is the distance, and D is the liquid diffusivity. One well-known solution to this equation, in an abbreviated form, for a slab-shaped solid, drying from one large face only is:

$$\frac{W - W_e}{W_c - W_e} = \frac{8}{\pi^2}\left[\exp\left\{-Dt\left(\frac{\pi}{2l}\right)^2\right\}\right] \tag{15}$$

or

$$t = -\frac{4l^2}{\pi^2 D}\left\{\ln\left(\frac{W - W_e}{W_c - W_e}\right) - \ln\left(\frac{8}{\pi^2}\right)\right\}, \tag{16}$$

where W is the average moisture content (dwb) at time t, W_e is the equilibrium moisture content (dwb), W_c is the moisture content at the start of the falling rate period (dwb), and l is the depth of the slab.

This expression holds for values of $(W-W_e)/W_c-W_e)$ less than 0.60.

Eqn (16) has been widely used to calculate drying times during the falling rate period. However, when it is used, it is assumed that D remains constant throughout the falling rate period. It is widely accepted now that the value of D changes with changes in moisture, i.e., it decreases as drying proceeds. Many authors have found that the falling rate period could be divided into two or more stages, with each stage having its own value of D.

D is dependent on temperature. The relationship most widely used to describe this dependence is of the form:

$$D_e = D_0 \exp\left(-\frac{Q}{RT}\right), \qquad (17)$$

where D_e is the average effective diffusivity, D_0 is the temperature-independent constant, Q is the energy of activation for diffusion, R is the gas constant, and T is the absolute temperature.

Many empirical models, derived from experimental data, have been used to represent falling-rate drying. One of the earliest and most widely used is:

$$\frac{dW}{dt} = -K_c\,(W - W_e), \qquad (18)$$

where dW/dt is the rate of drying (rate of change of moisture content) at a moisture content W (dwb), and K_c is the drying constant (or mass transfer coefficient). K_c is related to temperature thus:

$$K_c = a \exp\left(\frac{-b}{T}\right), \qquad (19)$$

where a and b are empirical constants.

Integrating eqn (18) gives:

$$\frac{W - W_e}{W_c - W_e} = \exp(-K_c t) \qquad (20)$$

or

$$t = -\frac{1}{K_c}\ln\left(\frac{W - W_e}{W_c - W_e}\right). \qquad (21)$$

Note the similarity between eqns (12) and (17). Although widely used, eqn (15) often does not apply to the whole falling-rate curve. The introduction of an empirical exponent, n, can widen its applicability thus:

$$\frac{W - W_e}{W_c - W_e} = \exp(-K_c t^n). \qquad (22)$$

Many other empirical models have been applied to describe falling-rate drying. Most are only applicable under conditions similar to those under which the model was developed. Many are specific to a particular food or related materials.

Neither the diffusion model nor the empirical model, outlined above, takes account of other changes that may occur during drying. Shrinkage may lead to changes in dimensions, density, and porosity of the material undergoing drying. These changes may influence the pattern of drying. Changes in the thermal properties of the material may influence heat transfer and, in turn, the pattern of drying. Many more complex models have been proposed that attempt to take account of these and other changes. Treatment of such models is outside the scope of this chapter.

Spray drying is widely used to dry *liquids and slurries*. The feed is converted into a fine mist or spray, which is brought into contact with heated air in a large drying chamber. Very rapid drying takes place, and a powder is formed, usually within 20 s. Because of the very large surface area created, evaporative cooling maintains the surface of the droplets close to the wet-bulb temperature of the air throughout most of the drying. If it is assumed that drying takes place under constant rate conditions, the time, t, for a spherical droplet to dry from an initial moisture content, W_0, to a final moisture content, W_f (dwb), may be represented by the expression:

$$t = \frac{r^2 \rho_l L_s (W_0 - W_f)}{3h_c(\vartheta_a - \vartheta_s)(1 + W_0)}, \qquad (23)$$

where r is the radius of the droplet, and ρ_l is the density of the liquid.

In practice, not all the moisture is removed under constant rate conditions. More detailed treatments of drying of droplets during spray drying are available in the literature.

Drying Using Natural Radiation

M. Mathlouthi, Université de Reims Champagne-Ardenne, Reims Cedex, France

Background

Drying of certain crops and foodstuffs is a very ancient and relatively easy technique for food preservation. Sun-drying has been used by early civilizations and is still used in many tropical and subtropical countries where solar energy remains a low-cost heat energy. However, the traditional method, which involves spreading the product in a thin layer on the ground or on a platform and exposing it directly to the sun has its drawbacks. The quality of the dried product is reduced owing to color deterioration by direct exposure to UV radiation, as well as damage to unprotected products by insects, rodents, and other animals, and microbial spoilage, especially as the relative humidity increases. Improvements in sun-drying have led to solar drying. This technique uses sun as a heat source, which increases the drying capacity of air by heating it and reducing its relative humidity in indirect solar dryers. Recent advances have produced cheaper solar dryers, suitable for the drying requirements of the crop, as well as an improved quality of the dried product. Whatever the drying system, using either direct exposure to the sun or circulation (natural or forced) of heated air in solar dryers, the driving force for dehydration remains the gradient of water vapor pressure between the product and the surrounding air. This explains why natural ventilation is convenient in dry areas like arid zones of Africa or the Artic, whereas the hot and humid air of certain tropical regions is inefficient for drying crops. Such climatic conditions necessitate the use of adapted solar dryers.

To take advangae of solar energy, collectors are used, generally made from low-cost packaging films readily available in developing countries where solar dryers have been introduced with the aim of reducing crop losses. Solar-energy-based dryers are generally low-temperature drying systems. Equilibrium in relative humidity between the air and the product is generally reached at a constant ventilation rate and an average temperature around 50 °C. This kind of drying concerns crops that are dried in bulk in their storage devices. Fruits with a high sugar and acid content, like raisins, figs, apricots, or dates, are particularly well suited to natural drying outdoors. Sometimes, a pretreatment is needed if the dehydration rate and storage stability of the product are to be improved.

Solar Drying Systems

Three types of application of solar energy are used to dry crops:

- Direct – absorption of solar radiation where natural convection of the surrounding air is the origin of mass and heat transfer;
- Indirect – application of solar radiation, which is used to preheat air in a solar collector before blowing it on the crop tray and releasing it through a chimney;
- Mixed-type drying systems, which use both direct solar heat and natural ventilation of the drying chamber with air heated in a solar air heater.

There is another type of classification that considers solar drying systems as passive or active, depending on whether they rely completely on solar radiation and natural air flow, or only partly on solar energy, and also on other heating systems, as well as on motorized fans. All active solar dryers use forced convection.

Direct Solar Radiation Drying

Traditional open-to-sun drying This involves spreading the crop, or the food on the ground, or placing it on horizontal shelves exposed to sun, air, and natural ventilation. From time to time, the crop is stirred to reduce the drying time. This type of sun drying is common in developing countries. Although this method seems simple and cheap, very often, crop losses result from fungal and insect infestation, or unexpected rain. The quality of the dried product is sometimes poor, such as the loss of riboflavin in couscous dried under UV sun radiation as compared with industrial hot-air-dried products. Even though large amounts of fruits and vegetables are still sun-dried, the development of indirect solar dryers seems the solution for the future if it is necessary to decrease the drying time, improve the quality, and minimize crop loss.

Direct solar-energy absorption dryer In this type of dryer, the solar radiation is used directly in the dryer, which is, in this case, a cabinet dryer equipped with a fan and sometimes an additional electric heat source (Figure 1), or a greenhouse tunnel covered with a glass or a polyethylene plastic cover about 150 μm in thickness and, in some cases, with UV and far-infrared protection. In the greenhouse-type dryer (Figure 2), the solar-heated air is circulated through the product by a fan. A metallic structure made of arches connected by longitudinal tubes and supported on vertical lateral tubes is used. This structure is covered with a polyethylene film of the same type as

that used in cultivation greenhouses. Recycling of air in a transparent plastic tube is possible. Fans at the air inlet and exit allow an increased ventilation rate.

Storage-type dryers have roofs that act as a solar collector. In other cases, both the roof and the wall act as collectors. The wall is usually black painted concrete covered with glass and is both a collector and a means of heat storage.

Indirect solar dryer In this type of dryer (also called a distributed-type air-circulation solar dryer), the crop is placed on shelves in an opaque drying chamber. The drying air is heated in a separate solar collector and distributed by either natural or forced (fan) circulation. In this dryer, the crop is not exposed to sun, thus preventing vitamin loss and other UV-sensitive reactions like lipid oxidation. The air temperature is higher than in direct sun-dryers, which reduces the drying time. A typical solar dryer is shown in Figure 3. Clearly, the equipment and maintenance costs of this type of drier are more than that of the direct sun dryer. Efficiency is increased if forced-air convection is installed. The optimization of indirect solar dryers also depends on the quality of the solar energy heating the collectors.

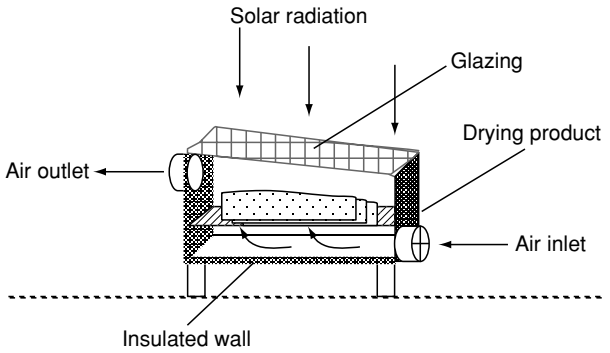

Figure 1 Cabinet solar dryer.

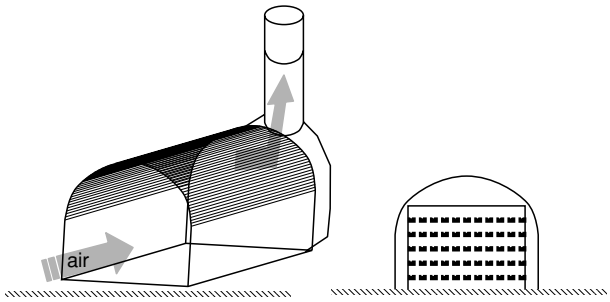

Figure 2 Greenhouse-type solar dryer.

Mixed solar dryer This type of dryer incorporates both direct and indirect solar-energy drying. The dryer consists of a preheated air chamber, a drying chamber and a chimney. However, the drying chamber in this case is glazed so that the product also receives direct solar energy as well as a flow of drying air (Figure 4). Depending on the countries and product, the heat absorber may be made of low-cost recovered byproducts, as in rice drying, where a layer of burnt rice husk covered with a transparent plastic sheet on an inclined bamboo network is used as the air heater's absorber. Direct absorption of solar heat in the drying chamber takes place through a transparent plastic film, which also protects the crop against rain and other degradation agents. In the multi-stacked dryer, different products can be dried at the same time on a series of shelves. Also, the drying chamber has a column exposed on one side to the sun through glazing and, on the opposite side, a wooden access door and vents, thus obviating the need for a chimney.

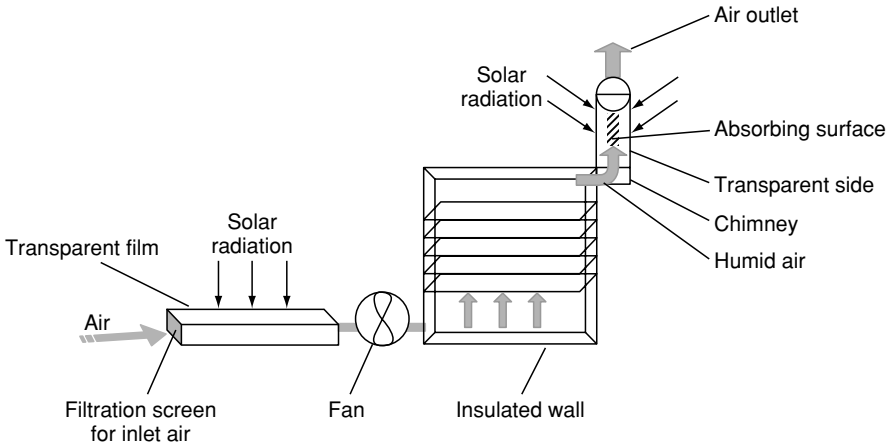

Figure 3 Indirect solar dryer consisting of a collector, drying chamber, and chimney.

Solar Heat Collectors

Solar collectors take advantage of the thermal energy of solar radiation. There are two types: the bare flat-type collector and the covered-plate heat absorber. The surface of the plate is usually painted black; this absorbs sun radiation and transmits it in the form of heat to the drying air. The air flow through the collector is by natural convection or by means of a fan. The efficiency of a collector can be determined by measuring the inlet and outlet temperatures, the surface of the collector and flow rate of the air, and the solar energy available.

Bare Flat-plate Collectors

These collectors consist of a simple air duct with the upper side acting as a heat absorber and the lower surface acting as an insulator (see Figure 5). Important losses of thermal energy are observed at the upper surface, which limits the use of such collectors to low-temperature drying like crop drying in storage silos. In this type of collector a flat plate of aluminum can be used as a heat absorber. The heat loss is reduced by placing the air duct in a box filled with glass wool insulation.

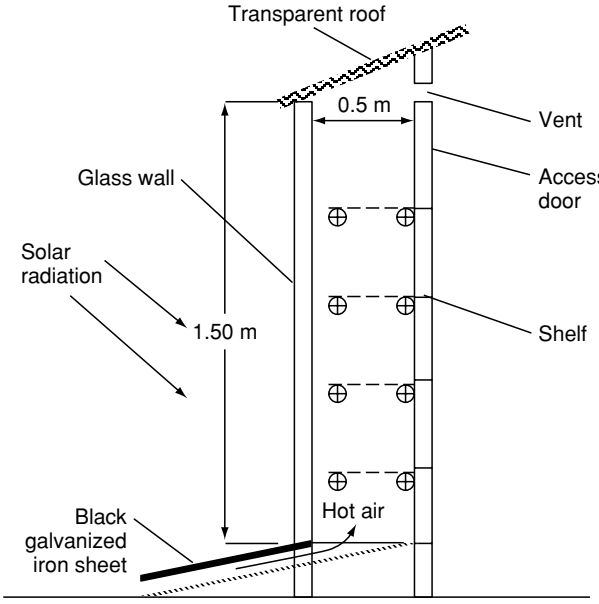

Figure 4 Mixed solar-energy dryer.

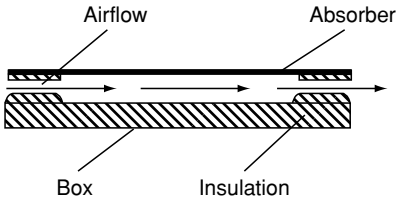

Figure 5 Flat-plate collector.

Covered-plate Heat Collector

To minimize heat losses from the upper side of the collector, glass, plexiglass, or transparent plastic is used as a cover material, placed parallel to the metallic absorber plate. Covered-plate solar-energy air heaters are much more efficient than bare-plate collectors. The air to be heated can be sucked between the absorber and the transparent cover, or sometimes underneath the absorber to prevent dust contamination at the surface of the absorber. In this case, the air circulates between the lower face of the absorber plate and the insulation layer, the upper surface of which is in contact with a static layer of air underneath the glazing. This type of back-pass air heater (Figure 6) is more efficient than one where air flows between the absorber and the cover.

Efficiency of Solar-heat Collectors

Efficiency is defined as the ratio of thermal energy used to heat the drying air over the total solar energy absorbed by the collector in the same time period. The heat used to warm air in the collector is expressed by:

$$Q_a = m_a C_{pa}(T' - T),$$

where Q_a is the heat transmitted to air in the collector ($J\,s^{-1}$), m_a is the mass flow rate of air through the collector ($kg\,s^{-1}$), C_{pa} is the specific heat capacity of air ($J\,kg^{-1}\,K^{-1}$), T' is the collector outlet temperature, and T is the inlet temperature (generally ambient).

If A is the collector area (m^2) and I the flux of incident solar radiation ($W\,m^{-2}$), the total incident energy of the exposed surface of collector is $Q_i = AI$, and the efficiency ratio (η) can be expressed as:

$$\eta = \frac{Q_a}{Q_i} = m_a C_{pa} \frac{(T' - T)}{AI}.$$

In forced-convection air dryers, m_a is easy to measure, as well as the inlet and outlet temperatures. For natural convection, the flow rate of air is difficult to

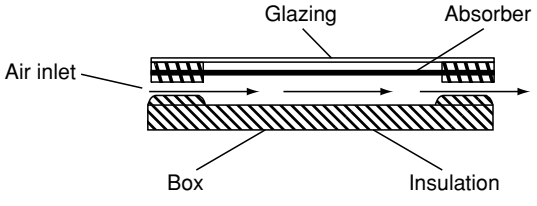

Figure 6 Back-pass air heater.

determine precisely, hence the efficiency ratio is measured. Incident solar radiation absorbed by collector depends on the properties of the material used for the design of the collector like absorbance, transmittance, and reflectance. It is also a function of the position of the sun relative to the collector, the solar altitude angle, and the sunrise and sunset of the collector orientation. A value of 1 kW per square meter of exposed surface may be considered as an optimum.

Application of Solar Drying to Selected Crops

Solar drying is an effective mode of dehydration especially for certain crops (cereal grains, grapes, figs, sweet pepper, thyme) in countries with good sunshine during the harvest period. Many developing countries have sufficient insolation for sun or solar drying, but the dryer needs to be of the right design to minimize crop losses resulting from contamination by insects, molds, and poor storage conditions. In developing countries, greenhouses can be used as solar dryers during the warm period of the year, thus reducing the cost of investment of setting up a new dryer. Solar collectors may be made from low-cost polyethylene film traditionally used to cover greenhouses. In all cases, covered heat collectors and drying chambers are preferable to open-air sun dryers to prevent crop spoilage.

Solar Drying of Grapes

Traditional drying of grapes is still used in many countries and involves spreading or hanging the product on galvanized wires (with a coverage of about 15–20 kg m^{-2}) on the racks. A typical dryer contains six to 10 racks each about 50 m long, 2 m tall, and 1.5 m wide. Racks are placed on open high land to allow free air flow. The period of drying varies from 8 to 20 days, depending on the grape variety, treatment, and climate conditions. The water content in the grapes is reduced from about 3 kg of water per kilogram of dry matter in fresh product to about 0.16 kg of water per kilogram of dry matter in the dried product. Solar dryers using either direct or indirect solar energy have higher drying rates than sun dryers. These rates are improved when grapes are pretreated. Pretreatment solutions contain 4–5% K_2CO_3 and 1–2% dipping oil. Changing the surface tension of grape by dipping for a few minutes in dipping solution increases water diffusion through the waxy cuticle and decreases the drying time.

The quality parameters of solar-dried grapes, especially color, moisture content, and acidity, are more uniform than those of the sun-dried product. Storage stability is improved with SO_2 gas pretreatment and conditioning in a modified atmosphere (1% O_2; 20% CO_2) packages.

Solar Drying of Other Crops

For obvious economic reasons, if a solar dryer is preferred to an open-air sun dryer, it should work to full output. Therefore, it has to be a multipurpose dryer equipped for both low-temperature (below 50 °C) and high-temperature (above 50 °C) drying, eventually using the calories produced by the combustion of agricultural waste as part of the total thermal energy required. Tunnel greenhouse dryers are very efficient during sunny days and can be used with an auxillary combustion heating system to ensure a continuous operation. This type of solar dryer is used for sweet pepper and garlic in Argentina. In terms of mold contamination, the quality of the product is better on sunny days than on cloudy, humid days. A complementary heating source is needed to improve drying during humid periods and to increase the working time. Products like thyme can be dried at about 50 °C using a wire basket solar dryer. Sun-dried thyme herb is suitable for packaging or grinding as a powder. In terms of the essential oils extracted after drying, sun-dried thyme is of a better quality than that of oven-dried thyme, but the percentage of oleoresin is the same for both drying methods.

Quality of Solar-dried Products

Sun drying usually takes too long, and even solar drying lasts several days. Such a long process favors degradation reactions, especially when the water activity is relatively high, above 0.60. Moreover, the storage conditions should be controlled so that the temperature is maintained below 10 °C for grain and nut storage, and the relative humidity below 40%. This requires cooling and dehydration of air. However, if precautions (e.g., the use of clean crops) are taken to minimize spoilage, high-quality sun-dried products can be produced. Other precautions include the use of covered plate absorbers and the use of clean drying air. The first stages of dehydration (first and second day) should be carried out on sunny and dry days. The most dangerous contamination is fungal damage, which can yield mycotoxins. Among the mycotoxins, such as ochratoxin, citrinin, and ergosterol found in grains and nuts, aflatoxins are the most important as regards toxicity, occurrence, and economic consequences, especially in developing countries.

Other degradation reactions such as browning, lipid oxidation or vitamin loss may be minimized by using adequate protection in the dryer. For example,

it is preferable to use low temperatures as well as the UV radiation filtration using colored glazing.

Conclusion

Solar drying has proved to be technically and economically valuable for several crops. It is, however, necessary to develop large-scale dryers that may be used throughout the year for different products to make them attractive to the farmers.

Protection against UV radiation, dust, insects, mold, and other sources of contamination, as well as temperature and relative humidity control, are needed to improve the quality of the product. Likewise, the storage conditions of solar-dried products should be tailored to the crop and the packaging optimized if a long shelf-life is required.

Fluidized-bed Drying

J G Brennan, The University of Reading, Reading, UK

Principles of Fluidization

If air is made to flow through a bed of solid particles supported by a perforated plate or grid, frictional drag will cause a pressure drop to develop across the bed. The drag, and hence the pressure drop, will increase as the air velocity increases. When the frictional force overcomes the weight of the particles they move apart, and the bed expands and begins to behave like a fluid. In this state it is known as a 'fluidized bed.' The air velocity at which fluidization first occurs is known as the 'incipient (or minimum) fluidization velocity.' This velocity can be calculated, for spherical particles, using the relationship:

$$v_f = \frac{(\rho_s - \rho)g}{\mu} \frac{d^2\varepsilon^3}{180(1-\varepsilon)}$$

where v_f (m s^{-1}) is the minimum fluidization velocity, ρ_s (kg m^{-3}) is the density of the solid particles, ρ (kg m^{-3}) is the density of the air, g (m s^{-2}) is acceleration due to gravity, μ (N s m^{-2}) is the viscosity of the air, d (m) is the diameter of the particles, and ε is the voidage of the bed (the fraction of the bed that is void). As the air velocity increases above the minimum value, bubbles of air pass up through the bed. These bubbles are small when they leave the perforated plate. As they pass up through the bed they coalesce to form larger bubbles. The movement of these bubbles causes mixing of the solid particles in the bed. As the air velocity increases, mixing becomes more vigorous. At some stage particles will leave the surface of the bed and fall back on to it. At a still higher velocity the particles become entrained in the air and are carried away in the exhaust air stream. The velocity at which this first occurs is known as the 'entrainment velocity.' This velocity may be calculated, for spherical particles, by means of the relationship:

$$v_c = \sqrt{\left(\frac{4d(\rho_s - \rho)}{3C_d\rho}\right)}$$

where v_c (m s^{-1}) is the entrainment velocity and C_d is the drag coefficient. C_d has a value of 0.44 when the Reynolds number of the air is in the range 500–200 000. When heated air is used to fluidize a bed of particles containing moisture, dehydration of the particles will occur. This is the principle of the fluidized-bed drier.

Fluidized-bed Driers

Food particles suitable for fluidized-bed drying should be in the size range 20 μm to 10 mm, uniform in size and shape, and not very sticky. They should not break up easily when subjected to impacts and abrasion in the bed. Some food materials, e.g., cereal grains, fluidize readily over a wide range of moisture contents. Other foods will only fluidize at low moisture content. In the latter cases the wet product may be fluidized by dispersing it in a bed of already dried material.

Fluidized-bed drying chambers equipped with a mechanical agitator to help disperse wet or sticky materials are available. The agitator is located near

Table 1 Typical gas velocities for fluididizing different-sized particles

Average particle size (μm)	*Velocity ($m\,s^{-1}$)*
100–300	0.2–0.4
300–800	0.4–0.8
800–2000	0.8–1.2
2000–5000	1.2–3.0

the feed inlet. It disintegrates the feed and disperses the pieces into already dry material, thus facilitating fluidization. Some semisolid foods may be converted into a form suitable for fluidized-bed drying by mixing them with some dried material, and extruding and cutting the mixture into suitably sized pieces.

The air velocity should be as high as possible to promote rapid drying. The upper limit is often determined by the loss of fine product, created in the bed, with the exhaust air. Some loss of fines may be tolerated in order to achieve high drying rates. The fine particles may be recovered from the outgoing air by means of cyclones or fabric filters. Typical air velocities for fludizing particles with densities in the range 1000–2000 $kg\,m^{-3}$ are presented in Table 1.

For most food applications the support for the bed is a simple perforated plate. For very fine particles more complex designs incorporating jets or bubble caps, similar to those in distillation plates, may be used. Fluidized-bed driers usually operate at atmospheric pressure. However, by suitable location of fans they may be run at pressures above or below atmospheric pressure. Heater plates may be incorporated into the drying chamber to improve heat transfer. These are not common in food applications. The drying conditions can be accurately controlled in batch-operated fluidized beds. High rates of drying and uniform moisture content in the product can be achieved. However, batch units are only used for small-scale operations.

There are two types of continuous fluidized-bed drier which differ in the pattern of flow of the particles and air. The plug-flow type (Figure 1a) has a relatively long narrow bed. The feed is introduced at the wet end and moves to the dry end in a plug-flow pattern where the dry product is discharged over an adjustable weir. The distribution of the residence time of the particles is relatively narrow so that uniform drying is accomplished. However, its application is limited to feed particles which are readily fluidizable. In the well-mixed, or backed-mixed, fluidized bed (Figure 1b) the ratio of the length of the bed to its width is unity or below. The particles are vigorously mixed and the bed will have a relatively uniform

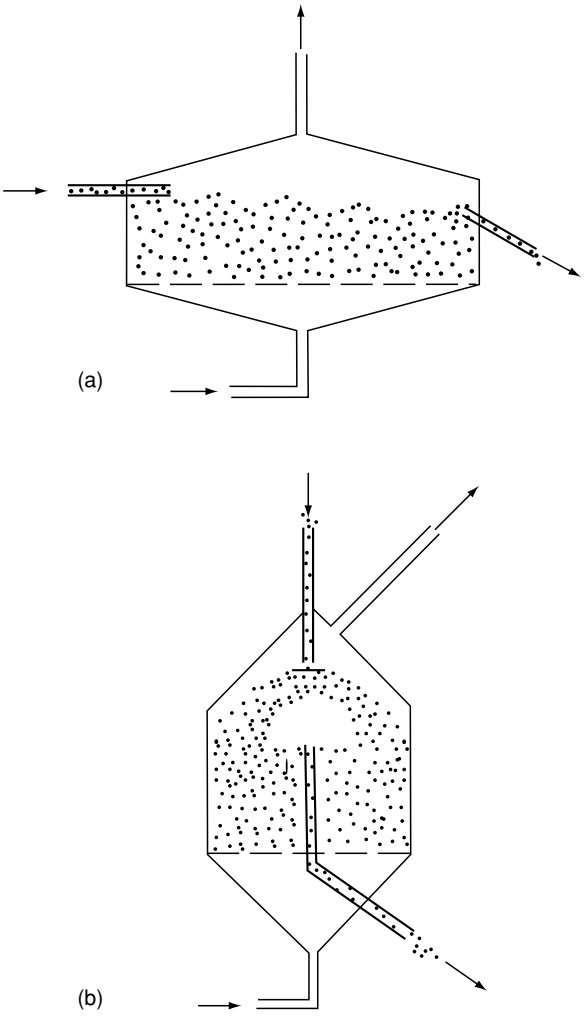

Figure 1 Representations of (a) a continuous plug-flow fluidized-bed drier and (b) a continuous well-mixed fluidized-bed drier. Adapted from Mujumdar AS (ed.) (1995) *Handbook of Industrial Drying*, 2nd edn, by courtesy of Marcel Dekker: New York.

temperature. The wet feed is introduced into a bed of relatively dry particles and is quickly dispersed. Thus, it can handle feeds that are difficult to fluidize. On the other hand, there is a broader distribution of particle residence time, as compared with the plug-flow design, and the product moisture content may be less uniform. The well-mixed bed is best at removing surface moisture, whereas the plug-flow type removes moisture from within the particles. The latter type is most widely used for food applications. Figure 2 shows a continuous plug-flow fluidized-bed drier equipped with a cyclone for the recovery of fines.

Vibrated Fluidized-bed Driers

Fluidized-bed driers may be fitted with vibrating bases, to help move the product horizontally from

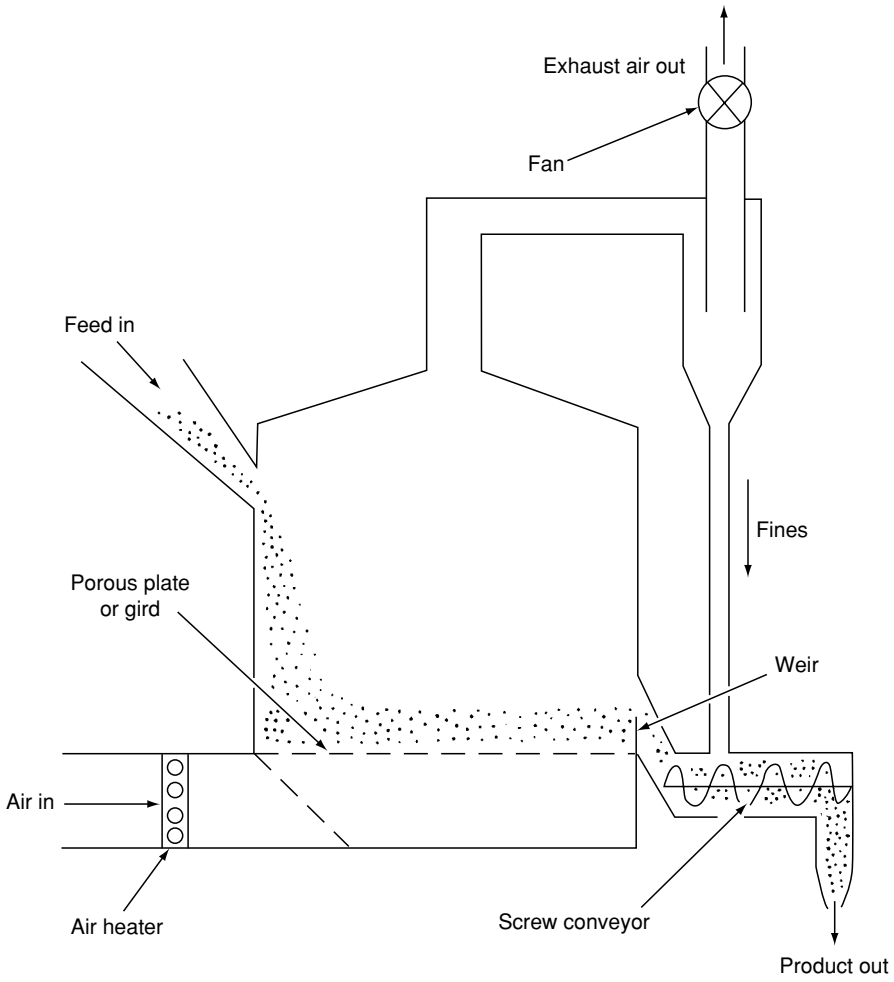

Figure 2 A continuous plug-flow fluidized-bed drier equipped with a cyclone for the recovery of fines. From Brennan JG, Butters JR, Cowell ND and Lilly AEV (1990) *Food Engineering Operations*, 3rd edn. London: Elsevier Applied Science with permission.

the wet end to the dry end. This motion is gentle and suitable for handling fragile materials and agglomerates susceptible to mechanical damage. A vibrating bed is capable of handling particles less uniform in size as compared with the stationary-type bed. A vibrating bed is also better at handling sticky materials. The air velocity required to keep the particles moving is usually much less in a vibrated bed than in a stationary one. Bases vibrate in the frequency range 5–25 Hz and a half amplitude of a few millimeters. Such beds are also known as 'vibro-fluidizers.'

Multistage Fluidized-bed Drying

A number of fluidized-bed driers may be used in series. This enables better control of the drying conditions at different stages in the cycle and can yield a product with a more uniform moisture content as compared with a single-stage drier. The use of a multistage system may also lead to energy savings. One possible combination is a well-mixed bed, to remove surface moisture, followed by a plug-flow bed to complete the drying. Alternatively, a number of plug-flow beds may be used in series. The latter arrangement is mainly used for the food applications. Up to six stages may be used. Vibrating beds are usually employed. The particles fall under gravity from one stage to the next. Such an arrangement is also known as a 'cascade system.'

Applications

Single-stage and multistage fluidized-bed drying systems are used for a wide range of food materials. These include peas, sliced beans, diced carrots, onions, potato granules, meat cubes, grains, flour, salt, and sugar. The air temperature is selected to suit each product. Vibrating fluidized beds are used as after driers and coolers following spray drying. The

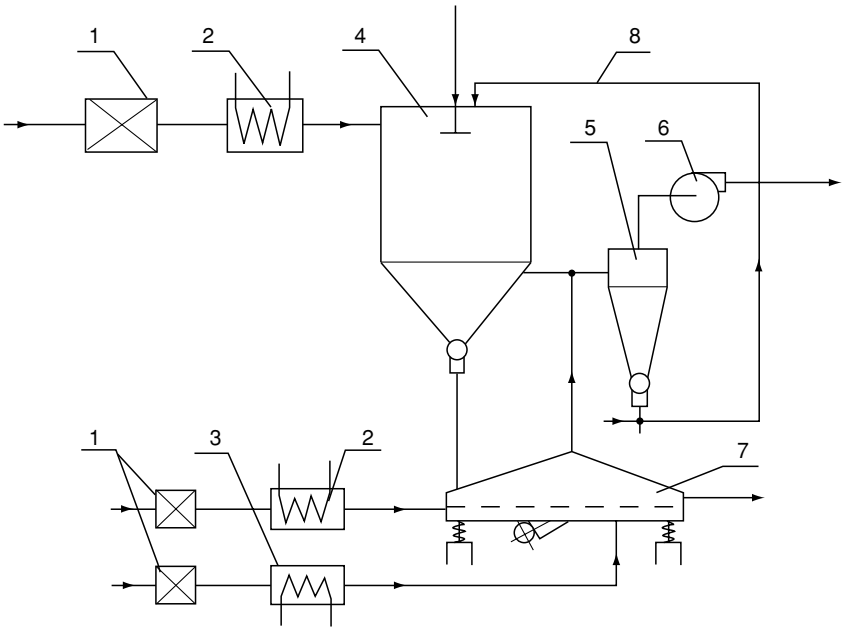

Figure 3 A two-stage spray-drying process for milk: 1, air filter; 2, heater; 3, cooler; 4, spray drier; 5, cyclone; 6, exhaust fan; 7, fluidized-bed drier; 8, return line for powder. From Mujumdar AS (ed.) (1995) *Handbook of Industrial Drying*, 2nd edn, by courtesy of Marcel Dekker: New York.

powder from the spray drier has a moisture content of 5–7%. This is reduced to 3–4% on a vibrofluidizer using dry air at a relatively low temperature. Such two-stage drying is said to facilitate better control over the quality of the product and lead to savings in energy as compared with straight-through spray drying. Some agglomeration of the powder particles may occur in the fluidized bed which can improve the reconstitution characteristics of the product. Such a system is shown in Figure 3. The product may be cooled in the same vibrofluidizer or in a second unit in series with it. Cooling the product facilitates handling and packaging. Spray driers are available with fluidized beds built into the main drying chamber. These are known as integrated fluidized-bed spray driers.

Spouted-bed Drier

One particular design of fluidized-bed drier is the spouted bed. In this type of drier the drying air enters at high velocity through a nozzle located centrally in the conical base of the chamber (Figure 4). This creates a spout of fast-moving particles up through the center of the bed. These particles return to the base of the chamber as a slow-moving annular bed surrounding the spout. A proportion of the inlet air flares out into this annular bed and flows upwards, countercurrent to the downward-moving particles, at a relatively low velocity. In the spout, high rates of heat and mass transfer occur, resulting in high initial rates of drying. As a result of evaporative cooling the temperature of the particles in the spout is kept relatively low. The later stages of drying take place in the annular bed under relatively mild conditions. This type of drier is suitable for drying relatively large particles, greater than 5 mm in diameter. It can cope with heat-sensitive materials. During start-up a high

pressure drop has to be developed across the bed to form the spout. Once this is formed the pressure drop decreases to a value less than that which develops across a conventional fluidized bed. A spouted-bed drier featuring tangential air inlet has also been reported (Figure 5). The air enters through slits at the bottom of the chamber. An open screw conveyer is located in the spout to control the upward movement of the particles, independently of the air velocity. This enables smaller particles to be dried as compared with a conventional spouted-bed drier. A high early air pressure drop is not required to initiate spouting. Wheat, corn, and diced carrot are among the foods which have been successfully dried in spouted-bed driers.

Toroidal-bed Drier

This is another novel design of fluidized-bed drier (Figure 6). A high-velocity stream of heated air enters the base of the process chamber through blades or louvers which impart a rotary motion to the air. This creates a compact rotating bed of particles, which may vary in depth from a few millimeters to 50 mm. High rates of heat and mass transfer are attainable in this bed, resulting in high initial rates of drying. This drier can accommodate a wide range of particle sizes and shapes and can be operated on a batch or continuous basis. Not much information on the performance of this equipment for drying foods has been published. However, preliminary studies, in which this author has participated, indicate that it has considerable potential for drying small particulate foods and liquid foods on a similar principle to the spouted bed above. It can be used for roasting products such as coffee beans and nuts, expanding pasta pellets, and possibly cooking or sterilizing other particulate. In a current study it is being used to produce puffed potato cubes.

Centrifugal Fluidized-bed Drier

This consists of a cylindrical chamber rotating about a horizontal axis (Figure 7). The cylinder wall is perforated and a high-velocity (up to 15 m s^{-1}) stream of air flows through these perforations and across the drying chamber. The feed enters at one end of the chamber and the dried product leaves over a weir at

the other end. Some 10–20% of the chamber volume is occupied by the food particles. These are made to fluidize during part of each revolution and form a stationary bed during the rest of the cycle. This drier has been used to dry sliced and shredded vegetables which are difficult to dry in conventional fluidized-bed driers and for puffing vegetable pieces, including rice grains, to produce a quick-cooking product.

Novel Applications for Fluidized and Spouted Beds

Fluidized beds of inert particles have been used to dry solid and liquid food materials. A whirling fluidized bed of glass beads has been used to dry diced vegetables and sticky products such as cooked rice. Mushrooms, carrot, beef, and shrimp have been dried at low temperature in a fluidized bed of activated alumina. Paste and liquid foods have been dried in spouted beds of inert particles. Blood has been dried in this way. In a recent study, model liquid foods were sprayed on to polypropylene beads in an experimental spouted bed drier (Figure 8). Drying occurred by a combination of convected heat from the air and conducted heat from the beads. The performance of this drier was compared with that of a laboratory spray drier. Early results indicated that the drying process in the spouted bed was rather more severe than in the spray drier. However, the evaporative capacity of the spouted bed was some six times that of the spray drier, which was a comparable size.

Fluidized beds may be used to produce agglomerated or granulated products. A liquid is sprayed on to a fluidized bed of particles, coating them. Collisions between particles cause them to adhere together to form agglomerates. When the agglomerates reach the desired size they are dried to a stable moisture content by raising the temperature of the fluidizing air. Both batch and continuous agglomerating systems are available (Figure 9).

A relatively new application for fluidized beds is the puffing of fruit and vegetable pieces. The pieces

are predried in a conventional hot-air drier such as a cabinet or tunnel, to form an impervious layer on their surface. They are then introduced into a fluidized bed, operating at a relatively high temperature. The water evaporates internally within the pieces, causing them to expand and producing an open porous structure. The puffed product is then dried down to a stable moisture content in a cabinet or tunnel drier. This has the effect of reducing the overall drying time and produces a product which reconstitutes rapidly. Alternatively, the dry product may be used as a snack food, low in fat, compared with fried products.

Drying Difficult Materials

To contain hazardous materials or unpleasant odors semiclosed-cycle fluidized-bed systems are available. In such systems a large proportion of the exhaust air is recycled. The air from the cyclones goes to a condenser/scrubber which removes the water from it as condensate. Only a small amount of air is released to the atmosphere; the rest is recycled through the heater and drier. The air vented from the system may be burnt off if necessary. Similar systems are available for spray driers. Application of these specialized types of driers to food dehydration is limited at the present time. However, as regulations relating to pollution of the environment become more stringent, the use of such systems may increase.

Spray Drying

J G Brennan, University of Reading, Reading, UK

Principles

This is the most commonly used method for drying food liquids and some slurries. The feed is converted into a fine mist or spray which is then mixed with heated air. Very rapid drying takes place, converting the liquid droplets into powder particles. Because of the small size of the particles – diameters usually in the range 10–200 μm – a very large surface area is available for drying. Also the distance that moisture has to migrate within the particles to the drying surface is relatively small. Thus, short drying times, 1–20 s, are a feature of this method of drying. There is also a significant evaporative cooling effect so that the surface temperature of the droplets does not rise much above the wet bulb temperature of the drying air until drying nears completion. Provided the particles, once dry, are swiftly removed from the drying chamber, heat damage to the product can be limited.

The main features of a single-stage spray-drying plant are shown in **Figure 1**. Inlet fan A draws air in through a filter B and pushes it through the air heater C into the drying chamber D. By means of pump E the feed material is pumped from feed tank F to the spray-forming device G. It is converted into spray which mixes with the drying air in the drying chamber D. The bulk of the dry powder thus formed is removed from the drying chamber via valve H and is carried pneumatically to a storage bin through duct I. The air is removed from the drying chamber via ducting J through one or more air/powder separators K and is exhausted to the atmosphere by outlet fan L. The fine powder recovered by the separators K may be added to the main product stream via valve M or recycled into the wet zone of the drying chamber via duct N.

Spray-drying Equipment

Air heating may be indirect using steam, fuel oil, or gas. Direct heating would obviously improve the thermal efficiency of a drier and in recent years natural gas has been used directly to heat the incoming air. There is some concern over the possible contamination of the dried products with nitrate and nitrite compounds and *N*-nitrosodimethylamine. The introduction of low NO_x (nitrogen oxide) burners has reduced this problem. However, work is still in progress to establish the level of contamination, if any, of food products dried by directly heated air.

The formation of a spray of the feed liquid within a specified size range is an essential feature of spray drying. Too wide a droplet size range can lead to nonuniform drying and/or build-up of powder on the inner wall of the chamber. Droplet size can influence important properties of the dried product such as its bulk density and reconstitution characteristics.

Spray-forming devices, also known as atomizers, are of three general types: (1) centrifugal or wheel atomizers; (2) pressure nozzles or jets; and (3) two-fluid or pneumatic nozzles.

A centrifugal atomizer consists of a disk or bowl on the end of a rotating shaft. The liquid feed is introduced on to the disk near its center of rotation. It accelerates to the peripheral velocity of the disk and is spun off, in the form of a spray, into the drying chamber. There are numerous different designs of spinning disk, some of which are depicted in Figure 2.

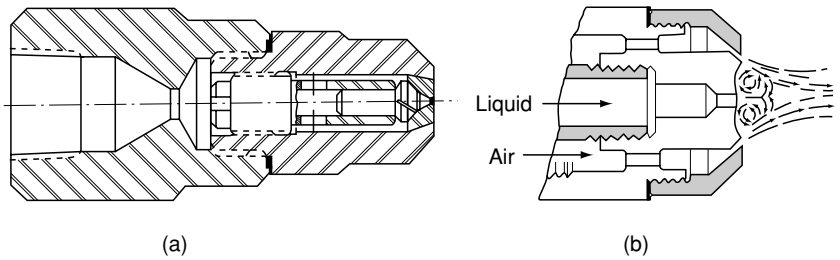

Figure 3 (a) Pressure nozzle; (b) two-fluid or pneumatic nozzle. Adapted from Brennan JG, Butters JR, Cowell ND, Lilly AEV (1990) *Food Engineering Operations*, 3rd edn. London: Elsevier Applied Science with permission.

Disk diameters range from 50 to 300 mm, they rotate at speeds of 50 000–10 000 revolutions per minute, respectively, and produce droplets with mean diameters in the range 1–600 μm. Centrifugal atomizers can produce uniform sprays within a wide range of droplet sizes. The size distribution of the droplets can be altered by changing the speed of rotation. Such atomizers are not subject to blocking or abrasion due to insoluble solid particles in the feed and can handle viscous materials at low pumping pressures.

A pressure nozzle (Figure 3a) features a small orifice, with a diameter in the range 0.4–4 mm, through which the feed is pumped at high pressure, in the range 5–50 MN m^{-2}. A grooved insert, located behind the orifice, imparts a spinning motion to the liquid, producing a hollow cone of spray. Pressure nozzles can produce quite uniform droplets with mean diameters ranging from 10 to 800 μm, which usually results in dried particles with hollow centers. The orifices in such nozzles may be abraded or blocked by insoluble solid particles in the feed. Very high pumping pressures are required to atomize viscous liquids.

In a two-fluid or pneumatic nozzle (Figure 3b) the energy in a high-velocity stream of gas is used to atomize the feed. The gas exits from the nozzle through an annular opening while the liquid feed exits through a circular opening concentric with the annular one. A Venturi effect is created and the liquid is converted into a spray. Such nozzles are subject to blocking and abrasion by solid particles in the feed. The size of the droplets can be changed by varying the gas–liquid ratio. They have relatively small capacities and can produce a spray with a broad spectrum of droplet sizes, especially with high-viscosity feeds.

A recent development involves the use of sonic energy to atomize highly viscous materials. A sonic resonance cup is located in front of a two-fluid nozzle. This creates a field of high-frequency sound waves that breaks up the liquid into droplets. This system is not yet being used commercially.

In the drying chamber of a spray drier the spray of feed contacts the heated air and drying takes place. There must be sufficient dwell time in the chamber for the particles to reach a suitably low moisture content but, once that is attained, the dry particles must be removed quickly from the chamber to avoid unnecessary heat damage. There are many designs of drying chamber available. These may be classified into three groups based on the direction of flow of the feed relative to the air, i.e., concurrent, countercurrent, and mixed flow. Countercurrent chambers are seldom used for food applications because of the risk of heat damaging the product. Concurrent chambers usually consist of a cylindrical body with a conical base. When drying large droplets of a heat-sensitive feed, in particular if the dried particles are tacky and tend to adhere to the wall of the chamber, a tall cylindrical body is used (Figure 4a). The feed is introduced at the top of the chamber, usually through a nozzle atomizer, and follows a fairly straight-line flow path to the bottom of the chamber. The wall of the conical section of the chamber may be cooled to facilitate removal of the powder.

Other concurrent chambers feature a shorter cylindrical body (Figure 4b). The air enters at the top of the chamber tangentially and follows a downward, spiral flow path. The liquid feed enters at the top of the chamber through a centrifugal atomizer. This design of drying chamber is widely used for drying foods which are not very heat-sensitive or tacky. A mixed-flow chamber features both concurrent and countercurrent flow patterns (Figure 4c). Such chambers find limited application in the food industry. The risk of heat damaging the product is greater than in concurrent chambers. Many other types of chamber are available, including flat-bottomed cylindrical and horizontal box-like designs.

In industrial-sized spray driers the bulk of the dried powder is removed directly from the chamber through a rotary valve or vibrating device. Some food powders, mainly those with high sugar or fat contents, become sticky when hot and adhere to the wall of the chamber. Various devices are available to assist in the removal of such products. Hammers may be made to strike the outside wall of the chamber at intervals

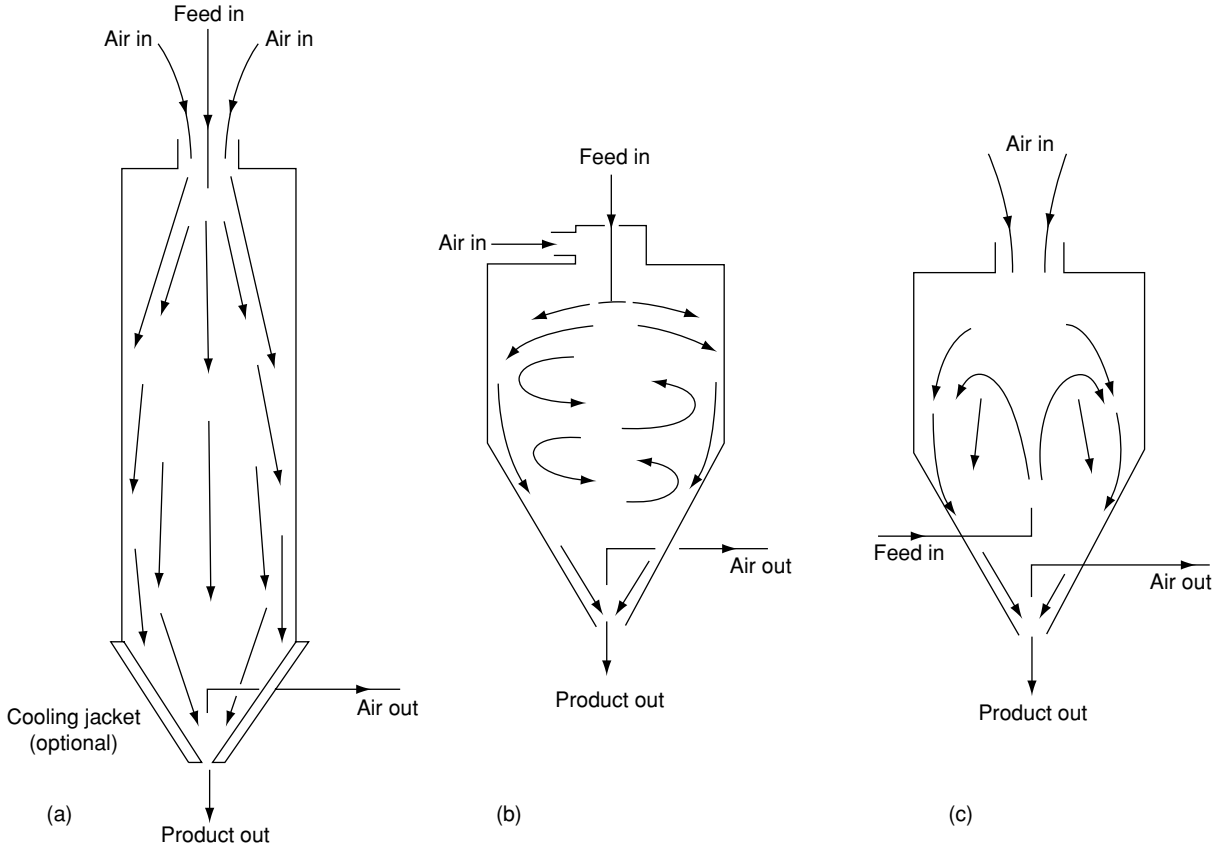

Figure 4 Different designs of spray-drying chambers: (a) concurrent with straight-line flow path; (b) concurrent with spiral flow path; (c) mixed flow.

to loosen deposits. Brushes, chains, or air brooms may sweep the inner surface of the chamber. Reducing the temperature of the chamber wall may help. This can be achieved by removing some of the insulation from the wall or by drawing cool air in through a jacket covering some or all of the chamber wall (Figure 4a). This warm air may then be introduced into the main air supply to the heater, thus recovering some of the heat lost from the chamber. Fine powder entrained in the exhaust air from the chamber may be recovered with the use of dry cyclone separators, filters, or wet scrubbing devices, singly or in various combinations. If some of the feed is used to wash the outgoing air in a scrubber and is then recycled as feed into the drier, savings in energy can result.

Semiclosed or closed spray-drying systems are available in which some or all of the drying gas is recycled. A scrubber-condenser is used to remove the water vapor from the gas. These systems may be used for drying materials with strong, unattractive odors or where gases other than air are used as the drying medium. Aseptic spray-drying systems are also available in which all the air entering the system is presterilized, usually by filtration, and the product is discharged into a sterile packing zone. Such systems are mainly used in the pharmaceutical industry but may find applications in food dehydration as hygienic requirements become more stringent.

Safety Considerations

There are fire and explosion hazards associated with spray drying of liquid foods. A dust explosion may occur when a fine combustible powder is dispersed in air and ignited. For an explosion to occur there must be a sufficient concentration of powder in the air and sufficient oxygen present to support combustion. Such conditions may exist in spray driers under normal operating conditions. Self-ignition may occur in food powders. Oxidative reactions are exothermic and the generation of heat by such reactions can be very fast at the temperatures encountered in spray drying. In thick layers of powder, heat generated in this way cannot escape quickly enough and the temperature rises rapidly, causing ignition. The critical thickness for ignition depends on the temperature and the powder characteristics. Obviously, to minimize the occurrence of self-ignition, the build-up

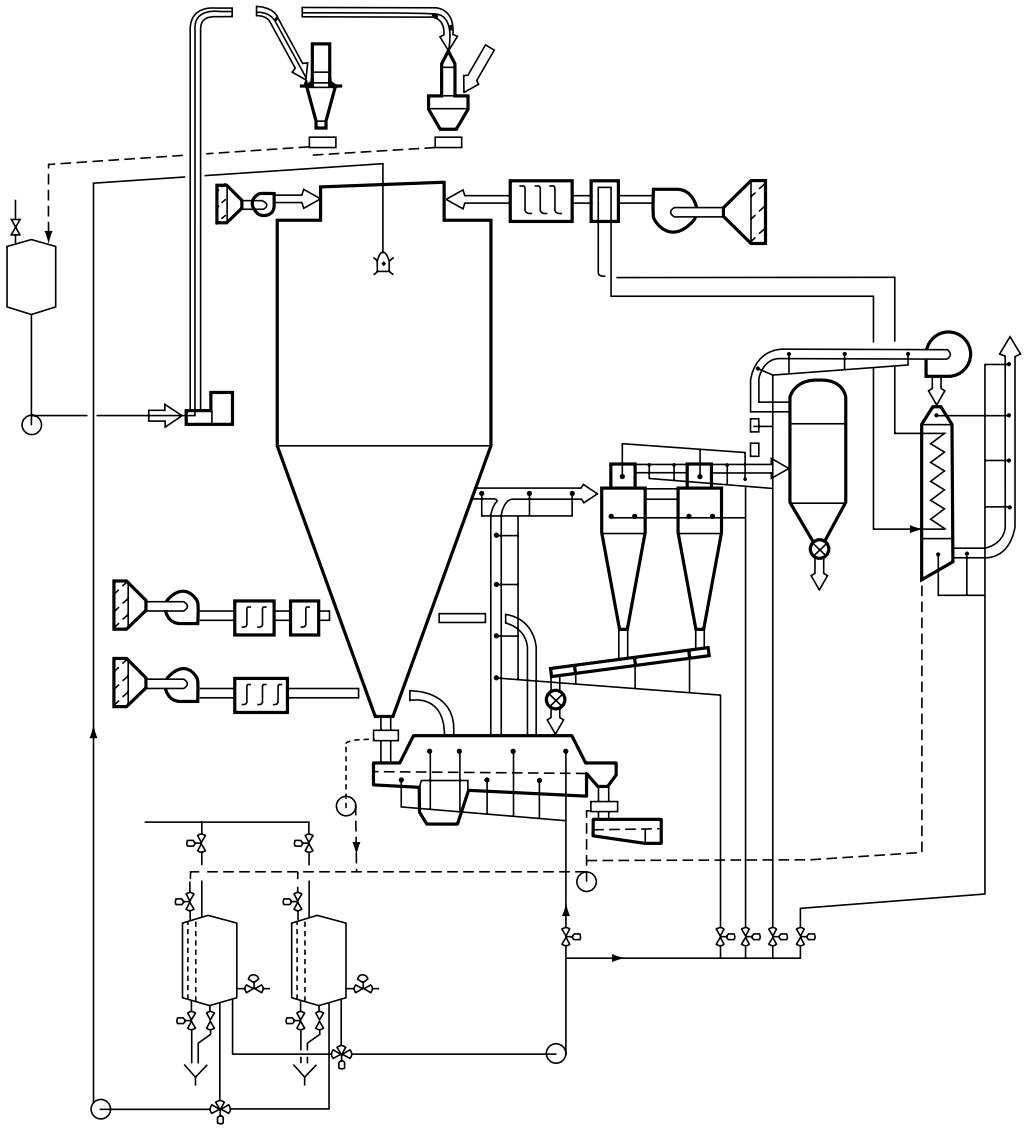

Figure 5 Cleaning-in-place (CIP) system for spray drier layout. From Masters K (1991) *Spray Drying Handbook*, 5th edn. New York: Longmans with permission.

of layers of powders in spray-drying systems should be avoided. Regular and efficient cleaning of the plant (see below) and the use of devices, such as those mentioned above, to remove powder deposits can reduce the hazard. There may be other causes of powder ignition such as heat generated by friction or electrical sparks. In spray driers featuring direct flame heating, very hot particles entering the drier in the heated air may ignite the powder. Good design and maintenance of equipment should minimize the chances of ignition occurring by these means. The fitting of weaker doors or panels, which are designed to fail at relatively low pressures, relieving the explosion, is the most common precaution taken to limit damage due to dust explosions in spray driers. Other measures such as containment or suppression of such explosions are not usually feasible in high-capacity driers.

Efficient cleaning of spray drier installations is essential. This may be done manually using high-pressure water jets. Rotating nozzle heads may be strategically located throughout the system so that all parts of the equipment are contacted by the cleaning fluid. Most modern plants are equipped for cleaning-in-place (CIP). Such a system is shown in Figure 5.

Energy Considerations

Spray drying is an energy-intensive method of removing moisture. In a straight-through spray drier, up to

6000 kJ of energy may be required to evaporate 1 kg of water. By comparison, in a six-stage multiple-effect evaporator with mechanical recompression, as little as 200 kJ may do the same task. Therefore, to conserve energy, liquid foods should be concentrated to as high a solids content as possible prior to spray drying. The upper limit of solids concentration is usually determined by the viscosity of the concentrate which, if too high, may result in poor atomization. The use of direct flame heating of the air to the spray drier is more energy-efficient than indirect methods (see above). The higher the air inlet temperature and the lower the air outlet temperature, the more thermally efficient the drying operation. The upper limit on air inlet temperature is usually determined by the heat sensitivity of the feed. For many foods 200 °C is this upper limit. Some can tolerate 250 °C. It is now possible to go as high as 300 °C for some foods when using modern, multistage spray-drying systems (see below). A low outlet temperature may lead to too high a moisture content in the product. Few driers operate well below 80 °C. Up to 50% of the exhaust air from the drying chamber may be recycled under certain circumstances and can lead to up to a 20% saving in energy. However, this must be balanced against a reduction in evaporative capacity and is really only feasible when high air outlet temperatures are used. Thus, it is not suitable if the product is heat-sensitive. Recovery of heat from the exhaust air leaving the drying chamber offers another opportunity to conserve energy. This may be achieved using air/air heat exchangers so that the incoming air is prewarmed with heat recovered from the exhaust air. There have been considerable improvements in the design of such heat exchangers in recent years. Alternatively, heat recovered from the exhaust air may be used to prewarm the liquid feed to the drier. This can be achieved by the use of wet scrubbers to wash the fines from the exhaust air (see above).

Finishing Operations

In the case of some powders, better control over product quality may be achieved by removing it from the main spray-drying chamber at a moisture content higher than the desired final value and finishing the drying in another type of drier. Vibrating fluidized-bed driers are most commonly used for this purpose. In this secondary drier some agglomeration of fine powder particles may occur, reducing the amount of very fine particles in the end product. If the fine powder recovered from the cyclones is recycled into the wet zone of the drying chamber, this will further reduce the amount of very fine particles in the product (Figure 1). Such a reduction usually facilitates the handling of the dry powder and improves its reconstitution characteristics. The use of such secondary driers can also lead to savings in energy as compared with single-stage drying. The powder leaving the secondary drier may be cooled in another vibrating fluidized bed.

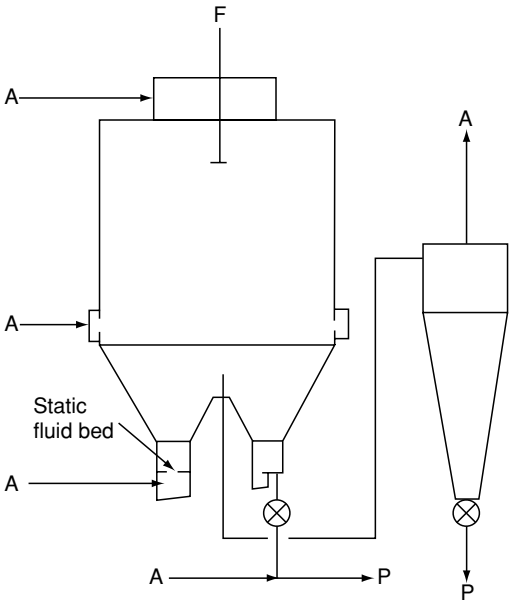

Figure 6 A two-stage layout with integrated static fluid bed in drying chamber: A, air flow; F, feed; P, dried product. From Masters K (1991) *Spray Drying Handbook*, 5th edn. New York: Longmans with permission.

Spray driers are also available which permit multistage drying in one unit. One design features a built-in fluidized bed (Figure 6). This bed is in the shape of a ring at the bottom of the chamber. Heated air is introduced at the top of the chamber and also at the bottom, fluidizing the particles in the annular bed. Drying takes place partly in the main chamber and partly in the fluidized bed. A further supply of air is introduced tangentially into the chamber. This sweeps the wall of the chamber, reducing powder build-up and improving air/powder separation. In the Filtermat drier (Figure 7) part of the drying takes place in the main chamber and the semidried powder falls on to a perforated, moving belt where it is dried to the required moisture content in two further stages, with a short holding period between, by a through flow of warm air.

Spray-dried products containing very fine particles may be difficult to reconstitute. When added to hot coffee, for example, dried milk powder may form clumps which float on the surface of the liquid and require vigorous and prolonged stirring to disperse. The most common solution to this problem is to

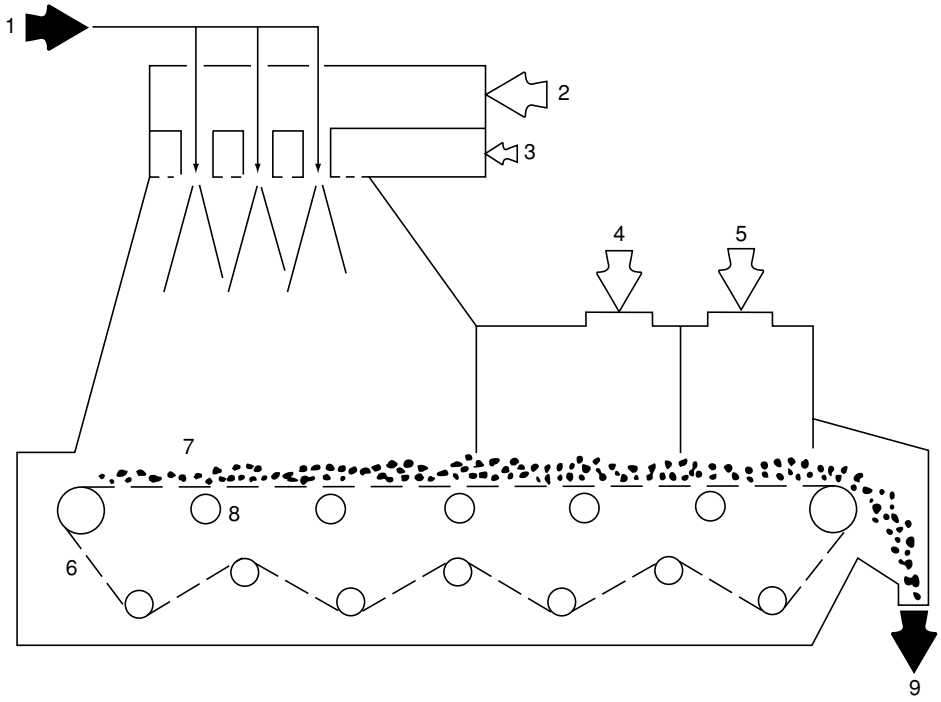

Figure 7 Filtermat spray dryer (DEC): 1, feed to nozzles; 2, primary drying air; 3, ceiling cooling air; 4, secondary drying air; 5, cooling air; 6, textile mesh belt conveyor; 7, powder layer; 8, exhaust air to cyclone; 9, product outlet. From Mujumdar AS (1995) *Handbook of Industrial Drying*, 2nd edn. New York: Marcel Dekker with permission.

increase the size of the powder particles. This may be achieved by adjusting the drying conditions, by recycling of fines, or by agglomeration in a secondary drier (see above). When these measures are inadequate, instantizing may be effected by rewetting the surface of the particles with steam, warm humid air, or a fine mist of liquid, promoting interparticle collisions by swirling the wetted powder in a vortex and redrying the agglomerated powder, often in a fluidized-bed drier.

Control of Spray Driers

Most modern spray driers are equipped with automatic control systems. The main parameter which is controlled is the outlet air temperature. In the case of driers equipped with rotary atomizers, the outlet air temperature is controlled by adjusting the rate at which the feed enters the chamber. The air inlet temperature is separately controlled by adjusting the fuel supply. When nozzle atomizers are in use, the feed rate needs to be constant, and the outlet air temperature is controlled by adjusting the combustion rate of the fuel. In both cases, an additional safety device must be fitted to avoid a rapid rise in outlet temperature should there be an unexpected drop in the feed rate. In addition to the above controls, the starting-up, shutting-down, and cleaning of the plant may be controlled by timing devices.

Spray-Dried Food Products

A very wide range of spray-dried food products is produced worldwide. A summary of typical operating conditions and some properties of a selection of dried powders is presented in Table 1.

Dairy Products

Skim milk is spray dried on a very large scale: some plants handle more than 1 million liters of milk per day. It is not a difficult material to spray dry with no tendency to adhere to the chamber wall and not being very hygroscopic. Many designs of drying chamber are used, featuring both centrifugal and nozzle atomizers. Skim milk powder produced in a simple single-stage drier contains a lot of fine particles, is dusty, and is difficult to handle and reconstitute. These properties can be improved by recycling fines, promoting agglomeration in secondary driers or integral fluidized beds or by rewetting.

Whole milk is rather more difficult to dry. It tends to be rather sticky when hot and can build up a deposit on the chamber wall. Hammers or other devices (see above) to assist in the removal of such deposits can be used. Handling and reconstitution characteristics can be improved by agglomeration. In addition, the dried particles may be coated with

Table 1 Typical drying conditions and properties of some spray-dried foods

Product	*Total solid content of feed (%)*[a]	*Air inlet temperature (°C)*	*Type of atomizer*	*Type of chamber*	*Air outlet temperature (°C)*	*Product moisture content (%)*[a]	*Particle size of powder (μm)*	*Bulk density of powder (kg m^{-3})*	*Notes*
Skim milk (ordinary)	40–50	180–230	Various	Concurrent	85–100	3.5–4.0	30–50	600–700	
Skim milk (agglomerated[b])	40–50	180–230	Various	Concurrent	85–90	3.5–4.0	150–200	450–600	Bulk density may be as low as 250 kg m^{-3} if rewetted

lecithin to improve their wettability when reconstituted in water or aqueous solutions.

Whey is also spray-dried. A number of drier designs, usually featuring nozzle atomizers, may be used. To reduce the hygroscopicity and improve the handling characteristics of whey powder, the lactose is crystallized into the stable α-monohydrate form, prior to drying.

Buttermilk is also spray-dried. Driers similar to those used for skim milk are used.

Icecream mixes have high sugar contents, up to 30%, which cause problems during drying. One solution is to keep back some of the sugar and add it to the dried mix. Two-stage drying yields a good noncaking powder. (*See* **Ice Cream:** Methods of Manufacture.)

Cheese is ground and mixed with water prior to drying. Some deposition on chamber walls may occur. This can be overcome using devices to assist in powder removal (see above) and/or two-stage drying. Strong odors can escape to the atmosphere during cheese drying. The exhaust air may need to be deodorized or a semiclosed drying system used (see above).

Butter and high-fat powder (60–80% fat) may be spray-dried. Precautions must be taken to avoid breakdown of the emulsion structure and the product must be cooled after drying.

Sodium caseinate after manufacture is relatively viscous and is fed to the drier at a lower than usual solids content (20–25%). Centrifugal atomizers and two-stage drying are usually used.

Eggs

Whole egg, egg yolk and egg white may be spray-dried. The feeds are pasteurized prior to drying. Glucose, if present in the dry powder, can give rise to the development of discoloration and off-odor during storage. Glucose may be removed, prior to drying, by fermentation using bacteria, yeasts, or enzymes. This process is mainly applied to egg white. Whole egg and egg yolk are fed to the drier at 25–27% and 45–48% solids contents, respectively. Centrifugal atomizers are usually used. Egg white feed usually contains 10–12% solids, but this may be increased by reverse osmosis.

Beverages

Instant coffee is another product spray-dried on a large scale. Ground, roasted coffee beans are extracted with hot water in semicontinuous or continuous extractors. The extract contains 20–25% solids which may be fed directly to the spray drier or preconcentrated up to 60% solids. Driers featuring tall cylindrical bodies (Figure 4a) are used, and nozzle atomizers. Air and spray follow a streamlined path down the tower. The conical base of the drier may be jacketed and cool air passed through this to keep the wall temperature low. Fines may be recycled to the drying chamber. Coffee powder may be agglomerated by rewetting. Instant coffee may also be freeze-dried. Coffee substitute made from mixtures of chicory, barley, rye, wheat, and coffee may be dried in a similar manner to the pure coffee. (*See* **Coffee:** Instant.)

Instant tea may also be produced by spray drying. Dried leaves are extracted with hot water to give an extract containing 3–5% solids. This extract is concentrated by vacuum evaporator. The volatile aroma compounds which flash off in the early stages of evaporation are condensed and added back to the concentrate prior to drying. Driers similar to those used for coffee extract are used but at lower inlet air temperatures. (*See* **Tea:** Types, Production, and Trade.)

Fruits and Vegetables

Whole fruits and fruit juices may be spray-dried. However, with the exception of tomatoes, additives must be used to facilitate drying.

Tomatoes are prepared for drying by the hot-break or cold-break processes. The former method is favored as the reconstituted powder made in this way has less of a tendency to settle than that made by the cold-break process. The pulped tomatoes are comminuted and sometimes homogenized and then concentrated to 26–48% solids by vacuum evaporation. The drier most commonly used has a relatively short cylindrical body and conical base. The whole of the drying chamber may be jacketed and cool air drawn through the jacket to cool the chamber wall. A centrifugal atomizer is used. The powder leaving the chamber is cooled on a vibrating fluidized bed.

Citrus and other fruits such as bananas, apples, pears, strawberries, raspberries, peaches, and apricots need to have fillers added to permit spray drying. Without such additives the wall of the drying chamber will become coated with sticky powder and the product will be tacky and hygroscopic, with a strong tendency to cake. The most common additive used is liquid glucose with a dextrose equivalent in the range 15–20. This may be added in amounts up to 75% of the fruit, on a solids basis. Skim milk powder has also been used as an additive. To insure good atomization the fruit must be comminuted thoroughly. Both centrifugal and nozzle atomizers and various designs of drying chamber, some featuring cooled walls and aftercoolers, have been used.

Whole vegetables and vegetable juices may also be spray-dried. These include carrots, potatoes, cabbage, peas, and asparagus. These are easier to dry than fruits. Again, efficient comminution is necessary and additives may be required.

Other Spray-dried Products

Beverage whiteners These are oil-in-water emulsions whose ingredients include vegetable fat, sodium caseinate, corn syrup, and emulsifying agents. They are spray-dried, usually using pressure nozzles, down to a moisture content of 2–5%. Often two-stage drying is used.

Vegetable proteins These may be extracted from soya beans, peanuts, potatoes, and other sources. They are spray-dried using concurrent chambers and pressure jet atomizers. Some dried products may be tacky and hygroscopic and require cooling during handling and packaging.

Single-cell protein (SCP) SCP is produced from methane, methanol, ethanol, and η-paraffins by fermentation, concentrated by centrifugation and spray-dried. The fine powder is often agglomerated. Relatively high inlet and outlet temperatures are used. There is a danger of dust explosion and semiclosed, self-inertizing spray-drying systems may be used.

Meat Purées of beef and chicken may be spray-dried for use in soups and sauces. Concurrent drying chambers and centrifugal atomizers are usually used. Blood from slaughterhouses is spray-dried to produce a range of blood, albumin, and plasma powders. Relatively low drying temperatures are used.

Fish byproducts A range of products, including soluble fish powder, fish meal, fish flour, and fish protein, produced by hydrolysis of fish flesh, is produced by spray drying. The odor released during drying can be a problem.

Enzymes A number of enzyme powders are produced by spray drying. To minimize inactivation, inorganic salts may be added and relatively low drying temperatures used. In some cases aseptic spray drying may be carried out.

Vitamins Vitamins from various sources may be spray-dried. Vitamins B and C are spray-dried directly. Vitamins A and D are usually microencapsulated (*See* **Vitamins**: Determination.)

Dielectric and Osmotic Drying

J G Brennan, The University of Reading, Reading, UK

Application of Dielectric Energy to Drying

Principles

Here the term dielectric heating is used to represent the radiofrequency (RF) and microwave (MW) bands of the electromagnetic spectrum. RF heating is in the frequency range 1–200 MHz and MW from 300 MHz to 300 GHz. By international agreement, certain frequencies have been allocated for industrial use, in order to avoid interference with telecommunications. These are RF 13.56 and 27.12 MHz and MW 2450 and a band within the range 896–915 MHz. The advantages of dielectric heat for drying, cooking, thawing, and melting of foods are that heat generation is rapid and occurs throughout the body of the food material. An additional advantage for drying is that water is heated more quickly than the other components of the food. In conventional methods of drying, heat is transferred to the surface of the food by convection, conduction, or radiation. It has then to transfer throughout the body of the food by conduction. Some penetration does occur in the case of radiant heat but this is limited and often difficult to

control. The penetration of electromagnetic waves in the dielectric range into materials such as foods depends on frequency and the characteristics of the material. The lower the frequency, hence the longer the wavelength, the greater the penetration. Penetration may be quantified by half-power depth, i.e., the thickness of the material, which reduces the wave energy to 50% of the incident level. The half-power depth for water is about 12 mm at a frequency of 2450 MHz and 75 mm at 100 MHz. Penetration into foods is less than into water.

In the case of dielectric heating, the heat is transferred into the body of the material rather than just to the surface. When a wet material is exposed to high-frequency electromagnetic radiation molecules, which are dipolar, such as water, are stressed by the alternating magnetic field and this results in the generation of heat. This is the main mechanism which causes heating on the application of MW energy. At the lower RF frequencies, ionic conduction plays a part. Ions present in the material are accelerated by the electric fields, and this leads to the generation of heat. Since most foods contain ions in the aqueous phase, RF heating can be effectively applied to them. The mechanism of drying using dielectric heating is different from that which operates when convected or conducted heat is used. The rapid generation of heat within the material causes rapid evaporation of water. This creates a total pressure gradient, which results in the rapid movement of liquid water and water vapor to the surface. Thus, shorter drying times and lower product temperatures are attainable compared to more conventional methods of heating.

Overheating of the surface can be avoided. Drying is more uniform as thermal and concentration gradients are less. There is also less movement of solutes within the material. Since the water absorbs most of the heat there is more efficient use of energy compared to drying by the application of convected or conducted heat. However, too high a heating rate can lead to scorching or burning of the material. If the water vapor becomes entrapped within the material, high pressures can develop, which can lead to the rupture of solid pieces.

Equipment

A basic RF (platen) applicator consists of two metal plates between which the food is located or conveyed. Often the conveyor belt may represent one of the electrodes. The plates are at different electrical voltages. The whole system is housed in a metal chamber to prevent leakage of radiation. In a stray field applicator a thin layer of material passes over electrodes of alternating polarity. In the staggered applicator rods extend beyond the plates to form staggered throughfield arrays between which the layer of material passes. This last type can cope with thicker layers Figure 1.

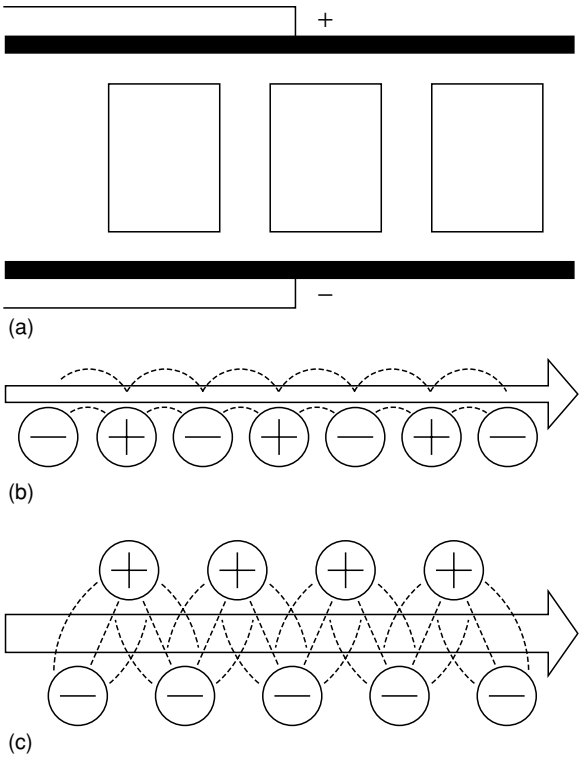

Figure 1 Electrode configurations for dielectric heating sysÙtems. (a) Platen type for bulky objects. (b) Stray field type for thin layers. (c) Staggered type for thicker layers. Adapted from Schiffmann RF (1995) Microwave and dielectric drying. In: Mujumdar AS (ed.) *Handbook of Industrial Drying*, 2nd edn, vol. 1, pp. 345–372. New York: Marcel Dekker.

In a basic batch MW applicator, MWs, generated by a magnetron or klystron, are directed into a metal chamber via a waveguide or coaxial cable. The food is placed in the chamber. To improve the uniformity of heating the beam of MWs may be disturbed by a mode stirrer, resembling a slowly turning fan, which causes reflective scattering of the waves. Alternatively, the food may be rotated in the chamber. In continuous systems, the food is conveyed through a chamber, which has a number of wave injection ports in its sides, top, and bottom.

Applications

In drying of foods, dielectric heating is usually combined with conventional heating. It may be used to preheat the feed to a hot-air drier. By raising the temperature of the feed quickly and causing moisture to move to the surface, it can decrease the overall drying time. Dielectric heating may be applied part-way through the drying cycle, when the food enters the falling rate period. (*See* **Drying**: Theory of Air-drying.)

This can boost the rate of drying. If dielectric heating is applied near the end of hot-air drying it can also shorten the drying time significantly and hence increase the throughout of the drier. It is more usual to use dielectric heating in the later stages of drying.

One of the major applications of RF heating is in the postbaking of biscuits. The objectives in baking biscuits are to produce a product of the right size, shape, color, and moisture content. In a conventional oven, reducing the moisture content to the desired level can take up a large part of the total baking time. The application of RF heating can shorten the baking time. The oven is set to produce biscuits of the right size, shape, and color, but the RF heating is used to remove the remaining moisture, without any further change in these properties of the biscuit. The capacity of an oven can be increased by more than 50% by the use of RF heating. Postbaking by RF heating has also been applied to breakfast cereals and cereal-based baby foods.

MW heating is used, in combination with heated air of high humidity, to dry pasta products. The humid air prevents cracking of the product. The drying time is reduced from 8 h, using heated air only, to 1 h. MW heating is used in drying onions. The moisture content is reduced from 80% to 10% by means of heated air and then down to 5% using MWs. This combined process results in more uniform drying and a saving in energy of up to 30%, compared to hot-air drying. Potato chips (French fries) and crisps are finish-dried after frying to prevent darkening, if the sugar content is high.

MW heating has been used in vacuum drying. (*See* **Drying**: Equipment Used in Drying Foods.) Pasta is dried under vacuum using MW heating. This results in much shorter drying times, compared to the use of conducted or radiant heat. There are reports of other dried products being produced in this way, including fruit juice, tea and enzyme powders, mushrooms, asparagus, and soya beans.

MW heating in freeze drying (*See* **Freeze-drying:** The Basic Process; Structural and Flavor (Flavour) Changes), has been widely studied. The loss factors of ice and liquid water are much higher than that of dry tissue. When a frozen food is exposed to MWs, the ice will absorb energy much faster than the solid. This should be an advantage in freeze drying. However, ionization of the rarefied gases can occur because of the very low pressures used. This can result in plasma discharge and overheating of the food. The use of higher-frequency MWs, 2450 MHz, can reduce this problem. The loss factor of liquid water is much higher than that of ice. If some melting of the ice occurs, the water formed will absorb energy quickly and vaporize. This could cause solid food particles to explode because of the build-up of pressure internally. Good control of the freeze-drying process should prevent this happening. The use of MW heating in freeze drying is technically feasible. However, it has not been used on a large scale as yet.

Osmotic Drying

Principles

This term is applied to the removal of water from fresh foods, mostly fruits and vegetables, by immersing pieces of the food in a solution with a higher osmotic pressure, and hence a lower water activity, than the food. This solution is sometimes referred to in the literature as the hypertonic solution. Water will pass from the food into the solution under the influence of the osmotic pressure gradient. In this process, the walls of the cells in the food act as semipermeable membranes. However, the membranes are not completely selective. Some soluble natural substances, such as organic acids, sugars, salts, and vitamins, may be lost with the water, while solutes from the solution may penetrate into the food. This gain of solutes by the food can contribute to the reduction in its water activity, but may affect the taste of the product.

Osmotic Agents

The solutes used to make up the hypertonic solution must be highly osmotically active, nontoxic, edible, with an acceptable taste and flavor. In the case of fruits, sugars are the solutes used to make up the hypertonic solution. Sucrose is the most widely used sugar, but glucose, fructose, glucose/fructose and glucose/polysaccharide mixtures, high-fructose syrups, and lactose have been used experimentally, with varying degrees of success. The addition of small amounts of sodium chloride (0.5–2.0%) to the sugar solution can enhance the rate of water loss. Other low-molecular-weight substances, such as malic acid, lactic acid, and even hydrochloric acid, can have a similar effect. There is some evidence that the molecular size of the osmotic solute can affect its penetration into the food. The smaller the size of the molecule, the greater the depth and extent of the penetration. For vegetables, sodium chloride is the solute most widely used. Glycerol and starch syrup have also been investigated.

Processing Conditions

In osmotic drying, the rate of water loss is high initially but reduces significantly after 60–120 min. However, it can take days for the process to reach equilibrium. A typical processing time to reduce the weight of the food by 50% is 4–6 h. Some researchers

have reported that, while water loss falls off rapidly in the first 2 h, the gain of solutes from the hypertonic solution continues for longer. The initial concentration of solute in the solution can affect the rate of water loss. Sugar concentrations in the range 40–70% are used. In general, the higher the initial concentration of the sugar, the greater the rate and extent of drying. Sometimes, the upper limit in concentration may be dictated by the gain of solids, which can affect the taste of the product, i.e., making it too sweet. In the case of vegetables, sodium chloride concentrations in the range 5–20% have been used. Again, at the high concentrations, the taste of the product may be adversely affected.

The temperature at which the osmosis takes place can affect the rate of water loss. Generally, increasing the temperature will increase this rate. However, there will be an upper limit on temperature above which the food may be adversely affected. Cell walls may be damaged resulting in excess loss of soluble materials, such as vitamins, from the cells. Discoloration of food may also occur. This upper limit on temperature will be different for different foods. Temperatures above 70 °C are seldom used, and for some heat-sensitive fruits, osmosis may be carried out at room temperature, i.e., c. 20 °C.

The size and shape of the food pieces can also affect the osmotic process. The smaller the pieces, the greater the surface area through which water loss can occur and hence the higher the rate of water loss. However, the smaller the pieces, the more cell damage will occur during slicing. This can result in excessive loss of soluble matter. The shape and size of the pieces may be dictated by the form of the end product, e.g., some fruits such as plums may be processed whole or in halves. Apples and peaches may be in slices or segments. Vegetables may be in the form of slices or cubes. The literature suggests that the upper limit on thickness is 10 mm.

Movement of the osmotic solution over the surface of the food pieces would be expected to increase the rate of water loss. However, vigorous mixing of the pieces is seldom desirable because it causes damage to them. The food pieces may be immersed motionless in the solution. To increase the rate, the solution may be recirculated through the tank by means of a pump. The pieces may be suspended in a vibrating basket in the solution. Another option is to pump the solution through a bed of the pieces contained within a tall vessel.

The weight ratio of food to solution can affect the process, in terms of rate of water loss and solute gain. In general, the lower this ratio, the higher the water loss and the solute gain. Ratios of 1:4 to 1:5 are commonly used.

Blanching, either in water or osmotic solution, will prevent browning. In the case of large fruit pieces, blanching can sometimes shorten the osmotic process, due to relaxation of the structural bonds in the fruit. For some small fruit pieces and for vegetable pieces, blanching can adversely affect the osmotic process, reducing water loss and increasing solids gain. However, this effect is different for different foods.

Recycling of Hypertonic Solution

Following the osmotic process, the isotonic solution will be diluted with the water removed from the food. In order to reuse this solution, its concentration has to be increased to that of the original solution. This can be done by adding more solute to the diluted solution. However, this will result in a surplus of solution which has to be used for some other purpose. An alternative approach is to reconcentrate the solution by vacuum evaporation. There will be a limit to the number of times the solution can be recycled as some darkening can occur. It is usually necessary to filter the solution free of insoluble solids before evaporation. It is necessary to monitor the microbiological quality of the solution which is being recycled. There can be a build-up of microorganisms, mainly yeasts, in sugar solutions, if the processing temperature is low. Pasteurization of the solution can overcome this problem.

Since there is no change of phase during osmotic drying, the energy requirements should be less that in conventional drying methods. Heat is required to dissolve the solute in preparing the hypertonic solution, to maintain the temperature of the solution and to evaporate water from the solution, if it is being recycled. Additional energy is necessary to mix and recirculate the solution. It has been reported that the energy consumption during osmotic drying of fruits is 100–2400 $kJ\,kg^{-1}$ of water removed, depending on the processing temperature and how the surplus solution is treated, compared to 5000 $kJ\,kg^{-1}$ when drying in heated air.

Further Processing of Osmotically Dried Foods

The amount of water removed in osmotic drying, typically about 50% of the fresh weight of the food, does not result in a shelf-stable product. The water activity attainable in fruits and vegetables is usually in the range 0.90–0.95. Consequently, osmosed products have to be processed further to obtain a product with an extended shelf-life.

Air drying Osmotically dried fruits and vegetables may be stabilized by further drying in heated air. The

rate of drying of such products is usually lower than that of fresh material and relatively low air temperatures may have to be used to avoid caramelization and case hardening. The sensory properties of such products are different to those produced by air-drying alone. They have a good color and flavor, with reduced acidity, and a soft chewy texture. Shrinkage is usually less than in air-dried products.

Vacuum drying Osmosed products may be stabilized by vacuum drying. The quality of such products can be superior to those completed by air drying but the process, which is known as osmovac, is more expensive.

Freeze drying Predrying by osmosis can shorten the drying time, and hence reduce, the cost of freeze drying. The end products are less brittle and less prone to browning than those freeze-dried without the osmotic step.

Freezing Freezing of fruits and vegetables is an energy-intensive operation. By partly drying food before it is frozen, freezing costs can be reduced. This process is known as dehydrofreezing. The partial drying prior to freezing can be achieved by osmosis. When thawed, such products can have a better texture, with less drip, than those frozen from fresh. Unlike conventionally frozen foods, they require rehydration after thawing.

Solar drying It has been reported that osmotic drying before solar drying can reduce the load on the solar driers and enhance product quality. Solar energy may be used to reconcentrate the solution before it is recycled.

The range of osmotically dried products available commercially is limited to date. Some good-quality fruit products are on the market. These are osmotically dried, followed by air or vacuum drying. However, there is considerable interest in this process worldwide.

Physical and Structural Changes

W F A Horner, University of Hull, Hull, UK

Introduction

The concentration of solutes as drying proceeds has consequences on the nature of foodstuffs: some of these changes are reversible and some are irreversible. The manner of drying, its conditions, and extent determine this reversibility and, therefore, how closely the characteristics of the rehydrated food resemble the material from which it originated.

Physical Changes

Changes in color and texture, accompanied, in solid structured materials, by shrinkage and deformation, are expected outcomes of drying. As solutes concentrate in the milieu, osmotic gradients cause water molecules to move out of their close association with hydrophilic macromolecules. The latter tend to aggregate: some, like starch and cellulose, to such an extent that they became almost crystalline. Such close aggregations of molecules are not easily dissociated on rehydration. This helps to explain the frequent observation, illustrated in **Figure 1**, that many foods with the same water content have a higher water activity-(a_w) (which usually means greater susceptibility to microbiological spoilage) when rehydrating than when dehydrating. Although dehydration may also cause changes in the structure of macromolecules, e.g., the denaturation of proteins, experimental evidence has shown that many such denatured structures hold more hydration water than undenatured structures. This is because the denatured form often exposes hydrophilic groups not exposed in the native form. (*See* **Water Activity**: Effect on Food Stability.)

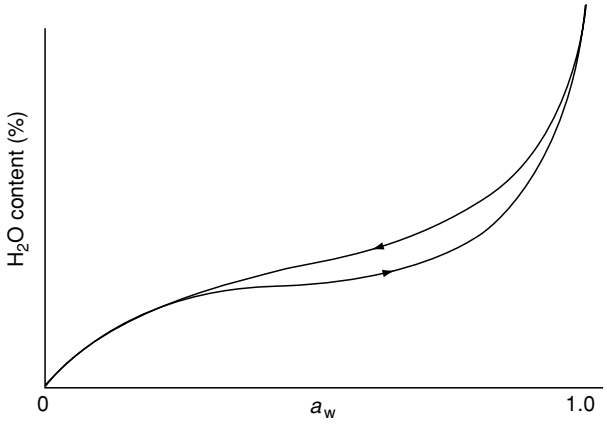

Figure 1 Typical food sorption isotherm showing hysteresis. Reproduced from Drying: Physical and Structural Changes, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

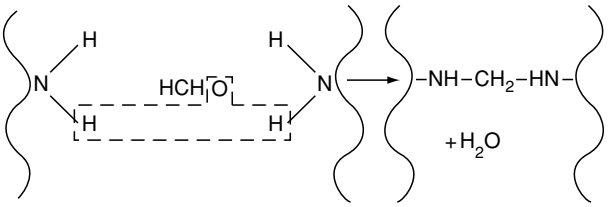

Figure 2 Formation of a methylene bridge between two protein molecules. Reproduced from Drying: Physical and Structural Changes, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

It seems likely, therefore, that the major textural changes in food, characterized by collapse of cell walls and membranes and the change from the gel-like to the fibrous, are due more to the purely physical moving together of macromolecules than to denaturation. Such aggregation may subsequently favor the cross-linking between macromolecules via hydrogen bonds and sulfur bridges, further restricting the extent to which rehydration can occur. If meat, for example, is overdried, down to the a_w 0.15–0.40 region, it reaches maximum toughness and elasticity. Moreover, upon rehydration, muscle tissue dried in air to this extent has lost its natural succulence. To chew such material is to chew inert wetted fibers which very quickly yield their absorbed water to become an unpleasantly dry ball of fibers in the mouth.

Texture Changes and Rehydratability

The modulus of elasticity in vegetable tissue decreases rapidly as, in drying, cells lose their turgor and the plant wilts. In this way, the trend in texture for vegetable tissue appears opposite to that in flesh foods as a_w decreases. It seems, therefore, that the textural properties of foods, such as crispness, hardness, and toughness, on drying, depend on their cellular nature. Pretreatment with a glycerol solution, however, helps to protect vegetable cell walls from disruption and fracture during freeze and air-drying and allows the tissue to return to its original shape on rehydration. Untreated tissue remains partly shriveled on rehydration.

In dehydrated animal tissues, aggregation of the actomyosin fraction causes the texture to become tough and woody so that the flesh rehydrates slowly and incompletely. The formation of methylene (-CH_2-) linkages between myosin molecules was thought to be responsible for the gradual toughening of fish muscle texture during frozen storage. The plausible initiator of such cross-linking was formaldehyde released when trimethylamine oxide, naturally present in marine and some fresh-water fish species, is enzymatically broken down to dimethylamine (eqn (1)). Formaldehyde from this reaction could react with certain protein end-of-side-chain groups like the amino group and possibly form methylene bridges between protein molecules (**Figure 2**). Analytical evidence suggests, however, that such methylene bridges between protein chains occur rarely, if ever. Spoilage product molecules, however, being much smaller than the structural protein molecules, are much more mobile and tend to react together, excluding water and causing irreversible texture changes. The muscle protein myosin, if very fresh, can dry like a gel and can be easily rehydrated. Myosin which is less fresh or is dried under harsh conditions tends to dry as difficult-to-rehydrate fibers.

$$N(CH_3)_3O \rightarrow HN(CH_3)_2 + HCHO \qquad (1)$$

Freezing is a form of dehydration and as such promotes the macromolecule aggregation which hinders the rehydration process. Nevertheless, it is used to improve rehydratability in dried vegetables. Ice crystal growth during freezing forces tissues apart and leaves pores in the material upon drying. Thus, being more porous, the dried food imbibes water more quickly upon rehydration. Water-holding capacity, however, is not improved. The use of cryoprotectants in freezing reduces the tendency of macromolecules to aggregate by holding more water molecules around them. (*See* **Freezing**: Structural and Flavor (Flavour) Changes.)

With the exception of freeze-drying, dehydration processes cause shrinkage which is greatest during the initial stages. If the rate is too fast, shrinking

capillaries bearing water to the food surface soon become blocked by solids carried in the flow. The surface becomes dry and impermeable – a condition known as 'case hardening' – halting the drying process whilst the interior is still wet. Flesh foods dried thus decompose from the inside but, with some vegetable foods, a high initial drying rate is advantageous because the final volume is fixed early in the drying process. As drying proceeds further, the tissues split and rupture internally, forming an open microstructure. The product, in this case, has a low bulk density and good rehydration characteristics. Such materials subjected to low initial drying rates shrink inwards progressively with process time, yielding a high bulk density product which is difficult to rehydrate. (*See* **Freeze-drying**: The Basic Process.)

Liquids like milk and hydrocolloid solutions are frequently spray- or roller-dried. The extremely short contact time (microseconds for droplets of 10 μm diameter) required to dry milk to a powder in a spray drier causes very little damage to components, loss of nutrients, or destruction of microorganisms. However, the powder produced, composed as it would be of particles which are mainly very small, does not easily or quickly reconstitute because surface tension effects on such tiny particles prevent efficient dispersal. To improve reconstitutibility, the fine powder is often rehumidified, causing particles to stick together, and redried as larger more easily dispersible agglomerates. This process is referred to as 'instantization'.

Roller-dried liquids and slurries are exposed to high temperatures for a longer period than spray-dried ones; indeed, the extra contact time may contribute to 'cooking' the paste as well as drying it. Instant or pregelatinized starch powder, which is used as the main functional component of instant pudding mixes, is manufactured in this way.

Unlike the corresponding spray-dried version, the roller-dried product tends to be coarse and more dispersible. Thermal damage to the nutrients and sensory characteristics of such products may be minimized by carrying out the roller-drying process in a vacuum chamber.

Flavor and Color Retention

In spray drying, where there is a huge temperature differential between feed material and drying medium, the consequent large loss of volatiles close to the point of liquid introduction to the chamber may be reduced by the addition of an emulsified oil phase to the feed which alters the droplet size distribution and the pattern of flavor loss. Flavor oils themselves, moreover, can be emulsified with suitable hydrocolloids dispersed in water (continuous phase) so that, on spray drying, the oil droplets are protected from evaporation by the hydrocolloid 'skin,' which instantly encloses them. This microencapsulation process yields almost odorless flavor powders which release their volatiles slowly – an advantage when baking a cake, for example – or quickly when the microcapsules are ruptured, as in 'scratch-and-sniff' perfume samplers.

The retention of the flavor components of a food material during the drying process in unaltered form is a major positive quality attribute for some dried products. Consumers are prepared to pay a premium, for example, on instant coffee expensively produced by freeze-drying which, in spite of losses due to the high vacuum, retains a greater proportion of the highly volatile characteristic flavors than does spray drying. (*See* **Coffee**: Instant.)

The loss of volatiles can be very serious in products which depend significantly upon their aroma for acceptability. Even for milk there is evidence that the loss, during drying, of volatiles such as methyl sulfides and the lower fatty acids may be responsible for the lack of 'fresh milk' flavor in the dried product. (*See* **Sensory Evaluation**: Aroma.)

Heat-induced reactions such as enzymatic and nonenzymatic browning may lead to significant changes in flavor as well as color. Such changes are not always undesirable; indeed, they may be an essential product attribute as in the case of black tea compared to green tea production. Enzymatic changes in dried foods are dealt with in greater detail in the following section, but control can be exercised by selection of the variety and stage of maturity of the material to be processed. In this way it may be arranged that the starting material is as deficient as possible in the substrate or enzyme involved in browning. Blanching vegetables before dehydration and excluding oxygen from the product, respectively, destroy the enzyme and prevent the oxidation stage of the sequence leading to browning. Sulfur dioxide acts both as an enzyme poison and reducing agent and is therefore frequently used to preserve the color of dried fruits and vegetables. Because it is volatile, it is easily driven off as the food is reconstituted and cooked. Normally, sulfur dioxide is applied to vegetable matter prior to drying through dipping them in a solution of sodium metabisulfite for a period which yields a product conforming to the maximum permitted limits for that chemical in that specific material. (*See* **Browning**: Nonenzymatic; **Preservation of Food**.)

Selection of the raw material can also play a significant role in maintaining the desired color quality of dried foods subject to nonenzymatic browning. Potato crisps, if made from stored potatoes, where

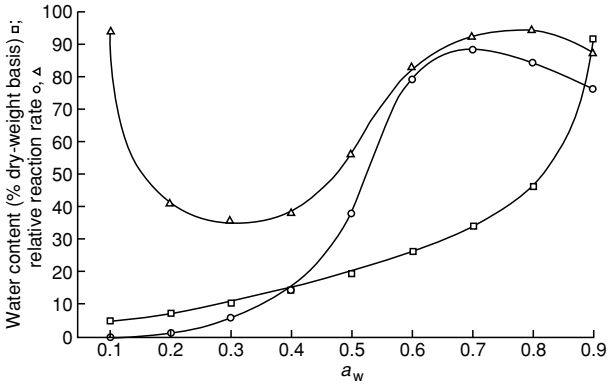

Figure 3 Dried product storage stability (susceptibility to lipid oxidation and Maillard browning) related to its water activity. Squares, sorption isotherm; triangles, lipid oxygenation; circles, Maillard browning. the starch has begun to break down to sugars prior to germination, become too dark before water content has been reduced by the frying process sufficiently to give the required characteristic crisp texture.

The Maillard nonenzymatic browning reaction sequence is initiated when the carbonyl group of reducing sugar reacts with the amine group of a protein peptide or amino acid. The dire effects of this on the visual quality of spray-dried egg have required that one of the reactants, glucose, be removed by treatment with glucose oxidase, before the drying process.

Fish which has spoiled considerably before drying contains substantially more of the mobile Maillard reactants than fresh fish and so becomes an unsightly brown color upon drying. Figure 3 shows how the rate of browning is affected by the water activity of the product. (*See* **Oxidation of Food Components**.)

Microstructure of Dried Products

Dried foods may be particulate (e.g., potato powder), glass/rubber-like (e.g., many sugar confections and pasta), fibrous, or a combination of these.

Particulate dry foods may range from simple crystalline chemicals, like salt and sugar, to amorphous conglomerates of highly complex substances like milk powder.

In many instances, dried foods are eaten without rehydration (e.g., dried fruits and sugar confections) and their chewy, tough, or brittle texture contributes to the pleasure of eating them. The size range of simple crystalline substances like sugars is critical in determining the smoothness of a fondant and the brittleness/crunchiness of a biscuit.

The manner in which lipid material is distributed in relation to the structural matrix (carbohydrate or protein) and interstitial components affects what is referred to as the 'shortness' in texture of the product. The lipid interrupts the potential continuity of such matrices which would otherwise lead to toughness and elasticity. This 'shortening' facility may be used to isolate relatively small units of glutenacious material so that no continuum is formed, in the baking of shortbread biscuits, for example, or to isolate layers of glutenacious matrices from one another, as in cream crackers and puff pastry.

Removal of water from foods inevitably leads to the precipitation of solutes and the aggregation of insoluble structural components – with consequent effects on texture and rehydratability. Some of the soluble and colloidal components of the food starting material, gelatinized starch, for example, form a glassy continuum within the food material as it dries. This phenomenon is a highly significant feature in the cook–extrusion of starchy materials. Indeed, the viscous glassy continuum formed in the extruder barrel momentarily holds the water, as it suddenly turns to steam the instant the material emerges from the exit die, and allows the extrudate to expand and quickly solidify as the steam escapes. The hygroscopicity and continuity of such glassy components favor very rapid rehydration – an unwelcome property with respect to long-term storage in humid environments for many cook-extruded products destined for the snack-food market. The 'melt-in-the-mouth' characteristic imparted by the products' aeration and hygroscopicity is, however, its strongest sensory advantage – although with some such products rehydration in the mouth is so rapid that the product tends to cling to the palate and the teeth. Packaging for these hygroscopic, aerated extruded products must provide an efficient barrier against the ingress of water vapor and – if, as is usual, the product contains a significant proportion of fat – oxygen. The porosity of dried foods greatly assists the process of oxidative rancidity which is also promoted (Figure 3) by the removal of the coating of water molecules around reactive sites at very low a_w. In many dehydration processes, an attempt is made to maximize dried product porosity (as in puff, foam-mat, and freeze-drying) to improve dehydratability. Less controlled drying processes often yield shrunken or case-hardened products which, due to the capillary constriction, are very difficult to rehydrate. Porosity and rapid hydratability are not always desirable properties in dried foods. In Indonesia, fish may be dried, smoked, and pressed alternately until a dry horny product (ikan kaju) is produced. This product, which is grated over soups as a condiment, resists rehydration from the humid

surroundings for a year or more. (*See* **Extrusion Cooking**: Chemical and Nutritional Changes; **Sensory Evaluation**: Texture.)

Effects of Drying on the Microflora of Foodstuffs

Dehydration is a method of food processing which relies for its effectiveness on the prevention of microbial proliferation by making the food environment too water-retentive for microorganisms to abstract it for their metabolic requirements (Table 1).

Lowering the a_w of many fresh foods from 1.00 to inhibit the growth of only some of the bacteria requires that around 90% of the water content of the raw material be removed unless drying is accompanied by the infusion of solutes as in salting.

The lowering of a_w from 0.95 to 0.60 (enough to suspend growth of all microorganisms) requires only a relatively small reduction in water content but, as drying merely suspends microbial proliferation, rather than destroying the organisms, outgrowth quickly recurs in dried foods as they absorb small amounts of water from a humid environment. Certain species of xerophilic yeasts and osmophilic molds are able to proliferate on material which is still apparently dry. The mold *Wallemia sebi*, associated with rotting wood, has often caused problems of surface spotting, 'dun' spoilage, in dried salt-cured fish. Halophilic bacteria, like *Halinobacterium salinaria*, can cause more severe damage, proteolysis, and putrefaction in salt-cured fish during the 'water reduction/salt-infusion' process if the ambient processing temperature is not kept below 10 °C. The characteristic coloration of the colonies of such organisms, which eventually pervade the entire product surfaces, gives rise to the description 'pink' spoilage. The microbial flora so far described cause spoilage of dried foods at intermediate water contents whether during desorption, in processing, or resorption during subsequent storage in too humid ambients. There are, however, pathogenic species which can affect the safety of dried food products, particularly if atmospheric moisture condenses upon the surfaces.

Certain molds produce mycotoxins whilst growing upon such surfaces. The most dangerous of these are the highly carcinogenic aflatoxins produced by the black mold *Aspergillus flavus*. Of the pathogenic bacteria, *Staphylococcus aureus* is the most tolerant towards low water availability, being capable of growth down to around a_w 0.8, although it is doubtful whether it would produce its exotoxin at these levels. Perhaps of greatest concern, though, is the ability of much of a food's contaminating microflora to survive and remain dormant in the dried food and then proliferate as the reconstituted food is held. Cases of *Salmonella* infection stemming from the use of dried infant formula foods contaminated with such organisms have emphasized this. (*See* **Mycotoxins**: Occurrence and Determination; ***Staphylococcus***: Properties and Occurrence; **Spoilage**: Bacterial Spoilage; Molds in Spoilage; Yeasts in Spoilage.)

It seems to be generally assumed that dried foods once rehydrated are consumed more or less immediately. Since this is not always the case, and because the heat exposure involved in most drying processes is insufficient to destroy pathogens the starting material may contain, careful selection of raw materials and hygienic processing conditions may not be sufficient to guarantee the safety of the product under all possible consumer usage circumstances. Heat or irradiation pasteurization of the starting material may have

Table 1 The water activity (a_w) of foods and microbial inhibition

a_w	*Food examples*	*Microorganisms inhibited*
1.00	Most fresh, high-water-content foods	None
0.95	40% sucrose or 7% salt (NaCl) solutions, breadcrumb, cooked sausage, canned ham, sponge cake, immature cheese	Gram-negative rods like *Escherichia coli*, spores of Bacillaceae
0.91	55% sucrose or 12% salt solutions, Parma ham, mature cheese, reduced-sugar jams	Most cocci and lactobacilli vegetative cells of Bacillaceae
0.88	65% sucrose or 15% salt solutions, salami sausage, Parmesan cheese, fishmeal	Most yeasts
0.82	Wheat flour, dry cereal grains and pulses, fruit cake, intermediate-moisture pet foods, traditional fruit conserves, dry smoked sausages, orange juice concentrates	Most molds and *Staphylococcus aureus*
0.75	26% salt (i.e., saturated NaCl) solution, honey fondants, rolled oats, rich fruit cakes, glacé cherries, salt-cured cod (prior to final drying), marzipan	Most halophilic bacteria
0.65	Dried dates, prunes, and figs, toffees and caramels, soft brown sugar, stockfish, fishmeal dried to 5% water content	Xerophilic molds
0.60	Licorice, fruit gums, salt-cured cod (after final drying)	Osmophilic yeasts

to be considered as an essential part of the process. For example, spray-dried egg should be produced from pasteurized liquid egg. Alternatively, the dry product itself may be treated. Some dried herbs and spices are irradiated to destroy a large proportion of their contaminating flora, especially potential pathogens. Chemical Changes

N Shilton, University College Dublin, Dublin, Ireland

Background

Drying of food products can be carried out by using a variety of different processes, ranging from solar drying, air-drying to the more expensive freeze drying. All of these processes influence the properties of the resulting product in some way, not least in the way that components of the food will undergo chemical reactions during the drying process. Usually, these reactions will be detrimental to product quality, but this is not always the case. For example, drying usually results in a reduction in volatiles due to vaporization, but in certain cases, the volatiles can increase as a result of drying; for example, it has been found that drying of basil leaves in a vacuum-microwave dryer actually increases the amount of volatiles present in samples when compared with fresh samples, as a result of chemical reactions.

There are many different methods of drying food materials. The main drying processes that have been identified as being studied with respect to chemical changes are solar drying, air convective drying, microwave drying, and freeze-drying. The effects of these drying processes on the constituents of food products will be examined in the context of the chemical reactions occurring during the drying process. The chemical changes occurring during the drying process will be examined, and not those that occur during storage.

Reaction Kinetics/effect of Water Activity

As water is removed from the product being dried, the water activity of the product decreases. As the water activity decreases, so too will the reaction rates of some chemical reactions, such as oxidation of free fatty acids. However, for a number of chemical reactions, such as Maillard browning and anthocyanin degradation, the reaction rate increases in the water activity range 0.4–0.8, before decreasing again, whereas other reactions such as autoxidation undergo an exponential type increase in reaction rate as the water activity is reduced to below 0.2. This can be related to an increase in the concentration of reactants as the moisture content falls, which can lead to an increase in reaction rates.

An examination of the chemical kinetics of drying shows that as the temperature of the product increases, so will the rate constant of the decomposition of food components, so it is recommended that foods

be dried at low temperatures or under vacuum. The chemical changes described in this section will show the types of chemical reactions that can occur if the drying process is not controlled carefully.

Effect on Proteins

The main effect of a drying process on proteins is that of denaturation. This is not a chemical reaction in itself (in the initial stages) and usually involves a change in the tertiary or secondary structure of the protein. However, severe denaturation will involve a chemical reaction in the formation or dissociation of disulfide bonds and coagulation of the proteins. The drying temperature will play an important part in determining the changes undergone by proteins during drying. The lower the drying temperature, the less thermal, and so potential chemical damage will be done to the proteins. This has the effect of extending the drying time of the product. An extension in drying time will also increase the risk of degradative reactions as the water activity passes through the critical zones described earlier.

During the spray drying of skim milk, milk proteins can undergo lactolyzation. High drying and outlet temperatures can cause extensive lactolyzation, but reducing the inlet and outlet temperatures that the degree of lactolyzation can minimize this reaction.

Amino Acids

Specific amino acids can be lost as a result of chemical reactions. For example, losses of lysine are higher with drum-dried milk than with spray-dried milk powder. This is most probably as a result of the direct contact with the hot drum, which causes thermal cross-linking between the disulfide bonds in the lysine. One of the most important reactions involving amino acids is the Maillard reaction; this is described in the section on Maillard browning.

Effect on Carbohydrates

For starchy products, such as potatoes, if the drying temperature is too high, there is a risk of gelatinization of the starch granules within the cells. This is often not desired. Increasing the drying temperature above 65 °C has also been found to increase the rate of glucose and fructose degradation during the drying of products such as onions. One of the most important reactions involving carbohydrates is the Maillard reaction; this is described in the section on Maillard browning. This reaction can also modify the resulting aroma profile of the dried product.

During the drying of prunes, three phases involving chemical changes to constituent carbohydrates can be identified; these correspond to the decreasing moisture content. As the moisture content is initially reduced, there is a hydrolysis of sucrose to give fructose and glucose, and at intermediate moisture contents, there is a rapid loss of this fructose and glucose as a result of the Maillard reaction. As the moisture content is reduced further, caramelization of the sugars will occur.

Maillard Browning

Nonenzymatic browning is the major chemical reaction that can take place during the drying of all types of foods. The most prevalent form of nonenzymatic browning that can occur is that of Maillard browning. This is a complex series of reactions that is initiated by the reaction of amino acids and a reducing sugar, in the so-called Amadori rearrangement, that leads, *via* a series of intermediate compounds, to give melanoidins, insoluble compounds with a characteristic brown color. The reaction is very heat-sensitive, and so during drying, the use of higher temperatures, in high-temperature short-time processing, can cause an increase in the reaction rate. Formation of the intermediate compounds takes some time, so it is possible for a dried product to be produced that has no visible signs of browning, but has in fact undergone substantial chemical reactions. This could have an impact on the nutritive quality of the product. The degree of Maillard browning can be controlled by the use of sulfite treatment, through the use of either a metabisulfite solution or sulfur dioxide.

Of potential concern is the possible production of carcinogenic compounds during the Maillard reaction, either as intermediate compounds or as compounds during the final color development. Dry heating also produces aminocarbolines, and the formation of these seems to be favored by free-radical reactions and a low water activity. However, the Maillard reaction can also produce antioxidative components, and these have been found to prevent oxidation in products such as oven-dried peanuts.

It has been found that harsher, higher drying temperatures will cause an increase in Maillard browning, but this can be controlled by monitoring the free amino acid levels in the product and adjusting the drying temperature accordingly. In pasta, a combination of high temperature and a high water activity during the initial stages of drying will contribute to cause nonenzymatic browning by the Maillard reaction. With pasta dried at high and low temperatures (50 and 110 °C), the higher processing temperature causes a large increase in furosine over the lower processing temperature. Furosine is an important precursor in the Maillard reaction.

The Maillard reaction can also result in the degradation of amino acids by the so-called Strecker degradation. This reaction produces aldehydes, ammonia, and carbon dioxide. The aldehydes contribute to the development of aroma during the Maillard reaction, with individual amino acids producing different aldehydes and so different aromas.

Effect on Fats

Oxidation of fats and lipids is most likely more of a problem during long-term storage of dried products. However, high-fat products or those containing unsaturated fatty acids are more likely to undergo chemical reactions during the actual drying process. Dried fish products are an example of a product type that is particularly susceptible to oxidative deterioration of fats and lipids. As oxidation and chemical reactions proceed, the relative proportions of saturated and monounsaturated fatty acids will increase, and the proportions of polyunsaturated fatty acids will decrease. Impingement drying, a high-temperature short-time process, of pressed fish cake can help minimize the oxidation of polyunsaturated fatty acids. However, the formation of free fatty acids during drying can also be a problem, and these will contribute to overall product degradation during subsequent storage. Polyunsaturated fat and carotenoid oxidation can be a problem in products such as dried egg powder. Low spray-drying temperatures are recommended in combination with the use of antioxidants.

Effect on Nutrients

Reactions involving minor nutrients during drying are of particular concern in considering the chemical changes during drying. For example, dried baby foods and infant formulae are products where nutrient destruction could be potentially harmful to the health of the consumer. The type of drying process chosen can have a major impact on the potential for nutrient degradation; for example, very few chemical changes occur during the spray drying of infant formulae, whereas roller drying can cause degradative reactions, such as nonenzymatic browning, by the Maillard reaction in the final product. In some cases, the dried product may have improved nutrient availability over more traditional processes; for example, it has been found that the bioavailability of nutrients in powdered formula is better than that in sterilized liquid formula. This is most likely because the powdered formula had a less severe heat treatment during drying than the sterilization step in the production of the liquid formula.

Effect on Vitamins

The water-soluble vitamins are sensitive to chemical degradation as a result of drying; for example, loss of vitamin C is dependent on the presence of heavy metals such as copper and iron, light, water activity, and the temperature of drying. Losses can typically run between 10 and 50%. Loss of thiamin during food processing has been extensively researched, and losses of up to 89% have been reported with certain combinations of moisture content, drying temperature, and drying time. In general, losses of water-soluble vitamins as a result of conventional drying processes are less than 20%, and for vegetables, these losses are generally less than 5%, except for vitamin C.

The type of drying process again has a major influence on vitamin retention. Freeze-drying preserves the vitamin C content more efficiently than processes such as oven drying or solar drying. This can be attributed to the high drying temperatures of the oven dryer and the slow drying rate of the solar drying process, and many researchers have reported a relationship between increased drying temperature and increased vitamin C degradation. Degradation of vitamin C has been found to follow first-order reaction kinetics in different products, such as guava and potatoes. In general, vitamin C is better preserved when rapid drying rates are used rather than with slower drying rates.

Losses of fat-soluble vitamins can occur as a result of oxidation and, again, can be linked with the drying temperature. Losses of vitamins A, D, and E are often reported to be negligible; the vitamin most prone to loss would appear to be β-carotene, with other studies reporting significant losses of carotenoids and tocopherols. It is often difficult to compare losses of vitamins, as retention will be dependent on a number of factors, such as the food material, type and extent of pretreatments, and drying conditions.

Effect on Dietary Fiber

Dietary fiber has also been shown to be modified during processing. Thermal processing of wheat bran, including by drum drying, causes an increase in soluble dietary fiber and a decrease in insoluble dietary fiber. The total dietary fiber content is unaffected.

Color Degradation

Color is often degraded during drying, especially during the drying of fruits and vegetables. Again, this can be correlated most often with drying temperature; for example, a more rapid drying process improves the retention of color as a result of reduced degradation of carotenoids and chlorophyls in many

vegetable products. Degradation of carotenoids is most often a result of oxidation, particularly as carotenoids have a high degree of unsaturation in their molecular structure.

Pretreatments can also have an effect on the carotenoid content of the final dried product; for example, blanching of carrots in water causes more carotenoid degradation during drying than steam blanching. However, pretreatments is beneficial, as unblanched controls will suffer the greatest degree of carotenoid losses. The use of additives such as citric acid, salt, and sodium metabisulfite can help retain carotenoid during convection drying. Treatment of carrots has been shown to have a pronounced effect on improving the carotenoid retention in carrots. Chlorophyl has been shown to be fairly stable at low moisture contents. However, degradation does occur at low pHs, when it is converted into pheophytin.

Again, the type of drying process used will affect the overall color retention. For example, in a comparison between hot-air drying and microwave drying, it was found that hot-air drying at 60 °C had the least effect on color degradation of kiwi fruit, whereas microwave drying caused the highest degree of browning.

Hygiene

M N Ramesh and A Chakkaravarthi, Central Food Technological Research Institute, Mysore, India

Introduction

Food hygiene is a subject of wide scope. It aims to study methods for the production, preparation, and presentation of food, which is safe, and shelf-stable. It covers the proper handling of every variety of foodstuff and drink, and the equipment and apparatus used in their preparation, service, and consumption. Good hygiene is a necessity in all food industries. The consumer has the right to demand both good quality and good shelf-life. The safe and hygienic processing of food products is becoming even more important as public awareness of food safety continues to increase. Hygienic design of any food-processing equipment is essential if a microbiologically safe product is to be produced. Food should be nutritious and attractive. It must be visibly clean and free from noxious materials which may lead to food poisoning or gastroenteritis. Foods heavily contaminated with food-poisoning germs may be normal in appearance, odor, and flavor. Microorganisms may be introduced directly from infected raw materials, from workers, or the environment during the preparation of foods. Poisonous substances may be produced by the growth of bacteria and molds in food.

The food-processing plant is made up of four basic components:

1. factory layout, structure, fittings, and perimeter
2. equipment
3. personnel
4. handling of foodstuffs from raw material to the final finished product

Plant for manufacture of food products should be laid out, preferably in straight lines of product flow. Final or intermediate processes must not be in a position where there could be cross-contamination by raw materials. Appropriate walls should physically separate the preparation areas for raw materials and dried materials.

The risk of contamination of food products with relevant microorganisms during open processing increases with the opportunity to grow in poorly designed driers as well as with the concentration of the microorganisms in the environment. The risk of airborne infection in open handling is much higher. This means that, in open drying, environmental

conditions in addition to appropriate drier design have an important influence on hygienic operations.

This is often overlooked, in spite of the well-known fact that microorganisms may be carried long distances in aerosols, which are easily produced during cleaning of yards, floors, and the outsides of machinery, not to mention water treatment. Another point of importance in open food processing is the traffic of people in process areas. As between the raw material area and the process area, staff, facilities, and even air should be kept strictly separated.

In a closed process the function of the equipment, the cleaning efficiency, and the control of process parameters are most important for hygienic operation. There is a tendency to trust automation rather than common sense for cleaning. Cleaning must be considered as a process, and the product of cleaning should be clean equipment. Inadequate cleaning may be due to mechanical malfunction, the wrong type or concentration of detergent, the wrong time and temperature during cleaning, or wrong water quality with regard to detergents used, or to several of these in combination. Inadequate cleaning should be discovered on process control and never be allowed to cause loss of product through poor hygienic quality. Inadequate cleaning, however, has many other economic consequences, beside the contamination risk. Poor product shelf-life, malfunction and corrosion of equipment, overconsumption of detergents and water, expensive waste water treatment, and energy losses are just a few examples.

Hygienic design of drier should be based on optimum combination of mechanical, process, microbial, and cost considerations. It is important that food product and process are designed by competent food scientists and technologists capable of understanding the individual importance and interrelationships of the physicochemical parameters. The water activity (a_w) requirement of the various microbiological agents of food spoilage and food poisoning should be understood and, particularly, the limiting a_w for known pathogens should be known.

Processing Condition

During conventional drying, hot air is used as a heating medium. Air carries many microorganisms. Concentrations of 100–10 000 microorganisms per cubic meter are quite normal. The concentration differs according to season and location. Therefore, depending on the food produced or processed, control of airborne microorganisms may be necessary.

Generally dry air with low dust content and higher temperature has a low microbial level. The organisms, which can be predominantly present in air, are spores of *Bacillus* spp., *Clostridium* spp., molds and some Gram-positive (e.g., *Micrococcus* spp., and *Sarcina* spp.) species as well as yeasts. If the surroundings contain a source of pathogens (e.g., animal farms or sewage treatment plant), different types of bacteria, including pathogens and viruses (including bacteriophages), can be transmitted via the air. Ducts may collect water and allow the growth of microorganisms, which are subsequently carried by the flow of air. It is important therefore to insure that air ducts are fully self-draining or that other measures are taken to prevent the accumulation of condensate.

The air used for drying must itself be of good quality; thus removal of moisture, oil, and particles from air is essential. Treatments such as inactivation or removal of microorganisms present in the air can be applied. Several methods may be used to reduce the number of microorganisms in the air. These include physical treatments and chemical agents or a combination of both. However, one of the most used methods of producing sterile air with higher assurance of sterility is filtration. Filtration is the removal of particles, including microorganisms, from the air. Air filtration has greatest particle potential of all the separation methods. Air sterilization is the physical removal of microorganisms from the air by filters of appropriate retention efficiency. Depth filters are made of cellulose, glass fiber mixtures with resin, or acrylic binders. The fibrous sheet filters have a low resistance to air flow and a large surface area. Such a filter is required to provide air with an extremely low microbiological load to aseptic areas.

Principles of Hygienic Design

The most important aim in the design of driers is to avoid pockets and crevices. A pocket is relatively large whereas a crevice is narrow and deep. Normally, a pocket is nothing to be afraid of: it is more important to avoid crevices, which can cause trouble, because the detergent solution is not able to rinse them clean. Sometimes hygienic design requirement may conflict with functional design requirements. In such cases, an acceptable compromise can be found. Where this is not possible hygienic design should be preferred and any deviation from the functionality of the equipment has to be accepted, to insure the microbiological safety of foods. Hygienic design should be based on an appropriate combination of mechanical, process, and microbiological requirements. Complying with hygienic requirements may increase the life expectancy of the equipment, and reduce maintenance needs, especially when cleaning-in-place (CIP) is built into the system, subsequently leading to lower manufacturing costs.

Equipment Design

Hygienic design of a very high standard is essential in the modern plant to minimize down time for cleaning and sterilizing. A drier used for drying food should not be of such a nature that the food is in danger of becoming unfit for human consumption, after drying. The planning of a dehydration plant is just as important as the design of the drier. A good drier can be dangerous if the planning is bad. Mechanization and automation have made great progress in the cleaning of the drier – both batch and continuous, previously cleaned manually. Earlier, the machines were opened every day, and if certain parts were not especially hygienic they were given an extra cleaning. But modern driers employ CIP with computer controls. This will not affect the cleaning efficiency of individual components, but the computer helps to optimize the total cleaning result.

To produce microbiologically safe dehydrated foods, a hygienically designed drier is needed. The drier itself can be a main source of bacterial contamination of foods, if the design and fabrication do not conform to high levels of hygienic standards. Hygiene in the drier is necessary to prevent food poisoning and to reduce food spoilage. The main factors affecting this are biological, but others, such as chemical and physical factors, also contribute. A well-designed drier is no safeguard against bacterial infection and other contamination unless it is accompanied by sound instructions for its installation, operation, cleaning, and maintenance.

To insure that it can be freed from relevant microorganisms, the drier must be properly cleaned before the process begins. Equipment must be hygienically designed. Where crevices and/or dead areas cannot be avoided for functional reasons, equipment may have to be dismantled for cleaning. It is easy to decontaminate a clean surface. The drier should be subjected to inspection and treatment to control vermin and infestation. Care must be taken to prevent the contamination of foods with rodenticide and pesticide residues.

Five principles on which a minimum standard could be established are:

1. All surfaces in contact with food should be inert to the food under the conditions of use, and constituents from their surfaces must not migrate into the food or be absorbed by the food in quantities which could endanger health.
2. All surfaces in contact with food must be smooth and nonporous so that tiny particles of food, bacteria, or insect eggs are not caught in microscopic surface crevices and become difficult to dislodge, thus becoming a potential source of contamination.
3. The drier should be so designed that all surfaces in contact with food can be readily disassembled for manual cleaning. In accordance with current practice, CIP techniques are preferred, but where this is not practicable the design must allow for the ready dismantling of the relevant parts for manual cleaning.
4. The drier must be so designed as to protect the contents from external contamination, including accidental ingress of foreign matter, for example, bolts, nuts, washers, and gaskets.
5. The exterior or nonproduct contact surfaces should be arranged so to prevent harboring of soils, bacteria, or pests in and on the equipment itself as well as in its contact with other equipment, and as far as possible with floors, walls, and hanging supports.

Three basic factors that are important for hygienic drier design are:

1. actual design, fabrication and finish
2. materials of construction
3. cleaning system adopted for the maintenance of the drier

The drier should be designed to prevent the entry of foreign materials, and the development of 'out-of-sight' dead spots, especially within the operation chamber and associated pipe work. Bolts and clips should be attached externally to maintain all internal product contact surfaces smooth and easily cleaned. For operator safety, all equipment should be made safe by electrical isolation during dismantling and cleaning. During the design of continuous driers, metallic belts are used to convey the material from inlet to outlet through the drying chamber. Such driers should be designed so that the whole of the belt is accessible for cleaning. The belts should be made endless, preferably by welding the two ends, instead of riveting, which may be a potential spot for microbial contamination. The transmission systems used to drive the conveyor should be kept out of the chamber and sealed to avoid any contamination from the driving system, as shown in **Figure 1**.

The hygienic design approach for the food industry differs from conventional design, as the hygienic requirements have to be integrated with conventional design to achieve good overall design results. The first design requirement is ease of cleaning and maintaining to insure that the drier will perform as expected and to prevent any contamination during the drying process. Under favorable conditions microorganisms grow very rapidly. Consequently, dead legs, gaps, and crevices, where microorganisms can be trapped and multiply, must be avoided. When support structures

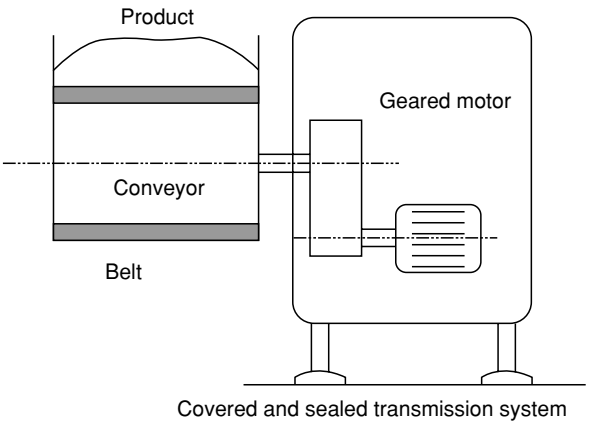

Figure 1 Transmission system for conveyor driers. Reproduced from EHEDG Guideline No. 3 (1994) Hygienic design of equipment for open processing. *Trends in Food Science Technology* 6: 305–310, with permission.

are attached to the floor or to walls, they must be provided with legs of suitable height to provide a minimum clearance for cleaning and inspection.

Fabrication of the drier as per design is an important consideration. The surface finish of the product contact parts should have an acceptable roughness value (*Ra*) of 0.8 μm when measured following ANSI/ASME B.46.1 methodology. Noncontact parts must be smooth enough to insure ease of cleaning. While welding joints, welds should be continuous and free of imperfections. Postwelding operations like grinding and polishing are mandatory.

Choice of Materials

Materials used for construction must be nontoxic, mechanically stable, inert, resistant to the product being dried (at all stages of drying), and also to cleaning and antimicrobial agents at the full range of operating temperatures, The material should also be smooth and with unpainted food contact surfaces. Care is needed to insure that food materials do not attack the metal; for example, acid reacts with mild steel, and salt with aluminum. Equally, the construction materials must not attack the foodstuff, for example, vegetable oil with copper. Appropriate services for cleaning operations, such as hot and cold water, drainage, compressed air, and vacuum lines should be adjacent for cleaning operations. It is easy to choose materials for machines used in the food industry, as those parts in contact with the food product or which are used as protection for the machines should be stainless steel. The other parts come into the category of normal machine construction.

Material selection is generally done separately for:

1. material not in contact, like frames, transmission, etc.
2. materials in direct contact with feed material, like trays, conveyors, feeding hoppers, scooping arrangement, and feeding chutes
3. materials for components like seals, gaskets and bearings, blowers, and ducting

Stainless steel is the universally accepted material for contact parts. Normally only two grades of stainless steel are used: AISI 304 and AISI 316 – a molybdenum alloy stainless-steel that is acid-proof. Both are weldable and can be machined by normal machine tools. AISI 304 is often used externally, as it is only needed to protect the machine from atmosphere, water, and sometimes spilled liquids. A choice must be made between AISI 304 and AISI 316 for parts which are in contact with the product. AISI 304 tolerates the most common cleaning solutions and is suitable for most purposes.

Cleaning Systems

Production operations require careful management on a clean-as-you-go basis to maintain good housekeeping, even during production at peak periods. A structured approach is required to the formal methods and the frequency of cleaning of all plant and equipment, including instructions for reassembly. Automatic cleaning, or CIP, should be introduced at more and more points. For example, a conveyor is used in continuous driers which can be cleaned automatically after use, with the help of cleaning nozzles. A great deal of manual work can be saved, as this type of conveyor is common in the food industry. The automatic wash system has been designed to achieve the advanced cleaning required in today's food-processing environment. The high-pressure wash system is designed to be housed over a conveyor belt unit and employed in the periodic cleaning-down and drying of the food-carrying belts at preset times. Absolute hygiene is required for modern food-processing plants and can be sized and fitted to incorporate any part of the food-manufacturing process line, continually achieving 100% cleaning.

Certain driers often have to be completely dismantled for cleaning, but the dismantling could be made simpler in many cases and involve fewer parts, with quick-releasing systems which are easy to remove. The spaces which are then to be cleaned should be open and incline outwards so that all product material and cleaning liquids can easily drain from the machine. Much has already been done in this field, but the food industry could encourage the manufacturers of the machines to make their

machines easier to clean – and eventually automatically cleanable.

During CIP, various flushing, cleaning, and sanitizing fluids are brought into contact with the wetted parts of the plant. Cleaning may be done on a once-through basis, or some of the cleaning agents may be recirculated to reduce consumption of water, chemicals, and energy. Cleaning is achieved by the physical action of high-velocity-flow jet sprays, agitation, and the chemical action of cleaning agents enhanced by heat. While mechanical forces are necessary to remove soil and to insure adequate penetration of cleaning solutions to all areas, most of the cleaning action is provided by chemicals – surfactants, acids, alkalis, and sanitizers.

A CIP system consists of piping for distribution and return of cleaning agents, tanks and reservoirs for cleaning solutions, heat exchangers, spray heads, flow management devices (supply-and-return pumps, valves, sensors and gages, recording devices) and a programmable control unit, as well as other items. Although a CIP system requires a significant initial capital investment, CIP is economical relative to manual cleaning in most large-scale processes. CIP greatly reduces labor. CIP methods often consume less water and chemicals relative to manual cleaning, especially if cleaning solutions are recycled. A properly designed, validated, and operated CIP system insures consistent and reproducible cleaning. Because there is little or no dismantling of equipment, the down time is reduced and more time is available for productive use of machinery. Consistent cleaning eliminates product contamination and associated rejection of batches. As another important consideration, the CIP technology enhances safety by eliminating or minimizing operator contact with hazardous cleaning agents, bioactive products, and potentially pathogenic biohazard agents. Other unsafe situations are avoided because worker entry into equipment is not required.

A safety lock-out mechanism must prevent leakage of detergent/disinfectant and foodstuffs during dehydration of food. Modern industrial detergents and disinfectants are often strongly acid or alkaline, and if consumed in error in sufficient quantity, could give rise to chemical poisoning. All CIP systems should be supplemented periodically by the more conventional strip-down methods of plant cleaning, with all couplings open and gaskets removed. Chemical disinfectants should be changed at intervals to prevent the development of microbial resistance.

In roller drying, used for manufacturing baby food products, hygiene hazards will occur owing to partly dried materials from the ends of the drier drum leaving the drum and entering the main dry-product collecting stream. This is more noticeable when 'outboard' dam plates bear on the ends of the drum and feed rolls, rather than inboard. To overcome this a reciprocating doctor knife has been used to insure the discharge of a continuous dried-product sheet, in combination with short end and face scrape which remove the partly dried material before it reaches the doctor knife and the dried-product stream. The applicator rolls are manufactured from SS316 stainless steel, and the main drum is hard-chrome-plated to insure that hygienic operating conditions are maintained.

1. Where slurries are fed to the drier, steps should be taken to prevent survival of microorganisms by increasing the overall heat treatment so that, apart from the heat exposure on the drum itself, the slurries are preheated before transferring to the applicator rolls. For thick slurries containing starch, this can also be achieved by using a scraped-surface heat exchanger or a steam injector.
2. Other slurries for roller drying, which are at temperatures optimum for microbial growth, are made up with ice at the milling stage to keep the slurries at low temperatures in the holding tanks before processing.

Dried foods are not always sterile. Some microorganisms and particularly bacterial spores will survive the dehydration process. There will be no growth until the addition of water for reconstitution and consumption. Spices, dehydrated soups, baby foods, and other convenience-dried foods may all contain spores, usually in small numbers. For example, the addition of spices to meat will introduce spores and add to the possibility of *Bacillus cereus* and *Clostridium perfringens* food poisoning.

The principles of good hygiene practice in dehydrated food factories are basically the same as in any other food-handling environment. The scale of food manufacture, and the unique processes developed to produce shelf-stable preserved foods for storage, distribution, and retail sale provide greater opportunities for food-poisoning agents to become hazardous. The most important factor for consideration is that attention to the cleanliness of plant surfaces alone is not enough; proper design and control of the complete process are essential to insure the absence of food-poisoning agents.

Food Hygiene in Dehydrated Food Manufacture

Dehydration reduces the moisture content to levels below which microorganisms cannot grow. Dehydrated foods, although not sterile, may be stored

Table 1 Relationship between water activity and growth of organisms

Water activity	*Foods*	*Predominant microorganisms*
1.00–0.95	Most fresh foods, e.g., meat, fish, poultry, fruits, and vegetables	*Clostridium botulinum, Salmonella* Most normal bacteria
0.90–0.95	Many cured-meat products	*Staphylococcus aureus* (anaerobic)
0.85–0.90		Most normal yeasts, *S. aureus* (aerobic)
0.80–0.85	Very high sugar or salt content	Most normal molds
0.75–0.80		Halophilic bacteria
0.60–0.75	Dried foods	Osmophilic yeasts and molds

Reproduced from Alur MD and Venugopal V (1999) Dried foods. In: *Encyclopaedia of Food Microbiology*, pp. 530–537. London: Academic Press, with permission.

indefinitely because of their low water content. The bacteriological state of a product depends on the degree of contamination before dehydration. The growth and metabolism of microorganisms require water in an available form.

Dehydration is a method of food preservation that arrests the activity of foodborne microorganisms and retards chemical changes in the food. Microorganisms require water in order to grow; however the amount of moisture that permits growth varies with different kinds of microbes. The term water activity is used to designate the amount of moisture available in foods. Drying decreases the a_w of a food below the limits required for microbial growth. The a_w of any food is in the range 0–1.0. The relationship between a_w and growth of organisms is shown in Table 1.

Water activity in the range 0.995–0.980 is best for most bacteria and spoilage is encouraged in meat, fruit, and vegetables. At a_w 0.98–0.93 spoilage by Gram-negative bacteria gives way to spoilage by certain Gram-positive organisms; below 0.93–0.85 micrococci, yeasts, and molds can grow. Below 0.85–0.60 certain fungi and yeasts predominate in spoilage and below 0.60 there is no growth. The function of preservatives, such as salt and sugar, is to reduce the a_w; heat may also remove water. The reduced a_w is important to prevent outgrowth of spores.

It is very important to prevent the entrance into the drying chamber of organisms which are capable of producing toxins. This applies to the toxigenic forms of *C. botulinum* and certain strains of *Staphylococcus aureus*. Dehydrated foods should also be free from certain intestinal microorganisms that are likely to be pathogenic to humans, e.g., members of the genera *Salmonella* and *Shigella*. The bacterial counts of dried foods should be low to avoid development of undesirable flavors during the period of reconstitution. Microorganisms respond to reduced a_w levels. The effect of reduced a_w is characterized by an extension of the lag phase, a suppression of the log phase, and a reduction in the total number of viable microorganisms. The minimal a_w levels for growth and toxin production of a number of foodborne pathogens are shown in Table 2. Hence, the drying process should be extended to reach the particular a_w to eliminate growth of such microorganisms. Heat applied during a drying process causes a reduction in the total number of microorganisms, but the effectiveness varies with the kinds and numbers of organisms originally present.

Table 2 Effect of water activity (a_w) on growth and toxin production by some foodborne pathogens

Pathogenic microorganisms	*Minimum* a_w	
	Growth	*Toxin production*
Aspergillus flavus	0.82	0.78
Staphylococcous aureus	0.84	0.86
Clostridium botulinum type A and B	0.92	0.82
Listeria monocytogenes	0.92	
Bacillus cereus	0.93	
Vibrio parahaemolyticus	0.95	
Salmonella spp.	0.96	
Clostridium perfringens	0.96	

Reproduced from Alur MD and Venugopal V (1999) Dried foods. In: *Encyclopaedia of Food Microbiology*, pp. 530–537. London: Academic Press, with permission.

Usually, yeasts and most bacteria are destroyed but spores of bacteria and molds survive, together with a few vegetative cells of heat-resistant bacteria. More organisms are killed by freezing than by dehydration during the freeze-drying process. If the drying process and storage conditions are adequate, there will be no growth of microorganisms in the dried food. During storage, there is a slow decrease in numbers of organisms. The microorganisms that are resistant to drying will survive. In particular, resistant spores of bacteria, molds, and some of the micrococci survive. In conventional drying of vegetables, the microbial flora will be modified during drying. If the equipment is not clean, an increase in counts may be anticipated. Temperatures up to 90 °C are used during the first stage of drying. The rapid moisture loss from foods during this period induces a cooling effect, and thus the temperature of the product will be 40–50 °C. Hence, reduction in microbial counts is small. In the second stage of drying the product temperatures are

higher (60–70 °C), which may kill the yeasts and many other bacteria.

Mycotoxin formation is more sensitive to a reduction in a_w than is the growth of the mold forming it. To prevent the formation of bacterial toxins or the development of organisms pathogenic to humans, the food product should be dried at temperatures where growth is unlikely to occur. At temperatures of 50 °C, it is probably the minimum. Where some heating below this temperature is unavoidable because of loss of quality in the product, the period of dehydration should not exceed 4 h. Bacterial growth generally does not occur in foods containing less than 15% water. Foods at a_w levels below 0.78–0.80 are not hazardous. They also indicate that mold species are generally more osmotolerant than bacterial species, both in their ability to grow and produce toxins at low a_w levels. *Staphylococcus aureus*, the bacterial species capable of growth at the lowest a_w, has been exploited in some food regulations. Foods can be protected against microbial deterioration by keeping their a_w below a certain value. The approximate lower limits of a_w at which bacteria, yeast, and molds can grow are 0.91, 0.88, and 0.80, respectively. Most food-poisoning bacteria, including C. *botulinum*, *Salmonella*, and *Shigella*, are unable to grow or produce toxins below a_w of 0.95 in foods. Some aerobic sporeforming bacteria such as *Bacillus cereus* can tolerate much lower a_w (0.93) and the most xerotolerant species, like *B. subtilis*, are able to develop at a_w 0.90. *Staphylococcus aureus* is the most xerotolerant and toxin-producing bacterium. The limit of growth in laboratory media is 0.86, but enterotoxin A, which is frequently encountered in foods, is not produced below a_w of 0.88 at 25 °C. Such a difference between a_w levels permitting growth and those allowing the production of toxins is also frequent for mycotoxins produced by toxigenic molds.

As a guide to the storage stability of dried foods, the 'alarm water content' has been suggested. This is the water content which should not be exceeded if mold growth is to be avoided. Although drying stops growth, it does not kill all bacteria in the foods. The 'alarm water' contents for some foods are given in Table 3. These values are equivalent to an a_w of 0.7, at which point microbiological stability can be expected.

Table 3 The 'alarm water' content of some foods

Food product	*Water (%)*
Dehydrated fruits	18–25
Starch	18
Dehydrated vegetables	14–20
Pulses, milk powder, dehydrated meat	15
Rice, wheat flour	13–15
Dehydrated whole eggs	10–11
Whole milk powder	8

Several organizations are specialized in producing guidelines and standards for food-processing plants. Organizations in the USA and Europe attempt to harmonize hygienic design standards and guidelines, facilitating international trade. Specifically, the USA-based 3-A organization (3-A Sanitary Standards Committees, St Paul, Minnesota, USA), NSF International (NSF International, Ann Arbor, Michigan, USA), and the European Hygienic Equipment Design Group (EHEDG) (EHEDG Foundation, Brussels, Belgium) have established cooperation by exchanging staff and by participation in joint working groups.

Equipment Used in Drying Foods

J G Brennan, The University of Reading, Reading, UK

Drying in Heated Air

A wide range of equipment is used in air-drying foods, including the following.

Cabinet or Tray Drier

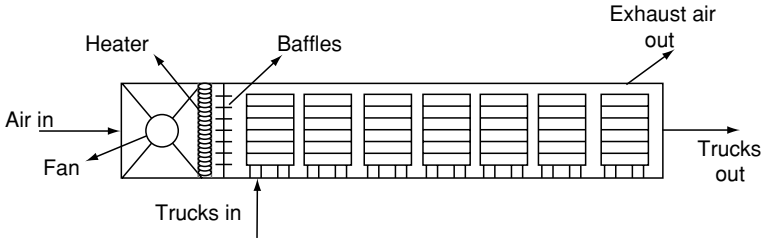
This is a batch drier consisting of an insulated cabinet fitted with a fan, an air heater, and baffles to direct the flow of the heated air between trays of food or through perforated trays and layers of the food material. Dampers control the intake of fresh air and the outflow of the exhaust air. These driers vary in size from small bench units, which house a few trays and are used to carry out laboratory studies, to large industrial installations which may take up to 25 large trays. In the case of industrial driers, the trays are usually loaded on to trolleys which are wheeled in and out of the cabinet. For large throughputs, a number of cabinets may be used in parallel with a staggered loading sequence. Such plants can handle several thousand kilograms of fresh vegetables in a 24-h period. Cabinet driers are used to dry sliced and diced vegetables and fruits, cubed or minced meat, and many other types of food.

Tunnel Drier

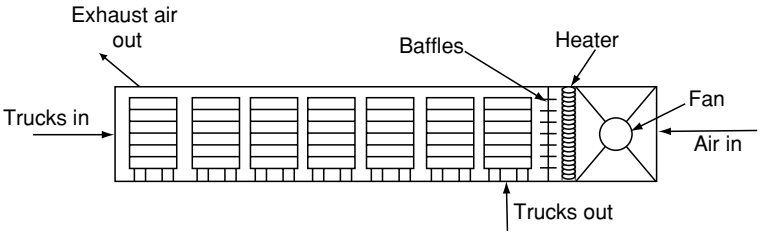
This type of drier can handle large quantities of vegetables and fruits on a continuous or semicontinuous basis. It consists of an insulated tunnel, up to 25 m long and 2 m × 2 m cross-section. Prepared food is spread in even layers on trays which are stacked on trolleys. When a trolley of fresh food is introduced into one end of the tunnel a trolley of dried material exits the other end. Heated air flows mainly between the trays, although some throughflow may occur. In a concurrent tunnel both the air and the fresh food enter the tunnel at the same end, the 'wet end,' and travel concurrently along the tunnel to exit at the 'dry end' (**Figure 1a**). This design of tunnel features high initial rates of drying. As the air moves along the tunnel its temperature falls and it becomes more humid. Consequently, the drying conditions at the dry end are poor and it may be difficult to attain low moisture contents. In the countercurrent tunnel (**Figure 1b**), the air is introduced at the dry end and travels countercurrent to the feed exiting at the wet end. The initial drying rate is lower than that in the concurrent design, but at the dry end the fresh, hot air meets the almost dry food. Hence, low moisture contents can be attained but there is a danger of heat damaging the food. Two tunnels may be used in series. The food first passes through a relatively short concurrent tunnel and then through a longer countercurrent tunnel. Thus, high initial drying rates can be achieved and, by using relatively cool but dry air in the countercurrent tunnel, low moisture contents can be attained without heat damaging the food. These features can be included in a single tunnel (**Figure 1c**), known as a center exhaust tunnel. In a cross-flow tunnel (**Figure 1d**), the air travels at right angles to the direction of flow of the feed. This facilitates uniform drying.

Conveyor or Belt Drier

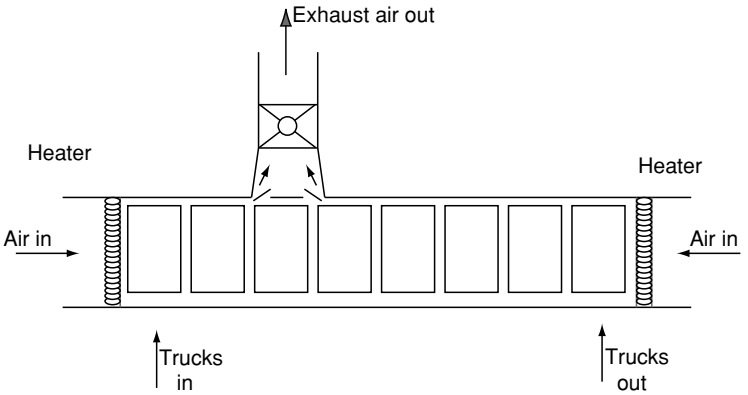
In this type of drier the food is carried through a drying tunnel on a moving belt made up of hinged, perforated metal plates or wire mesh. The conveyor is 2–3 m wide and up to 50 m long. The drying air is usually directed through the belt and layer of food, which may be 75–150 mm deep. Usually the air travels upwards in the early stages of drying and downwards in the later stages. Such throughflow driers may only be used for solid particles that form a porous bed. The throughput per unit floor area is much less than that of a conventional tunnel drier. Using two or more conveyors in series, with solids being redistributed on to the following belt, can increase the throughput and result in more uniform drying, compared to a single-stage drier.



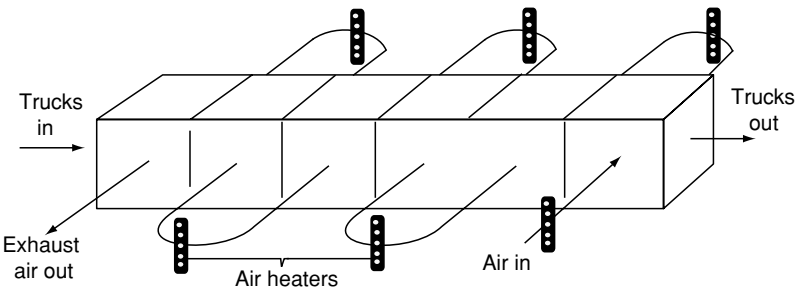
(a)



(b)



(c)



(d)

Figure 1 Tunnel driers: (a) concurrent; (b) countercurrent; (c) center exhaust, (d) cross-flow. Adapted from Brennan JG, Butters JR, Cowell ND and Lilly AEV (1990) *Food Engineering Operations*, 3rd edn. London: Elsevier Applied Science.

Nevertheless, it is a relatively expensive method of air-drying. Such a drier may be used to part-dry a food, e.g., diced vegetables down to 10–15% moisture. The final drying is carried out in less expensive equipment, such as a bin drier.

Bin Drier

This is a deep-bed, throughflow drier which is often used to finish off products that have been partly dried in tunnel or conveyor driers. It consists of a vessel fitted with a perforated base. Partly dried particles are placed in the bin to a height of up to 2 m. Dry air at relatively low temperature passes up through the bed of particles, at a relatively low velocity. Drying takes place over a period of up to 36 h. Moisture migration between particles can lead to a uniform moisture content in the product. Large bins are fitted with their own fan and heater. Smaller portable bins may be filled with partly dried particles direct form the first drier then moved and connected to a common air supply.

Fluidized-bed drier

This type of drier is being used increasingly for drying of foods. (*See* **Drying**: Fluidized-bed Drying.)

Pneumatic or Flash Drier

In this type of drier, food particles are fed into a fast-moving stream of heated air. They are carried in the air stream through ducting which is of sufficient length to give the required drying time. The dry particles are recovered from the air stream by a cyclone separator or filter. The ducting may be arranged vertically, known as air-lift driers, or horizontally. Relatively high air temperatures are used to reduce the length of the ducting. Expansion chambers may be incorporated into the ducting to facilitate control over the air temperature. Two or more of these driers may be used in series, with fresh air being introduced to each stage. To reduce the length of the ducting a closed-loop or ring drier may be used. The food particles circulate a number of times around the loop until they reach the required moisture content. They are then recovered from the air stream by a cyclone. There is a continuous supply of fresh air and feed to the drier and dried product is discharged continuously. Pneumatic driers are used to dry relatively small particles such as grains and flours and as after-driers on spray drier installations.

Rotary Drier

This consists of a cylindrical shell which rotates at an angle to the horizontal. The feed, consisting of particulate material, is introduced at the raised end of the shell and the product is discharged over a weir at the lower end. The shell is fitted with flights internally. As the shell rotates, the flights lift the material up and then it falls down through a stream of heated air, which may flow concurrently or countercurrently to the movement of the material. Rotary driers are not widely used for food dehydration. They are applied to grain drying and removing surface moisture from sugar and salt crystals.

Spray Drier

This type of hot-air drier is very widely used in the food industry for drying liquids and slurries. (*See* **Drying**: Spray Drying.)

Drying by Direct Contact with a Heated Surface

When a wet material is placed in contact with a heated surface, the necessary sensible and latent heat of evaporation is supplied to the material, mainly by conduction, and drying will take place. The general pattern of drying is similar to that of hot-air drying. There are two stages: an initial constant rate period followed by a falling rate period. However, if drying takes place at atmospheric pressure, the temperature attained by the material will be higher than that reached during hot-air drying, as the evaporative cooling effect will be less. To minimize heat damage, when drying at atmospheric pressure, the material is applied to the hot surface in a relatively thin layer. This results in short drying times, usually in the range 2–30 s. The drum drier is widely used for drying food liquids and pastes at atmospheric pressure. Alternatively, drying can be carried out at a pressure below atmospheric, i.e., vacuum drying, thus reducing the temperature at which drying takes place.

Drum, Film, or Roller Drier

A single-drum drier consists of a hollow metal cylinder rotating about a horizontal axis and heated internally, usually by steam. The feed is applied in a thin layer to the surface of the drum. As the drum rotates, drying takes place. The dried material is scraped off the drum surface by a knife some two-thirds to three-fourths of a revolution from the point of application of the feed. The drum may dip into the trough of feed material (Figure 2a) which boils on to the drum surface. This can lead to heat damage to the feed. Alternatively, two unheated rollers may apply the feed to the drum surface (Figure 2b). This method reduces the possibility of heat damage to the material. In the case of starchy materials, a number of rollers may be used to apply the feed (Figure 2c). The feed

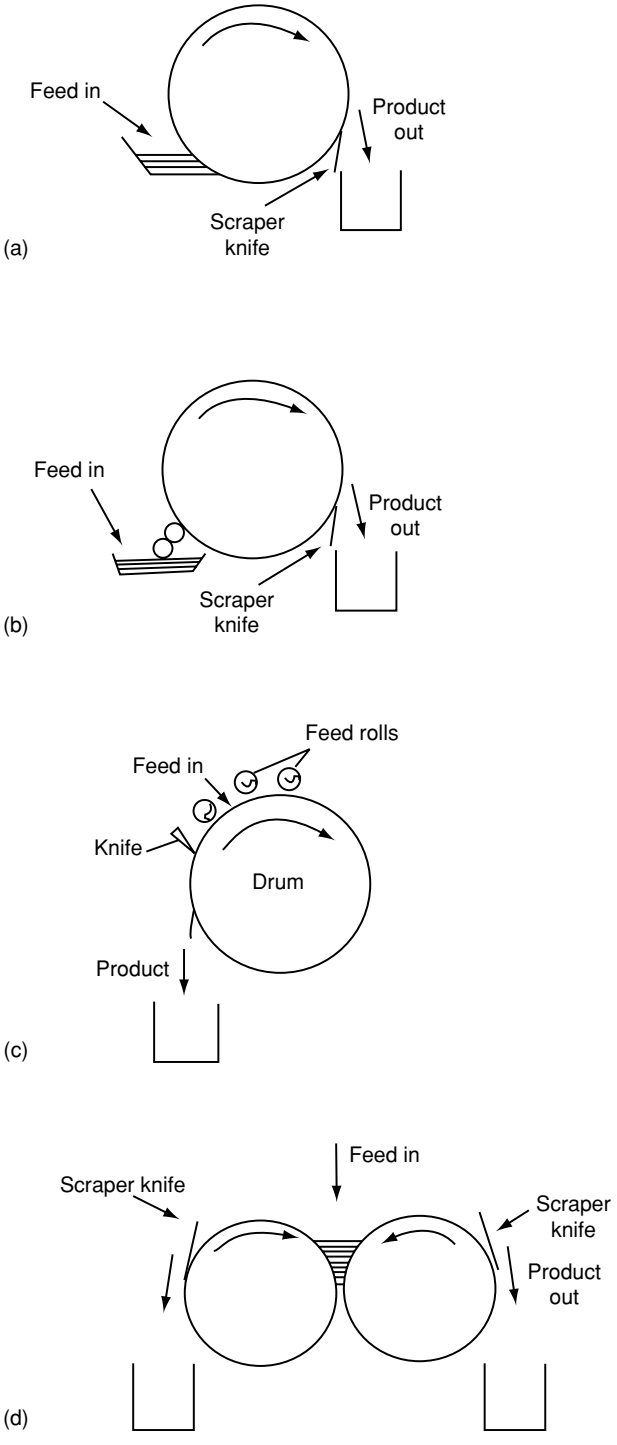


Figure 2 Drum driers – different feeding arrangements: (a) dip feed; (b) unheated roller feed; (c) multiroller feed; (d) double drum with trough feed. Adapted from Brennan JG (1994) *Food Dehydration – A Dictionary* and Guide. London: Butterworth-Heinemann.

is introduced between the first and second roller. The starch gelatinizes and the feed forms a rotating cylinder. Each of the other rollers applies a layer of the gelatinized material to the drum surface. Up to five rollers may be used.

A double-drum drier consists of two cylinders rotating towards each other at the top. The feed enters the trough between the rollers and boils on to both drums. The clearance between the drums may be adjusted to alter the thickness of the layer applied to the drums. This type of drum drier is used for low-viscosity materials that are not very heat-sensitive. The drum diameter ranges from 15 to 150 cm and length from 20 cm to 300 cm. The speed of rotation ranges from 3 to 20 rpm and surface temperature from 110 to 165 °C. They are usually made of chromium-coated cast iron or stainless steel. Potato flakes, instant breakfast cereals, made from an oat flour slurry, and ingredients for dried baby foods are some of the products made by drum drying. For very heat-sensitive materials vacuum-drum driers may be used. The drum is enclosed in a vacuum chamber and the pressure reduced to lower the temperature at which drying takes place. However, these driers have high capital and running costs and are not widely used in the food industry.

Vacuum Shelf or Tray Drier

This type of drier consists of a vacuum tight chamber, usually cylindrical and fitted with hollow shelves. These shelves are heated internally by steam, hot water, or some other thermal fluid which is circulated through them. The shelves typically measure 2.0×1.5 m and the cabinet may contain up to 24 of them. The food is placed on trays which sit on the heated shelves. The chamber is sealed and the pressure inside is reduced to 5–30 kN m^{-2} absolute, by means of a condenser and vacuum pump. The shelves are heated to 35–80 °C. This type of drier can be used for heat-sensitive liquid or solid foods. However, the capital cost, including the condenser and vacuum pump, is relatively high, and so are the maintenance costs. It is only used to dry materials that can bear the high costs of drying. It has been used for fruit juice concentrates, chocolate and malt-based drinks, chocolate crumb, yeast extract, and minced cooked meat for inclusion in ready meals or soup mixes.

Vacuum Band or Belt Drier

In this type of drier a continuous stainless-steel band or a belt made up of wire mesh or hinged metal plates moves clockwise over a heating and cooling drum, inside a vacuum chamber (Figure 3). Additional heat may be supplied by heated platens or radiant heaters. The feed, which must be a liquid or paste, is applied to the band by spraying or by means of a roller. The cooled product is scraped from the band by means of

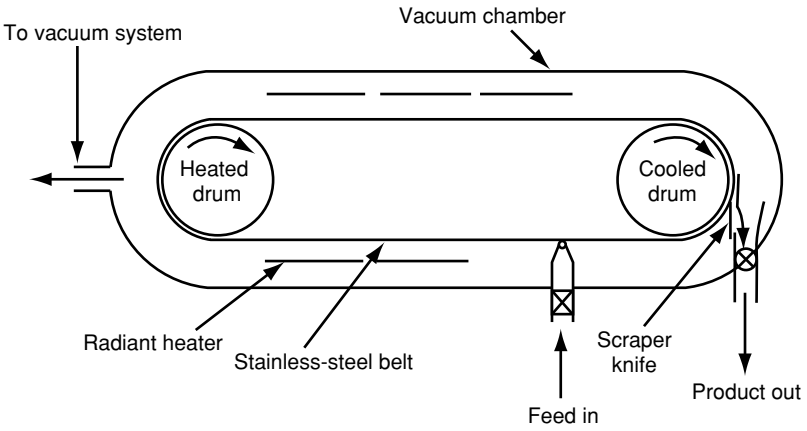

Figure 3 Vacuum band drier. From Brennan JG, Butters JR, Cowell ND and Lilly AEV (1990) *Food Engineering Operations*, 3rd edn. London: Elsevier Applied Science.

a knife and removed from the vacuum chamber via a sealed conveyor or rotary valve. The pressures and temperatures are similar to those used in the vacuum shelf drier. The vacuum band drier is costly to purchase and maintain and so is only used to dry relatively expensive materials, similar to those examples of liquid foods given above.

Drying by the Application of Radiant Heat

Apart from sun or solar drying (*See* **Drying**: Drying Using Natural Radiation), radiant energy is not used in industry to remove water in bulk from food materials. However, it has been used to remove small amounts of water from granular or powder materials.

Infrared Drier

In this type of drier a moving belt or vibrating deck conveyor carries the granular material beneath a bank of infrared heaters. Short-wave lamps are used for very heat-sensitive materials while long-wave bar heaters are used for less sensitive foods. Breadcrumbs, starches, tea, spices, cake mixes, and nuts are among the materials dried in this way.

EATING HABITS

H L Meiselman and R Bell, US Army Natick Soldier Center, Natick, MA, USA

Background

Eating habits refer to the wide spectrum of attitudes and behaviors associated with eating. These areas are sometimes comprised in the fields of study referred to as food habits or food choice. Eating habits can be outlined as follows: food attitudes, food acceptance, food selection, food consumption, and food waste. This follows the temporal sequence of eating, beginning with the attitudes that lead to the selection and consumption of food, through to what is not eaten (i.e., wasted). This section on eating habits will follow this temporal sequence and will end with a treatment of meals and meals patterns, since, ultimately, food selection results in the construction of meals that combine all of the influences on eating habits.

Attitudes

Attitudes are related to whether people eat, what they eat, and how much they eat. Attitudes are usually defined as psychological tendencies containing an element of evaluation. The evaluative component is considered to be an important part of what constitutes an attitude. Attitudes are both long-lasting and short-lasting. The long-lasting attitudes are also called traits, which represent the ways in which people differ from one another and tend to be stable over time and over situations. Some of the attitudes that have been considered with respect to eating are these long-term traits. Expectations are the attitudes that products will possess certain sensory attributes at certain intensities or, more generally, the beliefs that products will be liked or disliked to a certain degree. Modern cognitive theories argue that the effective stimulus in any situation is not solely the physical stimulus, but rather is the relationship between the objective stimulus and the preexisting cognitive basis against which the stimulus is judged. This makes the area of food acceptance more complex, because we need to consider the response to the actual food as well as the expectation of that food.

Specific Attitudes and Traits

A number of measures, or scales, have been developed to assess attitudes and traits toward foods. By measuring these attitudes and traits, one can apply them in research studies to learn what factors influence them and, in turn, how they influence eating behaviors. The measures are also valuable for segmenting consumers into subgroups, in which different variables might operate, or in which the same variables might operate differently. These measures come from various fields

such as market research, social psychology, and abnormal psychology. Several important criteria are involved in the assessment of such measures. In addition to the usual criteria of validity and reliability, one must examine the nature and size of the sample on which the measure was developed and validated, whether the measure has been used to predict specific behaviors, and whether the measure has been tested on diverse populations. Below are some of the major scales being used.

The Variety Seeking Tendency Scale (VARSEEK) is a measure of the intrinsic tendency to seek variety in the diet and was developed by van Trijp and Steenkamp in 1992 as a special case of general variety seeking by consumers. The scale has eight items, each of which is rated on a five-point scale (disagree–agree). Individuals who score higher in variety seeking tendency have shown more exploratory tendencies in purchase behavior and more vicarious exploration, and use innovativeness more than those who score lower on the scale. Certain product characteristics, such as the sensory variation between alternatives being offered, may determine whether the intrinsic desire for variety is expressed when making a food selection.

The Food Neophobia Scale (FNS) is a measure of avoidance of novel foods, or foods to which people have not previously been exposed. It consists of 10 items, five positively worded and five negatively worded. Each is rated on a seven-point scale (agree–disagree). This measure has been shown to be a good predictor of an individual's propensity to avoid foods they have not tried previously. In addition, by presenting information that reduces the uncertainty about how a novel food might taste, those individuals with higher levels of food neophobia become more inclined to try that novel food. The Food Neophobia Scale has potential application within the area of new product development of nontraditional food items. Variety-seeking tendency and food neophobia tend to measure the opposites of food seeking and food avoiding; this is reflected in their negative correlation of approximately -0.7.

Dietary restraint refers to the degree to which one tries to control one's eating. It is not a measure of how well one controls eating, but whether one pays attention to eating in an attempt to control it. Dietary restraint has received attention by obesity researchers and others and can be measured by several different scales. Females usually exhibit more dietary restraint than males. The Restrained Eating Scale of the Dutch Eating Behavior Questionnaire consists of 10 items with a temporal response format (seldom, sometimes, often, very often). Stunkard and Messick (1985) also developed a dietary restraint scale as part of their three-factor eating questionnaire, and Herman and Polivy (1975) used a scale comprising a series of statements that allow for the classification of a subject as being either a dieter or a nondieter. Dietary restraint has been used extensively within obesity research, but has broad applicability within eating habits research and with product development aimed at the diet-conscious eater.

It has been shown that measures of variety-seeking tendency, food neophobia, and dietary restraint are stable over long periods of time, and are thus valuable indicators of a group's or individual's tendencies.

Food Preferences

Food preferences are the evaluative attitudes that people express toward foods. Food preferences include the qualitative evaluation of foods, and also how much people like and dislike them. Quantitative food preference measurement has been a part of the field of food habits at least since the 1940s, when the US Army undertook it for menu planning purposes. These studies were summarized by Meiselman in 1988. Of course, nonquantitative food preference measurement has been around since any mother asked their family what they wanted to eat. Food preferences are usually reported either on a hedonic scale ('how much do you like or dislike a food?') or on a preferred frequency scale ('how often do you want to eat a food?'). The nine-point hedonic scale, designed to measure food acceptability, is also used for food preference measurement. (*See* **Food Acceptability**: Affective Methods.)

Food preferences have been analyzed in terms of a number of demographic variables, including race, gender, geography, age, taste physiology, and many disease states. Differences in food preferences have been reported with differences in age, gender, race, and other variables. One of the early theories of obesity argued that obese people had different taste preferences than nonoverweight people. However, this has been shown not to be the case. While gender differences in food preferences have been known for some time, Drewnowski and colleagues have put these differences into a different context, arguing that males prefer salty foods, and females prefer sweet and fatty foods (1997).

One of the main differentiators of food preferences is culture. Elizabeth Rozin has argued that different food preferences are basically rooted in differing flavor principles among cuisines. Flavor principles are the unique flavor components of foods of differing cultures. For example, Greek cuisine is characterized by the combination of olive oil and lemon, whereas southern French cuisine is characterized by

olive oil and herbs. Japanese cuisine is characterized by the use of soy sauce. These traditional flavors help the consumer to identify culturally acceptable foods, and the incorporation of these flavor principles can be used to overcome neophobia to new foods.

Food preference measurement can be linked to menu planning. Beginning in the 1970s, modelers have calculated the contribution of various meal components to overall meal acceptability. This has usually been done with paper and pencil tests, rather than with actual foods and meals. The overall results of these studies show that that the main dish in a meal accounts for the major portion of a meal's acceptability, often 50% or more. Hedderly and Meiselman (1996) used acceptance ratings of actual college meals to conduct these regression analyses, showing that meal components change in their contribution to overall meal acceptance when the style of meal is changed from full plated meals to sandwich meals to pizza meals. Moskowitz and others have also modeled food combinations, boredom in menus, and time preference relationships in menus, trying to predict how much consumers would like an item if they had eaten the item recently or a long time ago.

Food Acceptance

Food acceptance, or the level of liking for a particular food, has been extensively researched and has been covered elsewhere in this volume. (*See* **Food Acceptability**: Affective Methods.) In this section, we will briefly discuss the role of food acceptance in influencing eating habits.

How much someone likes a food should be an important factor in influencing the selection and consumption of food, that is, eating habits. Few people would argue with this rational assumption. However, despite many studies of food acceptance, very few have shown a strong relationship of acceptance with either food choice or food consumption. This is because food consumption and food selection are extremely complex behaviors; complete models to predict food selection and food consumption might need dozens, hundreds, or even thousands of variables. Food acceptance is only one of these variables, although it is probably one of the most powerful. Another reason is that food consumption and food selection are not always rational behaviors. In general, people do not spend a large amount of time thinking about what to eat at every eating occurrence, and many other factors (availability of time and product) may be more instrumental in driving any one set of food selections. So, by itself, acceptance is merely a good measure of how much someone likes a food, and not a predictor of selection or consumption; but in conjunction with measures of other variables, acceptance can be part of a series of factors that operate together to control eating habits.

Food Selection

Food selection, or food choice, is the study of those factors that influence choice. Several fields of research have examined this relationship, including physiology, psychology, economics, and consumer behavior, to name a few. This chapter focuses on food selection as being a function of the interactive combination of the person, the product and the situation in which a food selection is made. Several authors have attempted to model the factors involved in the complex food selection or food choice process.

One difficulty in studying food selection is that it is nearly impossible to control for all factors that might influence choice in a real food choice setting, such as a restaurant or supermarket, or even in the home. Therefore, many studies have tried to explain food selection by using controlled studies in the laboratory. The problem is, once you take away the key elements that might come into play in a real setting, all of which tend to confound the control of a laboratory study, you are no longer examining the very variables that might be the most critical in affecting selection. There is no easy resolution to this controversy, but one approach is to do both laboratory and natural setting research, using the laboratory as a way of generating hypotheses and testing relationships that would identify salient factors influencing choice that could easily translate to real settings, then following up by introducing manipulations of these salient factors in a natural choice environment.

A number of variables have been shown to influence food choice. Habitual behaviors can influence food usage, in certain instances even more so than food acceptability. Familiarity with specific foods, obtained with prior experience, is a strong contributor to food acceptance and food selection, especially for people who are slightly neophobic. Attitudes and traits and expectations also influence acceptability and choice. Persistent negative expectations or stereotypes are important in understanding the critical evaluations of institutional foods and other foods that are regularly criticized such as airline food. In addition, several of the attitudes and traits described earlier (e.g., food neophobia, dietary restraint) also function to drive food choice behavior.

A number of environmental or situational variables have been shown to influence food selection. Increased effort required to obtain food leads to decreases in food selection of that item, and often increased selection of another item to take its place.

The presence of other people leads to increased consumption, probably because meals are longer when eaten with other people present. Food packaging, the information contained on the package or on the food shelf, as well as the placement of the food in relation to other products can influence selection. Finally, the décor, design, and visual and auditory elements of the food selection facility can influence choice.

Food Consumption

No other topic has occupied more research within eating habits than the research devoted to measuring food consumption. This seemingly simple question of how much people eat and why has still not been conclusively settled, leading to numerous books containing plans for healthy nutrition and dieting. Other sections of this book deal with the complexities of food-intake measurement.

Food acceptance or palatability has been shown to be a major determinant of eating habits. People eat larger meals when they are eating food that they like. This has been demonstrated in studies of individuals based on their own food preferences, and in studies in which the food has been manipulated to make it less acceptable. Palatability is a significant factor for meal studies involving both single courses and multicourse meals, as well as for sandwiches and snacks. The palatability effect has been studied in adults as well as neonates and children. Palatability not only affects what you eat, but how you eat. More palatable meals are eaten faster, and people take bigger bites and chew less time with more palatable foods.

Food Waste

Food waste, or the disposal of food, has received much attention in both the sociological and economic literature. In the former area, the study of waste is based on the notion that we are all involved in a world of goods in which we desire to be affiliated with a social structure that has us participating in the process of disposal of food in social and cultural contexts. In economics, the research issue is the cost of food waste in financial terms. In the context of eating habits that we have framed in this chapter, food waste becomes a measurement by which we can infer food consumption, and also a measure of food acceptance.

Food waste is sometimes measured while measuring consumption, because often consumption is measured as the difference between what is provided and what is wasted. The measurement of waste is difficult and time-consuming, because edible food waste must be separated from inedible food waste such as bones. This type of quantitative research has taken place in studies of clinical nutrition and in studies of military ration testing. In the former, subjects are offered foods in a laboratory or clinic. Meal and edible plate waste are analyzed using specialized instruments for estimating the nutrient content of the uneaten foods. Measures include moisture, crude protein, crude lipid, ash, and fiber content; total carbohydrates are then calculated by the difference between what was offered and what remains after analysis. In military ration testing, soldiers in the field are fed a measured and controlled amount of food for a particular meal, set of meals, or days. Other sources of food are controlled. By weighing the food prior to consumption and weighing the leftovers or waste, one can subtract to obtain the weight of the food eaten. Approximations of protein, fat, carbohydrates, micronutrients, or even particular foods, can be made based on the weight of the disposed food.

Meals and Meal Patterns

The patterns of eating in humans are a function of the combination of many, if not all, of the variables mentioned in this chapter. Determining exactly what factors influence meal patterns depends upon how one defines a 'meal' and a 'meal pattern.' This seemingly simple problem is complex because the definition of a meal depends on your perspective. The nutritionist sees meals as combinations of nutrients, the chef sees meals as combinations of courses and dishes, the social scientist sees meals as opportunities for individual expression and for social interaction, and so on. Following this, meal patterns have been defined in several ways, including the macronutrients or energy content in an individual's diet, the amount of food consumed per meal, the interval between meals, and the presence of social interaction.

One of the most interesting parts of the daily meal pattern is the breakfast, the first and smallest meal of the day, following the longest fast of the day. Although there is great variability from person to person in the types of breakfasts chosen, in general, breakfast is different in make-up from the other meals; midday and evening meals are often composed of meat or fish along with starch and vegetables. Breakfast is not similarly composed. Further, breakfast differs greatly from culture to culture. Breakfast ranges from the often-chosen roll and coffee in Southern Europe to the more traditional large cooked breakfasts of England and parts of America. Breakfast is also the meal most often skipped, and the meal most often eaten alone. One can question whether sipping a coffee while walking down the street constitutes a meal and a breakfast.

Breakfast is usually followed by midday and evening meals. Traditionally, many cultures consumed three hot meals per day; now many cultures eat only one hot meal per day. Cultures also vary in which meal of the day is considered the main meal, which is usually heavier and is usually served hot. In some cultures, the main meal is the midday meal, and in others, it is the evening meal. While some cultures have a more narrow definition of what constitutes a main meal (for example, the 'proper meal' of the English consisting of 'meat and two veg'), other cultures have a broader definition of main meals. The development and spread of pizza meals, sandwich meals, and salad meals is gradually changing how we view meals.

De Castro studied meal patterns extensively using a diet-diary technique, and extended this work to a cross-cultural comparison of France, The Netherlands, and the USA. While the study is limited to small numbers of university students, the results portray interesting differences and similarities across cultures. Compared with the French and Americans, who are more similar, the Dutch students consumed more food, had more meals with shorter intervals, ate with more people present, and ate for longer durations at a slower rate. The Americans tended to eat bigger meals as the day proceeded, a behavior that was even more pronounced in the Dutch, whereas the French ate their biggest meal in the early afternoon. However, the researchers concluded that the similarities among cultures are stronger than the differences, suggesting underlying mechanisms for food intake and meals. They also cautioned that differences in methods can lead to differences in results. The spread of the global economy is increasing the need to better describe and understand cultural differences in eating in order to identify opportunities for broader distribution of food products and food service.

There is also interest in continual snacking and meal-taking, often called grazing. A Symposium on Assessing Eating Patterns presented a cross-section of relevant research on meals across many cultures. One study reported snacks as a percentage of total eating in eight European countries: the numbers ranged from 6 to 32% for women and from 7 to 31% for men. Studies in both Greece and Germany showed midmorning, midafternoon, and evening snacking in addition to the regular three-meal pattern. In Germany, snacks accounted for 20% of energy intake, and Swedish data indicated even higher percentages of daily intake in the form of snacks. In a national sample of young adults conducted in the USA, snacking prevalence was shown to have increased significantly from 77 to 84% over the past 25 years. The nutritional contribution of snacks to total daily energy intake went from 20 to 23%, likely due to a 26% increase in energy consumed per snacking occasion and a 14% increase in the number of snacks taken per day. Intake of high-fat dessert snacks has decreased, but the intake of high-fat salty snacks has doubled during the same time period.

A final set of factors that have been studied for their effects on food choices and intake is the increased emphasis on health, diet, and slimness in the past decades, all of which have prompted meal patterns centered on restrained eating. Although restrained eating normally can produce short-term, often cyclic changes in meal patterns among otherwise healthy individuals, there is a danger that the desire for being thin can lead to eating disorders. But the dangers of these restrained eating patterns are not limited to individuals with eating disorders.

The field of human eating habits is very complex and involves many disciplines, only some of which have been covered in this section. The study of human eating habits is expanding rapidly within each discipline and also between disciplines, as the connections between different aspects of human eating habits are being investigated. In addition, the relationship of eating habits to health and fitness is receiving more and more attention, and eventually we will come to understand more fully how eating habits affect general well-being.

EFFLUENTS FROM FOOD PROCESSING

Contents

On-Site Processing of Waste

E L Stover and C K Campana, Stover & Associates, Inc., Stillwater, OK, USA

Introduction

Biological waste water treatment is the primary method of preparing food-processing waste water flows for return to the environment. Increasing waste water loads on existing plants and more stringent government discharge requirements have put considerable pressure on the food-processing industry to refine and understand better the design and management of biological waste water treatment processes. Though activated sludge and other biological treatment processes are still frequently operated by general guidelines and 'rules of thumb,' facility design and operation must be guided by consideration of both the physical and biological aspects of waste water treatment. Various modifications and combinations of aerobic and anaerobic biological treatment processes are commonly used in the food-processing industry.

Biological Treatment Processes

Biological treatment processes, whether aerobic or anaerobic, are typically divided into two categories: suspended-growth systems and fixed-film systems. Combined or coupled fixed-film and suspended-growth systems are also commonly used for food-processing waste water treatment. These processes can be batch, semicontinuous, or continuous-flow processes. Suspended-growth systems are more commonly referred to as activated sludge processes, of which several variations and modifications exist. The basic system consists of a large basin into which the contaminated water is introduced, and air or oxygen is introduced by either diffused aeration or mechanical aeration devices. The microorganisms are present in the aeration basin as suspended material. After the microorganisms remove the organic material from the contaminated water they must be separated from the liquid stream. This is normally accomplished by gravity setting. After separating the biomass from the liquid, the biomass increase resulting from synthesis is wasted and the remainder is returned to the aeration tank. Thus, a relatively constant mass of microorganisms is maintained in the system. The performance of the process depends on the recycle of sufficient biomass. If biomass separation and concentration fail, the entire process fails. (*See* **Effluents from Food Processing**: Microbiology of Treatment Processes.)

Another type of suspended-growth system is the aerobic thermophilic treatment process. High-temperature and/or high-strength waste streams as well as waste biological sludges produced during mesophilic biological treatment are excellent candidates for aerobic thermophilic digestion. This process uses natural digestion to stabilize wastes in the 50–70 °C temperature range. A combination of mixing intensity control and oxygen injection rate are utilized to control the reaction rate, oxygen transfer rate, heat loss, and resultant bulk liquid temperature. The air (oxygen) is injected at the bottom of the enclosed reactor vessel, flows up through the bulk liquid, and is collected in the head space of the reactor. Major advantages include significant improvement over mesophilic treatment relative to chemical oxygen demand (COD) removal and volatile solids destruction at significantly lower hydraulic and solids retention times. Total solids reductions of 50–60% have been observed with waste biological sludges. The general requirements to maintain appropriate thermophilic temperatures include sufficient biodegradable organics (COD and/or volatile suspended solids) to provide heat of oxidation, an insulated reactor, and adequate mixing and oxygen transfer efficiency to minimize excessive heat loss.

Fixed-film biological processes differ from suspended-growth systems in that microorganisms attach themselves to a medium that provides an inert support. Biological towers (trickling filters), rotating biological contactors, and anaerobic reactors are the most common forms of fixed-film processes. Biological towers are a modification of the trickling filter process. The medium, which is normally comprised of polyvinylchloride (PVC), polyethylene, polystyrene, or redwood, is stacked into towers which typically reach 4.6–6.1 m (16–20 ft) high. The contaminated water is sprayed across the top and, as it moves downward, air is pulled upward through the tower. Forced air ventilation is also commonly used to insure adequate air flow and oxygen transfer from the gas phase to the bulk liquid. A slime layer of microorganisms forms on the medium and removes the organic contaminants as the water flows over the slime layer.

A rotating biological contactor (RBC) consists of a cylinder arrangement of plastic media, connected by a shaft, set in a basin or trough. The contaminated water passes through the basin where the microorganisms, attached to the media, metabolize the organics present in the water. Approximately 40% of the media surface area is submerged. This allows the slime layer to come into contact with alternately the contaminated water and the air where oxygen is provided to the microorganisms.

The combined or coupled fixed-film and suspended-growth processes offer many advantages for treatment of medium to high-strength food-processing waste waters when compared to use of either technology alone. The coupled process typically requires smaller land areas, and typically will have lower initial construction costs than a process consisting of a suspended-growth system alone. Electrical power costs for coupled systems are typically lower compared to comparable systems using only the suspended-growth process. Process control is usually less demanding because the roughing treatment provided by the fixed-film system helps dampen the organic loading variations on the suspended-growth reactor. When coupled systems are employed for nitrification, much of the organic loading will be removed in the fixed-film system, allowing the suspended-growth system to achieve stable, reliable nitrification.

There are several types of anaerobic reactors that incorporate into the design a relatively high sludge retention time (SRT) to account for the slow cell growth rate associated with anaerobic organisms. Anaerobic filters (AF), upflow anaerobic sludge blankets (UASB), and the Hybrid upflow sludge bed filter

process (Hybrid) are three anaerobic configurations commonly used to achieve and maintain high SRTs.

The AF reactor designs employ certain types of inert support material on which microbial biofilms develop as substrate passes through the reactor. This design enables these processes to operate at very long biomass retention times. Support or carrier material varies in size, shape, density, and placement according to the type of reactor design. The generic term 'anaerobic filter' usually refers to a fixed-film reactor. These processes use large support material such as rocks or plastic media designed for the purpose of forming a static bed in the reactor vessel. Waste flow through such media beds may be upflow, downflow, or horizontal. Other fixed-growth anaerobic systems employ much smaller media with high recycle rates of treated waste water in order to maintain the bed in a constant state of motion within the liquid medium in the reactor. Fluidized-bed reactors use relatively heavy support media such as sand or activated carbon and high recycle rates to keep the bed in a completely fluidized condition. Expanded bed reactors employ lighter material such as diatomaceous earth or ground corncobs and lower recycle rates to maintain the bed in a slightly suspended state. Both systems offer advantages in avoiding clogging, a major problem of the fixed-film anaerobic filters. Expanded beds can also handle suspended solids in the waste feed more readily. Fluidized and expanded beds, with their smaller media, provide much greater specific surface area for biofilm attachment. This means that much higher volumetric loading and conversion rates are possible than with static anaerobic filters, at the cost of additional pumping for recycle and somewhat complex operational requirements.

UASB reactors are the most common high-rate anaerobic treatment process. The process works on the principle of promoting sludge granulation by proper seeding with a granular inoculum of anaerobic bacteria, and adjusting organic loading and upflow feed rates so that biomass is retained as a dense blanket with a clear liquid zone above. Thus, the system acts similar to a biologically active sludge clarifier-thickener. The UASB is operated as a single-pass system, although waste sludge can be settled and returned. The exact biological or physical mechanisms controlling sludge granulation are still poorly understood, even though the UASB process is in successful commercial use. Start-up, however, can be facilitated by inoculating the reactor with well-granulated sludge from an operating system.

The Hybrid process has the advantages of both the upflow AF and the UASB processes while minimizing the disadvantages. The UASB has upward flow of waste water through a dense bed of active granular sludge with good settling properties, and then flows through a less dense blanket of suspended flocs. The waste water leaves the reactor via a solids/liquid/gas separation device at the top of the reactor. This system can retain high biomass concentrations (and high SRTs), but is limited by the settling properties of the granular sludge.

Biological Treatment Process Design

Prior to the last decade, and even today, design engineers have employed 'rule of thumb' techniques for the design of secondary biological waste water treatment processes for food-processing waste waters. Design of many biological systems has been based on empirical criteria derived from past experiences and working plants. Typical design criteria include detention time and biochemical oxygen demand (BOD) loading per unit volume. The need for employment of design models which attempt to describe the functional behavior of biological treatment processes has been recognized. Six of these models for the activated sludge process, which are identified according to the names of the investigators who had major roles in their development, are:

1. Eckenfelder
2. McKinney
3. Lawrence and McCarty
4. Gaudy
5. Weston
6. Stover and Kincannon

The aim of all of these design models is to provide more accurate predictive equations which are in keeping with the underlying metabolic and biological principles governing the waste water purification process. These modern concepts for design utilize various mathematical models which describe relationships governing microbial growth and substrate utilization or waste water purification. The two essential elements of these models are quantitative description of the properties of the growing biomass (the biological kinetic constants) and manipulative operating (engineering) variables. Methods have been developed to obtain the essential biokinetic constants from bench and pilot-scale investigations.

The mechanisms of waste water purification are the same for the suspended-growth activated sludge processes and fixed-film media biological filters and rotating biological contactor type of processes; however, there are physical differences that must be understood and properly evaluated for effective design. The state-of-the-art for design of these fixed-film processes has also been significantly advanced over the past few years. Initial design concepts

considered hydraulic flow rate or waste water organic concentration. More advanced approaches consider soluble substrate removal per unit surface area or contact time based on the assumption of first- or second-order reaction rate kinetics throughout the system. Still other approaches consider the relationship of treatment efficiency versus total organic loading over a wide organic loading range which allows determination of the proper design, considering variability in waste water characteristics as well as effluent quality requirements. Based on these kinetic design approaches, performance data, operating information, and kinetic design data can be obtained from bench and pilot-scale fixed-film systems for design of full-scale systems in a manner similar to activated sludge systems. These secondary biological kinetic design approaches advance the state of the art for consideration of the microbiological and biochemical aspects of biological treatment, as well as consideration of the engineered or operational control variables.

Scale-up Design Considerations

Variations in waste water characteristics, environmental conditions, and biological system performance must be evaluated to design properly a biological waste water treatment system to achieve the allowed effluent criteria reliably. Variability in waste water characteristics (flows and pollutant concentrations) and variability in biological treatment performance are two of the most important considerations during scale-up and design of food-processing waste water treatment facilities. It is extremely important during the experimental planning to develop waste water survey and biological treatability programs for collection of sufficient data to evaluate the variability and statistically analyze the data for design. The waste water characterization requires knowledge of the discharge characteristics due to production schedules and clean-up operations and development of sufficient characterization data for determining the design conditions, for example at the 50 and 90% probable flows and loadings. Consideration of the data variability from the biological treatability study due to the dynamic nature of the heterogeneous microbial populations is more complicated and in most cases has not been properly addressed during design of food-processing waste water treatment facilities.

Modern concepts used for designing biological waste water treatment processes for food-processing waste waters employ mathematical models that describe the relationships governing microbial growth and substrate utilization (aerobic or anaerobic processes). These modeling approaches require the development of biokinetic descriptive constants that can be developed from treatability studies. Stover and Kincannon have recently developed a mathematical model for both fixed-film and suspended-growth aerobic and anaerobic biological systems that eliminates the problem of variability in the biological descriptive substrate utilization constants. The problems with the scatter observed in the development of biokinetic coefficients utilized in other mathematic models have been eliminated by expressing the mass-substrate utilization rate as a function of the mass substrate loading rates. The specific substrate utilization rate (U) is plotted as a function of the food-to-microorganism (F/M) ratio in activated sludge systems and as a function of the mass loading rate in $\mathrm{kg\,day^{-1}}$ $1000\,\mathrm{m^{-2}}$ in fixed-film systems in order to determine the biokinetic constants of $U_{\max}$ and K_B. These constants are then utilized in the mathematical model, and the remaining variability in influent flow rate and influent substrate concentrations can be handled effectively.

Fixed-film Reactor Design

In the Stover–Kincannon model for fixed-film reactors a substrate material balance is conducted around the fixed-film system. The specific parameters of concern for concept design and operational process control for a biotower fixed-film process are shown in Figure 1, and the definition of each of these parameters is presented in Table 1. When considering a fixed-film reactor volume, a mass balance of substrate into and out of that reactor volume can be made as follows:

$$\begin{array}{l}\text{Mass of}\\ \text{substrate}\\ \text{into the}\\ \text{reactor}\end{array} = \begin{array}{l}\text{Mass of}\\ \text{substrate}\\ \text{out of the}\\ \text{reactor}\end{array} + \begin{array}{l}\text{Mass of}\\ \text{substrate}\\ \text{consumed}\\ \text{biologically}\end{array}$$

In the case of the fixed-film reactor, the reactor volume is expressed in terms of thousand cubic meters of media volume. Based on this approach, the mass balance of substrate into and out of the fixed-film reactor volume can be expressed as follows:

$$FS_i = FS_e + \left[\frac{dS}{dt\ A}\right]_G A \qquad (1)$$

where: F = flow rate ($\mathrm{m^3\ s^{-1}}$); S_i = influent substrate concentration ($\mathrm{mg\,l^{-1}}$); S_e = effluent substrate concentration ($\mathrm{mg\,l^{-1}}$); A = surface area of volume ($1000\,\mathrm{m^{-2}}$); and $\left[\frac{dS}{dt\ A}\right]_G$ = specific substrate utilization rate ($\mathrm{kg\ 1000\,m^{-2}\ day^{-1}}$).

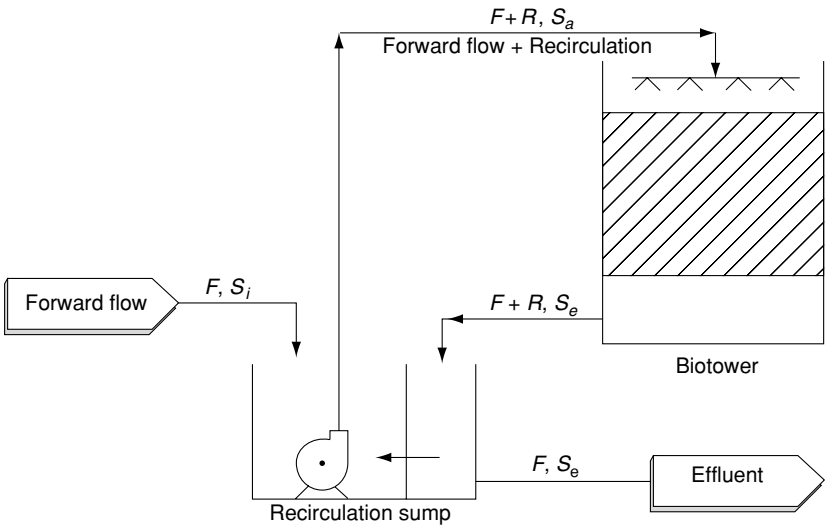

Figure 1 Basic process flow diagram for biotower system with operating parameters.

Table 1 Definition of biotower process parameters

F	Forward flow rate ($m^3\ s^{-1}$)
R	Recirculation rate ($m^3\ s^{-1}$)
$F + R$	Total flow to the biotower ($m^3\ s^{-1}$)
S_i	Substrate concentration in the forward-flow stream ($mg\ l^{-1}$)
S_e	Substrate concentration in the biotower effluent ($mg\ l^{-1}$)
S_a	Substrate concentration in the actual biotower influent ($mg\ l^{-1}$)
d	Biotower diameter (m)
h	Biotower media height (m)
A_v	Specific surface area of media ($m^2\ m^{-3}$)
n	Rotational speed of the distributor ($rev\ min^{-1}$)
N	Number of arms in rotary distributor assembly

The surface area represents the active mass of microorganisms. By plugging the following substrate utilization rate term developed by Stover and Kincannon,

$$\left[\frac{dS}{dt\ A}\right]_G = \frac{U_{max}(FS_i)/A}{K_B + (FS_i)/A} \tag{2}$$

into eq (1), the resulting expression can be solved for the required surface area of media for design, as follows:

$$A = \frac{FS_i}{\dfrac{U_{max}\ S_i}{S_i - S_e} - K_B} \tag{3}$$

where: U_{max} = maximum specific substrate removal rate ($kg/1000\,m^2\ day^{-1}$); K_B = proportionality constant ($kg/1000\,m^2\ day^{-1}$); and $(FS_i)/A$ = specific substrate loading rate ($kg/1000\,m^2\,day^{-1}$).

The expression can also be solved for the effluent substrate concentration that would correspond to a specific design loading and amount of media volume available, as follows:

$$S_e = S_i - \frac{U_{max}\ S_i}{K_B + (FS_i)/A} \tag{4}$$

Eqn (4) can then be used to evaluate system performance at existing facilities and project expected performance for future increased loadings. Eqn (3) can be used to determine design requirements to handle additional loadings.

The biokinetic constants, U_{max} and K_B, can be determined by linearizing eqn (2) or taking the reciprocal as follows:

$$\frac{1}{\left[\dfrac{dS}{dt\ A}\right]_G} = \frac{K_B}{U_{max}} \times \frac{1}{\dfrac{FS_i}{A}} + \frac{1}{U_{max}} \tag{5}$$

where:

$$\left[\frac{ds}{dt\ A}\right]_G = \frac{F(S_i - S_e)}{A} \tag{6}$$

Now, the reciprocal of the specific substrate utilization rate ($F\,(S_i - S_e)/A$) is plotted against the reciprocal of the specific substrate loading rate (FS_i/A). In this linearized form, the y-axis intercept is equal to $1/U_{max}$, and the slope of the line is equal to K_B/U_{max}.

Activated Sludge Reactor Design

In the Stover–Kincannon model for activated sludge reactors, a substrate material balance is conducted around the aeration basin and the secondary clarifier, in a similar manner to that for the fixed-film reactor

model. The specific parameters of concern for concept design and operational process control for activated sludge systems are shown in Figure 2, and the definition of each of these parameters is presented in Table 2. When considering an aeration basin volume, the mass balance of substrate into and out of that reactor volume can be expressed as follows:

$$\begin{matrix}\text{Mass of substrate into the reactor}\end{matrix} = \begin{matrix}\text{Mass of substrate out of the reactor}\end{matrix} + \begin{matrix}\text{Mass of substrate consumed biologically}\end{matrix}$$

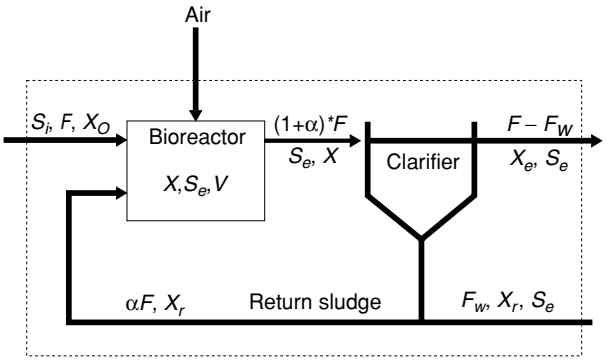

Figure 2 Flow diagram of the activated sludge process showing notation and mass balance envelope.

Table 2 Definition of activated sludge parameters

F	Influent flow rate ($m^3\ s^{-1}$)
S_i	Influent substrate concentration ($mg\ l^{-1}$)
X_o	Influent solids concentration ($mg\ l^{-1}$)
S_e	Effluent substrate concentration ($mg\ l^{-1}$)
X	Biological solids concentration, MLVSS (mixed liquor volatile suspended solids) ($mg\ l^{-1}$)
V	Aeration reactor volume (m^3)
X_e	Effluent suspended solids concentration ($mg\ l^{-1}$)
X_R	Recycle solids concentration ($mg\ l^{-1}$)
F_w	Waste sludge flow rate ($m^3\ s^{-1}$)
α	Recycle ratio
αF	Recycle flow rate ($m^3\ s^{-1}$)
U_{max}	Maximum specific substrate utilization rate ($kg\ kg^{-1}\ day^{-1}$)
K_B	Substrate loading rate at which the rate of substrate utilization is one-half the maximum rate ($kg\ kg^{-1}\ day^{-1}$)
Y_t	True cell yield
K_d	Endogenous decay rate
Y_{obs}	Observed sludge production yield ($kg\ kg^{-1}$ substrate removed)
F/M	Food-to-microorganism ratio ($kg\ kg^{-1}\ day^{-1}$)
U	Specific substrate utilization rate ($kg\ kg^{-1}\ day^{-1}$)

Based on this approach, when considering an activated sludge reactor volume, a mass balance of substrate into and out of the activated sludge reactor volume can be made as follows:

$$FS_i = FS_e + \left[\frac{dS}{dt}\right]_G V \tag{7}$$

where: F = influent flow rate ($m^3\ s^{-1}$); S_i = influent substrate concentration ($mg\ l^{-1}$); S_e = effluent substrate concentration ($mg\ l^{-1}$); V = reactor volume (m^3); and $\left[\frac{dS}{dt}\right]_G$ = specific substrate utilization rate ($kg\ kg^{-1}\ day^{-1}$).

By plugging the following substrate utilization rate term developed by Stover and Kincannon into eqn (7), the resulting expression can be solved for the required aeration basin volume for design, as follows:

$$\left[\frac{dS}{dt}\right]_G = \frac{U_{\max} X(FS_i)/XV}{K_B + FS_i/XV} \tag{8}$$

$$V = \frac{FS_i/X}{\dfrac{U_{\max} S_i}{S_i - S_e} - K_B} \tag{9}$$

where: $U_{\max}$ = maximum specific removal rate ($kg\ kg^{-1}\ day^{-1}$); K_B = proportionality constant, or substrate loading at which the rate of substrate utilization is one-half the maximum rate ($kg\ kg^{-1}\ day^{-1}$); FS_i/XV or F/M = specific substrate loading rate ($kg\ kg^{-1}\ day^{-1}$); and X = biological solids concentration ($mg\ l^{-1}$).

The expression can also be solved for the effluent substrate concentration that would correspond to a specific design loading, mixed liquor sludge concentration, and amount of reactor volume available, as follows:

$$S_e = S_i - \frac{U_{\max} S_i}{K_B + FS_i/XV} \tag{10}$$

Eqn (10) can then be used to evaluate system performance at existing facilities and project expected performance for future increased loadings. Eqn (9) can be used to determine design requirements to handle additional loadings.

The biokinetic constants, $U_{\max}$ and K_B, can be determined by linearizing eqn (8) or taking the reciprocal as follows:

$$\frac{1}{X}\frac{1}{\left[\frac{dS}{dt}\right]_G} = \frac{K_B}{U_{\max}} \times \frac{1}{\frac{FS_i}{XV}} + \frac{1}{U_{\max}} \tag{11}$$

where:

$$\left[\frac{dS}{dt}\right]_G \times \frac{1}{X} = \frac{F(S_i - S_e)}{XV} \tag{12}$$

Now, the reciprocal of the specific substrate utilization rate ($F\,(S_i - S_e)/XV$) is plotted against the reciprocal of the specific substrate loading rate ($FS_i / XV = F/M$). In this linearized form, the *y*-axis intercept is equal to $1/U_{max}$, and the slope of the line is equal to K_B/U_{max}. Once the biokinetic constants have been determined, the required *F/M* ratio at any given loading (F and S_i) can be determined to meet the required effluent quality reliably (S_e). The biokinetic constants, which represent the treatability characteristics of the waste water, can be determined experimentally for any given activated sludge process. These constants can be developed from pilot plant or laboratory-scale studies, as well as, from the full-scale plant data.

Aerobic Thermophilic Process Design Considerations

Evaluations, both bench-scale and pilot-scale operating systems, of aerobic thermophilic reactors have shown that these systems comply with the same types of monomolecular kinetic relationships previously described. Resultant data analyses have shown that the relationships of substrate removal versus substrate applied were applicable to aerobic thermophilic systems. This mathematical model has been used extensively in the design and operation of aerobic thermophilic treatment systems. It is important to note that the kinetics of microbial thermophilic growth exceeds the growth of mesophiles and higher substrate utilization rates increase the amount of substrate that can be effectively treated in a given reactor.

Primary design considerations for aerobic thermophilic biological treatment systems include the following:

- temperature
- aeration and mixing
- matching oxygen transfer with oxygen demand
- sufficient biodegradable organics
- food-to-microorganism ratio
- solids retention time
- kinetics of substrate removal and biomass growth
- heat loss management
- foam control

The thermophilic reactor and mixing and oxygen transfer system are designed for minimal heat loss, maximum mixing intensity, and maximum oxygen transfer capacity in order to optimize and control the reaction temperature. The reactor is designed to minimize heat loss at a variable operating liquid depth by minimizing the cross-sectional surface area to volume ratio. Then with proper reactor material of construction and insulation, the reactor temperature can be controlled by varying the liquid depth, the liquid mixing flow rate, and the air flow rate.

When considering liquid waste water treatment, the following factors are important relative to maintaining autothermal conditions:

- COD concentration/loading
- (F/M) ratio
- oxygen balance (COD balance)
- 12 700–13 200 kJ kg^{-1} O_2

The organics or COD goes to new biomass and carbon dioxide. The primary objective of thermophilic treatment is to convert the majority of the organics to carbon dioxide and heat energy while minimizing the biomass production. Nitrification is also inhibited above about 45 °C, such that excess oxygen requirements are not observed for nitrification. Excess ammonia-nitrogen reacts with the carbon dioxide to produce ammonium bicarbonate alkalinity to assist with reactor pH control.

When considering aerobic thermophilic treatment (stabilization) of waste biological sludges the following equation provides valuable insight into the reaction process:

$$C_5H_7O_2N + 5O_2 \rightarrow 5CO_2 + NH_3 + \text{Energy} + \text{Heat} \qquad (13)$$

By understanding this simple biochemical relationship and the following factors, maintaining autothermal conditions and process control can be related to the following factors:

- oxygen (COD) balance (1.42 K_gO_2/K_g VS (volatile solids) destroyed)
- VS concentration/loading
- VS destruction
- VS balance
- Nitrogen balance
- 18 800–19 200 kJ kg^{-1} VS destroyed

Anaerobic Process Design Considerations

In addition to controlling the loading rate, the mesophilic anaerobic microbes require an optimum temperature (30–35 °C), a pH range of 6.7–7.2, adequate nutrients, and no toxic organic or inorganic compounds. Certain trace inorganic nutrients and vitamins are needed in anaerobic treatment processes. Trace metals such as nickel, iron, cobalt, molybdenum, selenium, and tungsten are stimulatory to methanogens at low concentrations. It is extremely important to monitor and control these parameters during start-up and operations of anaerobic reactors.

In addition, adequate amounts of calcium and magnesium are required to promote the growth of sludge granules which are prevalent in the anaerobic sludge blanket and hybrid processes.

The most effective indicators of performance are pH, volatile acid to alkalinity ratio, and gas (methane) production. The key to successful start-up is to increase the biological solids inventory by gradual increases in the flow and organic loading to the plant. It is critical that the loadings are increased in proportion to the biomass in order to control the F/M ratio. This aspect of both plant start-up and stabilized plant operations can be monitored by the system pH, volatile fatty acids, volatile fatty acid/alkalinity ratio, COD removal efficiency, methane content of the gas, and reactor temperature. Adjustments are required when any of these parameters exceed preset acceptable operating ranges.

Generally, the volatile acid/alkalinity ratio should be maintained at less than 1.0 in order to obtain optimum system performance. When this ratio exceeds 1.0, immediate corrective action(s) should be taken, otherwise the volatile acids will cause a drop in the pH and the methanogen activity will decrease. The methane production is a direct measure of the metabolic activity of the methanogenic bacteria and, as such, has great potential as a diagnostic tool of anaerobic activity. The use of pH alone is not as sensitive an indicator of reactor activity because environmental changes will already have taken place before a pH change is noticed. However, knowledge of the pH is important to good operation of the system and should be maintained at approximately 6.7–7.2 for most applications.

Process Control Requirements

In many cases in the past, biological treatment processes for food industry wastes have been designed and operated by general guidelines or rules of thumb. However, with increasing treatment requirements, it becomes necessary for treatment facilities to be designed and operated more effectively to meet the required effluent quality while continuing to treat varying waste water flows and contaminant loads. Operators must be better trained and educated so that they are better equipped to monitor the biological system and make the proper corrections for changing conditions. The treatment facility to be operated must be designed with the greatest amount of flexibility consistent with the design conditions for that particular food-processing plant. This requires the design engineer to rely on experience and operational feedback from full-scale operations, as well as on parameters and observations obtained from laboratory and pilot plant operations. After transforming this operational experience into a treatment plant design, the design engineer should be responsible for proper training of the operators and for assisting in the facility's start-up.

Changing environmental conditions, especially fluctuations in the waste water characteristics, tend to disrupt the steady-state conditions that the biological treatment facilities are designed to approach. Environmental changes tending to disrupt steady-state conditions (shock loads) which cannot be, or have not been, smoothed by preventive engineering expedients must be accommodated solely by successful biological response or by combined biological and engineering remedial responses. To cope with these situations successfully requires thorough understanding of the process by the plant operational personnel and the incorporation of adequate operating flexibility into the system by the design engineer.

The key to maintaining operational process control and stable operations in biological treatment systems is to provide proper environmental conditions to the biomass or bacteria in the system. The hydraulic flow rate and organic loading rate, along with the variability in these parameters, are two of the most critical parameters relative to maintaining stable operating conditions; of course, pH, temperature, nutrients, dissolved oxygen, and lack of toxic or inhibitory substances are also critical to successful operations. When properly monitoring and controlling these parameters, the key to successful operations of activated sludge systems then becomes matching the number of microorganisms in the system to the organic substrate loading rate to the system, or controlling the F/M ratio of the system.

Operational Process Considerations

Kinetic approaches to successfully applying the required metabolic and biological principles of food-processing waste water treatment for both design and operations have been discussed herein. The kinetic constants $U_{\max}$ and K_B define the biological treatability characteristics of the waste water. These biokinetic constants are normally defined in terms of COD, BOD, and/or total organic carbon (TOC) for food-processing waste waters. They are used for design purposes and operational process control and decision making when properly defined. They provide significant operations value by denoting changing qualitative waste water characteristics, toxicity incidents, and refractory or residual nonbiodegradable organic substances. For high-strength carbohydrate waste waters without toxicity or refractory organics, $U_{\max}$ and K_B are very close to one another in terms of

BOD, COD, and TOC with values typically above 15 kg kg^{-1} day^{-1} in terms of COD. High residual/refractory organics or toxicity will affect both the *y*-axis intercept (U_{max}) and the curvature (K_B) of the specific substrate utilization rate (U) versus the specific substrate loading rate (F/M ratio). Both refractory organics and toxicity reduce U_{max}, and change K_B significantly from U_{max} numerically. Therefore, proper monitoring and use of these kinetic constants can provide an invaluable tool for changing water quality and maintaining stable operational process control of biological systems treating food-processing waste waters.

Microbiology of Treatment Processes

E L Stover and C K Campana, Stover & Associates, Inc., Stillwater, OK, USA

Biological Treatment

During biological treatment, the objective is to remove or reduce the concentration of organic and inorganic compounds by using microorganisms. With biological treatment, the organic material in the waste water is removed by the microorganisms through metabolic processes. The organic compounds may be used by the microorganisms to form new cellular material or to produce energy that is required to sustain the microorganisms.

Heterotrophic microorganisms are the most common group of microorganisms providing the metabolic process for removing organic compounds from contaminated waste water. Heterotrophs use the same substances (organic compounds) as sources of both carbon and energy. A portion of the organic material is oxidized to provide energy, while the remaining portion is used as building blocks for cellular synthesis. Three general methods exist by which heterotrophic microorganisms can obtain energy: fermentation, aerobic respiration, and anaerobic respiration.

In the case of fermentation, the carbon and energy source is broken down by a series of enzyme-mediated reactions, which do not involve an electron transport chain. In aerobic respiration, the carbon and energy source is broken down by a series of enzyme-mediated reactions in which oxygen serves as an external electron acceptor. Anoxic respiration is similar to aerobic respiration, whereby facultative heterotrophic microorganisms use nitrate or nitrite-nitrogen as the final electron acceptor in the absence of oxygen. In anaerobic respiration, the carbon and energy source is broken down by a series of

enzyme-mediated reactions in which carbon dioxide and sulfates serve as the external electron acceptors. These three processes of obtaining energy form the basis for the various biological waste water treatment processes.

Biological treatment processes whether aerobic or anaerobic are typically divided into two categories: suspended growth systems and fixed-film systems. These processes can be batch, semicontinuous, or continuous flow processes. Suspended growth systems are more commonly referred to as activated sludge processes, of which several variations and modifications exists. Fixed-film biological processes differ from suspended growth systems in that microorganisms attach themselves to a medium that provides an inert support. Biological towers (trickling filters) and rotating biological contactors are the most common forms of fixed-film processes. (*See* **Effluents from Food Processing**: On-Site Processing of Waste.)

Activated Sludge

The activated sludge process is the most commonly employed treatment process for the degradation of organics in waste water from the food-processing industry. This article will review activated sludge microbiology, identification techniques of filamentous microorganisms, nonfilamentous microbial problems, higher life forms, and current activated sludge control measures.

Activated Sludge Microbiology

The applicability of biologically treating a particular waste water is a function of the biological degradability of the dissolved organic chemical constituents present in the waste water. The degradation rate of a specific organic compound is a function of the molecular structure of that particular compound, the genera and species (type) of microorganisms utilizing it as a food source, and the time required for the microorganisms to develop the enzymes necessary for substrate utilization.

The basic mechanism for removal of organic materials from waste water by biological treatment processes can be represented by three chemical reactions occurring simultaneously: energy, synthesis, and endogenous respiration. Energy and synthesis are often referred together as oxidative assimilation, and involve the consumption by microorganisms of the organic materials present in the waste water. A portion of this organic material is used as fuel to supply energy for metabolism, while the remaining material provides building components resulting in the formation of new cellular material. Thus, the organic material can be considered as food or substrate consumed by the microorganisms, with the production of carbon dioxide.

In the initial growth phases of a batch-fed biological process when organic matter (food) is present, oxidative assimilation is the primary reaction; however, as the food supply diminishes, the organic matter within the sludge is utilized and results in endogenous respiration as the predominant reaction. In the continuous fed complete-mix activated sludge process, both oxidative assimilation and endogenous respiration occur simultaneously. The degree of oxidative assimilation compared with endogenous respiration is a function of the operating conditions. Higher organic loading rates favor oxidative assimilation, whereas lower organic loading rates favor endogenous respiration.

The reactions of energy, synthesis, and endogenous respiration can be represented by the following simplified equation (eqn (1)):

$$\text{Organic matter} + O_2 \xrightarrow{\text{Microorganisms}} \text{New microorganisms} + CO_2 + H_2O + \text{energy.} \quad (1)$$

This equation is a simplification of the biochemical equation (and of microbial growth); it is qualitative, since no numerical coefficients are included, and significant elements have also been omitted. Nitrogen, phosphorus, and trace quantities of other elements have been eliminated from the left side of the equation. Typically, the heterogeneous population of the active biomass in the activated sludge process consists of 95% bacteria and 5% higher life forms such as rotifers, nematodes, protozoa, etc. The main purpose of the biota in the mixed liquor is to remove (metabolize) the soluble organics in the influent waste water stream and create floc forming bacteria that will settle under gravity in the secondary clarifier, thus leaving a clear supernatant (effluent) that can be discharged.

Situations may arise where not all the bacteria become floc-formers, thereby causing a turbid final effluent. Certain waste water streams can contribute to dispersed bacterial growth, single-celled free-floating bacteria, and the proliferation of filamentous microorganisms. It must be noted that filamentous bacteria are not always the main culprit for bulking or rising sludge problems. In fact, some filamentous organisms can assist in settling by acting as a backbone, whereby floc forming bacteria can grow and attach, therefore, minimizing the potential for shearing of the floc. Also, the presence of some filaments can and do act as a 'catch all' filter for small particles

that do not settle in the final clarifier. Filamentous bulking most often occurs when filaments are present in large amounts, thereby causing sludge compaction and settling to be hindered in the secondary clarifier.

Filamentous Microorganisms

In most activated sludge processes, filamentous microorganisms are routinely observed and actually belong in the microbial population. Their presence in the activated sludge process may actually contribute to a good quality effluent as long as their abundance is held to a minimum. A massive growth of filamentous microorganisms most often leads to bulking problems in the final clarifier, thereby leading to the deterioration of effluent quality. At least 25–30 types of filamentous microorganisms have been found to exist in activated sludge with 10–12 types being the most predominant. Though much effort and research have been expended trying to classify and name all the filamentous microorganisms, the task has yet to be completed. Consequently, unknown filamentous microorganisms (due to a lack of specific genus names) are indicated by a four-digit number. The occurrence of various types of filamentous microorganisms has been correlated with waste water characteristics and operating conditions, as shown in Table 1. This type of information can be used as a diagnostic tool to aid in the identification of potential filamentous microorganisms and the possible reason for proliferation. The growth of filamentous microorganisms is similar to normal bacterial growth except for unicellular cell division. Separation of two new cells does not take place with filamentous organisms, and consequently filaments consist of chains, long or short, of cells. In these cells, normal cell division occurs, but the two cells stay together. However, the presence of a sheath (hollow outer structure) may inhibit cell separation; hence, a large chain of many cells can develop. Usually, the cross-walls between the cells within a filament can be observed when performing a microscopic examination.

Identification of Filamentous Organisms

When bulking of sludge occurs, it can be observed in the final clarifier. Prior to this, it can be microscopically evaluated whether the bulking is due to filamentous microorganisms and, if so, the specific type of filaments. A brief description of different morphological characteristics of filamentous organisms follows. For detailed assessment and identification, the manual *Manual on the Causes and Control of Activated Sludge Bulking and Foaming*, by Jenkins, Richard, and Daigger, is very helpful, or the computer-based rapid Filamentous Bacteria Identification Program 'FILIDENTPro™, Stover & Associates, Inc., which utilizes an enhanced algorithm and search tree that enables the user to identify filamentous organisms easily and reduces the potential for misdiagnosis, is a very good training and identification guide.

The size (length and diameter) and location of filamentous microorganisms vary greatly. Filaments may be long and stout, short and thin, protrude from the floc, be within the floc, be free-floating in the bulk solution, or various combinations of these, may have attached growth adhering to the sheath (Figure 1), and/or have an outer cylinder-shaped clear structure in which some filamentous bacterial cells are wrapped. However, not all filamentous bacteria have a sheath or even attached growth. The shape (straight (Figure 2), bent, coiled, mycelial, smoothly curved) of the filamentous microorganism must be noted, as well as the shape of the individual cells within the microorganism itself. Most often, the cells are rectangular or square, but the need to account for all possible shapes (oval (Figure 3), discoid, round-ended rods (Figure 4), barrel, coccus) is essential to know in order to correctly identify the filamentous microorganism. Other important physical characteristics that distinguish filamentous bacteria from one another are cell inclusions, the

Table 1 Dominant filament types indicative of activated biosolids operation problems

Suggested causative condition	*Indicative filament types*
Low DO	*Sphaerotilus natans, Haliscomenobacter hydrossis*, type 1701
Low *F/M*	*Microthrix parvicella, Haliscomenobacter hydrossis*, types 021N, 0041, 0675, 0092, 0581, 0961, and 0803
Nitrogen and/or phosphorus deficiency	*Sphaerotilus natans, Thiothrix* spp., type 021N; possibly *Haliscomenobacter hydrossis* and types 0041 and 0675
Low pH	Fungi
Septic wastes	*Thiothrix* spp., *Beggiatoa* spp., type 021N

presence or absence of septa, constrictions of the outerwall, motility, rosettes formation, and whether any branching is true (Figure 5) or false (Figure 4). These physical characteristics can be determined microscopically by using a phase-contrast microscope at 1000×.

In addition to identifying the physical morphology, staining of the filamentous bacteria enhances the identification procedure. The Gram Stain and Neisser

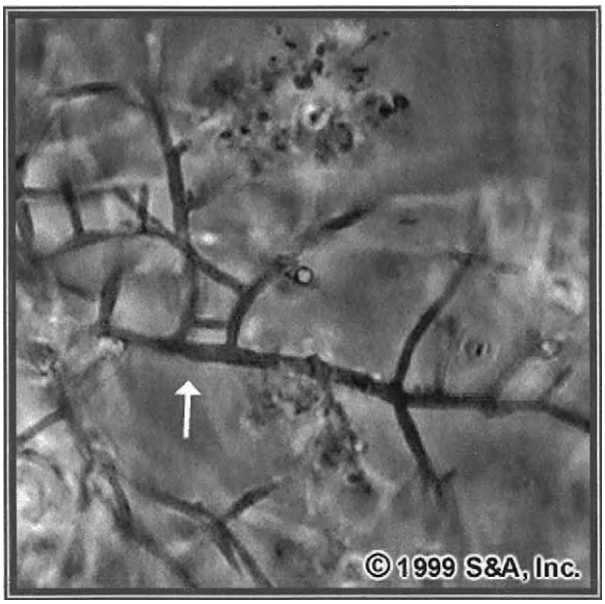

Figure 5 (see color plate 48) True trichome branching. True branching refers to contiguous cytoplasm between the branches. Filamentous bacteria, nocardia form. Subject to copyright and patent protection of Stover & Associates, Inc., as part of the FIL-IDENTPro™ Filamentous Bacteria Typing Program.

Stain are used extensively in the bacterial characterization process. The results are expressed as Gram-positive or -negative and Neisser-positive (Figure 6) or -negative. Other specialized slide preparation tests include:

1. **Sulfur oxidation test** – Ability of the bacterium to store sulfur granules.
2. **Crystal violet stain** – Used for determining whether a filamentous microorganism contains a sheath.
3. **India ink reverse stain** – Indicates the presence or lack of exocellular polymeric material (extracellular polysaccharides).
4. **PHB stain** – Detects intracellular storage of polyhydroxybutyrate.

Microscopic examination of the Gram, Neisser, and PHB stains should be at 1000× magnification with direct illumination (bright field). The India ink reverse stain should be observed at 100× magnification with phase contrast. Crystal violet and the sulfur oxidation test should be viewed at 1000× magnification phase contrast. A general outline is presented in Table 2, indicating important morphological characteristics and stains for the proper identification or typing of filamentous bacteria.

Filamentous bacteria serve as indicator organisms that, if correctly identified, allow for proactive measures to be initiated, thereby reducing the potential

for process failure. For example, identification of the filament, O21N (Figure 7) can indicate possible nitrogen-deficient operating conditions with high-strength food-processing waste waters.

Once filamentous bacteria become established, they possess a competitive advantage over other organisms relative to substrate utilization and growth. Hence, it is very important to identify the specific filament(s) that cause, or contribute to, bulking at each specific waste-water treatment plant. Early detection of site-specific problematic filamentous microorganisms often leads to heading-off of a bulking sludge condition before serious problems arise.

Nonfilamentous Microbial Problems

Though filamentous microorganisms play an important role in most activated sludge bulking episodes, nonfilamentous microbial growth can also cause negative impacts relative to proper settling and growth of the mixed microbiological culture in the activated sludge process. These include: dispersed growth, toxicity, floating sludge (denitrification) and nutrient deficiency.

1. **Dispersed growth** is generally characterized by single-celled bacteria in which floc development is negated and settling does not occur. This type of growth leaves behind a turbid, murky effluent. Most often, common dispersed growth problems are associated with industrial waste-water treatment facilities where the influent waste stream consists of soluble readily biodegradable organics operating at a high food-to-microorganism (*F/M*) ratio. Thus, the microorganisms are growing in a high log growth-rate phase that does not favor a floc forming settling sludge. Other possible sources of dispersed growth are nutrient (nitrogen and phosphorus)-deficient growth conditions and toxicity such as chronic heavy metals toxicity and associated deflocculation.
2. **Toxicity** or toxic shock loads can create severe operations problems in the activated sludge process. Toxicity implies reduced treatment efficiency and biological upset conditions that stem from the death of a microbe or metabolic impairment. Industrial waste streams often contain compounds, such as cleaning agents and/or surfactants that, in sufficient concentrations, can cause cell inhibition or, even worse, toxicity. Several microscopic bio-indicators can be employed to diagnose these types of problems, as follows:
   - loss or kill of higher life forms and/or protozoa;
   - biomass deflocculation often accompanied by dispersed growth and foaming in the aeration basin;
   - rapid increase in flagellate concentration and activity;
   - loss of biochemical oxygen demand $(BOD)_5$ removal; and
   - proliferation of filamentous organisms upon recovery from the process upset.

   Depending on the severity of the toxic load, the *F/M* ratio can be extremely high initially because of the bacteriological die-off, hence further development of dispersed growth. A spiked dissolved oxygen uptake rate of mixed liquor can be used to diagnose and detect toxicity especially in early stages. Waste-water additions that decrease the oxygen uptake rate by more than 4–5% generally indicate microbiological inhibition.
3. **Floating sludge** in the final clarifier is generally an indication that the aeration system is performing to the extent that the ammonia-nitrogen is being oxidized to nitrite- and nitrate-nitrogen (nitrification). The nitrite- and nitrate-nitrogen under anoxic conditions in the clarifier can be reduced to nitrogen gas and rise to the surface carrying the biological solids with it. This floating sludge condition can be generally corrected by increasing the return sludge rate, increasing the waste sludge rate, thus reducing the sludge inventory in the clarifier, by increasing the *F/M* ratio or, possibly, by adding specific inhibitors of the nitrification process to the system.

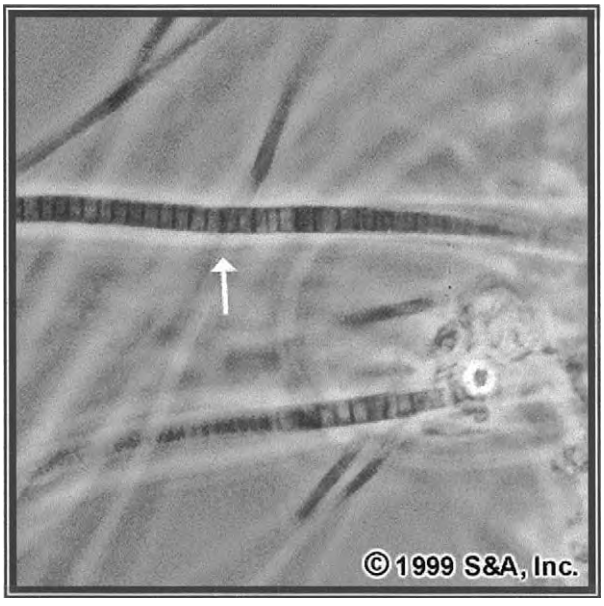

Figure 7 (see color plate 49) Filamentous bacteria type 021N. This slide was photographed at 1000× magnification under phase contrast. Subject to copyright and patent protection of Stover & Associates, Inc., as part of the FIL-IDENTPro™ Filamentous Bacteria Typing Program.

4. **Nutrient deficiency**: Micro- and macronutrient availability is extremely important in maintaining a healthy and active biomass in the aeration basin. The macronutrients, phosphorus and nitrogen, are typically more apt to be supplemented than the micronutrients. The need for the addition of micronutrients is rare because of the small concentrations required and the availability of these nutrients in most influent waste streams. Nutrient deficiency is usually associated with industrial waste-water treatment plants.

   The production of foam and the jelly-like consistency of the activated sludge mixed liquor are indicators of bulking problems associated with nutrient deficiency. The jelly-like (slime) consistency is a byproduct from the bacterial cell when production of necessary cell components such as protein is hampered because nitrogen is not available. The slime, more commonly called exocellular or extracellular polysaccharide, is a metabolic shunt product with surface-active properties that can lead to foaming in the aeration basin. Sludge grown inthis media consists of large globular floc forms that do not settle and compact in the clarifier. This condition can be observed microscopically by using the India ink reverse negative staining technique. Under normal conditions, the ink particles penetrate deeply within the floc, while penetration is blocked when large amounts of exocellular polysaccharides are present, resulting in a whitish 'ghost' appearance to the sludge (Figure 8). Certain filamentous organisms thrive under nutrient deficient conditions. The filaments most often related to nutrient deficiency are types 0041, 021N, 0675, and *Thiothrix* sp. Other filamentous bacteria may be present also; however, these filaments are typically indicators of nitrogen- or phosphorus-limiting conditions.

   The maximum theoretical amount of nitrogen and phosphorus required for biological synthesis is based on a BOD_5:N:P ratio of 100:5:1. This value can be increased or decreased, depending on the sludge retention time (SRT), *F/M* ratio, organic compounds being oxidized, etc. Maintaining soluble nitrogen and phosphorus residuals of at least 1.0 and 0.2 $mg\,l^{-1}$ respectively, generally allows sufficient nutrient availability. The addition of these macronutrients to the aeration basin should closely match the demand; however, a wide variation in the organic loading rate can make this task extremely difficult. Many microbiological problems, both filamentous and nonfilamentous, exist in activated sludge systems due to nutrient-deficiency problems. Care should be taken to insure that all the environmental operating conditions have been properly maintained.

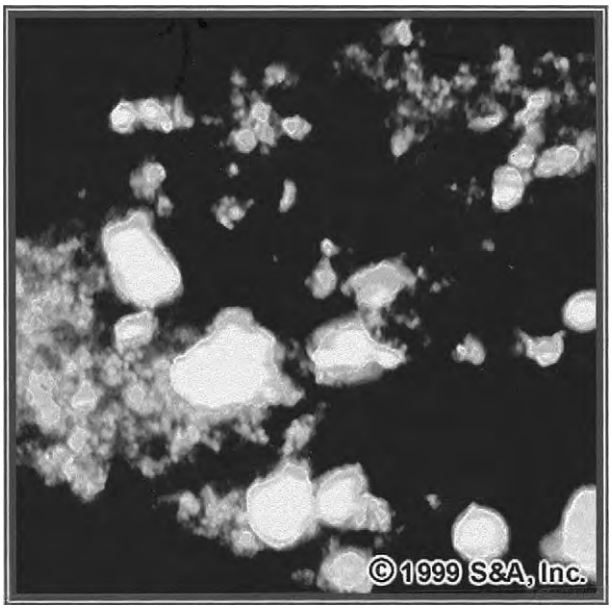

Figure 8 (see color plate 50) India ink staining for extracellular polysaccharide. India ink particles penetrate the flocs almost completely, at most leaving a small clear center. In activated sludge containing large amounts of extracellular material (as shown in picture), large clear areas indicate areas of low cell density. This slide was photographed at 10 × magnification. Subject to copyright and patent protection of Stover & Associates, Inc., as part of the FIL-IDENTPro™ Filamentous Bacteria Typing Program.

Protozoa and Activated Sludge

Effluent quality and plant performance can be related to higher life organisms present in the aeration basin mixed liquor. The biology of the activated sludge aeration basin consists of protozoa, rotifers, annelids, nematodes, and other higher life forms. Approximately 5% of the mixed liquor may be represented by 200 species of protozoa and other higher life forms. The protozoa is generally the most abundant organism in the aeration basin. Protozoa are all single-celled organisms that are hundreds of times larger than bacteria. Therefore, they are easily viewed under a microscope and can be used as an indicator organism of biomass quality.

Locomotion is usually accomplished by external hair-like flagella (tail) or through body movement. Ingested food particles are usually stored inside the vacuoles (food compartments) until enzymes break the food down for absorption through the cell wall. The role of these organisms varies from enhancing microfloral activity and decomposition, thereby aiding oxygen penetration, to contributing to

biomass flocculation. Microscopic examination of the biomass, when performed on a routine basis, such as daily, provides a picture of the condition of the biological population. Normally, microscopic evaluation of the biological solids is made under a 100 × magnification by placing a drop of biosolids on a glass slide. Increased magnification enhances the detail of the observed organisms. Microscopic evaluation of the biomass should be performed daily to monitor for increases or decreases in the various types of higher life growth in the biological population.

The major groups of higher life organisms in activated sludge are: rotifers, free-swimming ciliates, attached (stalked) ciliates, flagellates, amoeba, and higher invertebrates such as nematodes and annelids. The proliferation of certain organisms is dependent upon food availability, toxicity, and operating conditions. The four most common and readily observable indicator forms of higher life and the corresponding environmental conditions for proliferation follow:

- **Flagellated protozoa:** These organisms are normally oval and very small, and can be identified by their long whip-like tails (flagella) that are used for locomotion. The character motion of flagellated protozoa is undulating and relatively slow. If this type of higher life form is predominant, the biological system has a relatively high unstabilized organic content. This could indicate an unusually high BOD_5 loading or a low mixed liquor (biological solids) concentration.
- **Free-swimming ciliated protozoa:** These animals are also oval but are two to five times larger than the flagellated protozoa. The free swimmers can be identified by tiny hair-like cilia over their body. They move very fast in a darting fashion. If free-swimming protozoa are the predominant type of higher form of life, there is probably a moderate to low organic loading level in the system.
- **Stalked ciliated protozoa:** These organisms are much larger than the two previously mentioned and have a variety of shapes. They are equipped with a tail (stem) that they use to attach themselves to solid particles. Some types grow in a colony form that appears very much like a flowering bush; the bodies of the protozoa are located at the end of individual stems that attach to a main stem. Protozoa of this type can be identified by cilia located around the opening for intake of food. The cilia actually circulate water past the food-intake opening. The observer may be able to see small pinpoint particles being consumed by these animals. Stalked ciliated protozoa will predominate in a biological system that has a low organic level of unstabilized BOD of about 10–20 $mg\,l^{-1}$.
- **Rotifers:** These are the largest of the four types of higher life organisms discussed. They have flexible bodies that are also equipped with cilia, used to pull food to the rotifer as well as for locomotion, around the food intake opening. There are many types of rotifers, some of which have forked tails that are used to attach themselves to solid particles while feeding. A biological system in which rotifers predominate normally has a low organic level of unstabilized BOD.

All four forms can be observed in a system at any given time. The observer should attempt to identify which type of higher form predominates and then use the above guide for evaluating plant performance. These higher forms of microscopic organisms are very sensitive to toxic materials, and their presence or absence can help to indicate shock loads. The higher life forms will die before the bacteria are affected, so that routine observations can indicate trouble before it becomes so serious as to kill the bacteria. Also, the protozoa and other animals are strict aerobes, and therefore are indicators of ample dissolved oxygen. The microscopic animals can survive under anaerobic conditions for a few hours, but prolonged deficiencies of dissolved oxygen will be fatal. Low pH conditions will also cause a swift kill of the higher life forms. The protozoa, as well as the rotifers, are predators that continually remove small floc particles and dead microorganisms, and aid in the development of flocs. This predatory action keeps the bacterial population active and contributes to effluent quality by removing nonflocculated bacteria.

Reliable and stable operating conditions can be correlated to the type(s) of higher life organisms present in the system. Low effluent suspended solids concentration and low turbidity are normally achieved with a balance of free and stalked ciliates along with rotifers. A photograph of a rotifer of the type typically observed in activated sludge systems is presented in Figure 9. The establishment of a mixed microbial population in the aeration basin mixed liquor will result in optimum activated sludge performance.

Anaerobic Microbiology

Faculative bacteria are among the largest group of bacteria in nature. These bacteria can function in either an aerobic or anaerobic environment. The most common group of facultative bacteria are the Pseudomonas. Additional common facultative bacteria that have been identified in waste-water

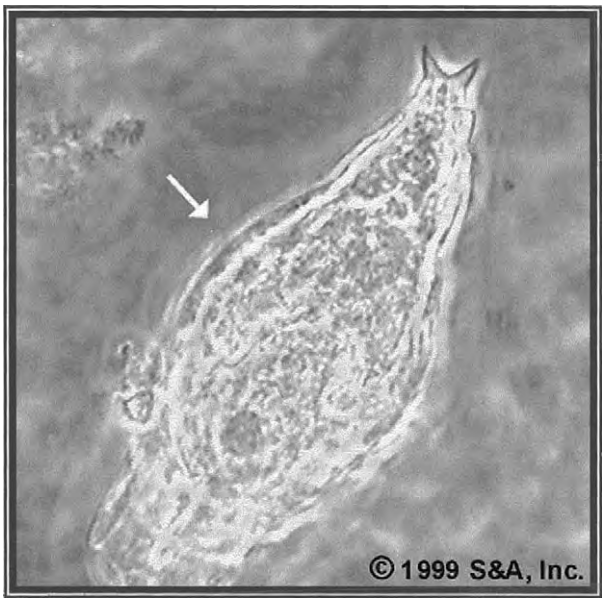

Figure 9 (see color plate 51) Unidentified species of the phylum Rotatoria, commonly called rotifers. This slide was photographed at 100 × magnification. Subject to copyright and patent protection of Stover & Associates, Inc., as part of the FIL-IDENTPro™ Filamentous Bacteria Typing Program.

treatment systems include *Alcaligenes*, *Achromobacter*, *Flavobacterium*, and various enteric bacteria.

The obligate anaerobic bacteria cannot tolerate dissolved oxygen. *Clostridium* is the major group of strict anaerobes. Sulfate-reducing bacteria are also strict anaerobes that belong to *Desulfovibrio*. They can metabolize a wide variety of organic compounds while reducing sulfates to various reduced sulfur intermediates, including hydrogen sulfide. The methane bacteria are also strict anaerobes that require a highly reduced environment for metabolism. They include *Methanobacterium*, *Methanosarcina*, and *Methanococcus*. Certain methane bacteria reduce carbon dioxide with hydrogen to produce methane and water, whereas others metabolize acetate. There is strong competition between the methane bacteria and the sulfate reducers. Even though bacteria are the primary microorganisms in anaerobic environments, protozoa have been observed in some anaerobic treatment systems. These protozoa have been described as flagellated and ciliated protozoa.

Desulfovibrio bacteria can use sulfates as their primary source of electron acceptors. The electron changes produce a series of reduced sulfur compounds, starting with thiosulfates and working through sulfur to sulfides. Energy transfer determines the changes in the sulfates. In the presence of excess organic matter that is readily metabolized by the *Desulfovibrio* bacteria, the reduction reactions go completely to sulfides as shown:

$$\text{Organic matter} + SO_4^{2-} \rightarrow H_2S + CO_2. \quad (2)$$

The hydrogen sulfide is partially soluble. As hydrogen sulfide is produced above its solubility level, it diffuses out of solution into the gases in proportion to its solubility.

At a pressure of 1.0 atm and a temperature of 35 °C, hydrogen sulfide is soluble to a maximum level of 2750 mg l^{-1} at pH 4.0. However, biological systems operate at pH values around 7.0, and as the pH increases above 4.0, hydrogen sulfide forms hydrogen bisulfide, as shown:

$$H_2S \leftrightarrow HS^- + H^+. \quad (3)$$

At pH 7.0, there will be approximately a 50:50 split with a total allowable sulfide concentration of 5765 mg l^{-1} ($H_2S + HS^-$). Formation of bisulfide therefore allows more sulfides to remain in solution. Since hydrogen sulfide is the culprit creating toxicity, toxicity can be reduced by raising the pH above 7.0 to drive the reaction toward bisulfide. Hydrogen sulfide levels below 200 mg l^{-1} should be maintained to eliminate toxicity problems.

The relative concentrations of electron donors (organic matter) and sulfates control the end-product formation. If the sulfate concentration is higher than the organic matter available for metabolism, the sulfate reducers do not have enough electrons to reduce the sulfates completely to sulfides. The overall reduction process can be expected to follow the pattern shown:

$$\text{Organic matter} + SO_4 \rightarrow [SO_3 \rightarrow SO_2 \rightarrow S_2O_3 \rightarrow S_2 \rightarrow HS \rightarrow S] + CO_2. \quad (4)$$

The thiosulfates are readily soluble, whereas, the free sulfur is insoluble.

Disposal of Waste Water

E L Stover, Stover & Associates, Inc., Stillwater, OK, USA

T H Eckhoff, M&M/Mars, Inc., Hackettstown, NJ, USA

Introduction

Waste waters produced from food-processing operations vary in general based on the class or type of food processes; however, they share many common characteristics. These common characteristics typically allow biological treatment processes to be used for food-processing waste waters prior to discharge to the environment or prior to recycle and reuse. Water quality standards and criteria have been developed, and are constantly being refined and upgraded for discharge and use requirements. Existing and new environmental laws are being enforced to protect the aquatic environment from effluent discharges. The newer regulations and approaches emphasize watershed-based water quality initiatives and ecological risk assessment. Waste minimization and waste reuse approaches are being emphasized.

Characteristics of Food-Processing Waste Water

The food-processing industry is highly diverse; this diversity is reflected in the enormous variety of food items produced worldwide. In general, the classes of food processors include bakeries, candy manufacturers, meat processors, breweries, specialty convenience-type food processors, baby food manufacturers, fruit and vegetable processors, and dairies. Each type of food-processing facility has waste water problems endemic to the specific processes involved and to the particular product; however, there are common characteristics of nearly all food-processing waste waters. Refer to individual food processes.

The primary waste water pollutants associated with the food-processing industry are food product, raw materials, solvents, detergents, cleaning agents, and disinfectants. These constituents give rise to high biochemical oxygen demand (BOD), chemical oxygen demand (COD), total suspended solids (TSS), total dissolved solids (TDS), nutrients (primarily nitrogen and phosphorus), pH, oil and grease, and color. In general, food-processing waste waters by their nature contain few, if any, toxic constituents. The US Food and Drug Administration (FDA) requirements preclude the use of hazardous or toxic constituents in the preparation and processing of food products. However, these same regulations often require a food processor to clean and disinfect equipment and facilities with compounds that could be problematic during waste water treatment. For example, products that contain quarternary ammonium compounds, which have a strong disinfectant capacity, can pose a problem during waste water treatment if used indiscriminately for production equipment cleaning. For the most part, food-processing waste waters are not considered to be hazardous to human health. A common factor in food-processing waste waters is the enormous volume of effluent generated. Water is used as an ingredient in many foods, and in all parts of the food-processing operation, including product washing, blanching, cooking, cooling, diluting, cleaning, and sanitation. The total volume of water discharged daily may vary greatly, from $2650\,m^3\,day^{-1}$ for a bakery to $2.65 \times 10^6\,m^3\,day^{-1}$ for a cannery of comparable size.

Food-processing industries generally dispose of their waste water by treatment prior to discharge directly to a receiving stream, a publicly owned treatment works (POTW), or land application site. Most food-processing plants utilize a biological treatment system to treat their waste water. These systems include aerobic and anaerobic processes, either independently or in combination. Because of the nontoxic nature of the waste water generated in the food-processing industry, this approach is generally very effective. Some of the disadvantages associated with biological treatment include the generation of biological sludge which must be disposed of, the requirement of a skilled treatment system operator, and the sensitivity of biological systems to climatic change or

process upsets. Prior to discharge, the waste water must be treated to meet certain criteria, depending on the intended route of disposal. These discharge criteria are discussed in the following section.

Water Quality Standards for the Disposal of Waste Water

In the USA, all waste water discharges (including food-processing industries) are regulated at several levels. The ultimate regulatory authority derives from the Federal Water Pollution Control Act (commonly referred to as the Clean Water Act, or CWA) and is administered by the Environmental Protection Agency (EPA), although many states have a delegated authority (in lieu of the EPA) to enforce the various parts of the regulations. This section discusses the basic objectives of the CWA, the administration of water quality standards by states, and the role of toxicity testing in evaluating water quality. Although this discussion presents discharge standards from a US perspective, many other countries have adopted, or will be adopting, similar approaches.

Environmental regulations have progressed in a similar fashion worldwide. Water use and waste water disposal have presented food manufacturers with similar problems in Central and South America, the UK, western Europe, Central Europe, and Asia. In the 1950s to 1970s, economic goals of manufacturers played a more important role in a country's economic development than environmental concerns. As water and waste water problems from all sectors of the economy took on a more national spotlight, environmental laws were passed in an attempt to curb the rising tide of water pollution. Water quality studies of rivers and lakes were begun in the 1970s, and continue today. Many countries have established waste water discharge limitations based on water quality standards. The European Union (EU) is attempting to establish a framework across western and central Europe in environmental legislation to protect rivers, lakes, and groundwater.

More stringent legislation on waste water dischargers, including food processors, has evolved at varying degrees in the many nations of Europe, states of Central and South America, and Asia. The UK and western Europe began enacting environmental legislation in the 1960s and 1970s. Central and Eastern Europe followed in the 1970s and 1980s, gaining on the experience of the USA and western Europe. Many multinational companies now see it as their responsibility and are usually required by local legislation to provide the best water and waste water treatment available to their facilities.

The Clean Water Act

The first comprehensive legislation for water pollution control was the US Water Pollution Control Act of 1948. This law adopted principles of state–federal cooperation in program development but limited federal enforcement authority and federal financial assistance. These principles were continued in the Federal Water Pollution Control Act in 1956 and in the Water Quality Act of 1965. Under the 1965 Act, states were directed to develop water quality standards establishing water quality goals for interstate waters.

These laws were ineffective and the industrial boom in the USA during the 1950s and 1960s brought with it a level of pollution never before seen in the USA. Scenes of dying fish, burning rivers, and thick black smog engulfing metropolitan areas were commonplace on the evening news. In December of 1970, the President of the USA created the US EPA through an executive order in response to these critical environmental problems.

Congress passed the CWA, Public Law 92–500, on 18 October, 1972. Although prior legislation had been enacted to address water pollution, those previous efforts were developed with other goals in mind. For example, the 1899 Rivers and Harbors Act protected navigational interests (commerce), and the 1948 Water Pollution Control Act and the 1956 Federal Water Pollution Control Act only provided limited assistance for state and local governments to address water pollution concerns on their own.

In the Federal Water Pollution Control Act Amendments of 1972, Congress established the National Pollutant Discharge Elimination System (NPDES) whereby each point source discharger to waters of the USA was required to obtain a discharge permit. The CWA required the elimination of the discharge of pollutants into the nation's waters and the achievement of fishable and swimmable water quality levels. The NPDES program represented one of the key components established to accomplish this task. In addition, the 1972 amendments extended the Water Quality Standards Program to intrastate waters and required NPDES permits to be consistent with applicable water quality standards. Thus, the CWA established a combined technology-based and water quality-based approach to water pollution control.

Each state administers the CWA by establishing specific water quality standards for the water bodies in its region. The water quality standards include a narrative limit and a series of specific numerical limits. Each state is required to establish narrative waste

water discharge limits to address Objective 3 of the CWA: 'The discharge of toxic pollutants in toxic amounts is prohibited'. The narrative limits are fully enforceable. Waste water dischargers must therefore comply with both local narrative and numerical limits.

Specific numerical limits are actual physical concentration limits and represent the water quality criteria that most waste water treatment plants were designed to meet. Currently all 50 US states and US territories have established water quality criteria. Specific numerical limits are developed by each state according to the following criteria: the water body-designated use and the water quality criteria necessary to protect that designated use. All US surface waters have been categorized by water body or segment of water body according to specific designated beneficial uses. These designated beneficial uses for each water body are established locally by each state and revised at least every 3 years through periodic reviews. Examples of designated beneficial use classifications include public water supplies, propagation of fish and wildlife, recreational purposes, agricultural, industrial, and navigation.

The exact categories incorporated by each state may differ; however, the basic principles outlined in the CWA for support and propagation of aquatic life and recreation in and on the water are conserved by all states. States often set specific standards for specific uses or establish standards to protect individual species, for example. Special standards are also established for outstanding national resource waters (ONRWs). These are ecologically unique waters with standards set to protect the highest potential water quality.

The water quality criteria for protecting the designated beneficial use for each water body are also established at the state level. The EPA has published criteria recommendations in the *Quality Criteria for Water 1986* (called the *Gold Book*), consisting of scientific information on the effects of specific pollutants on aquatic life or human health. These criteria are used by state regulatory agencies to establish enforceable local discharge limits.

The NPDES Permit

The monitoring and enforcement tool of states and EPA is the NPDES permit. All food-processing industries that discharge waste water directly to surface waters in the USA must have an NPDES permit. To address indirect discharges from industries to POTWs, the EPA, through CWA authority, established the National Pretreatment Program as a component of the NPDES Permitting Program. The National Pretreatment Program requires industrial and commercial dischargers to treat or control pollutants in their waste water prior to discharge to POTWs. Indirect dischargers (to a POTW) must meet specific pretreatment criteria under the authority of the POTW's NPDES permit to insure compliance by the permit holder. Violations of NPDES or pretreatment permit parameters could result in an administrative order (AO), financial penalties, or revocation of the permit, resulting in a cease discharge order and closing the facility. The 5-year NPDES permits contain region and site-specific effluent limits as well as specific effluent monitoring and reporting requirements. The specific numerical limits enforced by the NPDES permit are categorized as conventional parameters and toxicity limits. These toxicity limits are based on whole effluent toxicity testing with aquatic organisms monitoring endpoints such as survival, growth, and reproduction.

Conventional Parameters

Conventional parameters are those pollutants that were initially targeted under the CWA for reduction. These parameters include the following:

- biochemical oxygen demand (BOD)
- chemical oxygen demand (COD)
- oil and grease (O&G)
- total organic carbon (TOC) and total oxygen demand (TOD)
- suspended solids (SS) and volatile solids (VS)
- total dissolved solids (TDS)
- nitrogen forms
- phosphorus
- pH, alkalinity, and acidity
- heavy metals
- specific organic compunds

Although effluent limits on these parameters have reduced the threat of food-processing industry effluents to human health and the environment, more stringent controls are necessary to achieve the goals of the CWA.

Priority Pollutants

In 1987 the CWA was amended to require states to adopt statewide numeric water quality criteria for toxic pollutants (Section 303(c)(2)(B) of the CWA). If numerical criteria were not available, the states were required to adopt criteria based on biological monitoring or assessment methods. A 'hit list' of regulated toxic compounds has been established over a period of years; these compounds are generally referred to as priority pollutants.

The Role of Toxicity Testing in Water Quality Evaluation

The EPA issued a national policy directive in 1984 entitled *Development of Water Quality-Based Permit Limitations for Toxic Pollutants: National Policy.* The EPA policy established control of toxic discharges through the NPDES permit system. Many food-processing NPDES dischargers are now being required to monitor for whole effluent toxicity (WET) to determine if their waste stream is toxic under specific low-flow conditions.

A discharge that repeatedly fails the toxicity test may receive a compliance letter from the state or the EPA which requires the discharger to perform a toxicity reduction evaluation to bring the effluent into compliance. The EPA policy states that biological testing of effluents is an important aspect of the water quality-based approach for controlling toxic pollutants. Effluent toxicity data, in conjunction with other data, can be used to establish control priorities, assess compliance with state water quality standards, and set permit limitations to achieve those standards.

Future Developments in Water Quality Standards

While a major reauthorization of the CWA did not take place in the late 1990s, focused changes on specific issues occurred. The Clean Water Action Plan (CWAP) was released in 1998 and is a broad comprehensive program that emphasizes a watershed management approach to water pollution control, strengthened existing and proposed new water quality standards (WQS) for water bodies, and implemented nonpoint source (NPS) controls for water discharges. The USEPA has a commitment to the CWAP objectives of restoring and protecting water resources on a watershed basis and maintaining a partnership with the States in achieving water resource goals.

In the coming year(s), EPA will continue to implement the Total Maximum Daily Load (TMDL) Program, as well as other watershed based water quality initiatives. The States are required to develop lists of impaired waters. These are waters that do not meet water quality standards, even after point sources of pollution (i.e. NPDES dischargers) have installed the minimum required levels of pollution control equipment. A TMDL specifies the maximum amount of a pollutant that a waterbody can receive and still meet water quality standards, and allocates pollutant loadings among point and nonpoint pollutant sources. The draft rule has elicited much interest and debate from the regulated community and the states due to the probability that the rule will call for increasingly stringent effluent limits on point dischargers, resulting in capital expenditures for larger and more sophisticated waste water treatment plants. Even indirect dischargers to a POTW will be affected as their discharge limits may be lowered to relieve the burden on POTWs.

The water quality standards also contain antidegradation policies which are designed to protect improvements in water quality and existing high-quality waters. This would require new or expanding dischargers to obtain an offset of 1.5 times their proposed discharge before beginning to discharge. These proposed offset requirements are in addition to current Clean Water Act provisions requiring discharge limits to protect water quality standards. Water quality standards will ultimately play an important role in the decision making process for food manufacturers as to where to build new facilities or relocate for consolidation.

Future pollution control strategies can be summarized in two words: waste minimization. With the 1984 congressional amendments to the Resource Conservation Recovery Act (RCRA), also known as the Hazardous and Solid Waste Amendments (HSWAs), the national waste management priority was shifted from treatment and disposal to waste reduction and recycling. The EPA defines waste minimization as the changes that can be made to reduce or recycle waste material that would otherwise have to be treated and disposed. While this effort initially focused on hazardous waste generation and disposal, the effort was soon applied to waste sources in general and waste water treatment.

Waste water reclamation and reuse was a major focus of waste minimization programs and can also provide an alternative water supply. The potential uses for recycled waste water include process water, wash water, rinse water and dilution water. It is evident that waste minimization practices provide opportunities for water conservation and water resources management as well as pollution control.

Prior to appropriate recycling or reuse, the waste water effluent must meet certain criteria for its intended use. As previously discussed, the conventional parameters may often be limiting factors in the water quality necessary for an intended use. Waters high in suspended or dissolved solids, for example, may not be suitable for reuse without additional treatment to remove solids. The list of regulated toxic compounds complicates the issue further as food-processing establishments use more effective sanitizing and cleaning agents to meet other

regulatory requirements. (*See* **Cleaning Procedures in the Factory**: Overall Approach; **Sanitization**.)

Agricultural reuse of waste water has economic advantages. Considerable benefits are realized by agricultural growers using reclaimed effluent as a water source, including a more dependable water supply and reduced water pumping and fertilization costs. Additional treatment by carbon filtration, disinfection, and reverse osmosis may be required for subsequent potable water use. Groundwater recharge with reclaimed waste water is practised in many areas. Zero discharge processes are being designed in many modern food processing facilities, utilizing water reuse and recycling to meet other water needs. Membrane technologies such as microfiltration, ultrafiltration, and reverse osmosis, are used for rinse water recycling and other effluent treatment. (*See* **Water Supplies**: Water Treatment.)

Most industries are resistant to change. As long as waste water treatment and disposal are economically viable and water is readily available, waste minimization will not be integrated into standard plant practice. The EPA is promoting waste minimization by applying increasingly more stringent discharge limits on all industrial and municipal dischargers. In addition to conventional parameters, the EPA has begun to emphasize whole-ecosystem impact of pollutant discharges.

New water quality standards will reflect this emphasis. Three main areas of emphasis for future water quality standards will be sediment toxicity, bioassessment, and ecological risk assessment. Of these three main areas, sediment toxicity and bioassessment standards continue to be defined. Evaluating Standardized and validated sediment toxicity test methods now exist allowing monitoring of sediment quality. Because sediment often serves as a reservoir or depot for toxicant accumulation, monitoring the surface water itself only provides a partial picture of potential ecological hazard. Further, toxicity characterization procedures have been developed for sediments allowing suspect toxicants to be determined in solid-phase samples analogous to procedures developed previously for effluents or surface waters.

Emphasis on whole-ecosystem monitoring and watershed management has prompted the use of ecological bioassessment. The most widely utilized bioassessment practice includes biological surveys which monitor community structure, biological diversity, and the presence or absence of pollution tolerant/sensitive species. Various trophic levels ranging from benthic invertebrates to fish may be included in these surveys.

An emerging trend in ecological water quality monitoring within a given watershed is the establishment of site-specific water quality standards. Although the site-specific water quality monitoring approach has been used primarily with metals to date, the concept may eventually be broadly applicable to a large number of chemicals. This approach essentially compares the toxicity of a specific metal (i.e., Cu, Zn, Pb, Ni, etc.) to traditional biomonitoring test organisms in the laboratory prepared synthetic culture water to?the toxicity of the same metal in the receiving stream. Because many toxicity mitigating and exacerbating factors exist in nature which cannot be accounted for in the laboratory, this approach provides a reasonable approach for determining the potential bioavailability (toxic fraction) of the toxicant in a specific environment. Since no two ecosystems or watersheds are identical, this approach has merit in identifying criteria for each specific ecoregion. In essence, this approach combines the use of laboratory biomonitoring testing with the *in situ* toxicity monitoring.

Several areas have emerged recently in ecological risk assessment. First, the use of sentinel species to provide a general indicator of ecosystem health has become more widely noted within the last several years. One of the best recent examples of the use of a sentinel species in monitoring ecosystem health, is the identification of deformed amphibians in several different locations in North America. Amphibians represent a sensitive class of animals which have raised 'environmental flags' in regions where deformed specimens have been identified. Not only are amphibians indicators of general ecosystem health, but are also potential indicators of risk to the human population. Obviously, the gap between ecological risk suggested by an adverse response in a sentinel species and potential human risk must be bridged.

Although the significance between the presence of endocrine disrupting chemicals (EDC) and their impact in the environment is still being addressed, the second area of intense focus in ecological risk assessment is the identification and monitoring of EDC. Passage in 1996 of the Food Quality Protection Act (FQPA) and Amendments to the Safe Drinking Water Act (SDWA) reflected these concerns and required EPA to develop a screening program using appropriately validated test systems and other scientifically relevant information to determine whether certain substances may have an effect in humans that is similar to an effect produced by naturally occurring estrogen or other such endocrine effects.

Specifically, EPA was required to develop a screening program by August 1998; to implement the program by August 1999; and to report to Congress on the program's progress by August 2000. In 1996, EPA formed the Endocrine Disruptor Screening

and Testing Advisory Committee (EDSTAC), charging the Committee to provide advice on how to design a screening and testing program for EDCs. This report contains the findings of the Committee, and is organized into sections discussing the EDSTAC recommendations on: a Conceptual Framework; Priority Setting; Screening and Testing; and Communications and Outreach. As a result, the EDSTAC recommended that EPA's Endocrine Disruptor Screening and Testing Program (EDSTP) should address both human and ecological (wildlife) effects; examine effects on estrogen, androgen, and thyroid hormone-related processes; evaluate endocrine disrupting properties of both chemical substances and common mixtures. The Committee determined that a tiered approach would be most effective in utilizing reasonably available resources to detect endocrine disrupting chemicals and quantify their effects. The core elements of the approach include initial sorting, priority setting, Tier 1 Screening (T1S), and Tier 2 Testing (T2T). EDSTAC recommended that T1S include three *in vitro* assays, three *in vivo* mammalian assays, and two *in vivo* nonmammalian assays. Specifically, these assays included:

In Vitro

1. Estrogen receptor (ER) binding/transcriptional activation assay,
2. Androgen receptor (AR) binding/transcriptional activation assay, and
3. Steroidogenesis assay with minced testis

In Vivo

1. Rodent 3-day uterotrophic assay (subcutaneous),
2. Rodent 20-day pubertal female assay with thyroid,
3. Rodent 5–7-day hershberger assay, and
4. Frog metamorphosis assay and fish gonadotropic assay

EDSTAC recommended that the T2T battery include a mammalian two-generation reproductive toxicity study, or a less comprehensive test in accordance with the guidelines outlined above, and tests addressing four additional taxonomic groups, including amphibians, fish, and invertebrates as follows:

Mammalian Tests

1. Two-generation mammalian reproductive toxicity study; or
2. A less comprehensive test:
   a. Alternative mammalian reproductive test or
   b. One-generation test

Multigeneration Tests in Other Taxa

1. Avian reproduction (with bobwhite quail and mallard),
2. Fish life cycle (fathead minnow),
3. Mysid life cycle (Americamysis), and
4. Amphibian development and reproduction (*Xenopus*)

Composition and Analysis

M Tarbox, Technology Centre, Kingston Seymour, Clevedon, UK

Introduction

Effluents from food industries show great variability in flow and composition, are substantially organic and biodegradable, and tend to become acidic or start decomposing if their treatment is not immediate. The food industries considered in the present article are:

- meat and poultry
- dairy (processing of milk and milk products)
- breweries and distilleries
- fruit and vegetable processing, fruit juices
- sugar beet
- miscellaneous: egg processing, contact drying of foods, edible oil refining, prepared meals and foods, fish farming; cider, perry and alcoholic beverages

Meat and Poultry

Slaughtering and processing operations release mostly organic materials and the pollutants are classified by their potential effects on receiving water rather than as specific chemical compounds.

Meat and poultry effluents are characterized by high and variable 5-day biochemical oxygen demand (BOD_5), which are influenced by blood content. Improved blood collection is the most effective way of reducing BOD load. Wide differences in discharge volumes and strengths exist. Beef abattoirs produce 1.6–10.2 kg BOD per head and 0.4–3.4 m^3 per head, whilst poultry processors range over 13–45 kg BOD per 1000 birds and 20–32 m^3 per 1000 birds. **Table 1** shows potential pollution loads from modern slaughterhouses.

Table 1 Water volume and pollution per kilogram of carcass

Water volume (m^3) per kg of carcass	*Cattle 4.81*	*Pigs 6.11*	*Poultry 8.11*
Pollution			
COD[a]	32.3	27.3	21.0
BOD_5	13.2	13.2	9.3
FOG	5.2		
Total N	1.6	1.6	
SS	11.8	9.3	4.5

[a]Note that tripe and offal processing contributes more than 50% of the total chemical oxygen demand (COD) pollution.
BOD_5, 5-day biochemical oxygen demand; FOG, fats, oils, and greases.
Data from *Degre'mont Water Treatment Handbook*, 6th edn, vol. 1, 1991. Paris: Lavoisier.

Suspended solids (SS) are both organic and inorganic. Fats, oils, and greases (FOG) float on the surface of water and produce high BOD values.

Nitrogen results from breakdown of proteinaceous materials into amino acids and ammonia.

Bacterial counts are high and include a small percentage of pathogens. Positive results for fecal coliforms simply indicate the possible presence of intestinal pathogens. Coliform counts are in excess of 2×10^6 per 100 ml, which is comparable to crude sewage. Hygiene regulations in food factories show increasing concern to avoid salmonella infection. The risk of animal diseases, for example, anthrax and helminthic infection in some parts of the world, is an important consideration. (*See* **Food Poisoning**: Economic Implications; **Parasites**: Occurrence and Detection; **Zoonoses**.)

Dairy Processing

Milk, a major food commodity, is used for market milk (whole or skimmed, cream), butter, cheeses, anhydrous milk for use in icecreams and frozen desserts, and many other products.

Most (90%) of the pollution load in wastes is derived from dilutions of milk or milk products, but especially from cleaning and rinsing of residues in equipment. They are mainly organic, but large quantities of water are used for cooling or in the condensers of evaporators. Hygiene requirements and continuing trends for improved standards result in extensive use of cleaning compounds and biocides. (*See* **Cleaning Procedures in the Factory**: Overall Approach.)

The high strengths of dairy fluids emphasize the need to prevent wastage and spillage. The organic strengths of these materials are assessed by BOD and chemical oxygen demand (COD). Whole milk (BOD 100 000 mg l^{-1}) is about 250 times stronger

than domestic sewage. The major contributors to the BOD of milk are 4.8% lactose, 3.6% milk fat, 3.5% protein, and lactic acid. BOD is the generally accepted parameter for determining the pollution potential, and is the normal basic design parameter for effluent and sewage treatment plants, despite well-documented disadvantages of the test, e.g., a 5-day test with poor reproducibility ($\pm$ 20%). The COD test is relatively simple, cheap, gives better reproducibility ($\pm$ 5%), is quick (2.5 h), and is used by many dairy plants as a monitor of the effluent strength.

Characteristics of Dairy Wastes

Dairy effluents differ in composition from domestic sewage, often having higher BOD values (up to 2500 $mg\,l^{-1}$), and higher carbon:nitrogen ratios (11:1 compared to 3:1 for sewage). Wide ranges in BOD and COD are possible, but typical BOD averages are 2500 $mg\,l^{-1}$ and for COD 4000 $mg\,l^{-1}$, with BOD:-COD ratios 0.45–0.67.

The use of BOD coefficients assists in controlling processing plants. A BOD coefficient of 1.0 kg BOD per m^3 milk is equivalent to 1% of all the milk solids received, representing loss of the milk and product value and additional costs for effluent treatment. Wastage may represent 0.5–6.0% of the milk received, but an efficient plant has low coefficients (0.5 kg BOD per m^3 milk received; 0.5 m^3 water per m^3 milk received).

Milk fat losses give high BOD values which can be quantified in the standard FOG test using non-aqueous solvent extraction.

Eighty-five percent of the SS in dairy wastes is organic and noted for poor settlability. The values typically range from 400 to 2000 $mg\,l^{-1}$.

The pH value of dairy food waste water is most influenced by either acidic or alkali cleaning compounds. Variations throughout the working day typically range from pH 2 to 11, with daily averages being 4.4–9.4. Temperatures can show wide short-term variations from 11 to 72 °C.

Data from the International Dairy Federation for a number of countries show waste volumes of 0.5–37 m^3 per m^3 milk, indicating for high values the presence of cooling and evaporator waters, even stormwater.

Dairy processing plants show wide fluctuations in rates of flow, strength, and temperature, which are compounded by daily and seasonal fluctuations. In some countries, dairy plants are shut in wintertime. Quantity and strength of wastes are not related to plant size or degree of automation as the main factor is the control of waste (milk). Dairy wastes are free of toxic compounds, other than those that may be introduced by the use of cleaning chemicals and bactericidal compounds.

Whey from casein and cheese-making is a major source of pollution (BOD 34 000 $mg\,l^{-1}$; COD 75 000 $mg\,l^{-1}$). Although whey is often considered a waste product, whey processing methods are utilizing this material for food and animal feeds.

Membrane technology in the dairy and other food industries uses reverse osmosis modules in a range of configurations. Spiral-wound modules are well suited for waste water applications, including whey concentration. (*See* **Membrane Techniques**: Applications of Reverse Osmosis; Principles of Ultrafiltration.)

Breweries and Maltings

Brewing is carried out in most parts of the world. Malting is less widespread in its locations but is a precursor to brewing since malt is essential to the fermentation process.

Malting of barley is the first stage of brewing and whisky distilling, producing steep liquor which is a strong, deeply colored, readily putrescible liquid, prone to excessive frothing. The waste has high BOD, low SS, and lacks nitrogen and phosphorus. The COD:BOD ratio is generally less than 2, with COD up to 4300 $mg\,l^{-1}$ and BOD up to 2300 $mg\,l^{-1}$.

Brewing

In the brewing process, malt and other grains undergo enzymatic changes when insoluble compounds (starches) and high-molecular-weight protein compounds are converted to soluble sugars. After a cooking stage with hops, fermentation using yeast produces alcohol. Yeast is recoverable for reuse or use as food supplements and the draught beer is put into casks. Other beers such as lager, keg, canned, and bottled are aged in a secondary fermentation stage.

Large volumes of strong effluent are produced from most of the processing stages, but they are generally less polluting than maltings liquors.

Historically, spoilt beer was discharged into sewers as a requirement by HM Customs and Excise before allowing duty paid to be reclaimed. This practice continues under strictly controlled procedures.

Brewery wastes comprise 2.4–9.0 m^3 waste water per m^3 beer and 2.3–17.5 kg BOD per m^3 beer with typical BOD 775–1622 $mg\,l^{-1}$ and COD 1220–2944 $mg\,l^{-1}$ and a BOD:COD ratio of 0.67.

Distilleries

In the UK, barley and maize are the main carbohydrates for the production of whisky, gin, and vodka.

The initial processes are similar to brewing. A starch substrate is converted by enzymes into sugars and then fermented. Conversion is unnecessary when using molasses or cane juice. Processes are optimized to maximize the alcohol yield and exhaust the fermentable sugars. BOD of spent mash from cereals averages 12 000–34 000 mg l^{-1}, with pH 3.5–4.0.

Spent mash contains large amounts of organic acids and is liable to rapid anaerobic fermentation because of the high BOD and COD concentrations, producing hydrogen sulfide.

Effluents contain yeast and nonfermentable materials and comprise mainly washing, steaming, cleaning, and cooling waters, with overall average BOD values between 400 and 1600 mg l^{-1} (and up to 10 000 mg l^{-1} if there is no byproduct recovery).

Waste water and pollution load for a cereal distillery are 0.29 m^3 waste water per tonne cereal and 3.4 kg BOD per tonne cereal, respectively, assuming the stillage is used as cattle feed.

Fruit- and Vegetable-Processing Industries

Waste waters from these industries are mainly organic; much of the material is dissolved and highly reactive with bacteria. Special difficulties may arise owing to their high immediate oxygen demand, seasonal load variations, large variations in strength and volume, low pH, lack of nutrients, and the influence of product changes.

Carbohydrates, as simple sugars, such as mono- and disaccharides, promote acidification.

Waste water pH variations are a common problem at fruit and vegetable plants. In many potato-processing plants, most of the pollution load is from caustic or lye peeling, producing high pH values, when starch becomes swollen, partly hydrolyzed and gelatinized in the process and traces of soil are rendered colloidal. Lye peeling of potatoes may create effluent with pH value exceeding 11, BOD 2000 mg l^{-1}, and COD 3000 mg l^{-1}. Modern plants use alternative 'dry lye' methods of peeling which give lower-strength effluents.

Washing and peeling operations for fruit and vegetable canning and freezing produce 15–30 m^3 per tonne of raw product and 8–38 kg COD per tonne of raw product. Blanching creates approximately 5–10 m^3 of waste water per tonne of raw product.

Factories packing fruit and vegetables produce waste waters characterized by soil and plant residues, detergent cleaning compounds, bactericides, storage waxing compounds, and citrus-processing compounds.

Fruit Juices

Effluents are characterized by low pH due to high organic acid content, an imbalance of nutrients dueto low nitrogen and phosphorus, and considerable fluctuations in volume and loads, with the bulk of the pollution load dissolved and not readily settlable.

Typical waste water from apple processing is waste water volume 1.2 m^3 t^{-1}, BOD 1.4 kg t^{-1}, COD 2.0 kg t^{-1}, pH 5.5, BOD 2880 mg l^{-1} and COD 6374 mg l^{-1}.

Sugar Beet Mills

Effluent from sugar beet processing comprises surplus transport water and wash waters. The concentration of organic matter increases from the start of the beet harvesting campaign and reaches a plateau after 1–2 months. Excess transport water, stored in large ponds, may be slightly sugary, containing organic matter such as root hairs, and with a BOD increasing to 3000 mg l^{-1} or more by the end of a campaign.

The total water requirement for processing a tonne of beet is approximately 9–19 m^3, and concentrated effluents have BOD values 4000–5000 mg l^{-1}. Effluent volumes using water recirculation are estimated to be 1.2 m^3 per tonne of beet, 2–3 kg COD per tonne and 200–600 kg SS per tonne. COD values are approximately 1.5 times the BOD value.

Miscellaneous Waste Waters

Egg Processing

High BOD (up to 10 000 mg l^{-1}) and SS owing to product loss and cleaning processes.

Contact Drying of Foods

Evaporation equipment for milk can be used for gum arabic, flavorings, and caramel. The main effect occurs when a product is changed, requiring extensive cleaning out and giving high CODs and, for caramel, high color.

Edible Oil Refining

Sources of waste include leaks and cleaning operations, although refining processes transfer impurities into water, and there is oil–water emulsion. In modern refineries, oil production, refining, and washing stages generate 56–86 kg COD per tonne. Refinery wastes show values of BOD 500–6700 mg l^{-1}, SS 540–5850 mg l^{-1}, and FOG 300–4200 mg l^{-1}. BOD and SS values are directly proportional to FOG concentration.

Prepared Meals and Foods

Factories producing prepared meals may do little processing of raw materials since meat portions are prepared elsewhere, and vegetables are also generally preprocessed. Waste waters result from plant and equipment cleaning, continuously as product mix changes or as spillages occur. Vegetable rinsing and blanching, frying, cooking, and cooling water are other sources.

BOD generation ranges from 9 to 34 kg per 1000 kg of production with waste water concentrations of 600–4000 mg l^{-1}.

Waste from frozen bakery products results from cleaning of equipment and product loss. The major ingredients (flour, eggs, butter, and sugar) are high in BOD, SS, and fat; waste water strength is 2100–4300 mg l^{-1}, equating to 23 BOD kg per 1000 kg of product.

Manufacture of salad dressings, mayonnaise, mustard, and sauces produces high-strength waste waters derived from equipment cleaning, but volumes are relatively small. Typically BOD values are 2700 mg l^{-1}, but overall waste generation is as low as 8 kg per 1000 kg product with waste-water volume 0.3 m^3 per 1000 kg product.

Canneries for soups and baby foods use a variety of vegetables, meat, starch, and fruit ingredients and process raw vegetables on site. Waste-water sources are similar for fruit- and vegetable-processing industries. Wastes vary greatly in volume and strength; typical waste generation is 12 kg per 1000 kg raw product, with BOD value of 560 mg l^{-1}.

Factories making jams, preserves, and jellies produce wastes from cleaning equipment and cooking vessels and are strong owing to dissolved organic materials. Examples are 3–7 kg BOD per 1000 kg finished product with BOD strength 1100–3600 mg l^{-1}.

Confectionery production and bakeries generate high CODs due to sugars and cream, particularly associated with cleaning of utensils and equipment. Pollution loads can be considerably reduced by 'good housekeeping' techniques of brushing and collecting dry materials spilled on floors rather than hosing into drainage channels. A modern bakery using dry cleaning methods and silicone grease may have negligible effluent.

In summary, the prepared foods industries generate typical food-processing wastes with high COD and BOD concentrations, and organic suspended solids. The wastes are comparatively low in nutrients (phosphorus and nitrogen). FOG concentrations are significant where there is frying. Waste volumes and loads vary greatly and the following have been reported for a variety of prepared-food manufacturers: BOD 310–3200 mg l^{-1}; COD 560–7000 mg l^{-1}; SS 200–3700 mg l^{-1}; total P 4–22 mg l^{-1}; N 13–76 mg l^{-1}; FOG 82–2000 mg l^{-1}; with volumes 2.4–85 m^3 per 1000 kg and waste loads 5–26 kg BOD per 1000 kg, 9–53 kg COD per 1000 kg of production, and 1–21 kg SS per 1000 kg of production.

Fish Farming

Fish farms continuously abstract high-quality river or borehole water which is returned to the river contaminated by fish excreta and fish food residues. These large volumes impose considerable pollution loads on to rivers. Pollution is assessed by BOD, SS, and ammonia concentrations and stringent standards apply for Consents to Discharge. Consent is a legal document setting out the terms under which an industrial waste water may be discharged into a public sewer for conveyance, treatment and disposal by a water company in England and Wales (or local authorities in Scotland), or the terms under which the National Rivers Authority (or River Purification Board in Scotland) will allow a water company, local authority, domestic, or industrial effluent to be discharged into a watercourse. Consent values for fish farms may be absolute or differential, typically restricting the maximum increase in BOD, SS, and ammonia between inlet and outlet water to 3 mg l^{-1}, 6 mg l^{-1}, and 0.4 mg l^{-1}, respectively. Similar restrictions on increases apply to color (6 Hazen units), turbidity (3 Formazin turbidity units), and use of chemicals for controlling disease, e.g., Malachite Green (0.1 mg l^{-1}), formaldehyde (1.0 mg l^{-1}), and phenolic compounds (0.005 mg l^{-1}).

Cider, Perry, and Alcoholic Beverages

There is strong seasonal variation in effluent strength, peaking in late autumn with processing of new seasons' apples and pears. Effluents are characterized by low pH (a value of 5, sometimes offset where there is caustic washing of bottles), low SS (200 mg l^{-1}), soluble organic matter giving high BOD (1500–3000 mg l^{-1}), and COD (2500–5000 mg l^{-1}) and negligible nutrients (N, P).

Analysis of Food Effluents

The definitive guidelines for analysis of waters and effluents in the UK are the HMSO Blue Book series entitled *Methods for the Examination of Waters and Associated Materials*. First published in 1976, the series consists of individual books giving the methodology for both manual and automatic techniques for a specific parameter or groups of closely related parameters. Similar standard methods of analysis are used

in North America, Europe, and other developed countries.

The HMSO books are revised only occasionally and there is a tendency for the specialist laboratories to develop their own methods or new techniques and check them against those in the Blue Book. Thus, in 1991, little or no information appears in the Blue Book series on techniques such as capillary column gas chromatography, solid-phase extraction, gas chromatography mass spectrometry, plasma mass spectrometry, plasma emission, and automated discrete analysis. (*See* **Chromatography**: Gas Chromatography; **Mass Spectrometry**: Principles and Instrumentation.)

For routine work, the water companies generally take two types of samples from industrial and food-processing premises. First, spot samples are taken for quality control and compliance with the limits specified in the Consent to Discharge. Second, water companies take composite samples for charging purposes. Where treatment works discharge to rivers, trade wastes are charged on a volumetric and strength basis, the strength being assessed by a comparison of trade sample to domestic sewage using suspended solids and settled COD values. (At coastal sites, if there is no biological treatment, a strength factor based on COD is omitted since charges relate to the treatment given.)

Laboratories frequently observe that trade samples undergo a change in pH from the time of sampling to analysis, by as much as one pH unit. This is particularly noticeable with food wastes, although other factors such as the time lapse and storage temperature are influential.

The COD test is performed on the supernatant of the trade sample which has been settled for 1 h after the pH has been adjusted to pH 7. As a guide, trade samples are invariably stronger than they look. Sometimes settled CODs are higher than shaken values (i.e., unsettled CODs), especially when floating fats or greases are present.

Treatment plants for both sewage and trade wastes have biological capacity designed on a BOD basis. The variability in strength of food wastes requires a range of dilutions to be used to avoid all the oxygen being consumed during the 5-day BOD incubation period. A useful tip is to divide the shaken COD value by 8, the figure being indicative of the dilution factor to be used for the BOD test.

If chlorine is in an effluent, this should be removed before starting the BOD test. If the trade waste has a high or low pH, this should be adjusted to neutrality before starting the BOD test.

As a general guide for food wastes, the BOD value is approximately 50–75% of the COD value, and abnormally low ratios could indicate, for example, the presence of biocides.

The three most important routine analyses are BOD, COD, and SS, details of which are given below.

1. *BOD*. The amount of dissolved oxygen consumed by microbiological action when a sample is incubated for 5 days at 20 °C. Allyl thiourea is added to the dilution water if it is desired to inhibit nitrification in a sample containing nitrifying organisms, so as to obtain a value for carbonaceous BOD.
2. *COD*. The amount of oxygen consumed in a standard arbitrary manner with sulfuric acid and potassium dichromate upon boiling for 2 h.
3. *SS*. The solids retained after filtration through a glass-fiber filter paper (grade C, 70 mm in diameter) followed by washing and drying at 105 °C.

In certain instances more specific analyses may be required for analytes relevant to the particular food-processing operation in question. For example, dissolved or suspended tin may be a significant pollutant from canneries, or heavy-metal catalysts may be lost from hydrogenation facilities. It should be noted that in most of these cases significant pollution only arises from poor manufacturing control, and in these situations pollution also represents an economic loss.

The Use of Fresh Eggs

C G Belyavin, Chris Belyavin (Technical) Ltd, Newport, Shropshire, UK

Introduction

Eggs are an important part of the human diet in most countries around the world, and have been for many years. Concerns in recent years about the effects of egg cholesterol on heart disease have remained unproven. However, there has been a tendency for egg consumption per person per year to decrease in many societies over recent years, although the rate of decline has decreased, and in some countries, for example Italy and Austria, the downward trend has been reversed. The decline is partly as a consequence of an increase in awareness about a need for healthy eating and partly because of a change in people's living habits, with more married women working and a move away from a cooked breakfast, a traditional time for eating eggs, towards one based on cereal, toast, and fruit juice.

Egg production worldwide has more than doubled since the early 1960s. In 1961 Europe was the leading egg-producing region, accounting for almost 30% of the world total, closely followed by North and Central America and Asia. Today, Asia now has around 57% of world output, with North America and Europe in second and third places (**Table 1**).

Forecasts for 1999 indicated that production could exceed 46 million tonnes in that year and 47 million tonnes in the year 2000. Although there are some 150 or so countries in the world, the largest 50 poultry industries account for over 90% of world egg production. World trade in eggs is small, at around 1–2% of total production. The USA, The Netherlands, and China are the major exporters of eggs whilst Japan, Hong Kong, and Canada are the major importers.

Against the trend for increasing world egg production is this pattern of decreasing consumption per person per year. In the USA annual consumption per head of population has decreased from 390 eggs in 1952 to 242 in 1996. Figures for Europe are shown in **Table 2**.

In the UK in 1999, nearly 17% of eggs produced went into high-value egg products, showing an upward trend. A comparable figure for the USA would be nearer 30%. The remainder are either sold as shell eggs or are converted to liquid or dried egg as

a means of removing surplus shell eggs from the market. Therefore, the major use of fresh eggs is in their original form sold to consumers in shell as a food.

Storage and Shelf-Life Problems

Shell eggs are a fresh, perishable food and consequently are liable to the same deterioration in quality over a comparatively short period of time that can be associated with any other fresh food product. The problem in the case of eggs is increased by the fact that the shell of the egg is porous and, therefore, the internal contents, which represent the consumable part, are not totally protected from the external environment. This comes about because the origins of the egg were not as a human food but as a source of propagation for the bird and the egg represents a development chamber for the growing embryo. Therefore, the need for gaseous exchange across the shell is inbuilt into the egg via the porous nature of the shell.

Storage Conditions

The conditions under which the fresh egg is stored will influence the rate of deterioration of its quality. However, even the most carefully controlled storage conditions can do no more than slow down the rate of subsequent deterioration. Ideally, eggs should not be stored for more than a few days, although they can remain consumable for up to 21 days after packing.

The rate of deterioration is closely related to the loss of carbon dioxide through the shell and the consequent increase in alkalinity of the albumen. At higher temperatures the rate of carbon dioxide loss is increased and the egg appears stale within a few days. Lower temperatures result in a slight loss and the structure of the egg is maintained at an acceptable level for several weeks.

This tendency towards a deterioration in quality leads to a number of problems with the storage of hen eggs for human consumption. Quality loss manifests itself primarily as the loss of moisture through the shell. There is a breakdown of the egg albumen (white), causing it to spread on breaking the egg, a characteristic not popular with consumers. Essentially it is the thick gel-like albumen which slowly breaks down, resulting in more and more thin, watery albumen. These changes, occurring in the rest of the egg, are associated with a change in proportion of thick to thin albumen.

The egg yolk becomes enlarged, flattened, and mottled and the cushioning effect of the thick albumen is decreased. With advancing deterioration, the yolk becomes detached from any remaining thick albumen. These changes give the egg a stale appearance which is unacceptable.

As the storage temperature is raised the rate of quality deterioration accelerates. At a constant temperature, quality loss is most rapid in the first 2 or 3 days. At high temperatures, the albumen deterioration is substantial and occurs within hours of the egg being laid. Consequently if eggs are to be stored they must be collected frequently and placed in a low-temperature store as soon as possible.

Egg Weight Loss

The porous nature of the egg shell results in egg weight loss under storage conditions. The most important factors influencing egg weight loss are temperature and humidity. As the temperature rises, weight loss becomes increasingly rapid. Relative humidity also influences weight loss and this effect is particularly important at high temperatures. After the first 3 days the weight loss of eggs stored at both a constant temperature and constant relative humidity is almost linear – the same amount is lost each day.

Egg Storage

Egg storage needs to be considered from the point of view of short-, medium-, or long-term storage. Egg quality deterioration and weight loss, as described above, only become excessive when the storage temperature approaches 21 °C. In many countries around the world this temperature is not achieved for prolonged periods of time and is therefore not a problem in the context of short-term egg storage. If higher temperatures are a problem, or longer-term storage is planned, then sophisticated cooling techniques are

needed and the procedure for egg handling is governed by the requirements of the stored eggs. The longer the storage period, the more precise must be the environmental control.

If the eggs are maintained at a temperature of 8–10 °C and a relative humidity of 85%, the quality deterioration and weight loss are slow. Providing the initial egg quality is good and that only intact and naturally clean eggs are stored, they can be held under these permitted controlled conditions for 6–8 weeks and still remain acceptable. Once eggs are removed from such storage conditions to an environment compatible with that found in a supermarket, egg quality deterioration and weight loss are rapid.

Refrigeration is the only means by which eggs can be stored for long periods of time (several months). A temperature of 0 °C and a relative humidity of 85% close to the eggs is essential. Such storage is not encouraged within the European Union (EU) and a regulation states that eggs which have been refrigerated in premises artificially maintained at a temperature less than 5 °C shall not be sold as class A, first-quality eggs.

A further problem associated with egg storage is the persistent risk of condensation on the egg surface which can result in mold growth. If warm, moist air is allowed on to the eggs while in store or as they are being removed from the store, condensation or sweating will occur at certain temperature and relative humidity combinations.

Within the EU eggs that have been washed also cannot be sold as class A first-quality. This regulation applies because of the negative effect on microbiological keeping quality resulting from washing. In some countries, particularly the USA and Australia, egg washing is routinely carried out on all eggs produced for human consumption. Where practiced, egg washing should be carried out to strict standards in terms of water temperature and hygiene.

In some countries eggs are sprayed with an odorless, colorless vegetable oil to prevent loss of moisture and carbon dioxide from the egg during storage. As summer temperatures in several countries can exceed the optimum storage temperature for eggs for prolonged periods of time, this technique helps to prevent rapid deterioration of egg quality but does not improve microbiological keeping quality of eggs kept dry in stores. The oil is generally applied as the eggs move from the washer to the grader or as they move in their boxes along the packing line. The application of the oil is by finely calibrated spray, usually from above, and the oil runs down the egg to give it a complete covering.

Handling and Marketing of Fresh Eggs

In recent years there has been a marked change in attitude and requirements in relation to egg marketing which has significantly influenced the way that eggs are handled over the last 10 years.

Major retail groups (supermarkets) account for a large proportion of the sales of the eggs produced in the UK and, consequently, the requirements laid down by these groups very much influence the policy of the industry as a whole within the UK. It is likely that the market share of such retail groups will continue to increase as consumers respond to quality assurances offered by such groups.

The handling policy now implemented by major egg-marketing companies is one of getting eggs from the point of production to the point of sale as quickly as possible. Eggs have to be treated as a fresh food. A typical time scale now applied would be 48 h at most from production site to retail outlet.

This means that production sites may well be directly linked to, or be situated close to, a packing and quality control center. Where the production facility is not close to a packing center, or eggs have to be held for any period of time (maximum 3 days) prior to packing, they will be held in a short-term store controllable, to provide conditions in line with those described above, to insure the maintenance of optimum quality standards.

Mechanical handling of eggs is now a feature of any modern production and packing plant. Eggs would be transferred from the point of laying via narrow belts to slatted cross-conveyors capable of carrying 150 eggs per meter run of conveyor, moving at a speed of around 4 m min^{-1}. Depending on the production facility, the conveyor would either take the eggs directly into a grading and packing machine or to a farm packing machine which would place the eggs in trays containing either 20 or 30 eggs for subsequent transfer to a plant for grading and final packing. In the latter case the eggs would be stacked on pallets or trollies, each holding around 3200 eggs for easy handling by forklift truck or other means. The eggs would be transferred to the packing plant in temperature-controlled vehicles in most cases (**Figure 1**).

Eggs are a fragile product and are very susceptible to damage. Approximately one in 10 eggs (10%) fails to reach the market place as a grade A, first-quality egg, and the majority of those downgraded eggs are substandard as a result of shell damage or faults. Therefore, correct handling procedures at all stages of the egg collection and handling processes are fundamental to maintaining egg quality.

Figure 1 A temperature-controlled egg transporter. Courtesy of Thames Valley Foods Ltd.

Figure 2 A modern egg-grading and packing machine. Courtesy of Deans Food Group Ltd.

Egg Packing

On arrival at the packing plant the eggs are transferred from the main conveyor, if the production plant is close by, or from the pallets or trollies on to the grading and packing machine (Figure 2). The Dutch and Americans dominate the world market for egg-grading and packing equipment and such machines can grade and pack up to 100 000 eggs an hour. On such machines, egg quality is assessed by a combination of computer-controlled detection of cracks, dirt, and internal blood spots with visual candling involving one or two operators. This process involves shining a light into the whole egg while rotating it to emphasize shell faults and make some of the contents visible to the naked eye. The eggs are then automatically sorted into various sizes by weight prior to packing and selling. Electronics and computerization are playing an increasing role in the operation of a modern egg-grading and packing machine.

The EU operates a four-weight category system ranging from eggs weighing less than 53 g (small) up to eggs in excess of 73 g (extra large). The weight sizes are separated by 10 g bands, 53–63 g being medium and 63–73 g large. The USA operates a six-grade system with a minimum net weight per dozen as follows: jumbo (30 oz.), extra large (27 oz.), large (24 oz.), medium (21 oz.), small (18 oz.), and peewee (15 oz.). In some countries, typically the Middle and Far East, eggs are not graded into sizes prior to sale but are sold by the kilo.

A typical modern UK egg-packing station or plant should be built to food factory specifications and regularly inspected by its customers and DEFRA (Department for Environment, Food and Rural Affairs) egg inspectors, who will check for compliance with EU regulations relating to egg marketing. It would ideally be situated with no production source further than 75 miles (120 km) away, although its market could be several hundred miles away. Eggs can be laid and packed within 24 h, and with the customer within a further 24 h in recognition of the need for a fresh product at consumer level. This requires, and enables, full benefit to be made of egg cooling and the development of a 'cool chain' from producer to retailer. In the UK at least, eggs are not displayed in cool cabinets in retail stores.

A modern egg-packing plant in the UK selling eggs to major retailers could handle 800 combinations of eggs and packaging, taking into account sizes, brands, and pricing. A single plant could be servicing 2100 retail outlets, but only 10 major customers, and packing some 1.6 million eggs a day. The operation, including distribution, could require a staff of 220 working an 8-h shift 5 days a week. Five hours a day would be spent on cleaning operations and the maintenance of hygiene. It should of course be remembered that many much smaller operations exist in any egg production industry around the world and the standards set and achieved may vary considerably.

The management of a large, modern operation needs to coordinate the supply, packing, and distribution and would depend very much on computer technology to do this. Sales information and analysis would be produced and a rolling 5-year plan would be maintained.

Packaging

Egg packaging is an important aspect of handling and selling and represents about 50% of total packing costs. There are many different types of egg packaging, ranging from fiber trays holding 20 or 30 eggs to specific packs made from fiber, plastic, or polystyrene, or even biodegradable materials to comply with concerns of environmentalists. Such packs would generally contain six, 10, 12, or 18 eggs. Niche markets, such as organic and eggs rich in omega-3 fatty acids, have developed for shell eggs as well as those from alternative production systems such as free-range and barn, and the packaging will be used to sell eggs and the egg concept (Figure 3).

Figure 3 Egg-packaging material used for the distribution and marketing of eggs. Courtesy of Thames Valley Foods Ltd.

Egg packs are and will be used to promote an image giving more information on the production system and methods. Value-added shell egg products, such as extra fresh, can only be promoted through the packaging design.

Eggs from Other Species

Traditionally, it is the hen's egg that is most widely used for human consumption and around which modern poultry breeding and egg-marketing techniques have been developed. Eggs from other species, if consumed, tend to be a specialist product sold in exclusive restaurants or stores. A typical example of this would be quail eggs in aspic. Turkey eggs are not generally sold for human consumption and are used more for breeding to produce turkey meat for human consumption. Human consumption of duck, goose, and pheasant eggs is negligible and of no commercial significance today. Eggs from waterfowl are nutritionally richer than those of domestic fowls as their yolks comprise about 36% of the egg's total weight, compared to 30% for hens. The consumption of duck eggs declined significantly because of fears relating to salmonella associated with them.

Use in the Food Industry

C G Belyavin, Chris Belyavin (Technical) Ltd, Newport, Shropshire, UK

Introduction

The majority of eggs produced in the world are sold in shell for consumers to utilize in the home in traditional ways or for baking. In the UK only 17% of eggs produced go into egg products and in the USA the figure is nearer 30%.

Traditionally, surplus eggs not required for the shell egg market (normally the smaller sizes) and downgraded eggs were turned into egg products. Today, farmers have specific contracts to produce eggs for further processing and any egg that is damaged cannot be used for this purpose. There are essentially three types of egg products: liquid, dried, or frozen, with small markets for peeled, hard-boiled and hard-boiled pickled eggs. The main products are used widely in the bakery and confectionery trades along with other industries. **Figure 1** illustrates the many uses to which processed whole eggs can be put and also shows the way in which whole eggs can be used to produce value-added products for the food industry without going through the process of pasteurization with or without subsequent drying. Value-added products in the USA are often made with pasteurized eggs.

World trade in liquid egg is in excess of 110 000 tonnes traded annually, some 80% of which is traded between EU member countries. Outside of this area, the only significant major market is Japan which purchases around 15 000 tonnes a year. The Netherlands are the number one exporter closely followed by Belgium, between them accounting for about 45% of the total world trade.

Some 28 000 tonnes of dried egg are marketed internationally. Japan and European countries are the major buyers, with the USA being the major seller.

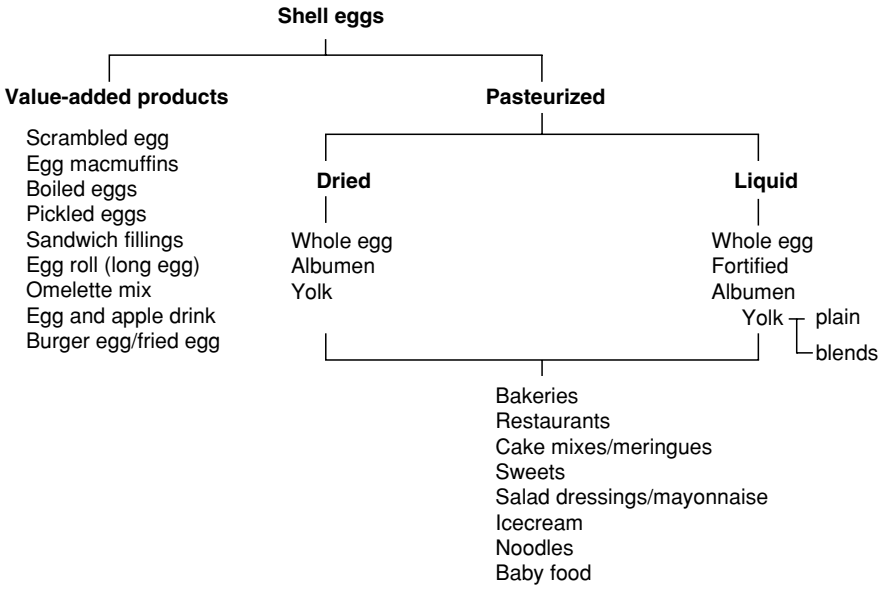

Figure 1 Eggs in the food industry.

When setting up an egg-processing plant it should ideally be located close to its supply of eggs. A constant supply of eggs is important in the efficient operation of the plant. The correct location enables the eggs to arrive at the plant in good condition, thus insuring that the resulting product is of good quality.

Liquid Egg Products

The production of liquid egg products takes place in specialist, large plants specifically designed for the purpose. Such a plant could process in excess of 36 million eggs a year. Mechanical equipment is used to break the eggs automatically and, if necessary, separate the egg yolk from the albumen. Such systems can handle up to 108 000 eggs an hour with electronic detectors to make sure that no yolk ends up in the white at the time of separation. A temperature of 10 °C is optimum for breaking and separating.

Further processing of eggs into liquid product is not a means of disposing of poor-quality eggs. In fact, the increasing concern about food safety and quality has meant that only surplus first-quality eggs and uncracked seconds are used in breaking plants.

At the time of breaking each egg will be visually inspected, either automatically or by an operator, to insure that no undesirable material is passed into the further processing line. Any eggs seen to be unsuitable will be rejected from the system at this stage and disposed of. The contents from the broken eggs are then passed through a sieve to remove any remnants of shell, the chalazae, which are the strands of protein which hold the egg yolk in place, and any other undesirable material.

About 50% of total liquid egg production in the USA is in the form of whole egg (yolk and albumen) and some may be fortified by the addition of extra yolk to increase the ratio of yolk to albumen over and above that found in a normal egg. The balance is divided between production of the separate components, i.e., either albumen or yolk. Liquid yolks may be sold as plain yolk or special blends such as sugared yolk or salted yolk. Such products not only meet the needs of specific customers but the addition of these agents to yolk also helps to maintain the consistency of the yolk, as without these natural additives it tends to separate into a thin liquid surrounding a congealed core if it is frozen. Whole egg tends to be standardized to a solids content of 24.7%. Separate egg white should not contain more than 0.03% yolk on a liquid basis and yolk tends to be standardized to a solids content of 43%.

In the past all these products would have been frozen rapidly in a blast-air freezer and held in this form until used. However, there has been a tendency in large-scale plants to chill the products and handle them as a fresh food, transporting them in refrigerated vehicles to their point of use. In this case, whole egg and yolk liquids are chilled to 4.4 °C and egg albumen to less than 7 °C. In this form the shelf-life of the product is only about 4 days but the costs of canning and freezing are avoided. Freezing is still adopted for small-scale use of liquid egg.

Bakeries as a group are the largest users of whole egg and separate albumen. Mayonnaise

manufacturers and salad dressing makers use large quantities of salted yolks and icecream makers use sugared yolks. Noodle makers and processors of baby foods use plain yolks.

Liquid egg or egg products are pasteurized (Figure 2) during their manufacture to prevent organisms such as salmonella becoming a major health hazard during their subsequent use and particularly after the eggs are removed from storage. Legislation to enforce this was introduced in the UK in 1964 and in the USA in 1966. The pasteurization process in the UK involves subjecting the product to a temperature of 64.4 °C (148 °F) for 2.5 min for whole eggs. Comparable figures for the USA are 60 °C (140 °F) for 3.5 min. Albumen is more susceptible to heat and so a slightly lower temperature is used, whereas the reverse is the case for yolk, where any salmonella is more heat-resistant. The alpha-amylase test is routinely used to test for adequate pasteurization.

Traditionally, liquid egg products were packed in metal cans or transported by large tankers. Today, modern packaging machinery enables the product to be put in large plastic bags contained in rigid outers and each bag can contain 500 kg of liquid egg which is drained from the container by means of a tap inserted in the bottom. The bag is then disposed of and the outer is returned to the manufacturer to be refilled. Product can be put into smaller cartons (Figure 3) which can be supplied to retail outlets for direct sale to consumers or larger cartons for supplying to hospitals and institutions. This is an expensive way of producing liquid egg because of the cost of the packaging. In these cases, liquid whole egg would be used for making scrambled egg and omelettes, for example.

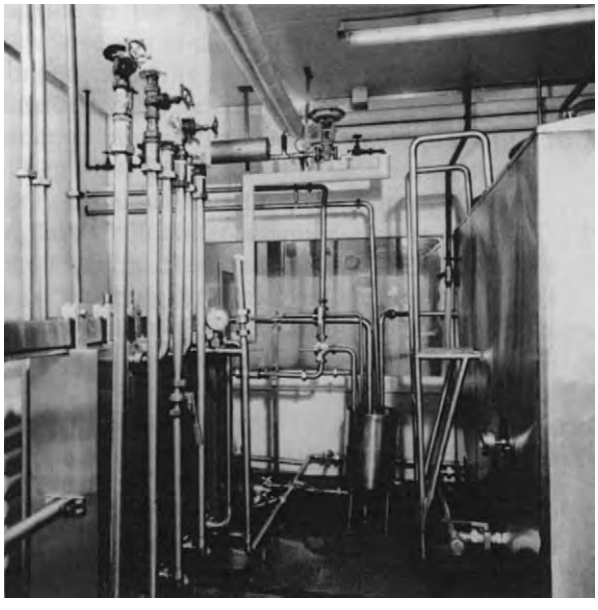

Figure 2 A liquid egg pasteurization plant. Courtesy of Oasters–Fridays (Cranbrook) Ltd.

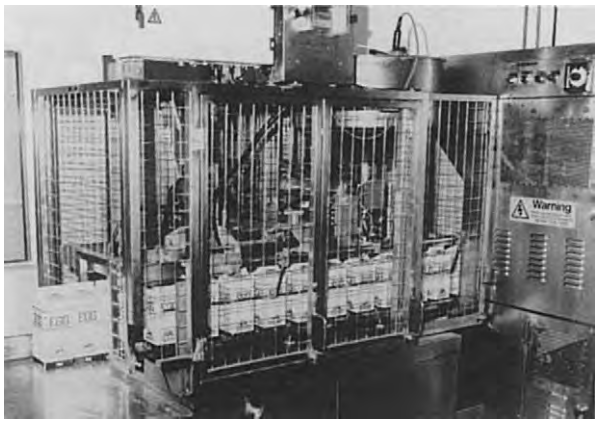

Figure 3 Liquid egg being packed into small cartons for retail sale. Courtesy of Oasters–Fridays (Cranbrook) Ltd.

Over the last 10 years, the production of egg products has been seen as the way in which any decline in egg consumption can be reversed. Consequently, a more diverse range of products is now available, including burger eggs, fried eggs, and meringue mix.

Freezing of Liquid Egg

If liquid egg is going to be frozen, to maintain a quality product, it is important that the freezing process should be rapid and that the frozen product should be stored at a low temperature. Cans of chilled egg should be subjected to an air blast at −30 to −40 °C to insure total freezing within 24 h, producing a uniform product without coagulation of the yolk. Subsequent storage should be at −10 to −20 °C. (*See* **Freezing**: Operations.)

Production of Egg Powder

The production of dried egg products is a further step beyond pasteurization. Spray drying is now the most common method for producing egg powder. However, some egg white is pan-dried and some whole egg is freeze-dried. Dried-egg products have a number of advantages which are listed below.

1. They can be handled and stored with ease and at low cost.
2. They are ready to use immediately with no thawing.
3. They are easy to handle in a hygienic way.

4. They are easy to remove from the container without scraping.
5. No bacterial growth can occur in powder at room temperature providing it is kept dry.
6. There is good uniformity.
7. There is precise control over the amount of water used in formulation.
8. There is no loss when used because dried egg is usually added directly to the batch.
9. No special transfer or storage equipment is needed.
10. Because the moisture content is reduced from around 74% to 2–4% by weight, there is a reduction in weight and volume and a concentration of food value.

A possible disadvantage of powder compared to liquid egg is a loss of 'fresh flavor' and a loss of certain functional properties such as aerating power unless treated with nonreducing sugars prior to heating. This, however, limits its use because of the sweetened nature of the powder.

There are now several different types of dried-egg products available which can be summarized under four major headings: dried egg white, dried plain whole egg and yolk, dried blends of whole egg and yolk with carbohydrates, and special types of dried-egg products.

The growth in egg drying is well illustrated by reference to the USA. Prior to 1941, less than 1% of the eggs produced went to drying plants. Government purchases stimulated drying operations to such an extent that 20 400 tonnes were produced in 1941, 107 000 tonnes in 1942, 118 000 tonnes in 1943, and 146 000 tonnes in 1944. The current annual volume is over 180 000 tonnes. A 30-dozen case of shell eggs will yield about 18 kg of liquid whole egg or 4.5 kg of dried product containing 2.5% moisture.

The handling of shell eggs prior to drying is no different from the handling of eggs that are to be kept liquid. The liquid material is put through a clarifier to remove any bits of shell and is then screened to remove the chalazae and vitelline membranes. Pasteurization is important, not only to control salmonella infection, but also to preheat the liquid so as to insure a low-moisture powder that will not show any scorching. A typical egg-drying plant is shown in Figure 2.

The liquid egg is then pumped under pressure of 17 250–34 500 kPa (2500–5000 lbf in^{-2}) to nozzles through which it is released into a large chamber where it immediately comes into contact with a stream of air that has been heated to temperatures of 120–175 °C. The enormous surface area created by atomization causes instantaneous evaporation of most of the moisture from the egg material and the formation of powder which falls to the floor as a fine powder while the moist air passes on out of the drying chamber at a temperature of 65–71 °C. It is important that the spray drier is designed so that the product stays at relatively low temperatures throughout the drying system and that the dried product is removed from the hot-air stream as rapidly as possible.

Modern driers produce a powder in which the moisture content does not exceed 2%. The temperature of the powder as it leaves the drier may be 65 °C or higher, and this must be reduced quickly to less than 29 °C if the product is to have good keeping qualities. Since the powder is extremely hygroscopic, the temperature must be reduced by contact cooling rather than by exposure to cold air. Two different powder-cooling methods are commonly used: first there is pneumatic conveying with cooling air and second, mixing the powder with carbon dioxide in the form of dry ice. After cooling, the powdered eggs are then packed immediately in sealed containers. Many of them are packed in carbon dioxide to remove the oxygen and lower the pH value in order to improve the keeping quality of the product.

Egg white can be dried in pans rather than through a spray technique. Pan-dried egg white can be in the form of flake or granular albumen or can be milled to a powder form. This form of egg albumen tends to have good whipping properties once reconstituted.

Chief users of dried-egg products are cake mix manufacturers, sweet makers, and manufacturers of meringue powders and, to a lesser extent, mayonnaise makers. Most dried-egg products made for commercial use are packed in polythene-lined boxes or drums. A common pack size would contain 25 kg of product. (*See* **Drying**: Theory of Air-drying.)

Quality of Dried-Egg Products

The quality of dried egg or dried-egg products can be affected by a number of factors. Important are quality of the eggs broken out to make the original product, handling methods, sanitation practices, conditions during processing, pasteurization procedures, drying, and the conditions under which the products are held in storage. Glucose (0.3–0.5%) is removed from liquid egg white prior to drying by fermentation using a yeast or bacterial culture, or by oxidation to gluconic acid using a glucose oxidase–catalase enzyme system. With glucose removed, dried egg whites are completely stable. If glucose is not removed, the product would be unstable because reducing groups from the glucose would combine with amino acids in the protein, leading to a condensation

reaction which would be followed by browning and the development of insoluble proteins. There could also be the development of off-odors and the loss of some functional properties during storage. Plain whole egg and yolk can be pasteurized and dried without removal of the glucose and consequently these are the least stable of the egg products.

Physical properties important in relation to dried-egg products are: bulk density, dispersibility, solubility, and reconstituted viscosity.

Storage of Dried-Egg Products

One of the real advantages of dried-egg products is their ease of storage. Most are relatively stable when stored at room temperature. Dried egg whites can be held under almost any storage conditions for an indefinite period of time. Dried products containing whole egg and yolk should be under refrigeration if held for long periods of time. Some of these are relatively stable at room temperature, particularly those where the natural glucose has been removed prior to drying.

Other Uses of Eggs in the Food Industry

Although liquid egg and dried egg still account for the majority of egg used in the food industry, there are other products which have evolved during the last 10–15 years which are commercially available.

The mass production of hard-boiled eggs has developed in recent years. Normally, white eggs are used in the process rather than brown because the shells remove from white eggs easier than from brown, resulting in less damage to the finished product. In countries where brown egg production predominates, such as the UK, this means that white eggs may have to be imported for the process from countries such as Denmark. However, in recent years flocks of white-egg-laying hens have been established in the UK specifically to supply the processing industry.

Again, only good-quality eggs are used in the process so that the final product is also of good quality. Normally in European Union countries small eggs would be used (under 53 g) for boiling as there is little demand for these sizes of egg in the shell egg market.

The eggs are gradually boiled as they move around a trough arrangement containing high-temperature water, with the objective of them being hard-boiled by the time they have completed a single circuit of the trough. The eggs are then removed, deshelled, and cooled. Once hard-boiled, the eggs can be used for a number of products. They can be pickled in jars in plain vinegar or with spices. They can be used in pies or salads and a major use in this form is in airline meals. Eggs damaged during the boiling or shelling processes would not necessarily be discarded. They can be diverted to the manufacture of sandwich fillings, such as egg mayonnaise, which can be packed into 5-kg tubs for distribution to sandwich manufacturers and the catering trade.

Problems associated with large-scale boiling of eggs, apart from that of deshelling, include optimizing the temperature for both the boiling and cooling processes, effluent discharges, and the prevention of black rings occurring at the junction between the yolk and the albumen. This is associated with the breakdown of sulfur-containing amino acids in the albumen producing hydrogen sulfide which reacts with iron released from the yolk to form iron sulfide.

Hygiene Measures

In all egg-processing plants producing egg products for human consumption a strict code of practice relating to hygiene is essential. Conventional egg products must now meet strict chemical, physical, and functional specifications which include moisture, fat, protein, ash, glucose, reconstituted viscosity, whipping ability, as well as functional performance in the foods in which they are used. Also included are microbiological standards for total plate count, coliform, yeast and mold, *Escherichia coli*, salmonella, coagulase-positive staphylococcus, and *Clostridium perfringens*. (*See* ***Clostridium***: Occurrence of *Clostridium Perfringens*.)

Many plants have a resident food technologist responsible for implementation of a quality control program using an inhouse quality control and microbiology laboratory. Every batch of product produced would be tested for contamination and production plants would be swabbed twice a week to test for the presence of undesirable organisms within such a program.

Structure and Composition

W J Stadelman, Purdue University, West Lafayette, IN, USA

Introduction

The term 'egg,' as used in this article, applies to eggs produced by chickens, or other avian species, for human consumption. Material is presented covering the formation of the egg, which helps to explain the structure of the complete egg. The structure is then discussed, including some data on abnormalities that might be found. The third section covers composition of normal eggs and the possibility of modifying composition through changes in management, nutrition, or genetics of the hen.

Formation of the Egg

The egg of the avian species is formed in the ovary and the oviduct. Figure 1 is a schematic diagram of the reproductive system. The ovary of the female chick contains numerous immature yolks, far in excess of the total number of eggs that the hen will produce.

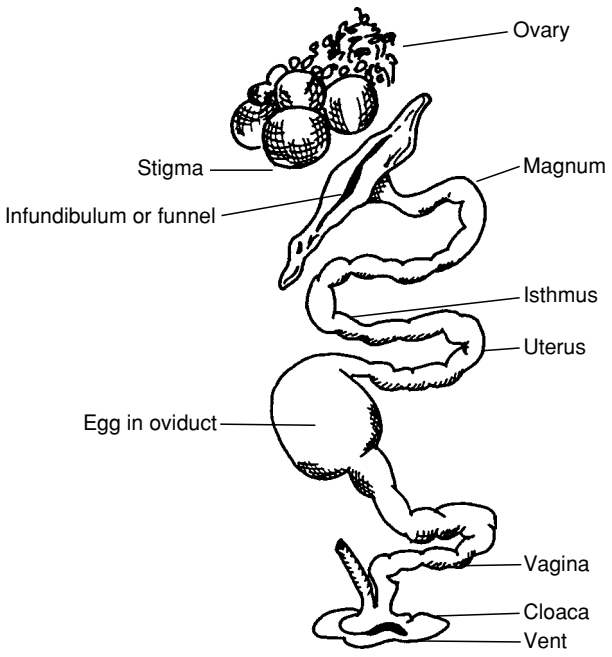

Figure 1 Schematic drawing of the reproductive system of a hen. Reproduced from Eggs: Structure and Composition, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The immature ovules remain small, about 1–3 mm in diameter, until about 10–12 days prior to ovulation. The yolk increases in size by the deposition of layers of yellow and white yolk material. Growth of the yolk from 6 to 35 mm in diameter occurs during the last 6 days prior to ovulation. The actual color of the yolk material is the result of fat-soluble pigments in the feed. The alternating yellow and white layers are the result of feeding schedules. During the last day of yolk development, a line of smooth muscle develops in the follicle surrounding the yolk. The area is known as the stigma. Just prior to ovulation, the stigma contracts, forcing blood from the surrounding blood vessels. The yolk is then released from the follicle and falls into the infundibulum, or funnel, of the oviduct. Formation of the egg white, shell membranes, and shell follows ovulation. The entire process from ovulation to oviposition (egg laying) takes 24–25 h in the hen.

The oviduct can be divided into five sections based on the portion of the egg produced in that section (Figure 1). These are the infundibulum, magnum, isthmus, uterus, and vagina. Each of these segments expand or shrink as the hen goes into or out of egg production. The weight of the oviduct of a hen in production is about 77 g and when she goes out of production the weight regresses to less than 6 g. When the hen returns to production the oviduct again increases to its previous weight.

The first albumen is deposited around the yolk in the posterior region of the infundibulum. This albumen is rich in mucin fibers. As the developing egg moves through the oviduct it rotates, twisting the mucin fibers to form the chalaza which tends to hold the yolk in the center of the completed egg. The yolk with adhering albumen then moves into the magnum region where more thick albumen is deposited around the forming egg. Most of the protein of the egg white is added to the forming egg in the magnum region of the oviduct. In the isthmus, the inner and outer shell membranes are deposited around the albumen. Through a mechanism called plumping, water is absorbed through the shell membranes and into the albumen, causing the egg to enlarge in size. Plumping occurs in the uterus where the shell is deposited. If a colored egg shell is produced, the pigment, an ooporphoren, is deposited on the surface of the shell in the posterior region of the uterus. Time spent in the vagina is short, but the protein cuticle or bloom is put over the shell in this region. Oviposition follows as the egg moves through the cloaca.

Time spent in each region of the oviduct is about 20 min in the infundibulum, 3 h in the magnum, 1 h in the isthmus, 20 h in the uterus, and a few minutes in the vagina. After the egg is laid, it cools to the environmental temperature from the body temperature of the hen, which is about 42 °C. During the cooling, the liquid shrinks slightly in volume. This reduction in volume causes a separation of the two shell membranes, usually at the large end of the egg, forming the air cell. As moisture and gases are lost from the egg during storage or incubation, the size of the air cell increases.

Structure of the Egg

The avian egg is a complex and highly differentiated reproductive cell. The structure of a cross-section of an egg is shown in Figure 2. Starting with the interior, component parts are yolk, albumen, shell membranes, and the shell.

Structure of the Yolk

The center of the yolk is the latebra, the immature ovule present in the immature pullet. The yolk material is deposited in concentric rings which vary in color depending on the feeding schedule and fat-soluble pigments in the feed of the hen. With normal commercial laying rations the rings vary as light and dark orange-yellow layers. During the yolk material deposition, the latebra neck keeps the germinal disk on the surface of the expanding yolk. The yolk is enclosed by a semipermeable membrane, the vitelline membrane. This membrane is usually about 0.025 mm thick.

Structure of the White

The inner thick or chalaziferous layer surrounds the vitelline membrane. The chalaza consists of mucin fibers which tie into the chalaziferous layer. The next layer of albumen is the inner thin layer, followed by an outer thick layer. The outer section is composed of thin white.

Structure of the Shell Membrane

The shell membrane is composed of two layers (Figure 2). The thickness of the two layers of the membrane varies among different breeds of chickens but is less than 0.02 mm. The membranes are composed of protein fibers that are arranged so as to form a semipermeable membrane. The passage of moisture and gases through the shell membranes is mainly by osmosis. The membrane is one of the primary barriers to bacterial invasion of the egg contents.

Structure of the Shell

The shell is organized as an inner mammillary layer, then a spongy layer, and finally, on the outer surface, the cuticle. The mammillary layer is composed of numerous roughly conical knobs or mammillae, which are oval-to-circular in cross-section. The outer ends of the mammillae are larger than the inner ends, so that spaces between the inner ends allow for a ventilation system which permits passage of gases throughout the shell just outside the shell membrane

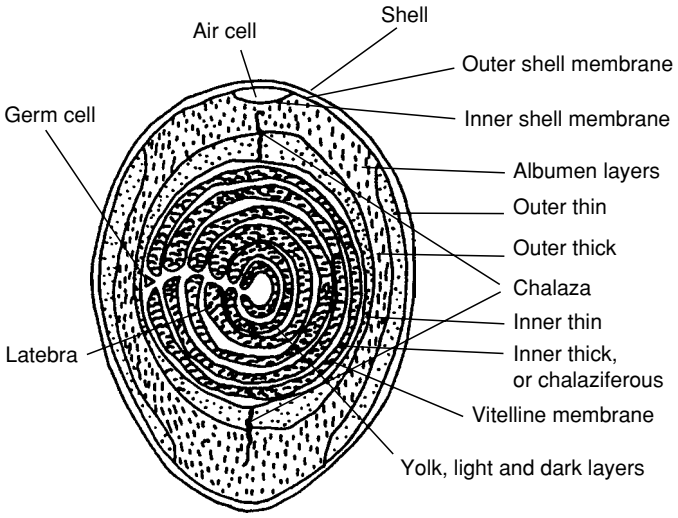

Figure 2 Schematic drawing of a cross-section of an egg. Reproduced from Eggs: Structure and Composition, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

layer. This structure allows gaseous exchange, which is essential for embryo development.

The spongy and mammillary layers are constructed in such a manner that there are numerous oval-to-circular openings through the shell. These are called pores. The normal egg has a greater concentration of pores on the large end, where the air cell is normally located, fewer in the equatorial region of the shell and fewest pores on the pointed end of the shell. The size of pores varies among shells of different hens, whereas eggs of a single hen are quite uniform in number, size, and distribution of the pores.

The outer surface of the shell is covered with a mucin protein which acts as a soluble plug for the pores in the shell. The cuticle is permeable to gas transmission.

Abnormal Eggs

The most common abnormality seen in freshly laid eggs is the double-yolked egg. Such eggs are produced when two yolks are released into the oviduct at about the same time. These eggs are most often produced by pullets just commencing egg production.

Meat spots in eggs are frequent. A meat spot is a bit of tissue from the lining of the oviduct. In white-shelled eggs, the spots are usually white and not noticed unless extremely large. Such large meat spots are removed during candling of market eggs. In brown-shelled eggs, most meat spots are brown and are thus noticed floating in the albumen. Again, large meat spots are removed during the candling operation. A less frequent abnormality is the blood spot. Blood spots are usually removed during the candling operation of shell-egg processing. Blood spots are most frequently found on the surface of the yolk and are the result of a drop of blood being lost from the capillaries of the yolk follicle at the time of ovulation. Blood-stained albumen is also possible if more than a drop of blood is lost during ovulation.

There are also abnormally shaped eggs owing to the malfunction of part of the uterus where the shell is formed. Rough-shelled and thin-shelled eggs are considered to be abnormal and are generally removed from a retail egg pack. Shell-less, thin-shelled, or soft-shelled (egg membrane only) eggs lack proper calcification. Many of these defective eggs are laid prematurely. The incidence of such abnormalities increases in aging hens that have been in production for more than a year.

Composition of the Egg

The avian egg is composed of all of those compounds needed for animal life, as evidenced by the hatching of a normal chick from a fertile egg. As a human food the egg contains all of the nutrients needed by humans with the exception of ascorbic acid (vitamin C).

The egg is naturally divided into the shell, egg white or albumen, and yolk. The shell is about 96% inorganic materials, largely calcium carbonate, with 4% organic material, largely protein, on a dry-weight basis. The egg albumen is primarily water, about 87%. The solids material is largely protein with small amounts of minerals and carbohydrates. The yolk is one of the most concentrated of all biological materials, with only 48% water in fresh egg yolk. The solids of egg yolk are made up of two-thirds lipid material and one-third proteins with small amounts of minerals and carbohydrates. The shell membranes are primarily proteins. Hens' eggs vary in relative amounts of the various parts but a general average is 10% shell, 1% shell membrane, 59% egg albumen, and 30% yolk.

Average proximate chemical composition of the edible portions of eggs is shown in Table 1. Refer to individual nutrients.

Egg Albumen Composition

There are a number of proteins in the albumen. Table 2 lists the identified proteins and gives some of the characteristics of each. The antibacterial nature of several of the proteins constitutes part of the defense against microbial invasions during the incubation of the egg. These defenses work equally well for shell eggs used as human food. These proteins have been separated and characterized. (*See* **Protein**: Chemistry).

Egg Yolk Composition

The egg yolk is a mixture of lipoproteins. An exception is phosvitin, which contains no lipid material and is a phosphoprotein. The protein content of yolk is about 16% and the lipid content varies from 32% to 35%, depending mainly on the strain of bird. The yolk lipid fraction is made up of 66% triglycerides,

Table 1 Ranges in chemical composition of the edible portions of eggs

Ingredient	*Whole egg (%)*	*Egg white (%)*	*Egg yolk (%)*
Water	72.8–75.6	87.9–89.4	45.8–51.2
Protein	12.8–13.4	9.7–10.6	15.7–16.6
Lipid	10.5–11.8	0.03	31.8–35.5
Carbohydrate	0.3–1.0	0.4–0.9	0.2–1.0
Ash	0.8–1.0	0.5–0.6	1.1

Table 2 Proteins in egg albumen

Protein	*Relative amount (%)*	*Characteristics*
Ovalbumin	54	Phosphoglycoprotein
Conalbumin or ovotransferrin	13	Binds metallic ions, iron, copper, and zinc
Ovomucoid	11	Inhibits trypsin
Ovomucin	3.5	Sialoprotein, viscous
Lysozyme or G_1 globulin	3.4	Lyses some bacterial cell walls
G_2 globulin	4.0 ?	
G_3 globulin	4.0 ?	
Ovoinhibitor	1.5	Inhibits serine proteases
Ovoglycoprotein	1.0	Sialoprotein
Ovoflavoprotein	0.8	Binds riboflavin
Ovomacroglobulin	0.5	Strongly antigenic
Cystatin	0.05	Inhibits thiol proteases
Avidin	0.05	Binds biotin

From Li-Chan ECY, Powrie WD and Nakai S (1995) The chemistry of eggs and egg products. In: Stadelman WJ and Cotterill OJ (eds) *Egg Science and Technology*, 4th edn. Binghamton, New York: Haworth Press with permission.

28% phospholipid, 5% cholesterol, and small amounts of other lipids. The major component of the phospholipids is phosphatidylcholine (73%), and other compounds are present in the following amounts: phosphatidylethanolamine, 15%; lysophosphatidylcholine, 6%; sphingomyelin, 2.5%; lysophosphatidylethanolamine, 2%; plasmalogen, 1%; traces of inositol phospholipid. The lipoproteins are classified as high-density lipoprotein (HDL), low-density lipoprotein (LDL), and very-low-density lipoprotein (VLDL). Density is determined by the percentage of lipid material in the molecule. The HDL fraction of the egg yolk consists of phosvitin and the livetins, α-, β-, and χ-livetin. These compounds all have less than 10% lipids. The LDL compounds are α- and β-lipovitellin and contain about 20% lipids. The VLDL lipovitellenin contains about 40% lipid. (*See* **Lipids**: Classification; **Lipoproteins**; **Phospholipids**: Properties and Occurrence; **Triglycerides**: Structures and Properties.)

Cholesterol in the egg is found only in the yolk. The concentration of cholesterol has been found to vary among hens The content of cholesterol per gram of yolk is relatively constant for a hen. For this reason, as the egg yolk size increases, the amount of cholesterol also increases. (*See* **Cholesterol**: Properties and Determination.)

Modifying Egg Composition

Composition of the egg varies slightly with egg size and to a greater degree among eggs from different hens, especially as hens of different strains are compared. The total solids content can be altered significantly by varying the proportion of yolk and white. Genetic selection has apparently made some change in the composition of hens' eggs, as evidenced by differences between the values listed in the US Department of Agriculture *Handbook 8.1*, published in 1973 and revised in 1989. One significant difference was in the saturated fat content of the egg which was found to be reduced by about 0.5%. Part of the difference might be attributed to changes in the diets fed to the laying hens. All nutrients in the egg, with the exception of zinc and choline, may be altered by feeding management or genetics, as reported by one or more research groups.

Modifying Shell Composition

The composition of the shell remains relatively constant, but shell thickness can be altered by reducing the calcium content of the diet. A vitamin D deficiency will also result in thin-shelled eggs. The composition of the shell does not change greatly, but the percentage of shell as part of the total egg may vary from less than 8% to over 12%. Shell membranes have not been found to vary significantly as a result of genetics, management, or nutrition of the hen.

Modifying Albumen Composition

The vitamin content of the albumen can be altered greatly by varying the vitamin content of the hens' diet. The mineral content can also be altered. The protein content remains constant for any hen but varies among hens from 9.7% to 10.6%. Specific amino acid content can be altered by dietary modification, but not sufficiently to affect total protein.

Modifying Yolk Composition

The fatty acid composition of hens' eggs can be altered by feeding fats of various composition to the hen. In addition, the vitamin and mineral content of the yolk can be changed by feeding.

Dietary Importance

W J Stadelman, Purdue University, West Lafayette, IN, USA

Introduction

Eggs are a complete food for a developing embryo of a chick. The only vitamin not found in eggs is vitamin C. Most nutrients in the egg are present in variable amounts depending on breeding, feeding, and management of the hens. The amino acids in the proteins of the egg are relatively uniform among eggs so that egg proteins are often used as the standard against which other protein food sources are evaluated in biological value studies.

Nutrient Distribution in the Egg

The proximate analyses of the edible portion of whole eggs, albumen, and yolk are given in Table 1 of the previous article **Eggs**: Structure and Composition. Values are included for pure yolk and commercially available yolk. The difference is that some albumen is included with the commercial yolk, as evidenced by a change in solids from 51.2% to 44%. The percentages of yolk and albumen vary among eggs from different hens and change with age of the hen, with the percentage of albumen increasing with age of the hen. For rough calculation the egg is composed of about 10% shell, 30% yolk, and 60% albumen.

The overall composition of the egg is influenced by breeding and age of the hens. Nutrition of the hen has little effect on the proximate analysis but can significantly modify the content of some of the nutrients in eggs.

Protein and Amino Acids

The egg white is a protein system consisting of ovomucin fibers in an aqueous solution of globular proteins. The thick and thin layers of egg white differ only in their ovomucin content. The protein fractions of egg white consist of ovalbumin, conalbumin or ovotransferin, ovomucoid, lysozyme, ovomucin, avidin, ovoglobulins, ovoinhibitor, and flavoprotein. The molecular structure and amino acid mapping of several of these proteins have been documented. (*See* **Protein**: Chemistry.)

The absence of lipid materials from the albumen makes possible the formulation of foods with the high protein quality of eggs and a complete absence of fats. The amino acid composition of the several component parts of the egg is listed in **Table 1**. It is apparent that whole egg, egg yolk, and albumen each have a good balance of amino acids. (*See* **Amino Acids**: Properties and Occurrence.)

Table 1 Amino acids in the edible portion of eggs (per 100 g)

			Yolk	
Amino acid (g)	*Whole*[a]	*Albumen*[a]	*Pure*[a]	*Commercial*[b]

[a]Based on data from USDA (1989) *Composition of Foods: Dairy and Egg Products*. USDA Handbook 8.1. Washington, DC: US Department of Agriculture.

[b]Based on data from Cotterill OJ and Glauer JL (1979) Nutrient values for shell, liquid/frozen and dehydrated eggs derived by linear regression analysis and conversion factors. *Poultry Science* 58: 131–134.

There are four major proteins in egg yolk. These are livetins, phosvitin, lipovitellins, and lipovitellenin. The livetins, (α, β, and χ) and phosvitin are classified as high-density lipoproteins; the lipovitellins (α and β) are classed as low-density lipoproteins and lipovitellenin is a very-low-density lipoprotein.

The amino acid balance of egg protein is almost perfect to meet human requirements. The amino acid content of eggs can be modified slightly by feeding and management programs. When hens are molted (loss of feathers), the cystine content of the eggs will be slightly reduced because of the high demand for this amino acid in the growth of new feathers.

Lipid Components

The lipids of the egg are all contained in the yolk in a fresh egg. There may be some migration into the albumen in stale eggs. Nearly all of the yolk lipids are present as lipoproteins. As mentioned above, they are classified as high-density, low-density, and very-low-density lipoproteins. The classification is based on percentage of the lipoprotein that is lipid material. The high-density lipoproteins contain very small amounts of lipid, usually less than 10%. Most human nutritionists consider the high-density lipoproteins to be desirable components of a diet. The low-density lipoproteins, α- and β-lipovitellin, contain about 20% lipids; lipovitellenin, the very-low-density lipoprotein, has 40% or more lipid content. This latter material is considered to be a harmful ingredient in the human diet as its presence tends to increase the serum cholesterol level.

A summary of lipid content is given in Table 2. The saturated fatty acids make up 38% of the total, monounsaturated fatty acids account for 46%, and the polyunsaturated fatty acids comprise the remaining 16%. The amounts of different fatty acids can be dramatically altered depending upon the fatty acids in the diet of the hen. (*See* **Fatty Acids**: Properties.)

A lipid component that has received much attention is cholesterol. According to the value given in Table 2, one large egg with a 17-g yolk has 213 mg of cholesterol. This is now considered to be the value, but a number of studies indicate a wide range of values, apparently the result of breeding, feeding, or management. Age of the hen will also influence the cholesterol content of an egg. This change is due to the increase in size of the yolk in eggs from older hens. The cholesterol level of an egg, on a per-gram-of-yolk basis, is relatively constant for any hen as long as the feed remains the same. The method of analysis for cholesterol in egg yolk can also influence results, as colorimetric methods generally give higher values than high-pressure liquid chromatography. Extensive works have been reported indicating that eggs in the diet of humans had slight or no effect on serum cholesterol levels in the blood.

Table 2 Lipid components of the edible portion of eggs (per 100 g)

		Yolk	
Fatty acids (g)	*Whole*[a]	*Pure*[a]	*Commercial*[b]
Saturated (total)	3.100	9.554	7.663

Minerals in Eggs

The egg is an excellent source of many of the trace minerals. The mineral content of egg components is listed in Table 3. The exact mineral content of the egg depends on the mineral content of the hen's diet. The content of all minerals analyzed for could be varied, with the exception of zinc. The minerals of the shell are not considered in the values given in Table 3 as the shell is not a normal item in the human diet. The shell is primarily calcium carbonate and could be a readily available source of calcium. Refer to individual minerals.

Vitamins in Eggs

The vitamins found in the egg vary with the level of vitamins in the layer's feed. The average levels of vitamins are given in Table 4. The fat-soluble

vitamins, A, D, and E, are found only in the yolk. Water-soluble vitamins are found in both albumen and yolk components. Refer to individual vitamins.

Designer Eggs

Niche markets for special eggs have resulted in some producers of eggs modifying the nutrient content of the 'normal' egg by enriching the diet of the hen with specific fatty acids, vitamins, or minerals. An example is the 'omega egg.' This egg is obtained by adding a rich source of omega-3 fatty acids (menhaden fish oil, specific algae products, or canola oil). The omega egg producers also increase the vitamin E content of the diet of their hens to get a higher level of both vitamin E and omega-3 fatty acids in the egg. The inclusion of omega-3 fatty acids in the human diet has been reported to reduce the incidence of heart-related problems. Other designer eggs can be produced with increased levels of vitamins, minerals, or other fatty acids. A likely future designer egg is one with increased conjugated linolenic acid.

General Considerations

The exact nutrient composition of eggs is dependent on many factors, including the breed or strain of the hen, age of the hen, diet of the hen, and other management factors.

The per capita consumption of eggs in the USA has declined significantly from a high of about 400 eggs per year in 1945 to a level of about 233 in 1990. The annual consumption of eggs then increased slowly to about 245 in 1998. The decrease in egg consumption has been attributed to three factors: (1) increased buying power, which allows consumers to purchase more expensive substitutes for eggs, such as meats and convenience foods; (2) changing eating patterns, including lighter breakfasts; and (3) concerns about the negative health effects of eating eggs – first the cholesterol issue and more recently the inclusion of *Salmonella enteritidis*, a pathogenic microorganism, in a low percentage of intact shell eggs. In 1990 over 20% of all eggs were converted to egg products prior to sale to the ultimate consumer in the USA. This percentage has increased to over 30% by 1998 as more convenience foods rich in eggs are being offered, as well as the fear of foodborne pathogen.

Microbiology

C E Clay, J L Lock, J Dolman, S A Radford and R G Board, University of Bath, Bath, UK

Introduction

The microbiology of eggs must be considered in a biological setting, namely their role in the breeding biology of birds. At the time of lay, an egg contains the nutrients, elements, and water required for embryo development. Natural selection has put in place a defense system that protects the food stored in the yolk from attack by saprophytic bacteria and microfungi. This article deals with the defense system of the eggs of domestic hens, the only species that has been studied in detail. It deals with the events that culminate in the breakdown of the defense system such that the yolk and white become grossly contaminated and, in most instances, markedly changed in appearance. Eggs may be endowed also with defense against pathogenic microorganisms harbored by the parents or present in the nest environment. This does not appear to have been studied in detail and will not be considered further.

The Defense

Physical and chemical systems contribute to the antimicrobial defense of an egg. The former resides mainly in the shell. Both systems occur in the albumen. The yolk appears to contain little, if any, defense against exploitation by saprophytic microorganisms.

The physical defense of the egg shell is most easily understood if its component parts are considered as resistances in series (**Figure 1**). The porous shell of calcite is bounded on its outer surface by a thin layer of glycoprotein, the cuticle (resistance R_1). At the moment of lay the cuticle is immature but it rapidly loses its amorphous state and becomes vesicular

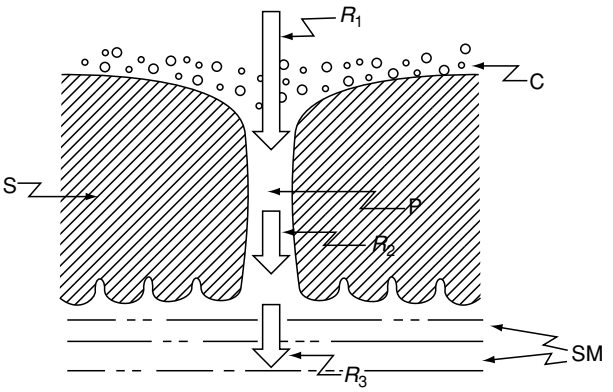

Figure 1 Schematic drawing of hen's egg shell in radial section showing the resistances (R_1, R_2, and R_3) to water movement. C, cuticle; P, pore; S, calcitic shell; SM, shell membrane. For further details, see Board RG and Sparks NHC (1991) Shell structure and formation in avian eggs. In: Deeming DC and Ferguson MWJ (eds) *Egg Incubation*. Cambridge: Cambridge University Press. Reproduced from Eggs: Microbiology, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

in structure with a fissured outer surface. Many of the fissures occur above the outer orifice of pores in the underlying calcite shell. These pores, which in the hen's egg have a straight posthorn morphology, number some $7–17 \times 10^3$ per shell and contribute resistance R_2 (Figure 1). The inner surface of the calcite shell is lined with two membranes. Both are formed from anastamosing fibers having a central core of elastin-like protein and a carbohydrate-rich mantle. These membranes constitute resistance R_3 (Figure 1).

If the germfree contents of an egg at oviposition are to become infected with saprophytic microorganisms, then such organisms have to penetrate the fissured cuticle, traverse the pore canal, and pass through the void spaces in the shell membranes. The agencies that promote translocation of microorganisms across the shell are considered below.

Any microorganism that penetrates the albumen encounters the principal defense system of avian eggs. The albumen contains upwards of six proteins having biological properties with the potential to kill microorganisms (e.g., lysozyme) or impede their growth (Table 1). Of the proteins cited in Table 1, ovotransferrin, a glycoprotein constituting about 12% of the total protein of egg white, plays a cardinal role. It binds two ferric iron atoms to a molecule at two different sites to produce a salmon-pink complex. The metal complexes dissociate in acid (< pH 6.5), but not in alkaline solutions (pH 9–10). Measurements of binding by equilibrium dialysis have shown that the binding constants for iron are very large (about 10^{30}). Changes in the pH of albumen favor iron sequestration by ovotransferrin as well as making egg white an unfavorable medium for microbial growth. At the time of lay, the albumen has a pH of 7.2–7.5 but, owing to the outward diffusion of carbon dioxide, the pH of the albumen drifts to a value of 9.0–9.5 within a few days when eggs are stored at ambient temperatures. The egg white is made an even more unfavorable medium for microbial growth through its minute content of combined nitrogen in a nonprotein form.

From a theoretical view point, lysozyme (a muramidase-*N*-acetylhexosaminidase, EC 3.2.1.17) would appear to be an important component of the antimicrobial defense. It hydrolyzes the β-4,1-glycosidic bonds in peptidoglycans, the exoskeleton of prokaryotic bacteria. Once lysed, this exoskeleton cannot prevent unfettered water uptake by the bacterial cell and the eventual lysis of its cytoplasmic membrane. Although lysozyme accounts for 3.4% of the proteins in the albumen, there is no compelling evidence that it has an important role in the chemical defense of the hen's egg.

Avian embryologists contend that the albumen supports the yolk and young embryo and cushions both from mechanical damage. The support stems from the viscous nature of albumen. Ovomucin is largely responsible for viscosity, and its contribution is augmented by electrostatic attraction between the negative charges of the terminal sialic acids of ovomucin and the positive charges of the lysyl Σ-amino groups of lysozyme. The viscosity of the albumen in a newly laid egg insures that the vulnerable yolk is held at the center of the egg and hence at the furthest distance from infection should microorganisms penetrate the calcareous shell and become lodged in the shell membranes. With storage, the albumen loses its viscosity, and the yolk floats upwards until contact is made with the inner shell membrane. In practice, therefore, the physical defense that the albumen contributes to the antimicrobial defense of eggs is transient. Moreover, there are reasons for believing that loss of viscosity favors bacterial movement in the albumen.

Table 1 Properties of the main proteins of hen albumen

Protein	*Amount in albumen (%)*	M_r	*Characteristics*
Ovotransferrin	12	80 000	Chelation of metal ions, particularly iron
Ovomucoid	11	28 000	Inhibition of trypsin
Lysozyme	3.4	14 600	Hydrolysis of β-1,4-glycosidic bond in peptidoglycans Electrostatic interaction with ovomucin
Ovomucin	3.5	ND[a]	
Ovoinhibitor	1.4	44 000–49 000	Inhibition of several proteases
Ovomacroglobulin	0.5	760 000–900 000	
Ovoglycoprotein	1.0	24 400	
Ovoflavoprotein	0.8	32 000	Chelation of riboflavin
Avidin	0.05	70 000	Chelation of biotin

[a]Value not determined or reported.

Course of Microbial Infection

It is generally accepted that the majority of hens' eggs do not harbor saprophytic bacteria or microfungi at the time of lay. The recent episode of egg-associated cases of food poisoning caused by *Salmonella enteritidis* phage type 4 (PT4) led to the contention that the egg contents may be infected during formation, by organisms either harbored by the ovaries (transovarian infection) or present in the oviduct (oviductal infection). A survey of upwards of 6000 eggs laid by hens known to harbor *S. enteritidis* PT4 demonstrated a low incidence (approximately 0.5%) of contamination of egg contents. Moreover, the majority of these eggs appeared to contain the contaminants in the albumen rather than the yolk. As yet there is insufficient evidence to draw conclusions about the behavior of salmonellae in eggs infected by the transovarian route during storage at chill or ambient temperatures. However, there is abundant information on the course of infection of eggs infected postoviposition with saprophytic bacteria or microfungi. (*See* **Food Poisoning**: Economic Implications; **Spoilage**: Bacterial Spoilage.)

With microfungi, contamination is confined to the shell's surface unless eggs are stored under very humid conditions. Under such conditions, hyphal development gives the shell a 'whiskery' appearance. Hyphae that penetrate the pore canals (Figure 1) spread progressively throughout the egg contents.

The available evidence suggests that free water and some agency to overcome the water resistance of R_1 and R_2 in Figure 1 are prerequisites for bacterial infection of the egg contents. If a warm egg is submerged in a cold suspension of bacteria, the decrease in volume of the yolk and white is greater than that of the shell. The partial negative pressure sucks water across the shell and lodges bacteria in the underlying shell membranes. The water resistance of the cuticle and pores (R_1 and R_2 in Figure 1) can also be overcome by imposing a positive pressure on eggs submerged in water or by suddenly releasing a negative pressure on eggs submerged in water.

Many studies have shown that Gram-positive bacteria, especially those of a coccal morphology, are the dominant contaminants on the surface of the shell. In contrast, the microflora of addled eggs is almost invariably dominated by Gram-negative bacteria (Table 2). The inference that selection of the latter at the expense of the former in the shell membranes has been supported by laboratory studies. (*See* ***Aeromonas***.)

The behavior of contaminants in the shell membranes is determined by storage temperature of eggs and the level of iron contamination of the water in which the contaminants were translocated across the shell. Storage of eggs at 4 °C selects psychrotrophic bacteria, such as *Pseudomonas putida*. At ambient temperatures, psychrotrophic organisms as well as mesophilic ones, such as *Proteus vulgaris*, occur in addled eggs.

Table 2 Types of organisms recovered from contents of eggs

Organisms	*Type of egg*	
	Rotten	*Tainted*
Coli-aerogenes	+	+
Proteus	+	−
Aeromonas	+	−
Pseudomonas	+	+
Alcaligenes	+	+
Achromobacter	+	+
Gram-positive	±	±

For details, see Board RG (1969) The microbiology of the hen's egg. *Advances in Applied Microbiology* 11: 245–281.

When relatively small numbers ($\leq 1.0 \times 10^3$ per ml) of bacteria suspended in water containing less than 1 μg of iron (Fe^{3+}) per ml are inoculated on to the shell membranes of recently laid eggs, very few organisms invade the albumen, and those that do appear to be in a quiescent state. At some stage in storage there is a rapid increase in the level of contamination of the egg contents and, when certain organisms are present, macroscopic changes in the white and yolk become evident (Table 3). The consensus of opinion is that a switch from the quiescent to active growth phase of contaminants in the albumen is the result of (1) chance collision of the contaminants with the yolk, or (2) contact of the yolk with an infected shell membrane. In either case, the yolk appears to short-circuit the chemical defense of the albumen by providing the contaminants with the Fe^{3+} which they require for growth.

If the water used to suspend bacteria contains > 1 μg of Fe^{3+} per ml, then there is a rapid build-up in the level of contamination of the albumen underlying the inoculated shell membrane, and a rapid onset of rotting of the egg contents, if appropriate organisms are present. In this situation, iron present in the water used to suspend the organisms is taken up by the mantles on the fibers of the shell membranes and used for growth by bacteria contained in the membranes. It is the continuous escape of organisms from the membranes that leads to a heavy contamination of the underlying albumen.

It was inferred above that only some of the organisms recovered from the contents of eggs cause macroscopic changes in the yolk or white. It is evident from

Table 3 Role of attributes of contaminants of addled eggs in the rotting process

Attribute	*Action*	*Organisms*
Pigment		
Nonwater-soluble	Discoloration of shell membrane at site of infection, occasionally in the white and on the surface of the yolk	*Cytophaga* *Flavobacterium* *Serratia*
Water-soluble	Discoloration of white	*Pseudomonas aeruginosa*, *P. putida*, and *P. fluorescens*
Proteases	Digestion of white and yolk	*Proteus* *Aeromonas*
Production of hydrogen sulfide	Blackening of the yolk	*Proteus* *Aeromonas*
Lecithinase	Breakdown of yolk emulsion	Coli-aerogenes
Slime production	Increase in viscosity of the albumen	Coli-aerogenes
Odor production	Characteristic odor emitted by infected eggs	*Pseudomonas maltophilia*
None of the above	No macroscopic changes even when eggs harbor 10^8 organisms per ml of albumen	*Alcaligenes* *Salmonella* *Citrobacter*

For further details, see Board RG (1968) Microbiology of the egg: a review. In: Carter TC (ed.) *Egg Quality – A Study of the Hen's Egg*. Edinburgh: Oliver and Boyd.

Table 3 that an organism needs one of four attributes in order to change the appearance of the yolk or white. Microorganisms lacking all of the attributes listed in Table 3 form populations of $>1.0 \times 10^8$ cells per ml of albumen without causing perceptible changes in the appearance of the yolk or white.

Nutritional Status

A Lehmann, Homerton Hospital, London, UK

Aging Populations

In the last 100 years, there has been a unique marked, continuing aging of the world's populations. Global life expectancy rose from 45 years in 1950 to 64 years in 1990; in the UK, for example, between 1950 and 2000, there was a fivefold increase in the number of people over 85 years old and a 10-fold increase in centenarians (in contrast, male longevity declined in Eastern Europe between 1960 and 1990). The increased life expectancy has been due to a reduction in younger mortality, mainly a reduction in infant mortality, but at present, the fastest growing age group is the elderly. In developing countries, the numbers and proportions of old people are rising with a 300% expected increase in the elderly populations this century (as yet, few demographic texts include epidemic HIV in their published calculations).

In the 1980s, it was hypothesized that increased longevity would be accompanied by 'compression of morbidity' into a shorter period at the end of life, and disability surveys suggest this may be happening very gradually. Nevertheless, the numbers speak very loudly in support of policies aimed at prevention and management of disability in old age.

Aging: Biology

The existence of a postreproductive lifespan in humans is unique among primates. Biological and social pressures are thought to have caused this evolution, e.g., by mother–daughter food-sharing, thus enhancing the daughter's fertility, or elders having knowledge of use at times of occasional disasters such as drought. Natural selection does not impact on individuals past child-bearing age: the aging process has resulted. It is no longer held that a few genes determine our aging rate: rather, the mechanisms are multiple and complex (even though a rare gene mutation may cause premature aging). Aging is likely to occur as a result of an accumulation of random cell and tissue damage, such as somatic mutations, oxidative damage, and the formation of aberrant proteins. The genes may affect somatic and intracellular responses to these random errors, and, of course, lifestyle, toxins, and the environment have profound effects on these processes.

It is important to grasp the consequent increase in variance of almost any parameter measured as people age. There is also a recurring question in old age research: which old people should be called normal? These two factors partially explain the relative delay in understanding the basics of nutrition in old age. It is generally believed that measures that might slow the aging process (as has already occurred to some extent) may also reduce illness and disability rates during old age. Hence the clinical importance of gerontology research.

Nutrition and Longevity. The Story of Dietary Calorie Restriction

It has been known for 60 years that there is one procedure that, if applied to laboratory rodents, reliably slows down the process of aging from a very early age (including prolongation of reproductive period) and in all its diverse manifestations: dietary caloric restriction (DCR). The control groups in some experiments were rodents fed *ad libitum* in captivity. Lengthy longitudinal primate studies are at present under way in the USA to test the potential role of DCR. It is not at present justifiable to extrapolate this finding and apply it to humans, although, presumably, such 'treatment' would reduce the morbidity associated with obesity. The population of Okinawa, Japan consumes fewer calories than other Japanese people, has a higher proportion of centenarians, and has lower overall death rates from both vascular disease and cancer. However, data below will demonstrate that demography and clinical research have most frequently highlighted the importance of undernutrition exacerbating the health of old people: if DCR is shown to have a role, it may be particularly so if started at a young age.

The Concept of Frailty

Frailty has been defined as the loss of a person's capacity to withstand minor environmental stresses. Although 'frailty' is sometimes used to avoid a precise definition of disability, in a more scientific way, it may be useful to help health workers understand what appears to be 'a syndrome of multi-system reduction in physiological capacity compromising an old person's function … and leading to unstable disability.' In frail elderly people, just treating the acute illness is often insufficient: in the clinical context, reduced musculoskeletal function, aerobic capacity, cognitive and neurological function, and nutritional reserve are the features measured to define frailty, because these deficits reduce the capacity for interaction with the environment. In an old patient presenting with an acute illness, all these different aspects of reserve and function need to be optimized if the patient is to have a chance of recovery. The frailty syndrome is sometimes seen as a downward spiral (or the 'dwindles' in the USA), and research confirms the frequently very major role of nutrition in the clinical context.

It is clinically useful to diagnose frailty by measuring the four key capacities, thereby identifying elderly people at risk of unstable disability with a view to reversing these problems if realistic. The suggested methods for measuring the components of frailty for muscle function include grip strength, ability to stand from sitting, aerobic capacity by measuring a 6-min walk in outpatients or a treadmill test, various cognitive tests, and practical functioning tests to assess the mind; and for nutritional state, body mass index (in people unable to stand or markedly kyphosed, demispan or other measures can be used to estimate skeletal size). (*See* **Nutritional Assessment**: Functional Tests.)

Nutrition, Diabetes, and Vascular Risk in Migrant Populations

It has been documented repeatedly that populations of apparently all genetic descents *other* than from temperate climates appeared to change from virtually zero rates of vascular disease associated with obesity, diabetes, hypertension, and hyperlipidemia (and a combination of these – syndrome X) to very high rates and severity of these if they moved from a rural, underdeveloped life to a 'western'-type urban lifestyle. All these conditions are age-associated illnesses and occur at younger ages, even sometimes at reproductive ages in women, and more severely than in European-descent populations. The changes can occur within one generation and are generally believed to be due at least in part to dietary changes in combination with reduced energy expenditure sometimes. This susceptibility to the Western lifestyle is found in genetically extremely diverse populations from Melanesia, the Indian Subcontinent, and Africa, and indigenous Indian people in the Americas, etc. Hunter–gatherers, who were the evolutionary ancestors of Europeans in a temperate climate, may have evolved in response to increased meat-eating and reduced vegetable intake in such a way that does not affect fertility. Increased fat intake has been suggested in the etiology of diabetes, e.g., in the Pima Indians. Several intervention studies support this hypothesis, e.g., if Australian Aboriginal people eat their traditional diet for 5 weeks, it very quickly reverses the diabetes and obesity that they present with. Baschetti has emphasized the role of high-density energy foods in causing these pathologies in susceptible populations and stated that the concentration of sucrose should not exceed $4.18\,\mathrm{MJ\,l^{-1}}$. Dietary potassium (in vegetables and fruit) is reduced by Westernization, and, since it is protective in this context, it has been suggested that potassium be added to drinks. Tropical and subtropical diets have a much larger ratio of vegetables to animal intake compared with those from temperature climates and it is interesting that the traditional Caribbean diet is closest to the present UK government recommended diet.

The high rate of vascular diseases in populations of tropical or subtropical descent is not purely due to these factors. Social factors are very significant, too, poverty being responsible for about 38% of the excess stroke morbidity in Afro-Americans compared with Euro-Americans. The potential health gains from lifestyle modification, however, clearly merit investment in appropriate education and facilities.

Usual Weight Changes During Aging

Both undernutrition and obesity jeopardize the health of old populations all over the world, particularly in urbanized societies. Most data derive from developed countries. Figure 1 shows the usual changes observed cross-sectionally in a representative UK sample.

The average trend of a slight slow weight loss after the age of 60 has been found in numerous surveys (see Table 1): one exception to this was a study in New Mexico on volunteers with no health problems and whom the authors described as socially privileged and unusually health-conscious. (Exclusion of any health problems in a UK community survey in Nottingham, which excluded old people living in institutions, would have meant that 95% of the elderly volunteers would have been excluded.)

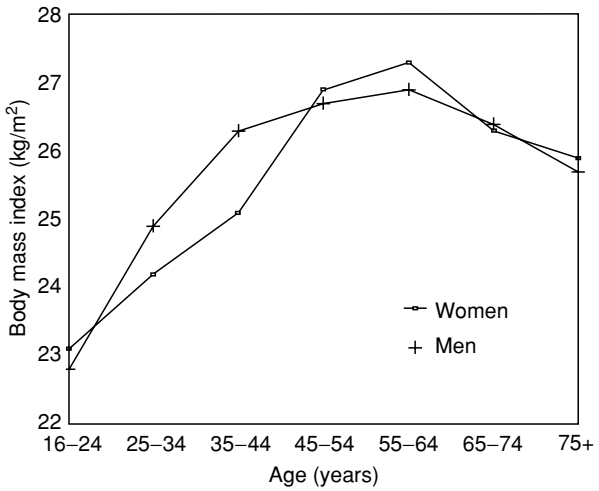

Figure 1 Mean body mass index by age and sex: health survey for England.

Explanations for the slight but distinct tendency for weight loss in old age are awaited. Metabolic changes so far studied during aging would be compatible with a tendency to gain weight. It has been suggested that appetite is reduced during aging by neuroendocrine changes. This 'anorexia of aging' should not be confused with the distinct epidemiology of old patients who notice anorexia and mention it to the health team, and in whom a search for a specific cause has a high yield. Low income, poor dentition, and solitary eating may be important, as may be rising taste or smell thresholds for which there is ample evidence. Since about 95% of the elderly population living in the community in the UK have some illness or limitation, these conditions, the drugs prescribed for them, or the social consequences of them also play a role. Resting metabolic rate is lower in older subjects, even after correcting for the changes in body composition, so this alone would cause weight gain if the diet were to remain constant or adjusting to energy expenditure. One hypothesis that might explain the observed changes and for which there is some limited support in research might be that, as we age, the energy costs of daily activities increase. Several authors have demonstrated that weight stability is associated with the best health in old age. The converse has also been shown: that weight loss is the most ominous predictor rather than thinness itself. People who are observed to be thin in old age include three groups: those who are lean and fit throughout life, smokers who are lean and not so fit, and those most at risk who have lost weight recently. This last group may be perceived as frail.

Body Composition Changes

During aging, there is a tendency for centripetal redistribution of fat, which is variable and includes internal fat deposition. The consequent practical problems for practitioners is the reduced use of limb subcutaneous fat measurements to reflect total body fat. Likewise, in old women especially, this trend plus height loss associated with osteoporosis may produce apparent abdominal protrusion and a very common false label of obesity by doctors assessing on the basis of abdominal examination. Muscle mass decreases during aging, although physical training can to some extent modify this trend. In illness or trauma, dehydration is very common in old people as kidney water conservation ability falls with age, and the threshold to thirst commonly rises with old age.

Gut Changes During Aging

For most purposes, these are negligible in terms of the old person's nutritional status. Probably, the most significant change is oral health, in particular the dental health, which, time and again every year,

Table 1 Longitudinal studies reporting weight change in old age arranged in descending order of magnitude of weight change found (combined group of men and women)

is shown in many studies to be a relevant factor in explaining undernutrition in the elderly. Esophageal motility may become disordered occasionally during aging, but a much more common finding is in the stomach, where gastric acid production may be reduced. The importance of this in terms of health is particularly the increased risk of gastroenteritis because the acid barrier is reduced. The small bowel and large bowel have a considerable reserve function, and aging *per se* is unlikely to affect this unless of course diseases develop.

What is Optimal BMI in Old Age?

With this question comes that of 'who defines the norm'? Tables most widely available for adults are based on young white volunteers. There are only a few longitudinal data available at present upon which to base BMI advice for elders in any population, and tables are mostly norms using percentiles based on cross-sectional studies, point surveys, and 'healthy' elderly volunteers rather than on health outcomes, unfortunately. As with all BMI descriptive data, the BMI norms have increased, particularly in Westernized societies, first in the USA and now in Europe. The norms established in the 80s were apparently no longer valid in the 1990s. The definition of 'norms' is particularly problematic in old age: in a typical UK community free-living volunteer elder population, only 5% of the over-65s have no medical problem. If all illnesses were excluded in establishing norms, these tables would be based on 5% of the elderly population – who could thus be described as super-fit elders. Compared with our knowledge about younger people, this state of ignorance regarding old people and BMI needs explaining, and may reflect the lack of research investment by public bodies and private companies.

Population Studies

A 1996 review on BMI in old age relied on data from a 1979 survey (Build Study) and had no people aged over 69 (see Table 2). What can be seen from this table, however, is that the optimum BMI in terms of mortality apparently rises very significantly with age. In Finland, a whole population local survey in Tampere of people aged 85 years and older showed a correlation between longer survival and higher BMI (see Figure 2).

A very large US survey of 22 000 subjects also showed a flattening of the U-shaped curve relating BMI to mortality with increasing age cohorts. The obesity risks of vascular disease and cancer do not disappear in old age, but it has been argued that selective survival of those less vulnerable to these risks occurs. The Nottingham Longitudinal Study of Activity and Aging, which measured BMI and health in 629 relatively well but not super-fit elders living in the community at the time of the initial survey, interestingly showed neither an increase in morbidity nor an increase in mortality in the low BMI volunteers initially and at 4-year follow-up. One possible explanation for this apparent anomaly is that whereas most population surveys include significantly disabled or ill elderly subjects, if these people are excluded, thinness has no apparent ominous significance, at least not over 4 years. This fits with the emphasis many authors and clinicians have put on nutrition *reserve* in elders and the importance of regaining this reserve after intercurrent illness or trauma. Nevertheless, the subject cannot be said to be fully understood as yet, and confounders are very likely to be significant and to vary from sample to sample. What the data do suggest, however, is that if old people are fit, well, and mobile, thinness has little ominous significance, but in any studies that include hospital attenders, it appears that thinness is a very powerful predictor of poor outcome.

In terms of disability prevention, the data from the US National Health and Nutrition Examination

Table 2 Effect of age on body mass index associated with the lowest mortality[a]

Age group (years)	*Body mass index (kg m^{-2})*	
	Men	*Women*
20–29	21.4	19.5
30–39	21.6	23.4

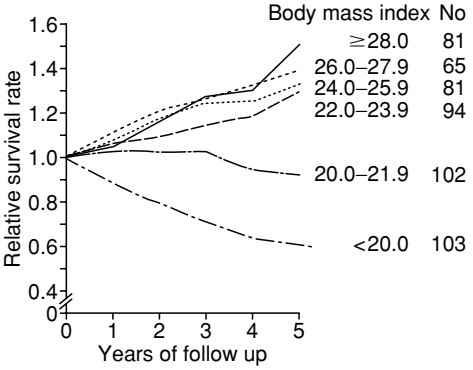

Figure 2 Five-year relative survival curves according to body mass index in subjects aged 85 and over.

Survey (NHANES) in 1994 supported the U-shaped curve hypothesis: *both* extremes of BMI in elderly volunteers apparently independently predicted worse functional status (independence in activities of daily living) (Figure 3). In the old group of women who had lost more than 5% of their weight over 8–16 years, there was an associated doubling in the rate of mobility disability, even after adjustments were made for age, smoking, and education. Weight loss rather than thinness was again the main predictor of poor outcome. In a detailed description of the NHANES follow-up, it was found that the initial BMI at both 15% extremes was an independent predictor of disability in old men and old women, even 11–13 years later, even after correcting for 22 potential confounders, and even after excluding those who died within 2 years of the first survey (in whom, it might have been argued, weight loss was a result of illness).

BMI ranges are therefore a changing phenomenon over time both within and between elderly populations. At present, outcome data are lacking on which to base advice to an elderly person regarding optimum weight, except that overweight is clearly related to joint pains. Survival is reduced in thinner elders overall, but a high waist–hip ratio is probably not advisable in the presence of hypertension, vascular disease, or diabetes.

Table 3 Factors associated with high-risk undernutrition in old age

Environmental causes

Hospital Patients

Surveys of nutritional status and health in old age that include disabled, ill, or traumatized elderly patients consistently highlight thinness and recent weight loss as powerful ominous independent predictors of health outcome. Although, with different methods, hospital inpatient surveys yield a wide range of prevalences for undernutrition in old hospital inpatients, in the UK, 40% is accepted by Government Department documents. The commonness of thinness in old inpatients may explain why staff (unlike relatives) usually miss the diagnosis and has prompted the growth of screening tools of varying efficacy. Research suggests that, so far, no questionnaire screening tools to be administered by nurses on general wards are safe, unlike their use by dieticians, and safer alternatives are either anthropometry or simply an eyeball estimation of whether the patient is thin, average, or fat: the nurse is asked to tick the relevant box. (*See* **Nutritional Assessment**: Functional Tests.)

The association and ominous significance of malnutrition with illness and disability are likely to be complex. In some cases, the illness or disability, or their attendant pharmacological and social consequences, may precede and cause negative energy balance. In others, the causal relationship may be reversed. In the clinical context, therefore, it is crucial to tackle both the illness and the malnutrition, if appropriate, and, to avoid recurrence, an attempt should be made to determine the sequence of events in each individual: sometimes, a third factor will have caused both the illness and the malnutrition simultaneously. In a study on very acute illnesses leading to old people's admission, using retrospective dietary histories, it was found that, compared with control groups, these patients had had lower dietary intakes over the preceding month – even though the criterion for inclusion was that the patients were absolutely fine the day before the day of admission. This suggests that

undernutrition may cause or precede very acute illness. Of course, in the clinical context, the reverse is also often found.

Frequently, depression and physical illnesses present simultaneously in the elderly, and in many, a vicious circle is present by the time treatment starts: malnutrition can perpetuate anorexia by increasing small bowel microbial overgrowth, which is even more likely to follow undernutrition in the elderly than in children because of the high prevalence of age-associated achlorhydria (in atrophic gastritis, now known to be due to *Helicobacter pylori* infection) in elderly patients. When depression and anorexia are both very marked and coexist in old age, endoscopy is indicated. In stroke patients, weakness in swallowing is commonly compounded by starvation from the time of stroke, and tube feeding is required to correct this starvation weakness of the bulbar muscles.

Negative energy and nitrogen balance very quickly and severely impair immune function, even in fit elderly volunteers, and even within 9 weeks of starting on an equal-calorie but low-protein diet. In the clinical context, it has been demonstrated that a low lymphocyte count, which can have numerous causes (e.g., inflammation, undernutrition), correlates closely with the risk of readmission of the patient.

What is less well known in elderly care is the importance of careful management of the refeeding syndrome, and work is awaited to see whether this and consequent hypophosphatemia are being missed, as is our clinical impression, in a number of cases of elderly patients in hospital. (*See* **Elderly**: Nutritionally Related Problems; Nutritional Management of Geriatric Patients; **Phosphorus**: Properties and Determination; Physiology.)

In rehabilitation wards for the elderly, research has confirmed very elegantly that poor nutritional status on admission and, in particular, weight loss during the preceding year are the most powerful independent predictors of poor outcome, even after correcting for numerous potential confounders, including 22 that did correlate with outcome. Equally important randomized controlled trials of nutritional supplementation have demonstrated lasting positive outcomes in elderly hip fracture patients and pneumonia patients: functional ability in the long term benefitted from the intervention, and average hospital stay was shortened.

When viewed together, these data explain the primary concern regarding undernutrition in elderly patients and consequent rejection of blanket obesity-avoidance advice intended for other adults, which is sometimes inappropriately followed by old patients.

-Specific nutritional deficiencies in hospital patients
Certain micronutrient deficiencies in old inpatients denote specific pathological conditions. Iron deficiency in old age (in particular postmenopause) in developed countries is due to gut pathology (e.g., ulcer or cancer) in over 90% of cases, according to two London studies. Vitamin D deficiency may be due to anticonvulsant medication, folate deficiency may reflect anticonvulsant medication but, more commonly, inadequate diet due to poor self-care, and this is common in early dementia. It was so common that it was thought to cause dementia, although, at present, the consensus appears to be that early dementia leads to difficulty organizing food if people are living on their own, and the first lab routine test to show this is folate. Folate deficiency is also very commonly associated with alcoholism. (*See* **Elderly**: Nutritionally Related Problems.)

Immobility itself in old age has been shown to be associated with more rapid protein turnover than is seen in fit peers: it was demonstrated long ago that, in the UK, housebound elderly people are in negative nitrogen balance. If protein turnover is more rapid in the elderly during immobility (and endocrine mechanisms are possible), a slight imbalance of intake or expenditure will lead more rapidly to more muscle loss while the body prioritizes visceral protein synthesis. This may explain the downward spiral of frailty sometimes seen in ill, traumatized or disabled patients.

Nutritional Status in Elderly Nursing Home Residents

Undernutrition is very common in this group. Many residents barely eat enough to maintain basal metabolism. The reason for poor nutritional status in advanced dementia may vary, and research has produced a range of answers, including insufficient time spent helping at meal times, inappropriate food consistency, and possibly a change in energy balance control. Drug effects on appetite or bowels and nutrient utilization also need to be considered in each case. Energy expenditure generally drives energy intake in humans – if an old person is less mobile, their appetite will therefore be reduced and micronutrient deficiencies will, and often do, result if the nutrient density of the food is not appropriately increased. Vitamin D deficiency is common in housebound elders without access to sunlight, and sufficient vitamin D consumption would require an unacceptably high intake of fatty fish. Quite why there are such high rates of general undernutrition in this group, however, is unclear, even if the individual micronutrient deficiencies are easier to explain. (*See* **Elderly**: Nutritionally Related

Problems; Nutritional Management of Geriatric Patients.)

In 1995, the Caroline Walker Trust produced multidisciplinary guidelines for optimal nutrition for institutionalized elderly. It is written to be understood by service users and service providers, and covers food provision, dental checks, weight monitoring, etc. plus triggers for referral for medical review (any unexplained 3-kg weight loss). The importance of formulating an individualized plan suitable for each elderly resident is emphasized.

Ethical questions regarding the degree of intervention considered appropriate in terminal illness and in dementia frequently occur in this setting. In several observational studies in nursing homes investigating the management of advanced dementia patients who appear not to be eating enough, tube feeding produced no benefit in terms of comfort and none in terms of survival.

Nutritionally Related Problems

J B Blumberg, Tufts University, Boston, MA, USA

Introduction

Nutrition influences the progressive loss of tissue function with aging and plays an important role in the genesis of several major chronic degenerative diseases. Aging influences nutritional requirements and nutritional status through changes in appetite and in pathways of nutrient absorption, utilization, and excretion (**Table 1**). Further, a variety of socioeconomic and psychological factors as well as the presence and treatment of current disease(s) common to older adults affect dietary patterns and nutritional status. Thus, some of the nutritional problems of the elderly are the consequence of long-term (chronic) interactions between diet and aging, beginning in adolescence and young adulthood, while others are associated with the more immediate (acute) result of old age itself.

Acute nutritionally related problems

Anemia

The most consistently reported hematopoietic change with aging is a higher prevalence of anemia which increases with each successive decade of life. Although anemia is prevalent among healthy elderly, its cause does not generally appear to be due to hemolysis or deficiencies of iron, folate, or vitamin B_{12}. Elderly people with this unexplained anemia have lower leukocyte and neutrophil counts than do nonanemic subjects. Experimental and clinical studies

Table 1

Change in physiologic function	*Change in nutrient requirement*
↓Muscle mass (sarcopenia)	↓Calories
↓Bone density (osteopenia)	↑Vitamins D and K, calcium
↓Immune function (anergy)	↑Vitamins B_6, C, and E, zinc
↓Skin cholecalciferol synthesis	↑Vitamin D
↑Winter parathyroid hormone production	↑Vitamin D
↓Calcium bioavailability	↑Vitamin D
↓Hepatic uptake of retinol	↓Vitamin A
↑Oxidative stress status	↑β-carotene, vitamins C and E
↑Levels of homocysteine	↑Folate, vitamins B_6 and B_{12}
↓Efficiency in pyridoxal utilization	↑Vitamin B_6
↑Gastric pH (gastric atrophy)	↑Vitamin B_{12} and folic acid, calcium, iron, zinc

suggest this anemia of aging is due to a reduction in bone marrow reserve capacity (erythropoietin-dependent progenitor cell proliferation) with decreased hormonal responsiveness to hematologic stress. Chronic inflammation is also a possible mechanism. However, any elderly individual with anemia must be fully evaluated for the possibility of drug-induced or occult gastrointestinal blood loss, bone marrow failure, chronic hemolysis, and nutritional deficiency before attributing an anemia to age alone.

Anorexia and Weight Loss

A decline in calorie intake is a well-recognized concomitant of increasing age. Surveys reveal that almost 20% of older adults consume less than 1000 calories (4.2 MJ) per day; among institutionalized elderly and those whose income is at poverty levels, the prevalence may increase twofold. Protein-calorie malnutrition is a common finding among geriatric patients. Marasmus may occur in older patients because the combination of a small but balanced caloric intake with a contribution from muscle-protein catabolism is sufficient to maintain serum albumin. Thus, weight loss is an ominous sign in the elderly which needs to be taken seriously.

The etiology of anorexia and weight loss in the elderly is multifactorial and includes both physiological and pathological causes. Age-related declines in metabolic rate due to loss of lean body mass (sarcopenia) and decreased expenditure of energy on physical activity contribute to lower calorie intakes in the elderly. Social factors such as poverty, isolation, and requirements for assistance with food shopping and preparation can be a source of impairment to adequate nutrition. Physical factors such as disabilities or immobility and poor oral health can also interfere with conducting activities of daily living associated with nutrition.

Psychiatric disorders, e.g., dementias and depression, as well as states associated with bereavement and isolation affect nutritional status. These conditions are not uncommon among the elderly and are usually associated with anorexia and weight loss. Among institutionalized elderly with low body weight and at risk of malnutrition or B vitamin deficiency, a higher prevalence of dementia and depression is noted. Indifference, memory loss, impaired cognition, and disturbed or erratic behavior associated with these conditions all contribute to reduced food intake. Inadequate nutrition may further exacerbate psychiatric symptoms. Experimental studies suggest an increased activity of the hypothalamic–pituitary–adrenal axis production of corticotropin-releasing factor and/or neuropeptide Y may be involved in the anorexia of some of these psychiatric conditions.

Several diseases common among the elderly affect food intake. Chronic obstructive pulmonary disease increases the effort required to eat. Congestive heart failure is associated with anorexia which is aggravated by the cachexic effect of cardiac glycosides used to treat the condition. Some cancers and all antineoplastic drugs can precipitate anorexia. Esophageal reflux can lead to pain on swallowing and decreased food intake.

Anorexia may also occur as a concomitant of normal aging. Gustatory papillae begin to atrophy in middle age and taste and olfactory thresholds increase with age. Studies in old animals indicate a reduced drive in the endogenous opioid feeding system, particularly the κ-receptor ligand dynorphin, and the increased satiety action of the gastrointestinal hormone cholecystokinin may provide a biochemical basis for the anorexia of aging.

Constipation

Constipation is a common complaint among the elderly, with women reporting this difficulty more frequently than men. The discomfort associated with constipation may affect an older person's food intake. The tone of intestinal smooth muscles and gastrointestinal tract activity diminish with age. However, the lack of dietary fiber, dehydration, and/or immobility appear to be the primary causes of most cases of uncomplicated constipation. A variety of drug treatments common among elderly patients, particularly those with anticholinergic actions, may also cause severe constipation. The requirement for assistance in using the toilet may cause an older adult not to respond to the urge to defecate which can result in a later inability to defecate at will due to desensitization of rectal stretch receptors. Important complications of constipation in the elderly include fecal impaction, abnormally large colon, and intestinal obstruction. Also, straining at stool may create sudden severe circulatory changes in the aged. In most instances, the treatment of simple constipation in the elderly includes advice to increase fiber consumption (and fluid intake) in the diet and/or as supplements (e.g., vegetable mucilloids and modified cellulose products). The pathogenesis of another age-related condition of the colon associated with the absence of fiber in western diets is diverticular disease.

Dehydration

Thirst and water intake are critical to the maintenance of fluid and electrolyte balance since it is only through such intakes that water deficits can be

replenished. Fluid and electrolyte disorders are common in the elderly and abnormalities in salt and water homeostasis are a significant cause of morbidity and mortality in geriatric patients. Older adults respond to dehydration with greater increases in plasma sodium concentration and osmolality than young subjects, yet do not become markedly thirsty and drink enough to dilute their body fluids to predeprivation levels. Thirst in response to heat stress and thermal dehydration is also reduced in the elderly despite a reduced capacity for thermoregulation (heat loss).

The mechanism of the thirst deficit in the elderly is not fully defined. Age-related changes in receptors that detect dehydration of the cell (osmoreceptors) and decreases in plasma volume (baroreceptors) and in the endogenous opioid system have been suggested to play a role in this condition. Changes in renal function with age, such as diminished glomerular filtration rate, urinary concentrating ability, and sodium-conserving capacity, can act to reduce the ability to conserve salt and water and predispose an older person to hypovolemia and dehydration. The decreasing activity of the renin–angiotensin–aldosterone system with age may also contribute to diminished sodium and water homeostasis in the elderly.

Older adults may become dehydrated when exposed to even mild stresses such as water restriction, fever, infection, or diarrhea. When the diminished thirst response in an elderly individual is accompanied by illness or physical incapacity that increases water loss or prevents access to water, dangerous dehydration may follow. In the elderly, dehydration is a common cause of renal impairment and failure and electrolyte disturbances. Dehydration and hyponatremia can also lead to confusional states that further interfere with fluid intake. While the extent of dehydration in free-living elderly has not been established, age-related impairments of thirst sensation place them at risk of dehydration.

Gastric Atrophy

Selective functions of the digestive tract experience some diminution of function with age, although many of these changes do not appear significantly to influence nutrient requirements in the elderly. An increased incidence of gastric acid hyposecretion (hypochlorhydria) resulting from atrophy of the gastric glands of the fundic mucosa of the stomach is noted among about 30% of people over 60 years. This gastric atrophy (type A) is asymptomatic but, when the condition is severe, is associated with pernicious anemia due to a decreased secretion of intrinsic factor. Gastric atrophy is also associated with faster gastric emptying rates and a higher pH with bacterial overgrowth in the proximal small intestine. These latter effects of gastric atrophy may interfere with the bioavailability of several nutrients, including calcium, iron, folic acid, and vitamin B_{12}. In addition to absorbing or utilizing these nutrients, the overgrowth of some aerobic organisms may contribute to the nutritional status of the host via the synthesis and secretion of some nutrients, e.g., vitamin K. The high intraluminal pH of the stomach and proximal small intestine found in gastric atrophy may also prevent the release of some nutrients from dietary fiber or protein and other food complexes. Dietary recommendations for several micronutrients should be adjusted for older adults with gastric atrophy and include the use of appropriate nutrient supplements.

Chronic Nutritionally Related Problems

Cancer

Cancer develops as a result of interactions between genetic and environmental factors. An estimated 90% of all cancer cases are attributed to environmental factors, including tobacco smoking, radiation, industrial pollutants, viruses, and diet. Analyses of epidemiological studies suggest that 35% of cancer deaths may be related to diet. Evidence linking diet and cancer has been derived from experimental *in vitro* and animal studies, metabolic and biochemical studies in humans, and epidemiological investigations. In general, the epidemiological studies have demonstrated that populations migrating from an area with its own pattern of cancer incidence rates acquire rates characteristic of their new location. Further, large changes in incidence rates for many types of cancer within genetically stable populations have been associated with changes in dietary patterns. Although the cumulative data for the relationship between both the causal and protective effects of diet and cancer are compelling, the evidence, particularly with regard to quantitative levels of specific nutrients, remains far from conclusive.

Various studies indicate that a high intake of total fat increases the risk of some types of cancer, notably cancer of the breast and colon but also of the prostate, rectum, and ovaries. Cancer mortality correlates better with total dietary fat intake than with the type of fat. However, several epidemiological studies have demonstrated a strong relationship between saturated fatty acids or animal fat and increased cancer risk. In contrast, animal studies indicate monounsaturated and *n*-6 polyunsaturated fats promote carcinogenesis more effectively, while *n*-3 fatty acids can reduce tumor growth rates. Several mechanisms have been proposed to explain the effects of fat on

cancer, including its alteration of steroid hormones and endocrine changes, immune function, cell membrane fluidity, and (for colon cancer) fecal floral and bile acids. Excess body weight and obesity are also associated with an increased risk of several cancers, including those of the breast, endometrium, ovaries, colon, rectum, prostate, and gallbladder. Other dietary factors, including alcohol and naturally occurring contaminants, e.g., aflatoxins and *N*-nitroso compounds, also pose a potential cancer risk.

Dietary patterns emphasizing foods high in fiber are associated with low rates of certain cancers, especially breast and colon cancer. The protective effect of fiber may be due to a concomitant reduction of total calories and fat and/or by altering gastrointestinal factors such as intraluminal pH, gut flora, and transit time. Fiber-containing foods such as fruits and vegetables are also important sources of β-carotene, vitamins A, C, and E, phenols, and indoles as well as a large number of other phytochemicals with potential cancer-preventive activity. Generous dietary intakes of β-carotene are associated with a reduced incidence of lung, breast, oral mucosa, bladder, and esophageal cancers; however, clinical trials with large supplemental doses of β-carotene resulted in an increased risk of cancer among smokers. Vitamin C has a potentially protective effect against esophageal, stomach, cervical, breast, and lung cancers. Low intakes of vitamin E are strongly correlated with risk of cancer in many, but not all, organs. β-carotene and vitamins C and E may share a related antioxidant, free radical scavenging mechanism against carcinogenesis. Evidence also suggests that calcium and selenium have protective effects against some forms of cancer.

While the evidence associating specific nutrients with cancer risk remains equivocal, dietary guidelines have been promulgated by a number of health organizations which recommend avoiding obesity, reducing total fat to 30% or less of calories, consuming high-fiber foods and a variety of fruits and green and yellow vegetables in the daily diet, and minimizing the intake of alcohol and smoked, salt-cured, and nitrate-cured foods. Evidence suggesting the ability of these dietary patterns or supplementation with putative protective nutrients to reverse existing cancers or lower rates of cancer recurrence is limited and equivocal.

Established cancers as well as antitumor treatments may have a variety of effects on the nutritional status of the affected geriatric patient. Anorexia and weight loss are common and may result in progressive wasting and undernutrition (cancer cachexia). Alterations in protein, carbohydrate, and fat metabolism are associated with many cancers. Malabsorption and protein-losing enteropathy are also a concomitant of various malignancies. Hormonal abnormalities induced by tumors may affect the status of different nutrients. Radiation, surgery, and drug therapies each have consequences which predispose the patient to potentially serious nutrition problems.

Vision Disorders

Aging is associated with extensive postsynthetic modifications to eye lens proteins resulting in aggregation with eventual polymerization and precipitation to form opacities or age-related cataracts. The prevalence of cataract increases with age, reaching about 50% in people 75–85 years old; prevalence rates are higher if early lens changes are included in the calculation. Oxidation of lens proteins is highly correlated with cataract and research studies provide evidence for a close relationship between cataractogenesis and nutrition. An elevated status of dietary antioxidants is strongly correlated with a lower incidence of cataract. Ascorbic acid concentration in the lens can be as much as 30 times that in plasma but decreases in aged and cataractous lens. Vitamin E is associated with protection against oxidative insults and glutathione-dependent antioxidant reactions are compromised in the lens with age and cataracts. The effect of other nutrients, e.g., folic acid, riboflavin, vitamin B_6, taurine, and tryptophan, has been examined but evidence supporting their protective role against cataractogenesis remains limited. Intake of the xanthophyll carotenoids, lutein and zeaxanthin, is inversely correlated with the incidence of cataract and cataract extractions.

Age-related macular degeneration (AMD) is the leading cause of irreversible blindness among older adults. The retina is rich in highly polyunsaturated fatty acids, particularly docosahexaenoic acid, and thus vulnerable to lipid peroxidation. This situation is compounded by exposure to light, high oxygen tension, and high concentrations of retinol. The macula contains a full complement of antioxidant defenses but is unusually rich in lutein and zeaxanthin, which provides its yellow pigment and optical density, and absent in β-carotene and lycopene. Observational studies indicate that generous intakes of lutein and zeaxanthin are associated with a significant reduction in risk of AMD. Zinc plays a role in the metabolic function of several antioxidant enzymes in the chorioretinal complex and limited evidence suggests increased zinc intake may benefit visual acuity in AMD patients.

Coronary Heart Disease

The progressive focal narrowing of coronary arteries by atherosclerosis, beginning as early as age 10, leads

to an inadequate circulation of blood in local areas of heart muscle. These changes can result in angina pectoris, myocardial infarction (heart attack), and sudden death in older adults. These and related disorders are termed coronary heart disease (CHD) and, in western countries, account for more deaths annually than any other group of diseases. The prevalence of CHD is greater among men than women and increases markedly in those over 65 years of age. Medical interventions and changes in lifestyle during the past two decades have reduced the age-corrected death rate from CHD by about 40%; however, without a further reduction in risk factors and/or an improvement in treatments, CHD prevalence and incidence will increase in the future because of the aging of the population. The causes of CHD are multifactorial and include cigarette smoking, high blood pressure, obesity, and high blood cholesterol (hypercholesterolemia).

The relationship between diet, lipoprotein metabolism, atherogenesis, and CHD has been defined by extensive scientific investigations conducted during the last 75 years. This work indicates a strong, continuous, and graded relationship between total blood cholesterol levels, the severity of atherosclerosis, and risk for CHD. Dietary saturated fat and cholesterol raise total blood cholesterol and low-density lipoprotein (LDL) cholesterol levels; LDL is the major atherogenic lipoprotein and accounts for most of the CHD risk associated with elevated plasma total cholesterol. Polyunsaturated and monounsaturated fat lowers total blood cholesterol and LDL cholesterol levels when substituted for saturated fat in the diet. High-density lipoprotein (HDL) is considered to protect against CHD and is associated with female sex, estrogen use, exercise, moderate alcohol consumption, and weight loss.

Diet is considered the cornerstone of therapy to reduce borderline (200–239 $mg\,dl^{-1}$) and high-risk ($\geq 240\,mg\,dl^{-1}$) blood cholesterol levels whether or not drug therapy is eventually added to the regimen. Dietary guidelines to reduce risk of CHD include recommendations of nutrient intake as a percent of total calories of less than 30% from fat (less than 10% from saturated fat, up to 10% from polyunsaturated fat, and 10–15% from monounsaturated fat), 50–60% from carbohydrates, and 10–20% from protein. Total calorie intake should be designed to achieve and maintain desirable weight. In addition, daily cholesterol intake should be less than 300 mg. Individuals at very high risk of CHD should further reduce saturated fat and cholesterol intake. Adherence to these dietary guidelines has been proven to lower blood cholesterol by 10–25%. Elevated plasma homocysteine is an independent risk factor for CHD. Homocysteine concentrations can be reduced by increasing the intake of folic acid, vitamin B_6, and/or vitamin B_{12}; however, prospective studies demonstrating a decreased incidence of CHD with B vitamin interventions have not been completed. Supplementation with vitamin E and/or fish oil may play a role in the primary and secondary prevention of CHD but the results of clinical trials are equivocal.

Diabetes

Type 2 diabetes, formerly called noninsulin-dependent diabetes mellitus, accounts for about 90% of all cases of the disease. The onset of type 2 diabetes is gradual (with no or mild symptoms), usually appearing in midlife among people who are overweight or obese. Although type 2 diabetics display normal pancreatic histology, secrete insulin in response to glucose ingestion, and have normal to high levels of circulating insulin, they are less able to use this insulin (insulin resistance). Type 1 diabetes, formerly called insulin-dependent diabetes mellitus, is characterized by an absolute deficiency of insulin caused by β-cell destruction of the islets of Langerhans in the pancreas. Type 1 diabetes usually begins abruptly in adolescents and young adults of normal body weight. No method has been identified which prevents type 1 diabetes and these patients require insulin administration for survival. Genetic predisposition appears to play an important role in both type 1 and type 2 diabetes. The specific cellular basis of hyperglycemia and related metabolic abnormalities in type 2 diabetes is not yet clear, although three defects appear to be involved: a diminished pancreatic β-cell response to glucose; a reduced synthesis or function of cellular receptors for insulin; and an impaired ability to utilize glucose following binding to cellular receptors. Clinical complications of diabetes include heart disease and stroke, kidney disease, blindness, nontraumatic leg and foot amputations, and death.

Dietary therapy is considered the key to the management of type 2 diabetes. Obesity is strongly associated with the onset and severity of type 2 diabetes with more than 80% of patients being more than 15% in excess of their desirable body weight at the time of diagnosis. Weight loss reduces insulin resistance as well as fasting and postprandial blood glucose levels in overweight diabetics. Dietary recommendations for the management of diabetes include: 50–60% of total calories as carbohydrate (emphasizing complex carbohydrates and water-soluble fiber); decreased protein in those with renal insufficiency; 30% or less of total calories as fat (with reduced intake of saturated fat); and limited alcohol intake (restricted entirely in poorly controlled diabetes). Limited and

equivocal evidence suggests a potential role for vitamins A, C, E, and niacin and the minerals chromium and vanadium in diabetes. Alternative sweeteners, e.g., sorbitol and saccharin, are accepted in diabetes management but their value is unclear. The control of hyperglycemia by diet and medication is associated with reduced risk of some of the long-term complications of diabetes.

Obesity

The determination of obesity in the elderly is problematic since few body weight standards specific to this age group are in use. The prevalence of obesity appears to increase with age. Weight gain normally occurs during the adolescent growth spurt and again during middle age. Basal metabolic rate and energy expended for physical activity decline during adulthood so that fewer calories are required to maintain energy balance; however, many middle-aged and older adults often do not adjust their caloric intake to compensate for their reduced energy requirements and gain weight even though they do not eat more than before. Body weight generally peaks between 35 and 55 years in men and between 55 and 65 years in women; body weight decreases thereafter in both sexes. Obesity aggravates many health conditions found among the elderly including arthritis, cardiovascular diseases and hypertension, and type 2 diabetes.

Osteoporosis

Primary osteoporosis is an age-related disorder characterized by decreased bone mass and increased susceptibility to fractures in the absence of other recognizable causes of bone loss. Postmenopausal osteoporosis (type 1) occurs in women within 15–20 years after menopause and is thought to result from factors related to or exacerbated by estrogen deficiency. Age-related osteoporosis (type 2) occurs in men and women over 75 years of age and may be more directly related to the aging process. Whites are at higher risk of osteoporosis than blacks. Other risk factors include dietary factors, cigarette smoking, physical inactivity, alcohol abuse, being underweight, and family history of osteoporosis. Osteoporosis is more than six times as common among women than men due to their smaller peak bone mass, earlier onset of bone loss, longer life expectancy, and lower calcium intake.

Substantial evidence supports a role for calcium as a protective agent against osteoporosis. High calcium intake during early years contributes to greater peak bone mass and during later years prevents negative calcium balance and reduces the rate of bone loss. Poor calcium nutriture is common among the elderly due to inadequate intake, an age-related decline in the capacity for calcium absorption, and the presence of diseases associated with reduced calcium absorption and/or increased calcium excretion. Vitamin D is essential for the efficient absorption of calcium but vitamin D status is quite low among the elderly due to inadequate intake and age-related impairments in the metabolic conversion of vitamin D to its biologically active form, including lower precursor concentrations of 7-dehydrocholesterol in the skin. Less well-established dietary risk factors for osteoporosis include low intakes of vitamin K or boron and high consumption levels of caffeine, protein, or alcohol. The principal measures employed in the prevention of osteoporosis include estrogen replacement in postmenopausal women, elemental calcium intakes of 1000–1500 mg day^{-1}, vitamin D intakes of 10–20 μg cholecalciferol day^{-1}, and a program of modest weight-bearing exercise. These measures may retard further bone loss in the elderly but will not restore lost bone or reverse the loss in height or collapsed vertebrae characteristic of osteoporosis.

Nutritional Management of Geriatric Patients

M S J Pathy, Cyncoed, Cardiff, UK
A Bayer, Llandough Hospital, Penarth, UK

Background

At all ages, adequate nutrition is critical for maintaining health and quality of life. In general, dietary protein and energy requirements are substantially less in the over 85s than those aged 65–74 years, and there is an increased need for certain vitamins and minerals. However, individual requirements are influenced greatly by lifestyle and by disease. Maintenance of physical fitness and strength in old age largely depends on continued physical and mental activity, with enough to eat and a diet that is sufficiently varied. Elderly people in low socio-economic groups, those in institutions, and the housebound who are receiving home care are especially vulnerable to undernutrition, through underprovision and inadequate intake. Drugs and disease may also interact with the complex metabolic processes necessary for breaking down and absorption of food. Increasingly, calorie overconsumption is a problem in Western society, with 25% of men and 35% of women in the 65–74 age range being reported as overweight and 10% being severely overweight.

In the UK, the Committee on the Medical Aspects of Food and Nutrition Policy (COMA) laid down general guidelines for dietary requirements of older people together with modifications in disease states. Table 1 summarizes the dietary reference values (DRVs), which replace the earlier recommended dietary allowances (RDA). The reference nutrient intake (RNI) represents the sum of the estimated average requirement (EAR) and two standard deviations.

Energy

A reduction in physical activity and lean body mass in old age lead to a decline in energy requirements by about one-third. However, there is no reduction in basal metabolic rate relative to the metabolically active cell mass. Infection, trauma (accidental or surgical), and the ergonomic impact of disability on daily living tasks all serve to increase energy demands. Dyspnea at rest or exertion (commonly seen in patients with chronic pulmonary obstructive airways disease) and impaired immunological response to infection also require increased energy intake as part of therapeutic management.

COMA recommends that 50% of food energy is derived from carbohydrate – a term that embraces starch and nonstarch polysaccharides. The main source of starch is influenced by ethnicity and culture, with bread, potatoes, breakfast cereals, rice, and pasta predominant in the UK. Distinction is made between intrinsic sugars (milk sugar, and sugar incorporated in the cellular structure of fruit and vegetables) and extrinsic nonmilk sugars (extracted from the fruit stem and roots of plants and added to food, confectionery, and soft drinks). A high extrinsic sugar intake may reduce the dietary quality and in the dentate increases the risk of caries.

Different carbohydrates have different glycemic indexes (Table 2). This is the area of the blood sugar curve produced by a food, compared with the equivalent amount of glucose. Glucose has an arbitrary glycaemic index of 100. Previously, white bread was taken as the standard. Excess high glycemic index carbohydrates are associated with a low high-density-lipoprotein (HDL) cholesterol concentration,

Table 1 Dietary reference values for older men and women (based on COMA recommendations)

Nutrition	*Sex/age (years)*	*Estimated average requirements (EAR)*	*Reference nutrient intake (RNI)*
Energy[a]	M 65–74	9.71 MJ	
	M 75+	8.77 MJ

rapid absorption, and a high postprandial glucose and insulin response, ultimately giving rise to decreased insulin sensitivity. Total cholesterol and low-density-lipoprotein (LDL) cholesterol are not influenced. One community study has confirmed that low-glycemic-index diets are associated with raised HDL cholesterol levels and the longitudinal Nurse Health Study reports that diets with a high glycemic index are associated with an increased risk of coronary heart disease (CHD). Increasing prominence is being given to the role of high-glycemic diets and the increasing prevalence of type 2 diabetes mellitus.

Fat is the most concentrated calorie nutrient. In the USA, it is recommended that 30% or less of calories should be derived from fat, of which no more than 10% should be saturated. The UK Health of the Nation aims to reduce average percentages of food energy derived from fat by at least 12% by 2003 and that derived from saturated fat by 35% by 2005. The chief source of saturated fat is meat, butter, cheese, and cream. Unsaturated fats are derived mainly from plant sources, especially nuts, olive oil, rapeseed oil, some margarines, and fish. Evidence supports the role of saturated fats and trans-fats (hydrogenated polyunsaturates) in atheromatous vascular disease, although infection may be the initial trigger. COMA recommended a reduction of saturated fat and total fat contribution to the diet. However, there is no correlation between polyunsaturated fat intake and LDL levels. Indeed, the unsaturated fat in fish and in olive oil – about 70% monounsaturated – enhances the plasma concentration of the vascular-protective HDL cholesterol. The Nurse Health Study showed that women taking at least one ounce (15 g) of nuts five times or more a week had a greater reduction in risk of CHD than those who took them less frequently. Experimental diets replacing animal fats with nuts lowered LDL cholesterol and raised HDL cholesterol. Walnuts are high in linoleic acids, but most nuts are rich in arginine, a precursor of nitric oxide. A major longitudinal study showed that an increase in polyunsaturated fat intake accompanied by a reduced consumption of trans-fats diminishes the risk of type 2 diabetes mellitus. Studies based on Mediterranean diets (characterized by abundant fruit and vegetables, especially garlic and onions, cereals, beans, nuts, seeds, olive oil, fish and poultry) have reported a reduced risk of CHD and cancer.

Although a reduction in total dietary fat has no affect in reducing blood pressure, increasing the dietary polyunsaturated : saturated ratio or changing to diets rich in linoleic acids produces a moderate blood-pressure reduction. However, one study reported that attempts to enhance compliance with dietary recommendations in the over-70s was only half as successful as in the 60–69-year age group.

Protein

By age 70, skeletal muscle may have lost an average of 40% of its cell mass. Protein synthesis decreases as body cell mass falls with age and is associated with a decline in function. Functional decline is not irreversible and maintenance of physical activity or physical training may increase muscle strength and cardiac output. Protein malnutrition is associated often with profound muscle loss and weakness, and impaired immunological competence. However, this stage is usually compounded by other nutritional deficiencies and by serious disease.

Debate continues about protein requirements in old age. Studies on free-living and institutionalized older people suggest that the daily protein requirement should be about 1.0 g kg^{-1} and about 12–14% total calories. Inflammatory conditions and tissue necrosis (e.g., pressure sores) increase the protein turnover and requirement, and pressure-sore healing rates are influenced greatly by dietary protein intake. Protein malnutrition may follow major surgery or severe acute illness in elderly people and can seriously impair subsequent rehabilitation if left untreated.

Vitamins and Minerals

Vitamin and mineral supplements are necessary to treat well-defined deficiency disorders, but their role is less certain in the absence of obvious clinical

abnormality. Many older people fail to make the reference values for vitamin D, but the synthesis of vitamin D_3 (cholecalciferol) by the action of sunlight (UVL with a wavelength of 290–310 nnm) on the skin contributes some two-thirds of the vitamin D stores. Standard household glass prevents the passage of any therapeutic wavelength of UVL, and housebound and institutionalized patients are particularly susceptible to vitamin D deficiency. Subtle degrees of vitamin D deficiency lead to secondary hypoparathyroidism, increased bone turnover and osteoporotic fractures. Common dietary sources of vitamin D include eggs, cheese, margarine (fortified with vitamins D and A), and oily fish. Randomized controlled trials of dietary supplementation with 17.5 μg (700 IU) and 20 μg (800 IU) of vitamin D and 500 mg of calcium per day show a reduced incidence of hip and other nonvertebral fractures, whereas 10 μg (400 IU) of vitamin D does not reduce the fracture rate. There is considerable evidence for using vitamin D and calcium supplements in the vulnerable elderly, provided overdosage is avoided. Exposure to sunlight, even diffuse sunlight, is also to be encouraged.

Water-soluble vitamin C is readily destroyed during food preparation and storage, and the COMA recommendation of 40 mg does not take this into account. The delay between preparation and delivery to the patient in hospital or nursing home or of meals on wheels to the person at home is often sufficient to substantially reduce the vitamin C content. Meals on wheels are reported to have lost some 90% of the vitamin C content by the time of delivery. Older people eat vegetables more regularly than young adults, but elderly men who live alone have diets poor in vitamin C-rich foods such as fresh green vegetables and fruit. Scurvy is uncommon, but chronic mild deficiency is not infrequent and may play a role in atherogenesis and stroke. The inverse correlation between plasma fibrinogen concentration and serum ascorbate levels suggests that vitamin C supplementation may be cardioprotective.

Vitamin A intake is very variable, but needs tend to decrease with age, as absorption may be increased, whilst plasma clearance is delayed. However, it is often difficult to be certain whether homeostasis is achieved, or whether subclinical vitamin A states are common and unrecognized. Failure of dark adaptation is a well-recognized vitamin A deficiency phenomenon, but dryness of the eyes and perifollicular hyperkeratosis are uncommon deficiency manifestations in the Western World. In some third world countries, vitamin A deficiency is the commonest cause of blindness. The potential benefit of the antioxidant properties of vitamin A and the closely related β-carotene have yet to be established.

Thiamin (vitamin B_1) intake is closely related to energy consumption. Older people generally eat breakfast ('something to eat within 2 hours of rising'), and this commonly includes cereals and fortified cereals containing adequate thiamin. If disease or institutionalization impairs energy consumption, thiamin intake may be deficient. Alcoholism may give rise to confabulation and short-term memory impairment (Korsakoff's psychosis) due to associated thiamine deficiency or, more rarely, Wernicke's encephalopathy – acute confusion, ataxia, and opthalmoplegia. Acute postoperative delirium is not improved by large parenteral doses of the vitamin B group of vitamins. Any associated low plasma thiamine concentration may be an epiphenomenon.

Pyridoxine (vitamin B_6) and folate are important cofactors for the metabolism of homocysteine, and both vitamins independently lower raised homocysteine levels, thought to play a key role in atherogenesis. The Nurse Health Study found that a long-term intake of 3 mg of vitamin B_6 and/or at least 400 μg of folate per day have a favorable impact on CHD. In the Framingham Study, 20% of elderly subjects had folate and vitamin B_6 levels below the recommended intake.

Folic acid in its conjugated form (predominantly polyglutamate) is present in a wide variety of food, especially green leafy vegetables, kidney, and liver. Hydrolysis of the polyglutamate to monoglutamates is necessary for absorption in the small intestine. Folate deficiency may be due to several causes, with inadequate intake the most common, often aggravated by prolonged cooking, which destroys the vitamin. Disease that impairs absorption (e.g., gluten enteropathy or ileal resection) or increases metabolic demand (e.g., vitamin B_{12} deficiency, the leukemias, myelofibrosis, hemolytic anemia, sideroblastic anemia) may result in deficiency. A number of drugs (e.g., trimethoprim, methotrexate, triamterene) inhibit conversion of folate to tetrahydrofolate, which is the main storage and metabolically active form of the vitamin. The anticonvulsants, phenytoin, primidone, and phenobarbitone, and the antibiotic, nitrofurantoin, may also result in folate deficiency, but the underlying mechanism has not been firmly established. Defective DNA synthesis through the purine and pyrimidine pathways following chronic dietary folic acid deficiency or drug-induced activity gives rise to a megaloblastic anemia. Provided that vitamin B_{12} deficiency is not present, treatment with as little as 200 μg daily of oral folic acid is rapidly effective. In practice, pharmacological doses of 1–5 mg daily are used. Folinic acid (Leukovorin), a form of tetrahydrofolate, is preferable if the deficiency is due to folate antagonist drugs. The COMA recommendation of 200 μg per day is adequate

for red cell formation but may not be optimal for homocysteine metabolism and vascular wall integrity.

Dietary deficiency vitamin of B_{12} is rare, except in strict vegans. This is predominantly due to the efficient recirculation of the vitamin and a reported half-life of 480–1360 days. The predominant cause vitamin B_{12} deficiency is loss of intrinsic factor production by the gastric parietal cells, most often due to autoimmune disease giving rise to pernicious anemia. Antibodies against parietal cells and less commonly against intrinsic factor may be found in the gastric juice or serum. The inability to separate vitamin B_{12} from its dietary binding protein may also cause vitamin B_{12} deficiency; lack of gastric acid and pepsin contribute, but an unequivocal explanation has yet to be established. Bacterial overgrowth as in blind loop syndrome competes for available vitamin B_{12} and reduces the amount available from absorption. Gastric surgery by removing some or all intrinsic factor producing cells leads eventually to a low serum vitamin B_{12} concentration.

Because the liver stores large amounts of vitamin B_{12}, evidence of deficiency does not occur for about 5 years, even after total gastrectomy. Ileal disease or surgery often gives rise to vitamin B_{12} deficiency. The gradual but progressive development of anemia and the well-hemoglobinized red cells often results in minimal symptoms until an advanced anemic state. The common symptoms of anemia – fatigue, breathlessness, and poor exercise tolerance, occur. Acute onset of heart failure and angina is not uncommon because of associated CHD and responds well to vitamin B_{12} treatment. Much has been written on the relationship of dementia to vitamin B_{12} deficiency. Although low serum vitamin B_{12} concentrations are not uncommon in demented elderly patients living in the community, there is little evidence of any improvement in cognitive function following B_{12} dosage. When some improvement does occur, it can better be ascribed to concurrent treatment of other comorbid states and correction of impaired total dietary intake and improvement of restricted functional and social activities. However, some neuropsychiatric states are improved by vitamin B_{12} therapy. Neurological symptoms are relatively rare. Symmetrical peripheral neuropathy usually involving the lower limbs is associated with paraesthetic symptoms and evidence of ataxia and posterior column involvement leading to lower-limb weakness and spasticity.

Reduced plasma vitamin B_{12} concentration is an early feature of deficiency, though initially, the blood picture may be normal. Later, macrocytosis and megaloblastic bone marrow changes are characteristic, with low white blood counts and multisegmented polymorphs. When diagnosis is equivocal, the Schilling test is justified. In the presence of anemia, it is useful to measure the reticulocyte response to vitamin B_{12} administration, which reaches its peak on the 4th or 5th day. Treatment of confirmed deficiency with 1000 mcg of intramuscular vitamin B_{12} daily for 2 weeks rapidly replenishes body stores. Subsequently, lifetime intramuscular injections every 3 months is a cost-effective treatment schedule. Absorption of 1–3% of an oral dose of 1 mg of vitamin B_{12} daily generally satisfies the daily requirement of 2–5 μg.

The latest recommended vitamin E requirement is 15 mg per day. Vitamin E deficiency may result from fat malabsorption or defects in the gene for the α-tocopherol transfer protein and may give rise to the insidious onset of peripheral neuropathy. A possible influence of vitamin E (and vitamin C and β-carotene) on excess free radical formation has led the media to speculate on an antiageing effect. Although no benefit has been seen in patients with Parkinson's disease, a placebo-controlled trial of vitamin E 2000 IU daily in people with Alzheimer's disease has suggested a possible slowing of the rate of disease progression. The antiadhesive effect of vitamin E combined with the platelet antiaggregatory effect of aspirin increases the risk of bleeding, and caution is appropriate with supplementary vitamin E in a dose greater than 500 IU per day.

Insufficient iron intake is mainly found in housebound and institutionalized older people. Meat and cereals are the major sources of iron in the diet; fruit and vegetables have much lower proportions. Some flour and cereals are fortified with additional iron. Vitamin C enhances, and phytates or tannins in tea interfere with, iron absorption. Early iron store reduction is demonstrated by low serum ferritin concentrations. As iron deficiency progresses, anemia may develop. Moderate to severe iron-deficiency anemia is mostly due to chronic gastrointestinal bleeding due to drugs (e.g., aspirin, anticoagulants, nonsteroidal antiinflammatory drugs) or disease. Symptoms of iron deficiency may follow the onset of anemia and include fatigue, shortness of breath or exacerbation of concomitant ischemic arterial disease, e.g., angina, congestive heart failure, and intermittent claudication. Treatment of iron deficiency is usually with ferrous sulfate, 200 mg two to three times daily until the hemoglobin and iron stores are replaced. Concomitant administration of ascorbic acid as fruit juice or as a 50-mg vitamin C tablet increases absorption and reduces gastrointestinal side-effects. In the presence of a malabsorption state, iron may have to be given parenterally, but the potential risk of anaphylactic response requires supervision. Dietary advice on foods rich in available iron is an essential part of the long-term strategy, but for

some elderly people, a small dose of oral iron may be a permanent requirement.

Dietary Fiber

Dietary fiber keeps bowel movements regular and prevents constipation when taken with a good fluid intake and adequate exercise. Long-term intake of dietary fiber decreases the risk of CHD and diverticular disease and helps management of diabetes mellitus and hyperlipidemia. Its role in the prevention of colorectal cancer is still under debate. Only a minority of older people consume the recommended daily intake of 25–35 g of dietary fiber. This may be achieved by eating more fruit and vegetables (preferably unpeeled) by substituting whole-grain breads and cereals for white bread and sugary cereals and adding wheat bran and beans to soups, stews, and other dishes. Excess fiber intake should be avoided, as it may impair the absorption of trace minerals.

Clinical Evaluation

Once clinical symptoms and signs appear, nutritional impairment is firmly established. The Mini Nutritional Assessment (MNA; Figure 1) can be undertaken in 15 min and has been used successfully in free-living older people, in residents of nursing homes, and in hospital inpatients. A Danish 5-year longitudinal study showed an increased mortality in subjects with an MNA score of less than 23.5. Subjects in a New Mexico Study with a high MNA score of 27 or greater were classified as having very good health.

Weight is the traditional simple measure of nutritional state and often goes unrecorded in medical and nursing-home case notes. The body mass index (BMI) (weight in kilograms/height, in meters, squared) is not always feasible in disabled and bed-bound persons, but the height can be calculated using the sitting knee height (knee to floor or heel) or the demispan (sternal notch to finger web in the outstretched arm). People aged over 65 years are recommended to have a BMI between 24 and 29. A BMI under 20 indicates undernutrition. Mortality rates increase in the very elderly with low BMIs (under 20).

Body fat distribution changes with age, and in both sexes there is an increase in abdominal fat distribution and an increase of omental fat. In women, a waist/hip ratio over 0.9 is associated with a threefold risk of CHD when compared with a ratio of less than 0.7. Waist circumference is an independent risk factor, and women with a waist circumference of greater than 97 cm (38 inches) have a threefold risk of CHD. Men with a waist circumference of greater than 100 cm (40 inches) have a 2.5- to 4.5-fold increase in one or more cardiovascular risks. Gall bladder disease, cancer, and osteoarthritis are more common in the overweight, and obesity, particularly abdominal obesity, is a significant independent risk factor for insulin resistance and type 2 diabetes.

In older underweight persons, the cornerstone of management is to identify and treat aggressively the cause of weight loss. Poor appetite may improve with treatment of depression or review of drugs, such as digoxin, dopaminergic agents, and anticholinesterases. Treatment of poor oral hygiene, swallowing disorders, or malabsorption syndromes will increase food intake and absorption. Good management of systemic diseases such as cancer, chronic organ failure, infection, and inflammatory disorders, and relevant metabolic diseases such as hyperthyroidism, all require attention to the nutritional state. Attention to social and economic factors and to countering physical disabilities may also be necessary. Highly restrictive 'medically indicated' diets, for example, for lowering cholesterol or managing diabetes, may also lead to unintentional weight loss and nutritional deficiencies, and a more relaxed, well-balanced, and varied diet is likely to be preferable.

Intentional weight loss in obese older people may be associated with functional and health benefits, though some studies indicate that being overweight later in life does not pose a significant health risk. Weight reduction is a partnership between patient and medical advisors. Without this approach, it is difficult to maintain motivation and trust on the part of the patient. Randomized controlled studies firmly establish that low-fat diets produce weight loss. A slowly progressive increase in exercise levels has only a small impact on weight but has a more substantial benefit on function and improves insulin sensitivity.

Nutritional Management in Specific Medical Conditions

Pain and discomfort from inflammation of the gums, mouth, or tongue and missing or illfitting dentures will hinder adequate chewing and decrease food intake. Preventive dental care (from an early age) is the best management, and maintaining active dental health policies is especially important for those in institutions. When maintaining adequate nutrition becomes a problem, high-protein–energy liquids and soft nonacidic foods may be best tolerated, and a mild topical local anesthetic mouthwash before meals may help to relieve pain. Inadequate saliva production arising from infection, anticholinergic drugs, radiation therapy, or Sjogren's syndrome will interfere with taste and swallowing and may be partially

NESTLÉ NUTRITION SERVICES

Mini Nutritional Assessment MNA®

Last name: First name: Sex: Date:

Age: Weight, kg: Height, cm: I.D. Number:

Complete the screen by filling in the boxes with the appropriate numbers.
Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

Screening

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe loss of appetite
1 = moderate loss of appetite
2 = no loss of appetite ☐

B Weight loss during the last 3 months
0 = weight loss greater than 3 kg (6.6 lbs)
1 = does not know
2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)
3 = no weight loss ☐

C Mobility
0 = bed or chair bound
1 = able to get out of bed/chair but does not go out
2 = goes out ☐

D Has suffered psychological stress or acute disease in the past 3 months
0 = yes 2 = no ☐

E Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems ☐

F Body Mass Index (BMI) (weight in kg) / (height in m)^2
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater ☐

Screening score (subtotal max. 14 points) ☐☐
12 points or greater Normal – not at risk – no need to complete assessment
11 points or below Possible malnutrition – continue assessment

Assessment

G Lives independently (not in a nursing home or hospital)
0 = no 1 = yes ☐

H Takes more than 3 prescription drugs per day
0 = yes 1 = no ☐

I Pressure sores or skin ulcers
0 = yes 1 = no ☐

J How many full meals does the patient eat daily?
0 = 1 meal
1 = 2 meals
2 = 3 meals ☐

K Selected consumption markers for protein intake
• At least one serving of dairy products (milk, cheese, yogurt) per day? yes ☐ no ☐
• Two or more servings of legumes or eggs per week? yes ☐ no ☐
• Meat, fish or poultry every day yes ☐ no ☐
0.0 = if 0 or 1 yes
0.5 = if 2 yes
1.0 = if 3 yes ☐.☐

L Consumes two or more servings of fruits or vegetables per day?
0 = no 1 = yes ☐

M How much fluid (water, juice, coffee, tea, milk…) is consumed per day?
0.0 = less than 3 cups
0.5 = 3 to 5 cups
1.0 = more than 5 cups ☐.☐

N Mode of feeding
0 = unable to eat without assistance
1 = self-fed with some difficulty
2 = self-fed without any problem ☐

O Self view of nutritional status
0 = views self as being malnourished
1 = is uncertain of nutritional state
2 = views self as having no nutritional problem ☐

P In comparison with other people of the same age, how does the patient consider his/her health status?
0.0 = not as good
0.5 = does not know
1.0 = as good
2.0 = better ☐.☐

Q Mid-arm circumference (MAC) in cm
0.0 = MAC less than 21
0.5 = MAC 21 to 22
1.0 = MAC 22 or greater ☐.☐

R Calf circumference (CC) in cm
0 = CC less than 31 1 = CC 31 or greater ☐

Assessment (max. 16 points) ☐☐.☐
Screening score ☐☐
Total Assessment (max. 30 points) ☐☐.☐

Malnutrition Indicator Score
17 to 23.5 points at risk of malnutrition ☐
Less than 17 points malnourished ☐

relieved by spraying the mouth with artificial saliva solution. Normal age-related changes in taste result in older people being more sensitive to bitter and sour flavors and less sensitive to sweet and salt. A declining sense of smell means that food aromas that stimulate the appetite must be several times stronger than usual.

Problems with swallowing (dysphagia) may be due to inflammatory, traumatic (e.g., postintubation),

and neoplastic causes in the mouth or esophagus, mechanical or neuromuscular causes, or a pharyngeal diverticulum. Management is primarily directed to resolution of the causative factors, but there will be an intervening period of a need for nutritional maintenance, or, where the underlying cause cannot be treated, long-term nutritional support may be required. Stroke, motor neurone disease, and, less commonly, Parkinson's disease may be associated with severe swallowing problems. Following an acute stroke, swallowing difficulties are generally transient and resolve within a week. However, in 15% of patients, swallowing impairment with risk of aspiration excludes oral nutrition. Dehydration leads to rapid deterioration, and intravenous fluids are required in the first few days. Three options are available for nutritional maintenance until safe swallowing returns. Parenteral nutrition is only practical for a few days and has a very limited role in poststroke management. Fine-bore nasogastric tube feeding is commonly the interim measure for nutritional provision. In the first week or so, emphasis is on energy and protein intake, but a balanced nutrient provision with attention to micronutrients and mineral content becomes essential for longer-term management. Percutaneous endoscopic gastrostomy is well tolerated and is the method of choice for long-term management. The benefits of early PEG feeding have yet to be established, but ongoing randomized trials should provide evidence-based guidance.

In motor neurone disease, the early stages of dysphagia are managed by thickening all fluids and liquidizing and adapting solid food to a thick custard consistency. Unfortunately, food consumption can easily take on an 'eat to live' meaning with the loss of social and pleasurable aspects of eating.

Alzheimer's disease is the commonest cause of dementia in later life. Weight loss is usual, sometimes even early in the disease, and vitamin deficiencies and disturbed eating behavior are common. Where the cognitively impaired individual lives alone and has difficulty in buying or preparing an adequate diet or forgets meals, the cause of the weight loss is readily apparent. In later stages, restlessness and agitation may result in excessive energy expenditure, or aversion to food may develop. Often, however, there is no obvious cause of weight loss. Carers may be able to provide accurate dietary information to enable monitoring of the patient's nutritional status using the MNA. There is current interest in the possible role of inadequate intake of folate and raised homocysteine in the etiology of cognitive impairment. However, it is also likely that vitamin deficiencies may develop as a result dementia. Antioxidant vitamins may have neuroprotective effects and, in the experimental animal, can improve cognitive function. High-saturated-fat diets are reported to be associated with an increased likelihood of cognitive impairment, whereas polyunsaturated fats have a negative influence. Tube feeding of people with advanced dementia has no measurable influence on survival and raises important practical and ethical concerns.

Decline in glucose tolerance and type 2 diabetes mellitus is increasingly common in old age. A raised 2-h postprandial glucose test is associated with increased mortality. Dietary management has changed considerably over recent years. From the early 1990s, reducing dietary fat intake, particularly saturated fat, has been recommended. Currently, a reduction in saturated and trans-fats is advised, but no restriction on monosaturated and polyunsaturated fats. Increasing emphasis is also placed on replacing high-with low-glycemic-index foods. A change in lifestyle is important in both prevention and treatment, and it is inappropriate to consider diabetes in isolation from other risk factors. Hypertension affects at least 50% of older diabetics, and reduced sodium intake enhances the overall management of high blood pressure.

Undernutrition in Institutionalized Patients

Many hospital patients and residents of long-term care facilities cannot feed themselves, and many are malnourished. Since the serving and checking of meals have become a 'nonnursing duty' in the UK, awareness of the patient's nutrient intake may be limited. Meals are often kept for some time in heated wagons before serving, and some nutrients are largely destroyed. Older people are more likely to eat food provided when it is served warm, with portion size individualized, and the eating environment is considered. In one study, in which plated meals were weighed before and after serving, elderly patients were shown often to have inadequate time or ability to cut and eat their meals. When all food was cut up into bite-sized pieces, food consumption improved significantly. Food must also be placed within reach of disabled patients. An uncluttered, well-lit dining room with minimal distractions, providing consistent seating at mealtimes and attractive table settings will enhance eating. Attention to poor hearing enhances enjoyment of mealtime conversation. People with physical disabilities may benefit from feeding aids such as nonskid place mats, weighted cutlery with thick handles, plates with wide, curved lips that help keep food on the plate, and cups with easy-grip handles and special lids for sipping. Cyclical menus should be available, recognizing individual

preferences and offering properly prepared and appetizing meals. Dividing up the daily food ration into lighter, more frequent snacks may be more acceptable than the traditional three meals a day. Special events such as picnics and family dinner parties and special menus for festive occasions such as birthdays will encourage an interest in eating. Patients requiring a softer or liquid diet would benefit by having their food presented creatively.

Water is an important nutrient that is often overlooked. Thirst lessens with age, so older people need to adopt the habit of drinking fluids regularly, or dehydration can occur easily. This is a particular problem in the physically or mentally frail and the institutionalized, who are especially susceptible to the dehydrating effects of fever, vomiting, and diarrhea.

Undernutrition in People at Home

The elderly person living alone is at especial risk of malnutrition. Grief from the loss of a spouse or family and friends, loneliness and depression, greater use or abuse of alcohol, which may substitute for an adequate food intake, lack of sufficient money for food, and disability affecting shopping or preparation of food may all contribute. Poor vision is also an independent determinant of poor eating, leaving people less confident in their ability to cook and less able to get out for groceries. Support from relatives, neighbors, and homecare assistants providing and preparing food deserves recognition. Eating should be a social event, and older people should be encouraged to eat with family and friends whenever possible.

Relevant community services for older people include meals on wheels, which provide hot meals up to 7 days per week to homebound people in their own homes. However, arrangements are often inflexible, and there is limited ability to conform to special dietary needs. Frozen meals delivered weekly and which can then be easily reheated in a microwave oven may be a more appropriate and palatable alternative. Day centers and luncheon clubs have a useful role in supplementing the diet and reinforce the social aspects of feeding. An emergency store of essential food items in case of unexpected illness or bad weather is a useful precautionary measure.

Electrolytes and their Significance

Electrovalent solids exist as crystal lattices composed of ions bound together by a strong electrostatic force of attraction between positive and negative charges. The solutions of such substances in water conduct electricity and are therefore called electrolytes. Electrolytes are classified as anions or cations, depending upon their direction of movement in an electric field. If an electrolyte bears a positive charge, it will migrate to the cathode (negative pole) and is called a cation. Sodium and potassium are common examples of cations. If the electrolyte bears a negative charge, it will migrate to the anode (positive pole) and is called an anion. Chloride and bicarbonate are examples of anions.

In body fluids, the major electrolytes exist as free ions, while the trace metals primarily occur in combination with proteins. The electrolytes play very important roles in the physiology of living organisms. In the human body, virtually every metabolic process is dependent on, or is affected by, electrolytes. Electrolytes are involved in the maintenance of the body's osmotic pressure, water distribution in the various body fluid compartments, maintenance of proper pH, involvement in oxidation – reduction reactions, acting as cofactors for enzymes, and regulation of neuromuscular irritability or excitability. Thus, abnormal levels of electrolytes could be the cause or consequence of a variety of physiological disorders, which make the determination of eletrolytes one of the most important functions of clinical laboratories. (*See* **Coenzymes; pH – Principles and Measurement.**)

The major electrolytes found in the body are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), chloride (Cl^-), bicarbonate (HCO_3^-), phosphate (HPO_4^{2-}), and sulfate (SO_4^{2-}). In clinical laboratories, the most common electrolytes requested in a medical diagnosis are commonly referred to as the 'electrolyte profile.' This panel includes four electrolytes: HCO_3^-, Cl^-, Na^+ and K^+. (*See* **Calcium**: Physiology; **Magnesium**; **Potassium**: Physiology; **Sodium**: Physiology.)

Specimens Required for Electrolyte Analysis

Electrolytes can be assayed from many body fluids, including serum, heparinized plasma, whole blood, vitreous humor, sweat, urine, gastrointestinal fluid, and aqueous extract from feces. In clinical laboratories, serum and urine are the body fluids from which electrolyte analyses are most frequently performed. These fluids are easily obtained from the patient, and the reference levels (normal) for these fluids are available. When the electrolyte level of body fluid is required, serum is considered the most practical specimen. When electrolytes are to be determined from urine, a timed collection is the preferred method. Timed-collection specimens are needed to allow a comparison of values with reference ranges or for the determination of rates of electrolytes lost from the body. These specimens can be stored at 2–4 °C or can be frozen for delayed analysis. The average serum levels of common electrolytes are as follows:

- bicarbonate (expressed as total carbon dioxide), 22–31 mmol l^{-1};
- chloride, 98–106 mmol l^{-1};

- sodium, 135–145 mmol l^{-1};
- potassium, 3.5–5.0 mmol l^{-1};
- calcium, 8.5–10.2 mg dl^{-1};
- magnesium, 1.8–2.4 mg dl^{-1}.

Analytical Methods

Many methods exist for the assay of electrolytes. These methods include flame emission spectrophotometry (FES), atomic absorption spectrophotometry (AAS), electrochemical analysis with ion-selective electrodes (ISE), redox titration, colorimetry, and fluorescent probes. In the clinical laboratory, the majority of the analyses are performed by FES, ISE, and colorimetry. (*See* **Calcium**: Properties and Determination; **Sodium**: Properties and Determination.)

Flame Emission Spectrophotometry

Flame emission spectrophometry is most commonly used for the analysis of Na^+ and K^+. When metals such as Na^+ and K^+ are sufficiently heated in a flame, they emit light of wavelengths characteristic of the metal. The metal ions absorb heat energy, which causes electrons to be driven out of their normal orbital position. These excited metal atoms are said to be in high-energy states and are very unstable. The extra energy is given off in the form of light. When Na^+ and K^+ are excited, they emit spectra with sharp, bright lines at 589 and 768 nm, respectively. Within certain limits, the amount of light given off by the excited atoms is proportional to the concentration of the metal ions in the solution. To prepare a flame emission spectrophotometer for detecting Na^+ and K^+, standard solutions containing known concentrations (two levels) of these electrolytes are aspirated into the instrument. The digital readout is then set to the known concentrations of the fluid being aspirated. When the flame photometer has been so calibrated, the fluid containing the unknown concentration is aspirated, and the result indicating the concentration is read from the digital display.

Another FES-type system, inductively coupled argon plasma (ICAP), utilizes the principle of atomic emission spectrophotometry. It is similar to FES, except that the plasma has a much higher excitation temperature. This results in lower limits of detection, a wide dynamic range, and virtual freedom from chemical interference. It is possible to use ICAP for the analysis of metals, such as sodium and potassium, as well as many nonmetals, such as sulfur and boron; however, Cl^- cannot be assayed by using ICAP spectrophotometry. Although the principle of ICAP has been used to develop automated instrumentation, at present this system has not been used in clinical laboratories.

Atomic Absorption Spectrophotometry

Atomic absorption spectrophotometry is not commonly employed in clinical laboratories. As AAS is much more sensitive than FES, AAS is used as a reference method for many analytical procedures. The principle on which AAS is based is similar to FES. In AAS, however, the flame serves to dissociate the element from its chemical bonds and place it in a ground state at which it is capable of absorbing light of a wavelength specific for the element. The method involves using hollow cathode lamps containing the metal of interest. The metal in the lamp is subjected to an electric current, causing it to emit light at a characteristic wavelength specific to the element in the lamp. This light passes over a burner to a special detector that measures emitted intensity.

To prepare an AAS for analyzing electrolytes, a standard solution containing a known concentration of the metal of interest is aspirated into the burner; the atoms in this field absorb the light proportional to their concentration in the fluid. The resulting decrease in intensity of the beam of light given off from the hollow cathode lamp is then set on a digital readout to reflect the known concentration. Once the instrument has been so calibrated, the unknown fluid is aspirated, and the electrolyte concentration can be obtained from the digital display. This method can be used in the analysis of Na^+, K^+, Ca^{2+}, and Mg^{2+}.

Ion-selective Electrodes

Potentiometry with ISE is a comparatively recent development in the electrolyte analytical field. It is the measurement of the electrical potential difference between two electrodes, which, in contact with one or more electrolyte solutions, form an electrochemical cell. A high-impedance voltmeter measures the electrical potential difference between the two electrodes. Ion-selective electrodes respond preferentially to a particular ion species in solution. Some potentiometric analytical methods use an ion-selective indicator electrode and a reference electrode. A method developed by Eastman Kodak and used on their Ektachem analyzer uses two identical ISE mounted in a single-use disposable slide. The reference fluid containing ions at fixed concentration is applied to the reference electrode. The sample fluid is simultaneously applied to the indicator electrode. The two solutions are allowed to form a liquid junction in the bridge portion of the slide. This arrangement constitutes a concentration cell.

The specific components of the cell vary according to the ion being tested. Over the physiological range, the relationship between the measured cell potential and the logarithm of the molal concentration of the ion being tested from the fluid is linear. The junction potential is produced between the reference fluid and the sample fluid in the bridge portion of the analysis slide. The magnitude and sign of the junction potential depend on the total ionic concentration and composition of the fluid but are primarily determined by the Cl^- and Na^+ concentrations. The magnitude of this term is minimized by using a reference fluid having ionic concentrations near physiological averages. Applications of this have been developed for the analysis of carbon dioxide (CO_2), Cl^-, Na^+, and K^+. The results are normally reported in molar units.

Other methods employing ISE technology use electrodes of a nondisposable variety. Glass electrodes are made from specially formulated glass with added oxides of various metals. For example, the most practical sodium electrode is made of specialized glass, selective for Na^+. A solid-state electrode employing a homogeneous membrane of silver chloride is used for Cl^- analysis of sweat by direct measurement from the skin surface. A liquid ion-exchange electrode with an ion-selective carrier embedded in a polyvinylchloride matrix is used for chloride analysis of body fluids. A liquid ion-exchange membrane electrode, incorporating the antibiotic valinomycin as the K^+ binder, is the most selective for potassium. A gas electrode is available for total CO_2 (HCO_3^-) analysis. This involves a combination of a glass pH electrode and a reference electrode in contact with a weakly buffered electrolyte solution behind a membrane permeable to CO_2 gas. When the CO_2 gas is forcibly released from the sample, it diffuses through the membrane and reacts with water in a buffer solution, resulting in a change in the hydrogen ion activity of the buffer. The pH electrode senses the change in hydrogen ion activity, which is an indication of the concentration of the CO_2 present in the sample fluid. Ion-selective electrodes have been incorporated into many automated systems used in clinical laboratories for assaying the 'electrolyte profile.'

Redox Titration

Redox titration is characterized by the transfer of electrons from one substance to another with an end point determined calorimetrically or potentiometrically. This method is used for the determination of Ca^{2+}. Calcium is precipitated as calcium oxalate, which is treated with sulfuric acid. The oxalic acid formed is redox-titrated with potassium permanganate (oxidant). This method is time-consuming and is not used in clinical laboratories.

Colorimetry

In clinical laboratories, colorimetry is commonly employed for the analysis of Ca^{2+} and Mg^{2+}. The analysis is based on reacting the metal with an indicator dye to form a colored complex. The density of the resulting complex is related to the concentration of the metal and can be measured spectrophotometrically. A common dye used for assaying total calcium in body fluid is *o*-cresolphthalein complexone. This reagent contains other compounds (8-hydroxyquinoline, urea, and ethanol) which serve to mask interferences and enhance the reaction. Magnesium is commonly determined by complexing Mg^{2+} with a Calmagite reagent, resulting in another chromophore which can also be measured spectrophotometrically. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Fluorescent Probes

The assay of intracellular levels of Ca^{2+} can be conducted in living cells by the use of fluorescent probes. These dyes are introduced into the cell as an ester derivative which is nonpolar and thus freely diffusible across cell membranes. Once within the cell, the compounds are hydrolyzed by nonspecific esterases present in the cytosol. The resulting cation is trapped within the cell owing to its inability to traverse the plasma membrane. Thus, the cation gradually accumulates intracellularly. When excited at a given wavelength, its fluorescence reflects the concentration of free cytosolic calcium.

Water–Electrolyte Balance

Y L Cheng and A W Yu, The Chinese University of Hong Kong, Hong Kong, China

Background

The water–electrolyte balance is regulated tightly in the human body for the normal function of cells and organs. The kidneys have a critical role in regulating the composition of water and several important inorganic ions (sodium, potassium, chloride, bicarbonate, hydrogen ion, calcium, and phosphate) in the body and thus homeostasis. This is maintained by an appropriate balance between the excretion of these electrolytes by the kidneys and the daily intake. Hypernatremia and hyponatremia (excess and inadequate plasma sodium), hyperkalemia and hypokalemia (excess and inadequate plasma potassium) are the most common electrolyte disorders and result from an imbalance between intake and excretion of water and these electrolytes. This article is a consideration of the interactions of hormones and the autonomic nervous system on renal tubules in maintaining the water–electrolyte balance.

Water Balance

Water Content in the Body

Water is the most abundant component in the human body. Total body water is about 50% of body weight for normal adult women and about 60% of body weight for normal adult men. Fat has far less water than other body tissues. Consequently, women, obese people and the elderly contain less water in proportion to their body weight because, generally, they have proportionately more body fat.

Body water is distributed in two major compartments that are separated by cell membranes: the intracellular fluid (ICF) and the extracellular fluid (ECF). Approximately two-thirds of the total body water is in the ICF and one-third in the ECF. The distribution of total body water in each compartment is shown in Figure 1.

Water distribution in the ICF and ECF depends on the number of particles (electrolytes and macromolecules) confined in these compartments. The concentration of an individual substance in the two compartments may not be equal because the cell membrane has different permeabilities and channels for different substances. The concentration of a substance in a solution can be expressed as osmolality. Some substances, such as urea and alcohol, freely cross most cell membranes. 'Effective osmolality,' or tonicity, refers to the osmolality that contributes to non-freely permeable substances. Water will move across the cell membrane along the osmotic gradient, i.e., from a compartment with a low effective osmolality to a compartment with a high effective osmolality, until the tonicity is equal on both sides of the membrane. The normal plasma osmolality is about 285–295 mosmoles (mOsm) per kilogram of water.

Water Intake and Water Output

In the steady state, water intake must be equal to water output. For a normal adult, the usual water intake is about 1.5–2.5 l per day (which includes ingested water and water contained in foods), and the endogenous water production by oxidative metabolism is about 0.5 l per day. Water loss is through urine (about 1–2 l per day), 'insensible water loss' by evaporation of water through skin and lungs (about 1 l per day), and stool excretion (about 0.1–0.2 l per day). Urine is the only route by which water excretion

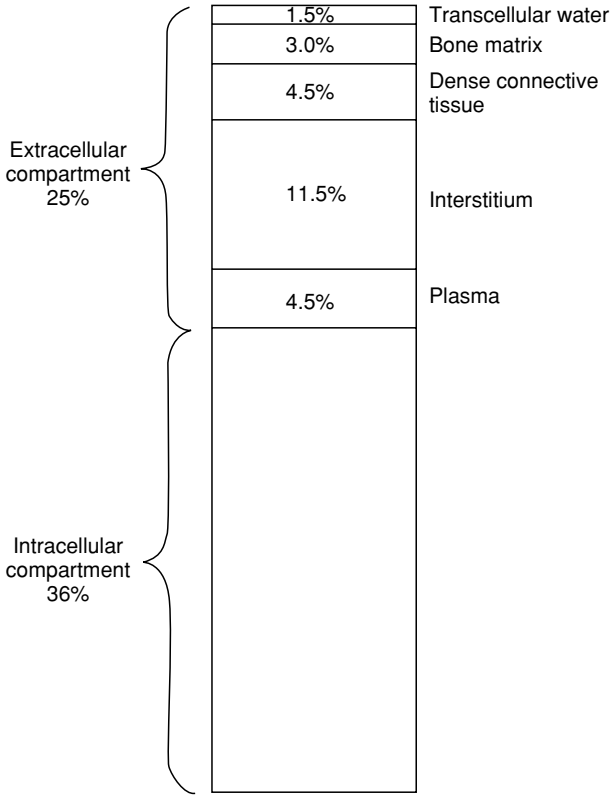

Figure 1 Distribution of body water in typical adult men, expressed as a percentage of body weight.

can be closely regulated. Apart from water intake, urine output also relates directly to the solute excretion, and it cannot be reduced below a certain minimal value required to carry the solute load. This is known as 'obligatory kidney water loss.' In order to produce a maximally concentrated urine (urine osmolality approximately 1200 mOsm kg^{-1}), for instance, a daily solute load of 600 mOsm requires a minimal obligatory urine output of 0.5 l per day (600 mOsm divided by 1200 mOsm kg^{-1}) to excrete the solute.

Regulation of Water Balance

Water balance is the result of the interaction of thirst and arginine vasopressin (AVP), which is also termed antidiuretic hormone, to maintain a stable plasma tonicity. The sensation of thirst promotes water intake, and AVP regulates urinary water excretion. AVP is a nine-amino acid polypeptide that is synthesized in the hypothalamus and stored in the posterior pituitary. Upon stimulation, AVP is released into the blood circulation. It then binds to the receptor (known as AVP receptor 2) on the basolateral membrane, opens up the water channel (known as the aquaporin-2 channel) in the apical membrane of the principal cells of the collecting ducts in the kidneys, and increases the water permeability. The medullary interstitium surrounding the collecting ducts is hypertonic with an osmolality up to 1200 mOsm kg^{-1}. When the water channels are open, water is reabsorbed along the osmotic gradient. In the absence of AVP, the kidneys excrete a large amount of hypoosmotic fluid rapidly. Urine osmolality reflects the kidneys' ability to dilute (removal of water) or concentrate (conservation of water) the urine. In a normal adult, the urine osmolality varies from 80 to 1200 mOsm kg^{-1}.

Thirst is more important than the AVP mechanism. In the absence of AVP secretion (e.g., patient with cranial diabetes insipidus), urinary water loss will increase. If the thirst mechanism is intact, water balance can still be maintained by an increase in water intake. However, patients with a defective thirst mechanism will be predisposed to dehydration, even if the AVP mechanism is normal.

Control of Thirst and AVP Secretion

Both osmotic and nonosmotic factors are involved in the regulation of thirst and AVP release. Amongst these, the osmotic factor (i.e., plasma tonicity) is more important. The factors and their effects are summarized in Tables 1 and 2.

The osmolality sensor (osmoreceptor), the thirst center, and the AVP secretory cells are located in the hypothalamus. The sensor is a group of specialized cells that is remarkably sensitive to the changes of tonicity in the ECF. When there is a water deficit (Figure 2), plasma tonicity will increase. The osmoreceptors will send a signal to both the thirst center and the AVP secretory cells. Intake of water will be increased, and the kidneys will retain water via the action of released AVP.

Conversely, when there is excessive water (Figure 2), plasma tonicity will decrease. Both the thirst center and secretion of AVP will be inhibited to promote net urinary water loss. These responses act as a feedback loop to keep the plasma tonicity and, hence, the body water content within tight limits.

Table 1 Control of thirst

Factors	*Stimulation*	*Inhibition*
Osmotic	↑ Tonicity	↓ Tonicity
Nonosmotic	↓ ECF volume	↑ ECF volume
	Congestive heart failure	Dopamine antagonists
	Hormones/drugs

Kidneys and Water Balance

A nephron is the functional unit of the kidneys. Each kidney contains approximately one million such units. A nephron is composed of a glomerulus and a renal tubule (Figure 3). The renal tubule is subdivided further into the proximal convoluted tubule, the loop

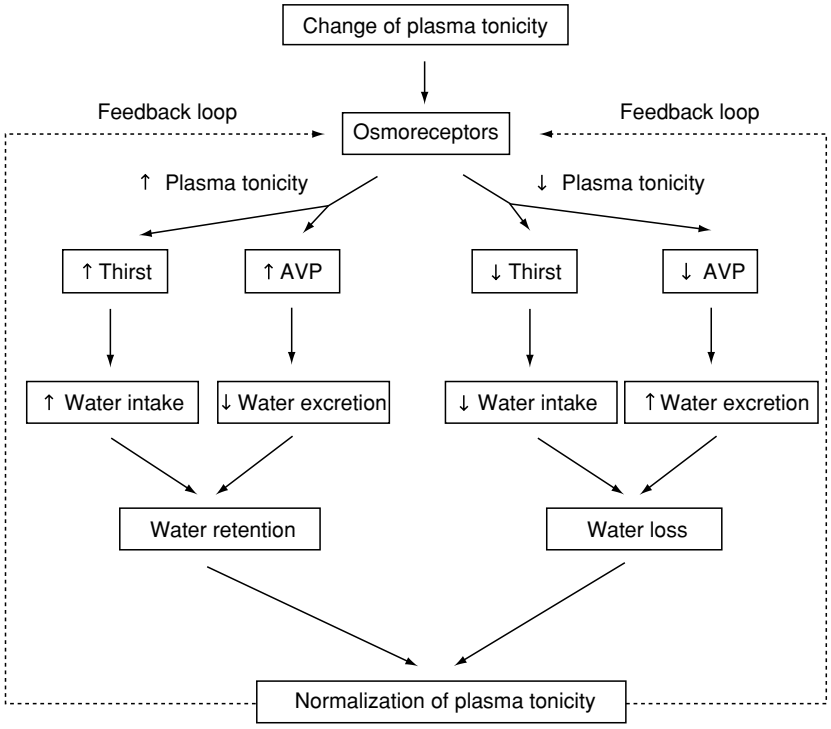

Figure 2 Pathway of water conservation/excretion. AVP, arginine vasopressin.

of Henle, the distal convoluted tubule, and the collecting duct.

The glomeruli filter about 180 l of fluid (which contains water, electrolytes, and glucose) each day. Up to 90–99% of the filtered water is reabsorbed by the renal tubules. It is reabsorbed passively in the proximal convoluted tubules (60–70% of the filtered water) and the descending limbs of the loops of Henle, with down osmotic gradients created by the active transport of sodium and chloride out of the lumina. Water is not permeable in the ascending limb of the loop of Henle and the distal convoluted tubule. The final urine volume is determined by the action of AVP on the collecting ducts.

Sodium Balance

Sodium Content in the Body

For a normal adult, total body sodium content is about 55–60 mmol per kilogram of body weight. The distribution of sodium in different compartments of the body is shown in Figure 4.

Sodium is the major cation in the ECF. Its concentration is about 135–145 mmol l^{-1} and 3 mmol l^{-1} in the ECF and ICF, respectively. The high sodium content in the ECF is maintained by sodium–potassium–adenosine triphosphatase (Na^+–K^+ –ATPase) pumps. The Na^+ –K^+–ATPase pump is located in the cell membrane, and it hydrolyzes a molecule of adenosine triphosphate to release energy to pump three sodium molecules out of the cells (from ICF to ECF) and to transport two potassium molecules into the cells (from ECF to ICF). In normal circumstances, sodium and its accompanying anions (mainly chloride) contribute to more than 90% of the effective osmolality in the ECF. As noted previously, effective osmolality determines the volume in the corresponding compartment. Therefore, sodium is the major determinant of the ECF volume. An excess in total body sodium content leads to expansion of the ECF volume, and a deficit in total body sodium content is associated with contraction of the ECF volume. A stable ECF volume is essential to maintain tissue perfusion, because the plasma volume (one of the compartments in ECF) is directly proportional to the ECF volume.

Sodium Intake and Excretion

A typical Western diet contains approximately 150 mmol of sodium per day. However, social and cultural differences in dietary habits can have a significant effect on sodium intake. Amounts of sodium can be up to 300 mmol per day in some areas in Japan to less than 30 mmol per day in the New Guinea Highlands. In normal health, the amount of sodium

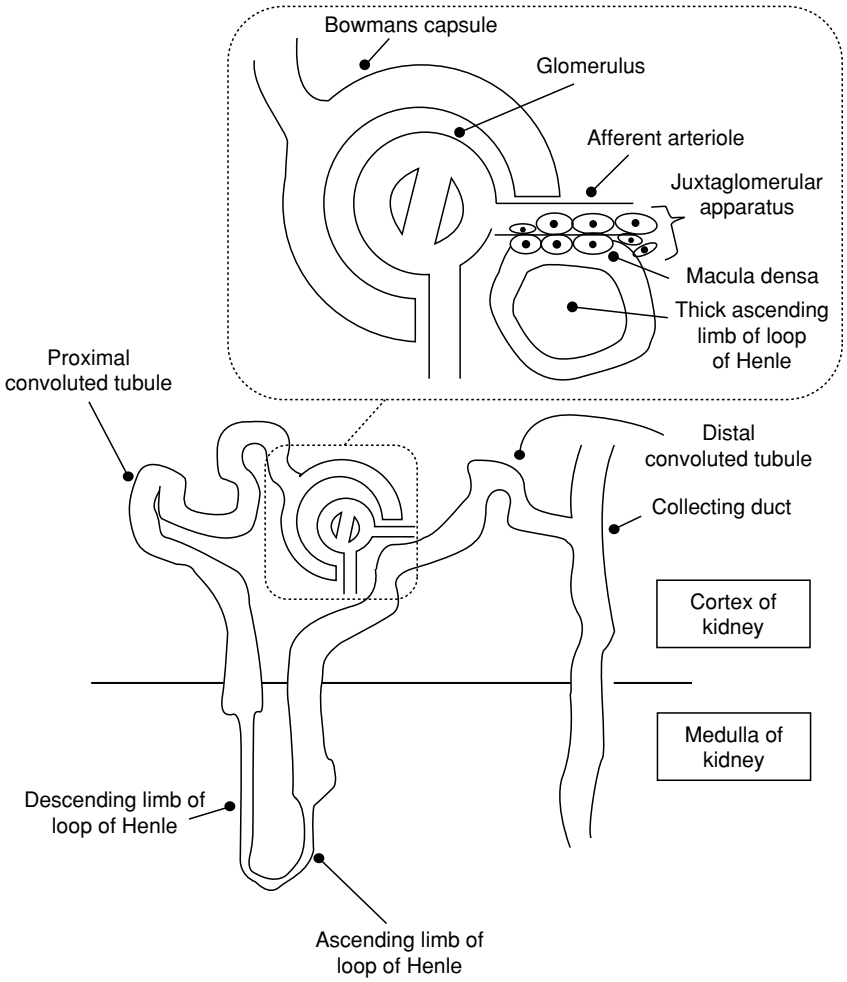

Figure 3 Nephron and juxtaglomerular apparatus.

excretion in the stool (about 5 mmol per day) and sweat (about 10 mmol per day) is small and cannot be regulated. Urine is the only route by which sodium excretion can be precisely regulated to match the sodium intake. Depending on the dietary intake and the status of body sodium content, urinary sodium loss can range from less than 1 mmol in a state of sodium deficit, to more than 500 mmol per day in a state of sodium excess. Thus, the kidneys have an important role in maintaining sodium balance and ensuring a stable ECF volume.

Kidneys and Sodium Balance

In people with normal kidney function, the glomeruli filter about 25 000 mmol sodium each day. This amount is approximately six times the total body sodium. Consequently, control of sodium reabsorption is important in maintaining sodium homeostasis. As shown in Table 3, most of the filtered sodium (60–70%) is reabsorbed at the proximal convoluted tubules. Twenty to twenty-five per cent is reabsorbed at the thick ascending limbs of the loops of Henle, and another 10–15% is reabsorbed at the distal nephrons (distal convoluted tubules and collecting ducts).

Although the distal nephron is responsible for a relatively small amount of sodium recovery, this segment of renal tubule is important for fine-tuning sodium reabsorption.

There are two pathways by which sodium is reabsorbed from the lumen to the renal tubular cells: the paracellular pathway and the transporters at the luminal membrane (Figure 5).

The paracellular pathway refers to channels between renal tubular cells. Sodium is freely permeable in these channels in the proximal convoluted tubule and the thick ascending limb of the loop of Henle, but not in the distal nephron. The transporters at the luminal membrane are different in various segments of the renal tubule (Table 3). There are generally three

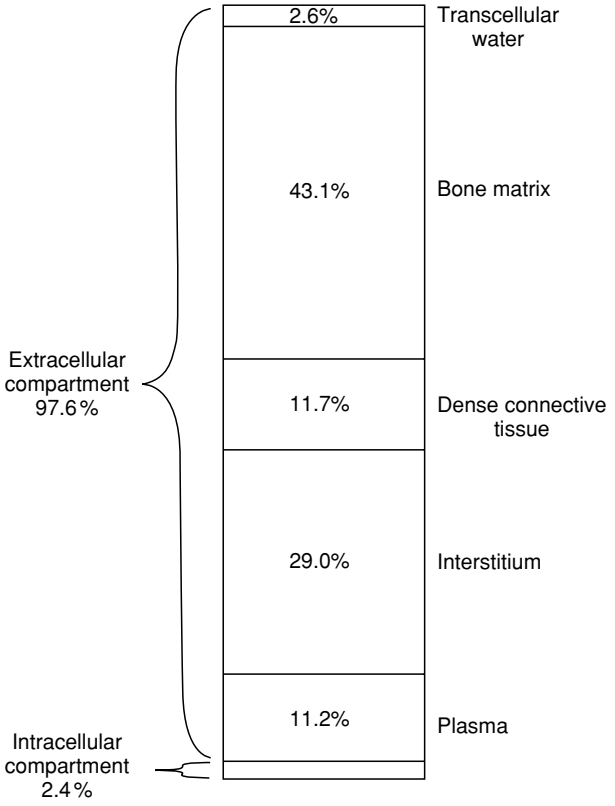

Figure 4 Distribution of body sodium, expressed as a percentage of total body sodium content.

classes of transporters, namely *sodium exchanger*, *sodium cotransporter*, and *specific sodium channel*. The *sodium exchanger* moves sodium into the cell in exchange for another cation (for instance, potassium and hydrogen ion) moving out of the cell. The *sodium cotransporter* couples sodium entry with the entry of other solutes, such as amino acids, glucose, phosphate, potassium, and chloride. The *specific sodium channel* is present in the principal cells of the cortical and medullary collecting duct (the intercalated cell is the other cell type in the collecting duct that is involved in acid or bicarbonate secretion and potassium reabsorption). Under the effect of aldosterone, the channel opens and allows passage of sodium ions only.

The pathways share the same mechanism for sodium transport (Figure 5). There are Na^+–K^+–ATPase pumps that operate across the base of renal tubular cells and also across their lateral walls into the intercellular spaces (also known as the basolateral membrane). The pumps pump out sodium and keep the intracellular sodium at a low level, which then provides a steep electrochemical gradient favoring reabsorption of sodium from the lumen, through the various pathways (paracellular pathway and sodium transporters), into the cells. Having entered the renal tubular cell, the sodium then moves across the basolateral membrane into the peritubular space by the Na^+–K^+–ATPase pumps. The sodium then enters the peritubular capillary and returns back to the ECF.

Regulation of Urinary Sodium Excretion

Numerous mechanisms have been implicated in the regulation of sodium balance and maintenance of a stable ECF. It is unclear whether there are any other mechanisms that have not been discovered yet. The identified mechanisms are overlapped and extensively interrelated. Failure of one of the mechanisms does not result in significant long-term effects. This arrangement is important to maintain stability of the ECF volume. The more constant the ECF volume, the more the body will be protected from changes in the external environment.

The sensing mechanisms include: (1) *mechanoreceptors* in the walls of large blood vessels and cardiac chambers (detecting changes in vascular distension); (2) *chemoreceptors* in the renal tubule (macula densa, responding to an alternation in luminal sodium and chloride ions concentration); (3) *volume receptors* in the central nervous system (sensitive to a change in sodium level in the cerebrospinal fluid); and (4) *peripheral tissue receptors* (monitoring the adequacy of tissue perfusion). The sensors feed back signals to several mediating mechanisms, and the kidneys are then 'informed' by renal nerves, hormones, and physical factors to retain or excrete sodium in the urine.

Factors that affect sodium reabsorption by the renal tubule are listed in Table 3. The major mediating mechanisms are described below.

-Tubuloglomerular feedback The thick ascending limb of the loop of Henle has a cortical segment that closely relates to the afferent arteriole of the parent glomerulus. The cells in this particular segment of the renal tubule constitute the macula densa. The macula densa, the corresponding afferent arteriole, and the nearby extraglomerular mesangium are collectively called the juxtaglomerular apparatus (Figure 3). Changes in the delivery and composition of the fluid flowing past the macula densa elicit changes in glomerular filtration of the same nephron via the interaction of angiotensin II and nitric oxide. For instance, an increase in the delivery of fluid to the macula densa or a low sodium and chloride concentration in the fluid will stimulate the juxtaglomerular apparatus. The renin–angiotensin system is then activated to reduce urinary sodium excretion.

Table 3 Tubular sodium absorption

Renal tubule	*Amount of reabsorbed sodium (%)*	*Sodium reabsorption pathways*		*Factors that stimulate luminal transporter to enhance sodium reabsorption*	*Factors that inhibit luminal transporter to decrease sodium reabsorption*
		Paracellular pathways	*Luminal transporters*		
Proximal convoluted tubule	60–70%	Presence	Sodium–hydrogen ion exchanger	α-Adrenergic agonist[a] Angiotensin II[a] Thyroid hormone[a]	Dopamine[a] Parathyroid hormone[a]
			Sodium–amino acids/glucose/ phosphate cotransporter		
Loop of Henle (thick ascending limb)	20–25%	Presence	Sodium-2 chloride–potassium ion cotransporter	Arginine vasopressin	Loop diuretics Prostaglandin E_2 Cytochrome P450 metabolites of arachidonic acid
Distal convoluted tubule	10%	Absence	Sodium–chloride ion cotransporter	Aldosterone Angiotensin II Sympathetic nerves	Thiazide diuretics
Collecting duct	5%	Absence	Sodium channel	Aldosterone[b] Arginine vasopressin[b]	Potassium-sparing diuretics[b] Atrial natriuretic peptide[b] Bradykinin[b] α_2-Adrenergic agonists[b] Atrial natriuretic peptide[c] Prostaglandin E_2[c]

[a]Factors affecting the sodium–hydrogen ion exchanger.
[b]Factors affecting the sodium channel at the cortical collecting duct.
[c]Factors affecting the sodium channel at the medullary collecting duct.

-Renin–angiotensin system and aldosterone When there is sodium depletion or a reduction in kidney perfusion (for instance, secondary to a low ECF volume), the juxtaglomerular apparatus releases an enzyme, called renin, in the circulation. Renin then acts on angiotensinogen to release angiotensin I. The latter is converted to angiotensin II under the action of the angiotensin-converting enzyme. Angiotensin II stimulates the release of aldosterone, a hormone produced by zona glomerulosa cells of the adrenal cortex.

Angiotensin II reduces urinary sodium excretion by constricting the glomerular arterioles and decreasing the volume of glomerular filtrate, by enhancing sodium reabsorption at the proximal convoluted tubule, and by increasing the responsiveness of tubuloglomerular feedback to a given concentration of sodium and chloride ions at the macula densa. Aldosterone enhances sodium reabsorption by opening up the specific sodium channels at the collecting ducts, and by stimulating the action and synthesis of Na^+–K^+–ATPase pumps at the basolateral membrane of renal tubular cells.

-Sympathetic nervous system The kidneys receive a rich supply of sympathetic nerves. There is evidence that sodium and volume depletion activate renal sympathetic nerves. The kidneys then conserve sodium by constricting the glomerular arterioles, by increasing sodium reabsorption at the proximal convoluted tubules, by increasing renin release from juxtaglomerular apparatus, and by interacting with AVP and atrial natriuretic peptide (ANP).

-Atrial natriuretic peptide Atrial natriuretic peptide is a peptide hormone and is synthesized by atrial myocytes in cardiac atria. When the ECF volume is expanded, the atrial wall distends, and ANP is released. ANP enhances sodium excretion by inhibiting sodium reabsorption at the collecting duct.

Response to Dietary Sodium Intake

Although the relative importance of the different regulatory mechanisms is not well established, many studies suggest that the renin–angiotensin system, aldosterone, and the sympathetic nervous system appear to be more important in conserving sodium

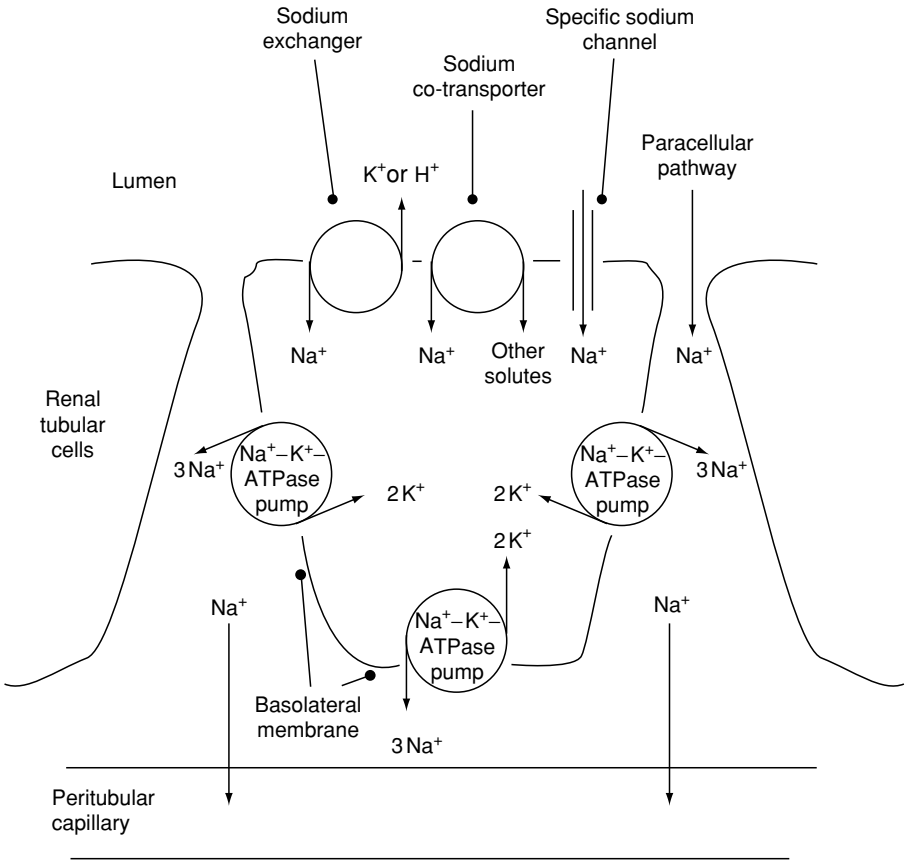

Figure 5 Renal transport of sodium. K^+, potassium ion; H^+, hydrogen ion; Na^+, sodium ion; Na^+–K^+–ATPase pump, sodium–potassium–adenosine triphosphatase pump. The sodium exchanger moves Na^+ into the cell in exchange for another cation (e.g., K^+ and H^+), sodium cotransporter couples sodium entry with the entry of other solutes (e.g., amino acids, glucose, phosphate, K^+ and chloride ion), and the Na^+–K^+–ATPase pump pumps out three Na^+ and transports in two K^+.

for people with a low sodium intake, and the tubuloglomerular feedback seems to be more important in excreting excessive sodium for people with a very high sodium intake.

Potassium Balance

Potassium Content in the Body

The total body potassium content is dependent on sex, age, and, most importantly, muscle mass (which contains 60–75% of total body potassium), and is approximately 40–45, and 50–55 mmol per kilogram of body weight for normal adult women and men, respectively. These values decrease with age and are 20% less in the elderly because of a decrease in muscle mass.

About 90% of the body's potassium is in the ICF. Only 0.4% of the body's potassium is distributed in the vascular space of the ECF (Figure 6).

Potassium is the major cation in the ICF, and the intracellular potassium concentration is approximately 150 mmol l^{-1}. In the ECF, however, the plasma potassium level normally ranges from only 3.5 to 5.0 mmol l^{-1}. The intracellular-to-extracellular potassium concentration ratio is the most important determinant of the resting membrane potential of neuromuscular tissue. Disturbances in this ratio will predispose patients to several clinical disorders, such as cardiac arrhythmia and neuromuscular problems.

Factors that Maintain the Potassium Distribution Between ICF and ECF

Potassium leaks passively from the cell to the ECF space through the ion-selective potassium channels in the cell membrane. A high intracellular potassium concentration is maintained by Na^+–K^+–ATPase pumps that actively transport potassium molecules back into the cells. Factors that alter the activity of Na^+–K^+–ATPase pumps and ion-selective potassium channels affect the transcellular potassium

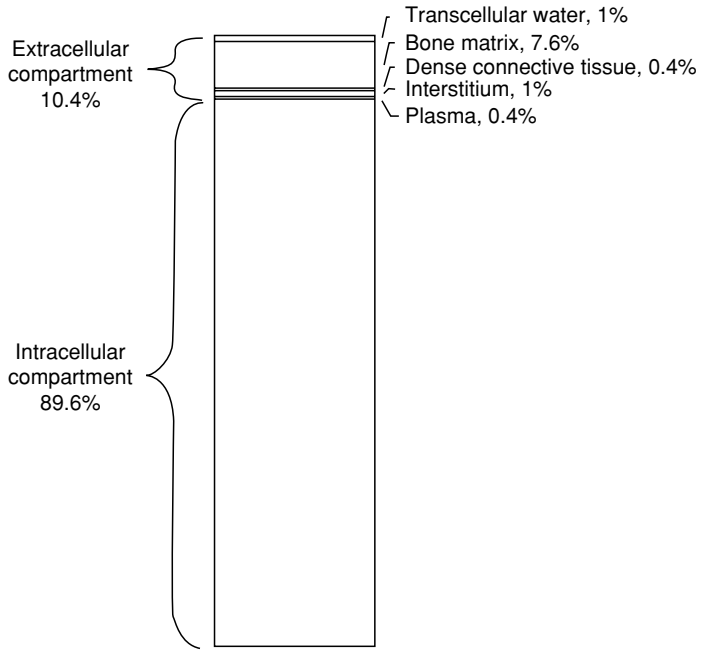

Figure 6 Distribution of body potassium, expressed as a percentage of total body potassium content.

Table 4 Factors that regulate the transcellular potassium distribution

	Movement of potassium
Acid–base status	
Acidosis by mineral acid (e.g., hydrochloric acid)	ICF → ECF
Acidosis by organic acid (e.g., lactic acid, β-hydroxybutyric acid, methylmalonic acid)	No effect
Alkalosis	ECF → ICF
Insulin	ECF → ICF
Glucagon	ICF → ECF
β_2-Adrenergic agonist	ECF → ICF
α-Adrenergic agonist	ICF → ECF
Aldosterone	? ECF → ICF
Hyperosmolality (e.g., mannitol, hyperglycemia)	ICF → ECF
Exercise	ICF → ECF

distribution, resulting in hypo- or hyperkalemia without any change in the total body potassium content. These factors are listed in Table 4.

Potassium Intake and Excretion

Potassium is present in all protein-containing foods, particularly meats. Each gram of dietary protein contains approximately 1 mmol of potassium. Hence, potassium intake is directly related to protein intake. The average Western diet provides 60–100 mmol of potassium each day. In the steady state, about 80–95% of the daily potassium intake is excreted in urine, 5–20% is excreted in the stools (mainly by the colon), and less than 5% is eliminated in sweat. However, in renal failure (with a glomerular filtration rate of less than 20 ml min^{-1}) or diarrhea, potassium loss from the gastrointestinal tract can be significant. Moreover, potassium loss in sweat may be important if perspiration is excessive.

Kidneys and Potassium Balance

About 720 mmol of potassium is filtered through the glomeruli each day. Both potassium reabsorption and secretion occurs in renal tubules. The majority of the filtered potassium (66–75%) is reabsorbed passively at the proximal convoluted tubules and actively (via the sodium-2 chloride–potassium ion cotransporter) in the ascending limbs of the loops of Henle so that only 5–10% of the filtered potassium remains in the early distal convoluted tubules. Fine regulation of potassium excretion occurs at the distal nephron. The collecting duct is the major site of potassium secretion. Under the effect of Na^+–K^+–ATPase pumps at the basolateral membrane of the tubular cell (resulting in a high intracellular potassium concentration) and the effect of sodium absorption via the sodium channels at the luminal membrane (resulting in a negative electrical gradient in the lumen), an electrochemical gradient is set up to promote potassium secretion via the potassium selective channels on the luminal surface of the principal cells of the collecting duct. Factors that modify

Table 5 Factors affecting potassium secretion by the collecting duct

Factors	*Potassium secretion*
Plasma potassium concentration	
↑	↑
↓	↓
Urine flow rate at distal nephron	
↑	↑
↓	↓

Dietary potassium intake	
High	↑
Low	↓
Potassium-sparing diuretic	↓

potassium secretion by the collecting duct are listed in Table 5.

In the medullary collecting duct, potassium reabsorption occurs again. Potassium reabsorption is accompanied by proton secretion that is mediated via hydrogen–potassium ion (H^+–K^+) exchange pumps in the luminal membrane of intercalated cells of the medullary collecting duct. The activity of the H^+–K^+ exchange pump increases with potassium depletion and decreases with potassium loading.

It should be noted that the amount of potassium excreted in the urine depends on the relative degree of potassium secretion and reabsorption at the distal nephron. Moreover, it is clear, therefore, that the net potassium excretion is tightly linked to sodium reabsorption and hydrogen ion secretion in the distal nephron. Generally, renal regulation of sodium and hydrogen ion balance takes priority over regulation of potassium balance.

Response to Dietary Potassium Intake

Urinary excretion of a potassium load occurs over 24–48 h. It is not surprising that other factors, which are rapid and extremely sensitive to a change in potassium intake and output, are involved to maintain the constancy of the ratio of potassium concentration between the ICF and ECF.

High dietary potassium intake triggers several protective mechanisms to increase the cellular uptake of potassium, and to excrete the excessive potassium load by the colon and kidneys. The increase in cellular uptake of potassium is mediated through the release of insulin and catecholamine (Table 4) and probably mediated through an increase in activity of Na^+–K^+–ATPase pumps in skeletal muscle as well. Hyperkalemia stimulates aldosterone secretion. This hormone increases the colonic excretion of potassium directly as well as indirectly through an increase in Na^+–K^+–ATPase pump activity in the basolateral membrane of the colon.

Most of the potassium load is excreted by the kidneys. Similar to the colon, aldosterone increases urinary potassium secretion through an increase in Na^+–K^+–ATPase pump activity, and by increasing the potassium channels of the principal cells of the collecting duct. In addition, a high potassium intake inhibits sodium reabsorption, and hence water reabsorption, at the proximal convoluted tubule and the thick ascending limb of the loop of Henle. Consequently, sodium delivery and urine flow to the distal nephron increase. Moreover, hyperkalemia decreases renal ammonia production, which in turn stimulates aldosterone secretion. All these factors work directly on the distal nephron to increase potassium secretion (Table 5). The adapted kidney can excrete up to 20 times more potassium than the baseline.

Basically, the adaptation response to a low potassium intake is the reverse of that to a high potassium diet. The cellular uptake of potassium decreases by a decrease in the number of Na^+–K^+–ATPase pumps in skeletal muscle but not in other tissues like red blood cells and cardiac muscle. This shifting of potassium extracellularly from skeletal muscle aims to correct an extracellular potassium deficit caused by a low dietary intake. The colon and kidneys also conserve potassium by decreasing the secretion and increasing the reabsorption of potassium, respectively.

Acid–Base Balance

E W Kun and A W Yu, The Chinese University of Hong Kong, Hong Kong, China

Introduction

Virtually all cellular, tissue, and organ systems are sensitive to changes in the hydrogen ion (H^+) concentration in the body. They function best at an extracellular fluid H^+ concentration of 35–45 nmol l^{-1} (each nmol l^{-1} equals 10^{-6} mmol l^{-1}). This concentration is extremely low compared with other ions; sodium (Na^+), for example, has a 3 million times greater concentration. Therefore, H^+ concentration is commonly expressed as pH, a negative logarithm of H^+ concentration. Maintenance of acid–base balance in the body is important because H^+ binds avidly to proteins and changes their shape and function. Many essential metabolic, enzymatic, and transmembrane transport processes can be jeopardized because of alterations of the protein structure and function, resulting in severe organ dysfunction and clinical consequences. With an increase in body H^+ concentration, a patient may experience hypotension, depressed myocardial contractility, and sensorium. With decreased body H^+ concentration, the patient may develop coronary spasm, cardiac arrhythmias, hyperreflexia, muscle spasm, and seizure (Table 1).

In normal conditions, H^+ varies little from the normal value of approximately 40 nmol l^{-1}, even though acids and bases are continually being added to the extracellular fluid. This can be achieved by three homeostatic mechanisms: (1) intracellular and extracellular buffers; (2) changing partial pressure of carbon dioxide in the blood by altering the ventilation rate; and (3) renal H^+ excretion. The basic principles of acid–base physiology and the role of the kidneys and lungs in acid–base balance will be discussed in this article.

General Concepts

An acid is defined as a compound capable of donating an H^+, and a base is a compound that is capable of accepting an H^+. Examples of acids in the body include H_2CO_3, HCl, NH_4^+ and $H_2PO_4^-$, and examples of bases in the body are HCO_3^-, Cl^-, NH_3 and HPO_4^{2-}.

Food and cellular metabolism produces more acid than base. Base is lost in the feces daily. The net effect is the addition of acid to the body fluids. To maintain acid–base balance, acid must be excreted from the body at a rate equivalent to its addition. Acidosis (a disease process that tends to decrease the pH) results if acid addition exceeds excretion. Conversely, alkalosis (a disease process that tends to increase the pH) results if acid excretion exceeds addition. Systemic pH can still be maintained within a normal range at acidosis or alkalosis because of compensatory mechanisms, which are discussed in the section below. If these conditions or processes are left unopposed, the pH will increase or decrease from the normal range, and result in acidemia ($pH < 7.35$) or alkalemia ($pH > 7.45$). Metabolic acidosis results from a primary reduction in plasma bicarbonate concentration and respiratory acidosis results from a primary increase in CO_2 partial pressure (P_{CO_2}). Metabolic alkalosis is a result of a primary decrease in plasma bicarbonate concentration and respiratory alkalosis is a result of a primary decrease in P_{CO_2}. An increase in P_{CO_2} secondary to compensation for metabolic alkalosis is not called respiratory acidosis; a secondary decrease in P_{CO_2} in response to metabolic acidosis is not called respiratory alkalosis.

Acid and Alkali Generation

The major constituents of the human diet are carbohydrates, fats, and proteins. In normal conditions, 15 000 mmol CO_2 is generated from the metabolism of carbohydrates and fats. Although not an acid, this CO_2 will combine with H_2O to form H_2CO_3; therefore, it is termed a volatile acid, reflecting the fact that it has the potential to generate H^+ after hydration with H_2O. An accumulation of this endogenously produced CO_2 will result in respiratory acidosis (Table 2). Fortunately, this large quantity of CO_2 is eliminated by alveolar ventilation, and acid–base balance is maintained.

However, nonvolatile acids (mostly sulfuric acid) are primarily generated from the metabolism of proteins. For example, oxidation of the sulfur-containing amino acids cysteine and methionine yields sulfuric acid (H_2SO_4), whereas metabolism of lysine, arginine, and histidine generates hydrochloric acid (HCl).

Table 1 Clinical manifestations of an acid–base imbalance

Increased acidity (pH < 7.20)	*Increased alkalinity (pH > 7.55)*
Hypotension	Perioral and extremity paresthesias
Depressed myocardial contractility	Muscle spasms
Mental confusion	Hyperreflexia
	Seizures
	Coronary spasm
	Cardiac arrhythmias

Table 2 Generation of acid

Volatile acid – respiratory acidosis
CO_2 production (cellular metabolism)
Nonvolatile acids – metabolic acidosis
Dietary protein and phospholipid metabolism (sulfuric acid, phosphoric acid)
Diabetes mellitus (β-hydroxybutyric acid and acetoacetic acid)
Hypoxia (lactic acid)
Decreased tissue perfusion, e.g., vigorous exercise, heart failure, shock
Decreased renal H^+ excretion (e.g., renal failure, renal tubular acidosis)
Loss of HCO_3^-
Gastrointestinal losses in stool, e.g., diarrhea, external fistulae
Urinary losses of HCO_3^-, e.g., proximal renal tubular acidosis, drug (acetazolamide)

Part of this nonvolatile acid is neutralized by the bicarbonate (HCO_3^-) generated through metabolism of the amino acids, such as aspartate and glutamate, and certain organic anions, such as citrate. The net amount of nonvolatile acid produced depends on dietary intake. Ingestion of a meal with a large amount of meat will result in more acid production, whereas a vegetarian meal can result in less acid generation. In general, approximately 1 mmol kg^{-1} body weight of nonvolatile acid is added to the body each day (50–100 mmol day^{-1} for adults) on a typical diet. The nonvolatile acids are buffered initially, followed by renal excretion of the H^+.

In abnormal clinical conditions, e.g., diabetes mellitus and hypoxia, whereby carbohydrates and fats are incompletely metabolized to CO_2 and H_2O, other nonvolatile acids are produced (Table 2). In diabetes mellitus, when insulin levels are abnormally low, fatty acids are oxidized to yield energy. This leads to the production of acetone and two ketoacids (β-hydroxybutyric and acetoacetic acid). During hypoxia, oxygen delivery to cells is inadequate, glucose is metabolized anaerobically to pyruvate and then to lactate and an H^+ (one per lactate). Therefore, normal individuals performing vigorous exercise, patients with reduced cardiac output (heart failure), and those with hypotension (shock) usually have higher lactic acid levels. The acid produced will combine with HCO_3^- and lower the plasma HCO_3^- concentration producing metabolic acidosis:

$$H^+ + HCO_3^- \rightarrow H_2CO_3$$

With an increased production of acid, the kidneys may increase excretion of H^+ and maintain the acid–base balance. However, in the presence of renal diseases (renal failure or renal tubular acidosis), endogenous acid production or ingestion of acid-producing substances, e.g., aspirin (salicylic acid), methanol, and ethylene glycol, may exceed the capacity of the buffer system and renal excretion of H^+. This will result in metabolic acidosis (Table 2).

The loss of HCO_3^- from the body is also equivalent to the addition of acid and produces metabolic acidosis. This is commonly associated with gastrointestinal or renal loss of bicarbonate (Table 2).

Whereas the stomach is an acid-secreting organ, the gastrointestinal tract distal to the stomach is bicarbonate-secreting. The small bowel has a daily secretory volume of 600–700 ml and this may be markedly increased if the small bowel is diseased. The biliary system secretes about 1 l of fluid per day containing an HCO_3^- concentration of 60 mmol l^{-1}, whereas the pancreas secretes 2 l day^{-1} with an HCO_3^- concentration reaching 120 mmol l^{-1}. Most of the secretions are reabsorbed, but with diarrhea and external drainage of pancreatic, biliary, or small-bowel juice (external fistulae), the loss of HCO_3^--rich fluid results (Table 2).

As mentioned above, alkali can also be produced by the metabolism of certain amino acids but it is neutralized by the larger amount of dietary acid produced. A net alkali excess can only occur when there is exogenous alkali ingestion, primary increase in ventilation with lowering of P_{CO_2} (respiratory alkalosis), and excessive H^+ loss from the stomach or kidneys (metabolic alkalosis). Milk-alkali syndrome is seen in patients with gastric distress who consume large amounts of milk and antacids containing calcium carbonate and sodium bicarbonate. Suppression of parathyroid hormone secretion caused by hypercalcemia from absorbed calcium contributes to failure to excrete the alkali load. Chronically, nephrocalcinosis and renal failure develop, which further reduces the excretion of the absorbed alkali, causing metabolic alkalosis (Table 3).

The Buffering System

One of the major ways in which large changes in H^+ concentration are prevented is by buffering. A 'buffer'

Table 3 Generation of alkali

Volatile alkali – respiratory alkalosis
CO_2 removal (hyperventilation)
Nonvolatile alkali – metabolic alkalosis
Loss of acid
Gastrointestinal losses in gastric fluid, e.g., vomiting, gastric suction
Urinary losses of H^+: diuretics, licorice excess, hyperaldosteronism, Bartter's syndrome, Cushing's syndrome
Exogenous alkali loads
Milk-alkali syndrome
Sodium bicarbonate ingestion

is a pair of substances that can donate or accept an H^+ to moderate changes in H^+ concentration or pH. This is the most immediate mechanism of defense against changes in physiological pH. The major buffers in the body are H_2CO_3-HCO_3^- (pK_a 6.1), $H_2PO_4^-$-HPO_4^{2-} (pK_a 6.8), and H-protein$^-$. The dissociation constant (pK_a) and pH determine whether a buffer pair will bind or release the H^+ in the solution. When the pH is 1.0 unit below the pK_a, H^+ will bind to the buffer pair, whereas at 1.0 unit above the pK_a, H^+ will release.

Bicarbonate/carbon dioxide is the most important extracellular buffer in the body. This buffer system can be described by the following reactions:

$$\underset{\text{(gaseous)}}{CO_2} \leftrightarrow \underset{\text{(aqueous)}}{CO_2 + H_2O} \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \quad \text{(Carbonic anhydrase)}$$

$$40\,\text{mmHg}\ (5.3\text{kPa}) \qquad 1.2\,\text{mmol}\,l^{-1} \qquad 24\,\text{mmol}\,l^{-1} \tag{1}$$

The hydration/dehydration of CO_2 is the rate-limiting step and is enhanced by the enzyme carbonic anhydrase (CA). When H_2CO_3 is formed, it is ionized to H^+ and HCO_3^- virtually instantaneously. The relationship of pH, HCO_3^-, and P_{CO_2} is described by the Henderson–Hasselbalch equation:

$$\text{pH} = \text{p}K_a + \log\{[HCO_3^-] \div [0.03 \times P_{CO_2}]\}$$

where pK_a = 6.1, HCO_3^- is in mmol$\,l^{-1}$, and P_{CO_2} is in mmHg.

When nonvolatile acid is added to the body fluids, the reaction of eqn (1) is driven to the left. HCO_3^- is consumed during the buffering and plasma HCO_3^- concentration is reduced. In contrast, when acid is removed from the body, the reaction is driven to the right. More HCO_3^- is produced from the dissociation of H_2CO_3 (carbonic acid) and HCO_3^- concentration increases. With a normal plasma HCO_3^- concentration of 24 mmol$\,l^{-1}$ and an extracellular fluid volume of 14 l, this HCO_3^- buffer system can potentially buffer 340 mmol acid. However, for optimal function of this system, regeneration and maintenance of normal HCO_3^- concentration by the lungs and kidneys are required.

In addition, the bones can release buffer compounds such as $NaHCO_3$, $K\,HCO_3$, $CaCO_3$ and $Ca\,HPO_4$ into extracellular fluid when stimulated by a decrease in the plasma HCO_3^- concentration. It has been estimated that as much as 40% of the buffering of acute acid load takes place in the bones. The role of bone buffers is even greater in chronic acidosis, such as that seen in chronic renal failure. One of the consequences is that acid loading directly increases Ca^{2+} release from the bones and urinary Ca^{2+} excretion, promoting stone formation. An inappropriately high-protein diet may increase acid load (a normal diet produces about 70 mmol acid per day) and promote calcium stone formation. In patients with end-stage renal disease, a disorder associated with progressive acid retention caused by impaired urinary acid excretion, there is a gradual reduction in bone calcium stores.

Plasma phosphate and protein also act as extracellular buffers but they are less important quantitatively (plasma phosphate concentration is 1 mmol$\,l^{-1}$ versus 24 mmol$\,l^{-1}$ HCO_3^-).

$$H^+ + HPO_4^{2-} \leftrightarrow H_2PO_4^- \tag{2}$$

$$H^+ + \text{protein}^- \leftrightarrow \text{H-protein} \tag{3}$$

However, intracellularly, phosphate and protein are important buffers besides HCO_3^-. In metabolic acidosis, about 43% of buffering occurs in the extracellular fluid and 57% of buffering is mediated by intracellular buffering. Whereas extracellular H^+ is buffered immediately, buffering by intracellular buffers takes about 2–4 h. This is the time required for H^+ to diffuse into interstitial spaces and enter cells, which occurs more slowly.

Respiratory Control of Acid–Base Balance

Alveolar ventilation provides oxygen for oxidative metabolism and eliminates the CO_2 produced by these metabolic processes in order to maintain P_{CO_2} at about 5.3 kPa (40 mmHg). Approximately 15 000 mmol CO_2 is produced daily and eliminated by the lungs. The stimulation to ventilation is located in the chemoreceptors in the brainstem respiratory center (medulla oblongata) and to a lesser extent in the carotid bodies located near the bifurcation of the carotid arteries. The chemoreceptors are sensitive to changes in the cerebral interstitial pH. With increased CO_2 in the blood, cerebral interstitial pH will decrease and result in the stimulation of ventilation that will return P_{CO_2} to normal. In contrast, interstitial pH will increase with decreased plasma CO_2, resulting in ventilation inhibition (**Figure 1**).

Alveolar ventilation is also affected by metabolic acid–base imbalance. Acidemia caused by metabolic acidosis can increase minute ventilation from the normal of approximately 5 l min^{-1} to greater than 30 l min^{-1} as the arterial pH decreases from 7.40 to 7.00. The central chemoreceptors are relatively insulated by the blood–brain barrier and only CO_2, but not HCO_3^-, rapidly crosses the blood–brain barrier. Hence, the effect on cerebral interstitial pH is slower, and a full ventilation response to nonvolatile acid or a

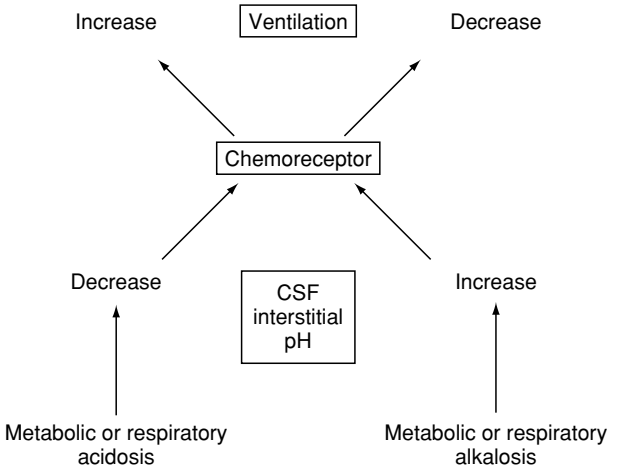

Figure 1 Respiratory control of acid–base balance. CSF, cerebrospinal fluid.

decrease in plasma HCO_3^- may only be achieved in 12–24 h. The P_{CO_2} will decrease by 0.16 kPa for every mmol l^{-1} reduction of HCO_3^- concentration. Conversely, ventilation decreases with metabolic alkalosis with a consequent increase in P_{CO_2} (0.08 kPa per every mmol l^{-1} increase in HCO_3^-), lowering the pH towards normal.

An acid–base imbalance can also be initiated by a change in carbon dioxide tension of body fluids. A primary increase in P_{CO_2} (primary hypercapnia), $P_{CO_2} > 6.0$ kPa, results in respiratory acidosis. This needs to be distinguished from the secondary hypercapnia that results from the correction of metabolic alkalosis. Hypercapnia (respiratory acidosis) could develop from increased CO_2 production, decreased CO_2 excretion, or both (Table 4).

The administration of large carbohydrate loads (greater than 2000 kcal day^{-1}) and parenteral nutrition to critically ill patients may increase CO_2 production. This is rarely the sole cause of hypercapnia. Increased CO_2 decreases cerebral interstitial pH, resulting in an increment in respiratory drive, and the overproduction of CO_2 is usually matched by increased excretion and the generation of respiratory acidosis is prevented. Patients with a marked limitation in respiratory reserve (e.g., chronic obstructive lung disease) and those receiving constant mechanical ventilation may not be able to match the CO_2 production with its removal, resulting in respiratory acidosis (Table 4). Therefore, it is recommended that patients with chronic obstructive airway disease avoid a high-carbohydrate diet to avert further retention of CO_2.

However, excessive alveolar ventilation relative to the prevailing carbon dioxide production results in primary hypocapnia and respiratory alkalosis. This is usually attributed to hyperventilation as a result of increased ventilatory drive, hypoxia, and maladjusted mechanical ventilators (Table 5).

The body responds to hypercapnia and hypocapnia in two phases (acute and chronic). The acute phase takes about 5–10 min to complete. If hyper/hypocapnia persists (chronic phase), adaptation requires a few days to complete.

In acute hypercapnia, CO_2 diffuses into the cells, forming carbonic acid which is buffered by intracellular buffers (such as phosphate or hemoglobulin), resulting in an increase of plasma bicarbonate concentration (Figure 2). On average, plasma bicarbonate concentration increases by 0.8 mmol l^{-1} for each kPa acute increase in P_{CO_2}. Mild increases of Na^+ and K^+ are also observed in addition to the increment in plasma bicarbonate concentration.

Table 4 Causes of primary respiratory acidosis

Increased CO_2 production
High-carbohydrate diet with constant mechanical ventilation
CO_2 insufflation during endoscopic procedures
Decreased CO_2 removal
Pulmonary disease
Asthma
Chronic obstruction airway disease
Pulmonary fibrosis
Mechanical ventilatory defect
Pneumothorax
Hemothorax/hydrothorax
Adult respiratory distress syndrome
Muscular or neuromuscular diseases (e.g., Guillain–Barré syndrome, amyotrophic lateral sclerosis, multiple sclerosis)
Defect in respiratory drive
Brainstem infarct
Sleep apnea
Drugs (opiates and sedatives)
Other
Cardiac arrest
Shock
Severe pulmonary edema
Massive pulmonary embolus

Table 5 Causes of primary respiratory alkalosis

Increased central nervous system respiratory drive
Anxiety
Brain infarction, trauma
Sepsis and fever
Drugs (salicylate, nicotine, doxapram)
Tissue hypoxia
Severe anemia
High altitude
Cyanotic heart disease
Pneumonia
Iatrogenic
Increased mechanical ventilation

If hypercapnia persists, an adaptive increment in plasma bicarbonate concentration is markedly amplified as a result of increasing renal acid excretion, generating new bicarbonate that is returned to the blood. Plasma bicarbonate increases by 3.0 mmol l^{-1} with each kPa chronic increase in P_{CO_2}. The renal response usually takes 1–2 days to develop fully.

In contrast, adaptation to hypocapnia is associated with an immediate decrement in plasma bicarbonate of 1.5 mmol l^{-1} for each kPa acute decrease in P_{CO_2}. With persisting hypocapnia, renal adaptation requires 3–4 days to complete. This results in a larger decrement in plasma bicarbonate (3.8 mmol l^{-1} for each kPa of chronic decrease in P_{CO_2}). The relative changes of P_{CO_2}, HCO_3^-, and pH in various acid–base disorders are summarized in Table 6.

Renal Control of Acid–Base Balance

Despite the efficacy of respiratory and buffering systems in maintaining the acid–base balance, the ventilation rate is limited, and the body buffers eventually deplete if the dietary acid load (50–100 mmol H^+) is not excreted in the urine. The kidneys have the important role of regulating the systemic bicarbonate concentration and defending against acid–base imbalance. The kidneys make appropriate adjustments in the secretion of HCO_3^- and H^+. The renal response requires several days to complete. There are two components in this regulatory process: (1) reabsorption of filtered HCO_3^-, and (2) generation of bicarbonate by net H^+ excretion.

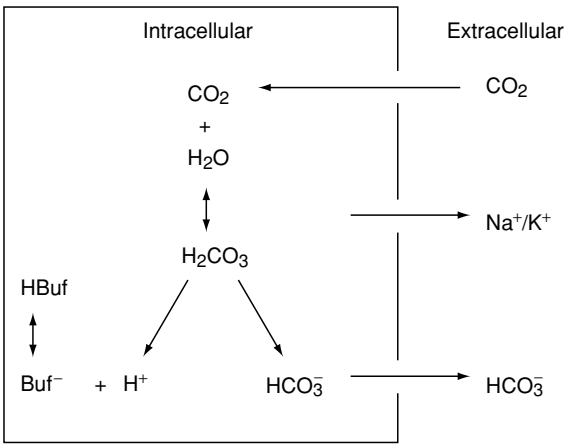

Figure 2 Intracellular buffering response to respiratory acidosis. Buf^-, buffer.

Reabsorption of Filtered Bicarbonate

The glomeruli filter about 4300 mmol bicarbonate per day. About 80% of the filtered bicarbonate is reabsorbed in the proximal tubules, whereas the remainder is reabsorbed in the distal segments. CA has a central role in reabsorption of HCO_3^-. The filtered HCO_3^- generates carbonic acid (H_2CO_3) by combining with the excreted H^+. CA, located in the brush border of the proximal tubular cells, rapidly dissociates H_2CO_3 into water and CO_2. CO_2 then diffuses into the tubular cells where it combines with the OH^- from H_2O, forming HCO_3^- and H^+. H^+ is excreted by Na^+-H^+ antiporters and the HCO_3^- leaves the cells and enters the peritubular capillary blood by Na^+–3 HCO_3^- cotransporter in the basolateral membrane. The tubular fluid pH decreases from 7.40 in the filtrate to about 6.70 by the end of the proximal convoluted tubule (Figure 3).

Renal Tubular H^+ Excretion

The above process reclaims the filtered bicarbonate but does not participate in the excretion of the dietary acid load. The H^+ requires combination with buffers or the formation of ammonium for excretion. Weak acids (titratable acids) filtered from the glomeruli, mostly monobasic phosphate (HPO_4^{2-}), act as important buffers in the tubular fluid (Figure 3). This can account for the excretion of 10–40 mmol H^+ per day. Buffering by phosphate and, to a lesser extent, other buffers such as urate and creatinine is called titratable acidity. In the presence of an acid load, the amount of titratable acidity cannot be easily increased.

Table 6 Changes of pH, P_{CO_2} (kPa) and HCO_3^- (mmol l^{-1}) in simple acid–base

Disorder	*pH*	P_{CO_2}	HCO_3^-	*Expected changes*
Metabolic acidosis	↓	↓	↓	$\Delta P_{CO_2} = 0.16 \times \Delta [HCO_3^-]$
Metabolic alkalosis	↑	↑	↑	$\Delta P_{CO_2} = 0.08 \times \Delta [HCO_3^-]$
Respiratory acidosis	↓	↑	↑	
Acute				$\Delta [HCO_3^-] = 0.8 \times \Delta P_{CO_2}$
Chronic				$\Delta [HCO_3^-] = 3.0 \times \Delta P_{CO_2}$
Respiratory alkalosis	↑	↓	↓	
Acute				$\Delta [HCO_3^-] = 1.5 \times \Delta P_{CO_2}$
Chronic				$\Delta [HCO_3^-] = 3.8 \times \Delta P_{CO_2}$

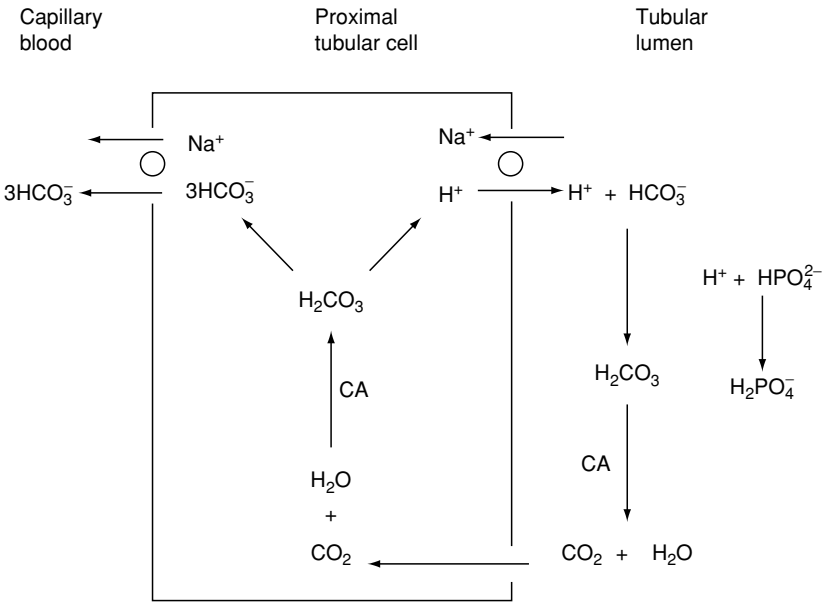

Figure 3 Bicarbonate reabsorption and acid excretion in the proximal tubule. CA, carbonic anhydrase.

Ammonium excretion constitutes the major adaptive response to an acid load.

Ammonium Excretion

The excretion of H^+ as ammonium (NH_4^+) is an important step in acid–base regulation because the rate of NH_4^+ production and excretion can be regulated in response to the physiological needs. NH_4^+ excretion in the urine represents acid excretion and generation of new bicarbonate by the kidneys.

$$H^+ + NH_3 \leftrightarrow NH_4^+$$

The normal rate of NH_4^+ excretion in the urine is about 30–40 mmol day^{-1}. It can be increased to > 300 mmol day^{-1} after a maximum acid load.

NH_4^+ production in the kidneys takes place predominantly in the proximal tubules. Glutamine (primarily from the liver) is the major precursor of ammonia in the kidneys. Glutamine is metabolized in the kidneys to glutamate and NH_4^+.

$$\text{Glutamine} \rightarrow 2NH_4^+ + \text{glutamate}^- \rightarrow 2NH_4^+ + \alpha\text{-ketoglutarate}^{2-}$$

The metabolism of α-ketoglutarate generates two HCO_3^- that are returned to the systemic circulation.

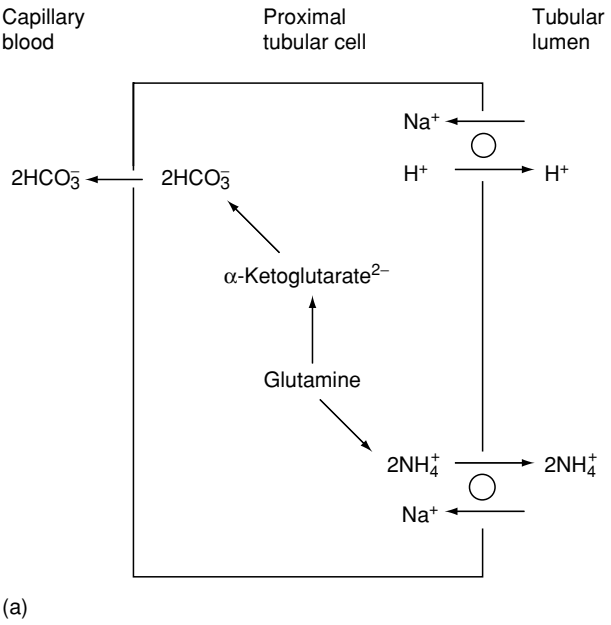
In the proximal tubules, NH_4^+ is secreted into the tubular lumen by Na^+-H^+ antiporter with NH_4^+ substituting the H^+, and the HCO_3^- enters the blood (Figure 4a). Some secreted NH_4^+ is reabsorbed in the ascending limbs of loops of Henle into the medullary interstitium where it exists as both NH_4^+ and NH_3. In the collecting tubules, lipid-soluble ammonia (NH_3) passively diffuses into the lumen and combines with secreted H^+ to form NH_4^+ (Figure 4b). Cationic NH_4^+ is lipid-insoluble and excreted in the urine because back-diffusion into the cells cannot occur.

Regulation of Renal Bicarbonate Reabsorption and Acid Excretion

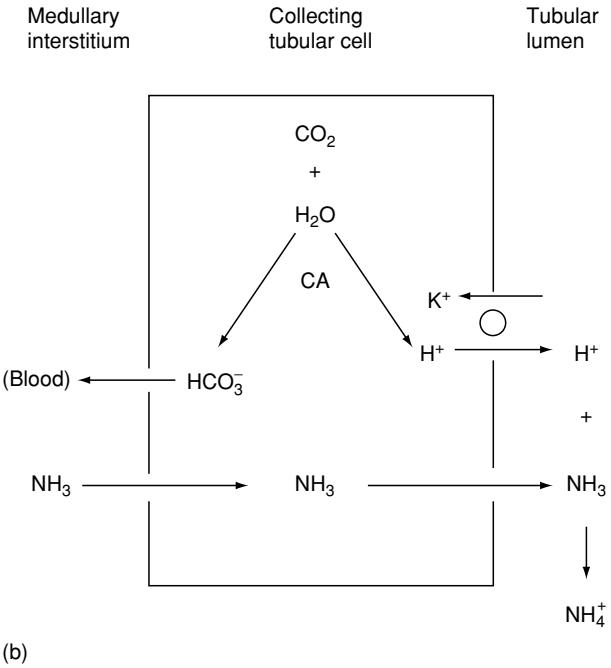
A variety of factors, such as intracellular pH, effective circulating volume, changes in plasma potassium concentration, as well as several hormones, may affect bicarbonate reabsorption and acid secretion, leading to alkalosis or acidosis (Table 7).

Decreases in intracellular pH, as a result of metabolic acidosis (increased H^+) or respiratory acidosis (increased P_{CO_2}), will increase the availability of H^+ for excretion. At increased acid load or metabolic acidosis, plasma bicarbonate concentration is decreased. A greater concentration gradient allows HCO_3^- to diffuse out of the tubular cells. A decrease in intracellular HCO_3^- will lower intracellular pH and provide a signal to increase HCO_3^- reabsorption and H^+ secretion. In respiratory acidosis or alkalosis, changes in intracellular pH are mediated by the diffusion of lipid-soluble CO_2 into or out of the cells.

The effective volume status can influence bicarbonate reabsorption. Decreases in the effective circulating volume increase bicarbonate reabsorption, whereas increases in the effective circulating volume



(a)



(b)

Figure 4 Acid excretion as ammonium in (a) the proximal tubule; (b) the collecting tubule. CA, carbonic anhydrase.

inhibit proximal bicarbonate reabsorption. This is clinically important in patients with volume-depleted metabolic alkalosis. The inability to excrete excess HCO_3^- prevents resolution of metabolic alkalosis. In this situation, Na^+ reabsorption (together with HCO_3^-) prevents further volume depletion at the expense of systemic pH.

Table 7 Factors affecting renal HCO_3^- reabsorption and/or H^+ excretion

Increase	*Decrease*
Metabolic acidosis	Respiratory alkalosis
Metabolic alkalosis with volume depletion	Volume expansion
Respiratory acidosis	Hyperkalemia
Volume depletion	Parathyroid hormone
Hypokalemia	
Angiotensin II	
Aldosterone	

Table 8 Sequential event in response to an acid or alkali load

	Duration
Extracellular HCO_3^- buffering	Immediate
Respiratory response by changing P_{CO_2}	Minutes to hours
Intracellular and bone buffering	2–4 h
Adjustment in renal HCO_3^- reabsorption and H^+ excretion	24 h to few days

The plasma potassium concentration varies inversely with both HCO_3^- reabsorption and H^+ excretion. With potassium loss, hypokalemia causes a transcellular shift of potassium out of the cells (which contain approximately 98% of total body potassium). To maintain electroneutrality, Na^+ and H^+ move into the cells. Intracellular acidosis results, stimulating HCO_3^- reabsorption and H^+ excretion.

Several hormones also influence bicarbonate reabsorption and H^+ excretion. Angiotensin II stimulates bicarbonate reabsorption in the early proximal tubules by increasing the activity of both the Na^+-H^+ antiporters and the basolateral Na^+-$3HCO_3^-$ cotransporters. Aldosterone, however, acts on distal nephrons and promotes H^+ excretion in the collecting tubules.

The parathyroid hormone inhibits proximal HCO_3^- reabsorption by inhibiting Na^+-H^+ antiporters in luminal membranes and Na^+-$3HCO_3^-$ cotransporters in basolateral membranes. The physiological importance is unknown because the extra HCO_3^- delivered out of the proximal tubules is mostly reabsorbed in the distal tubules. However, patients with primary hyperparathyroidism and hypercalcemia tend to have metabolic acidosis.

Summary

In summary, the pH of body fluids is maintained within a narrow limit by the coordinated function of the buffers, lungs, and the kidneys. Volatile and nonvolatile acids together with other acids and alkali ingested must be excreted to maintain acid–base

balance. The sequential responses to acid or alkali load are depicted in Table 8. The kidney is the ultimate organ to control acid–base balance by adjusting the amount of H^+ excretion. With kidney failure, acid–base balance cannot be maintained despite the presence of other intact buffering systems.

ELECTROPHORESIS

R J Fritsch, Kraft General Foods Research and Development Inc., Munich, Germany
I Krause, Technical University Munich, Weihenstephan, Germany

Background

Electrophoretic techniques are among the premier methods for the separation and analysis of proteins in foods. This article reviews the basic principles of analytical electrophoresis and the most important separation and detection modes, including the use of immunoreagents, and applications to food analysis/authentication. (*See* **Protein**: Determination and Characterization.)

Principles

Electrophoresis is a general term that describes the migration and separation of charged particles (ions) under the influence of an electric field. An electrophoretic system consists of two electrodes of opposite charge (anode, cathode), connected by a conducting medium called an electrolyte. The separation effect on the ionic particles results from differences in their velocity (v), which is the product of the particle's mobility (m) and the field strength (E):

$$v = mE. \quad (1)$$

The mobility (m) of an ionic particle is determined by particle size, shape, and charge, and the temperature during the separation, and is constant under defined electrophoretic conditions.

Electrophoretic conditions are characterized by the electrical parameters (current, voltage, power), and factors such as ionic strength, pH value, viscosity, pore size, etc., which describe the medium in which the particles are moving.

The removal of heat generated by the passage of electric current is one of the major problems in most forms of electrophoresis. Any temperature difference causes variations in the rates of migration through the

Table 1 Modes of electrophoresis and basic characteristics of systems

Mode	*Characteristics*
Zone electrophoresis	Continuous electrolyte systems, continuous pH and ionic strength, sieving effect possible depending on support medium
Isotachophoresis	Discontinuous electrolyte system, concentrating effect, migration at same velocity
Isoelectric focusing	Continuous electrolyte system, stable and linear pH gradient, no molecular sieving effect

[a]These types of detection are applicable to both the sieving and nonsieving media.

medium, resulting in distortion in the bands of separated molecules. Clearly, it would be ideal if electrophoretic analyses could be carried out at a constant temperature.

The different separation modes and their basic characteristics are summarized in Table 1; a more detailed discussion follows in subsequent sections.

Formats

Generally, all modes of electrophoresis can be carried out either in 'free solution,' in which no anticonvective stabilizers are used (see *capillary zone electrophoresis*), or in a 'support medium,' where anticonvective support matrices suppress the thermally driven convection currents and diffusion in the electrophoretic medium.

In supporting media, the mobility and sharpness of separations can be influenced by additional factors. These include adsorption and ion-exchange effects with the matrix, inhomogeneities within the support matrix, and electroendosmosis. Furthermore, support media offer visualization of separated zones in a conventional format where strips, foils, and slabs can be easily stained, destained, and manipulated in ways not possible for free solutions.

The most commonly practised formats and techniques of electrophoresis in food analysis are listed in Table 2. Gels made from polyacrylamide and agarose are the supporting media of choice today. The use of cellulose acetate strips is popular for routine screening work where the ease of handling, commercial availability of ready-to-use material, and rapidity are relevant attributes. Paper and thin-layer electrophoresis (e.g., on silica gel) are successfully used for the analysis of high-molecular-weight polysaccharides and lipopolysaccharides.

Agarose Gel

Agarose is a highly purified polysaccharide derived from agar, a natural product of red seaweed. Commercially available agarose materials show different, well-characterized levels of electroendosmosis, due to the presence of sulfate and carboxyl groups in agar. Although electrophoresis on agarose gel has been eclipsed by the use of polyacrylamide in the analysis of most proteins and glycoproteins, it remains invaluable in applications where a very large pore size and hence nonrestrictive gel is required, e.g., in:

- immunoelectrophoretic procedures, especially those relying on an immunodiffusion step (immunoprinting and immunofixation);
- the separation of very large molecules with an average hydrodynamic radius above 5–10 nm, such as

antibodies, lipoproteins, some membrane proteins, nucleic acids, and viruses.

Agarose gels, although quite rigid, are much less elastic than polyacrylamide and so are more easily torn and require careful handling.

Polyacrylamide Gel

Favored for producing well-defined, mechanically stable, and chemically inert matrices of variable pore size, polyacrylamide gel (PAG) is probably the most widely used gel medium in electrophoretic food analysis today. The gels are mechanically strong, easy to handle, and completely transparent. Owing to the relatively small pore size, diffusion is limited, so PAG usually provides a better resolution for most proteins (with a molecular weight less than 500 000) than other gel media.

PAG is formed through polymerization of acrylamide monomers with the cross-linking comonomer *N*, *N*′-methylenebisacrylamide, in the presence of free radicals usually provided by the chemical initiator ammonium persulfate or the photochemical initiator riboflavin. The polymerization reaction is regulated through the addition of *N*, *N*, *N*′, *N*′-tetramethylethylenediamine, which provides a source of tertiary amines.

The pore size of the gel can be easily adjusted by controlling both the concentration of acrylamide (% C) and the relative proportion of the cross-linking agent BIS to acrylamide (% T). This results in well-defined molecular sieving properties, providing an additional separation effect dependent on molecular size.

Sample Pretreatments

If sample proteins are insoluble or liable to aggregation or precipitation during an electrophoretic separation, dissociating and unfolding agents such as urea or nonionic detergents (e.g., octylglucoside and Nonidet P-40) are added to the sample or to the gel. Uncharged thiol reducing agents such as β-mercaptoethanol or the odorless compounds dithiothreitol or dithioerythritol are used to protect free thiol groups in proteins against oxidation (loss of enzymatic activity) and disulfide bond formation. Indeed, since these reagents will also cleave disulfide bonds, they can be added together with a dissociating agent such as urea or, preferably, sodium dodecyl sulfate (SDS) to cause the deliberate dissociation of proteins and their aggregates into their constituent subunits. This approach is successfully used in SDS–PAG electrophoresis where samples are run with and without the use of these thiol reducing agents to give an estimate of the degree of protein cross-linking by inter-and/or intramolecular disulfide bonds.

Prior to isoelectric focusing, samples must be desalted, e.g., by ultrafiltration or dialysis.

Gel Electrophoresis

Gel electrophoresis is zone electrophoresis in a chemically inert gel matrix, such as polyacrylamide or agarose. The sample is applied in a small volume as a narrow zone, e.g., in gel slots. As the electric field is applied, each sample component migrates according to its own mobility in a gel medium of constant pH and ionic strength. The separation into 'pure zones' is achieved by maximizing the differential rate of migration, while minimizing zone spreading (dispersion) due to heat convection and diffusion.

At present, there are three different geometrical forms in which gel electrophoresis can be carried out: horizontal slabs, vertical slabs, or vertical cylinders (rods) of gel, often also referred to as tube gels. Slab gels in thinner layers are preferred to thicker slab or tube gels, as they offer faster separation, sharper zones, and more rapid and efficient cooling and subsequent staining. In PAG electrophoresis, there is a clear preference for the horizontal system utilizing ultrathin gel layers polymerized on to carrier foils. The advantages of horizontal versus vertical systems are easier handling, use of premanufactured gels, more efficient cooling, reduced material costs, availability of fully automated systems, and flexibility towards other forms of electrophoresis such as isoelectric focusing.

PAG Electrophoresis

PAG electrophoresis (PAGE) is the most widely used method in the analysis of complex mixtures of proteins. PAGE of proteins can be broadly classified in the following way:

1. Homogeneous systems with only a single separating gel and using continuous buffer media.
2. Multiphasic (discontinuous) systems, where the stacking gel, a nonrestrictive large pore gel, is layered on top of the separating gel, a small-pore gel. Each gel layer is made with different buffers, which may vary in pH, and/or ion mobility, and/or ionic strength (conductivity).

In the stacking gel of a multiphasic system, sample components are separated in the isotachophoresis mode with no molecular sieving effect. After passing the boundary between stacking and separating gel, the sample components are then separated by size and charge in the usual way. The very high resolving power of this method, which is often referred to as

disc PAGE, is due to the formation of very sharp zones produced by the gel and buffer discontinuities. The production of thin starting zones makes disc PAGE very suitable for use with dilute sample solutions.

Gradient PAGE provides a resolution superior to that of a gel of single concentration. Polyacrylamide can be cast in slabs or tubes in which the concentration of acrylamide increases in a continuous manner (e.g., linear or concave) over the length of the gel, thereby producing an increasing sieving effect due to decreasing pore size.

PAGE of food proteins is most efficient in the presence of the anionic detergent SDS. SDS wraps around the polypeptide backbone, breaking up noncovalent protein aggregates (dimers, tetramers, etc.), and cancels differences in intrinsic charge of the proteins. In this way, SDS converts the proteins to rods of negative charges with equal charge densities, i.e., it confers a negative charge to the polypeptide chains in proportion to their length and imparts the same free solution mobility to all proteins, regardless of their identity. Separation of SDS-denatured proteins occurs principally by sieving effects, with lower-molecular-weight proteins migrating more rapidly through the gel. The rate of migration of a protein can be compared to the rate of migration of standard proteins of defined molecular weight, and fairly accurate estimates of protein molecular weight can be obtained. In combination with pore size gradients and discontinuous buffer systems, SDS–PAGE can be an even more powerful and efficient method for protein separation.

Because SDS–PAGE separates molecules according to size, it is a highly favored technique in the preparation of two-dimensional protein maps,a particularly when coupled with a method separating principally according to charge differences in the second dimension.

Isoelectric Focusing

In isoelectric focusing (IEF), amphoteric analytes, such as proteins and macropeptides, are separated according to their isoelectric point (p*I*) values in a stable and linear pH gradient. The gradient increases from a low pH at the anodic end to a high pH at the cathodic end. The samples may be applied at any position, before or after the pH gradient has been formed. When an electric field is applied, the charged sample components move towards the electrode of opposite charge. As each component migrates through the pH gradient and progressively encounters differences in pH, it becomes increasingly less charged. Eventually, it arrives at a pH equal to its p*I*, where its net charge is zero, and its migration stops. Thus, each component is concentrated, or sharply focused, into a narrow zone at its p*I* position, where it remains stationary as long as the electric field is maintained. To counteract the decrease in solubility of proteins approaching pH values close to their p*I*, solubilizing agents such as urea may be included.

The pH gradient is most effectively formed with the use of a complex mixture of synthetic amphoteric molecules (aliphatic polyaminopolycarboxylic acids) known as ampholytes (e.g., ampholines). When an electric field is applied to these ampholytes, they each migrate to their respective p*I*. A relatively stable pH gradient can be formed over the range pH 2–11 and also almost any portion thereof. The development of immobilized pH gradient gels (known as immobilines) has led to a significant improvement. In these gels, amino and carboxy groups (acrylamide derivatives) are covalently attached to the gel-forming polyacrylamide backbone.

IEF is performed in essentially nonsieving media, such as in free solution with a density gradient, PAG of high porosity or in agarose with very low electroendosmosis agarose. Horizontal flat-bed systems with thin or ultrathin layers of PAG are the most suitable. The commercial availability of premanufactured gel slabs has made analytical PAGIEF in both ampholine and immobiline systems even more efficient and accurate. In addition, toxicity problems from handling the neurotoxic acrylamide monomers are avoided. IEF in agarose gels is particularly appropriate for large molecules or when a second-dimension immunodiffusion or immunoelectrophoresis stage is also to be used.

IEF is a powerful technique that can separate proteins differing in p*I* by as little as 0·001. IEF is also a very simple and accurate method for determining the p*I* of a protein.

Isotachophoresis

In isotachophoresis (ITP), sometimes also referred to as steady-state stacking or displacement electrophoresis, separation results from the different mobilities of identically charged ions in a discontinuous electrolyte system with two different solutions, a leading and a terminating electrolyte. The sample is inserted between these two electrolyte solutions. In a specific separation, either cations or anions can be determined, but not both at once. If sample anions are being determined, the leading electrolyte must contain an anion of higher mobility (e.g., chloride) than any of the sample anions of interest, whereas the terminating electrolyte must contain an anion of lower mobility (e.g., glycine) than any of the sample anions of interest. When the electric field is applied, all negatively charged ions begin to move towards the anode, arranging themselves in order of mobility.

Separation of the sample ions takes place between the leading and terminating electrolytes during migration. When the system has reached equilibrium, each individual ionic sample component moves separately as a 'pure' band. Each pure band is stacked between the sample component of next highest and lowest mobility. Thus, in the 'anion-train,' consecutive sample analyte zones form behind the leading ion zone (chloride), which acts as the 'locomotive,' and in front of the terminating ion zone (glycine). The sample zones travel in order of decreasing mobility at the same velocity as the leading electrolyte zone. These differences in mobility cause a stepwise change in the electric field strength from one analyte zone to the next, resulting in an important concentrating effect. Backward or forward diffusion into a preceding or following band is not possible. As a consequence, the concentrating or stacking effect at the boundary between bands produces sharp zones and prevents diffusional broadening.

Analytical-scale ITP is routinely performed in free solution in small-bore capillary tubes and with the use of a constant current at a well-defined pH value, and with on-line detection. The resolved bands emerge as rectangular peaks, not as the common Gaussian-shaped curves in chromatographic separations. Bands can be identified by measuring the electric field strength within the band, by placing two microelectrodes side by side in the capillary channel. Quantitative information is contained in the length of the band. In ITP, electrical detection is most commonly used, although thermal and ultraviolet absorption detection are also applied.

Analysis of Separated Zones

The most important techniques for analysis of electrophoretically separated proteins are summarized in Table 2. Other techniques such as autoradiography and fluorography of radiolabeled analytes so far have not played a significant role in food analysis.

Staining

The most common procedure for analysing proteins separated in gels is staining with a variety of dyes that bind to proteins. Usually, the staining procedure involves the use of a fixative, such as trichloroacetic acid, to precipitate proteins and prevent their diffusion out of the gel. Gels are then soaked in a staining solution, such that the entire gel is uniformly stained. Nonprotein-bound dye must be removed in a destaining rinse. The length of time required for both the staining and destaining steps primarily depends on the thickness of the gel, with the use of ultrathin gel slabs saving a considerable amount of time.

Proteins in gels are most frequently stained with Coomassie Blue or Amido Black dyes, or with photographic amplification systems using silver. The detection limits for Coomassie Blue staining are roughly 100 ng of protein in a band, whereas silver staining is about 100 times more sensitive. Once the gel is stained, it can be photographed or scanned by densitometry for a record of the position and intensity of each band. In general, the accuracy and precision obtainable from this quantitation procedure are not on a par with what is routinely obtained by high-performance liquid chromatography. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Specific staining techniques exist for phosphoproteins, lipoproteins, glycoproteins, and nucleic acids. Enzymes can be localized by assaying for their enzymatic activity, e.g., by converting substrates to sparingly soluble products, which can then be coupled chemically to azo dyes. Agarose gels and cellulose acetate strips are very suitable for direct localization of immunoreagents due to their pore size. Immunofixation and immunoprinting are popular techniques where antibodies and antigens, respectively, migrate towards each other by diffusion (immunodiffusion). Subsequent staining after the removal of unbound antigens and antibodies allows selective detection of specific protein fractions.

Blotting

Blotting refers to the transfer of separated zones of macromolecules, e.g., proteins or nucleic acids, to thin sheets of derivatized paper or adsorptive membrane matrix, such as nitrocellulose or polyvinyldifluoride (PVDF) to which they bind. Immobilized on the surface of a thin matrix, macromolecules are more easily and uniformly accessible to detection reagents and react more sensitively and faster. The common transfer methods are based on simple diffusion (diffusion blotting), solvent flow with/without vacuum (capillary or Southern blotting), or electrophoretic elution (electroblotting). The detection of transferred protein components on blots is carried out with all the procedures described above, specific assays for enzymes included.

Immunoblotting/Enzyme Labeling

Immunological detection of proteins is suitable with all types of immobilizing transfer matrix. After proteins or nucleic acids are transferred, all additional matrix binding sites must be blocked with an excess of nonspecific protein. Then, an antibody specific for a certain class or type of protein is bound and, finally, a second antibody directed against the first antibody. This second antibody can be fluorescence-labeled, radiolabelled, or conjugated to an enzyme for

location by ultraviolet illumination, autoradiography, or enzyme activity, respectively. Almost any enzyme for which a suitable assay method exists could be coupled in theory to an antibody by cross-linking reagents (e.g., carbodiimide, glutaraldehyde, etc.), but alkaline phosphatase and horseradish peroxidase, for which there are several simple and sensitive detection methods, are very popular. The use of these enzyme-labeled antibodies in combination with blotting results in extremely sensitive procedures, which can clearly detect as little as 100 pg of protein on a membrane. (*See* **Enzymes**: Uses in Analysis.)

Immunoelectrophoretic Techniques

Immunoelectrophoresis consists of a combination of an electrophoretic step with the subsequent precipitation of antigen–antibody complexes (immunoprecipitates). The most common procedures in food analysis rely upon the migration of antigenic proteins through or into an antibody-containing gel. Buffers and pH values are usually chosen so that only the antigens migrate, and the antibodies either do not move at all or, at most, migrate only very slowly and thus remain evenly distributed throughout the gel during the whole electrophoresis. The most popular techniques are:

1. Counterimmunoelectrophoresis, sometimes referred to as countercurrent or crossed-over immunoelectrophoresis: in agarose gel of high electroendosmotic flow, antigens electrophoretically move towards uncharged antibodies, which are carried by the electroendosmotic flow in countercurrent, and precipitin arcs are formed.
2. Grabar/Williams method: normal zone electrophoresis in agarose gel is followed by an immunodiffusion stage. Antibody diffusion from troughs in the gel cut parallel to the line of electrophoretically separated components and precipitin arcs are formed.
3. Laurell rocket techniques: antigen proteins are transported electrophoretically through a gel slab containing antibodies at a pH value at which the antibodies remain essentially immobile, resulting in the formation of 'rocket'-shaped precipitate peaks whose height and area are linearly related to the antigen concentration. These techniques allow quantitative analysis of antigens, but are not applicable to complex mixtures.
4. Crossed immunoelectrophoresis. Agarose zone electrophoresis or isoelectric focusing in one dimension is followed by electrophoresis into an antibody-containing gel slab in the second dimension, with the formation of mountain-like precipitation peaks. Qualitative and/or quantitative analysis of peak area is possible.

For many purposes, the formation of an opaque precipitation are in a transparent gel will be relatively clear and perfectly adequate. If desired, the sensitivity of detection can be greatly enhanced by the application of the usual protein-staining techniques (see above) after the removal of nonprecipitated protein (uncomplexed antigens and antibodies). An alternative to staining is the use of radiolabeled, fluorescent, or enzyme-tagged reactants (see Immunoblotting/Enzyme Labeling).

The use of immunoelectrophoresis in food analysis is limited by the availability of specific antibodies, so that cross-reactions with other nontargeted proteins are avoided. (*See* **Immunoassays**: Principles.)

Capillary Zone Electrophoresis

Although conventional gel electrophoresis is extremely powerful and versatile, it is often a slow, labor-intensive technique. Analyses often require several hours, and often several days to complete. But in the last 10 years, rapid instrumental methods have been developed for free solution electrophoresis in capillary tubes with on-line detection. Existing new techniques currently available to the analytical chemist are capillary electrophoresis (CE) in general, and capillary zone electrophoresis (CZE) in particular.

CZE is performed as free solution electrophoresis in capillaries with inside diameters of only 20–200 μm. These small dimensions aid heat dissipation and minimize zone broadening caused by molecular diffusion and convection currents in the electrophoretic medium. As a consequence, relatively high voltages can be used, which allow highly efficient separations within 20 min. Each end of the capillary, filled with electrolyte, is immersed in a separate reservoir containing the same electrolyte and a high-voltage electrode.

CZE is strongly influenced by the degree of inertness of the capillary, especially towards polar interactions with buffer ions and/or analytes. Separations by CZE in inert capillaries (e.g., Teflon) are based only on the different mobilities of charged molecules in an electric field, as in conventional zone electrophoresis. In contrast, CZE in noninert capillaries (e.g., fused silica without a protective coating) uses the separating forces of both electrophoretic migration and electroendosmotic flow.

In these cases, cations in the electrolyte (predominantly protons) associate loosely with the capillary wall, blocking the negative charges of the silanol groups of uncoated fused silica. The hydrated cations are pulled towards the cathode, inducing a bulk fluid flow (the electroendosmotic flow, EEF) in that direction. The EEF can be strong enough to move all species (positive, negative and neutral) in the same direction,

though with different velocities. The EEF may ruin a separation (e.g., by adsorption of the analyte to the wall), but it can also be a crucial feature of the method.

State-of-the-art fully automated CZE instruments introduce samples automatically into the capillaries either by electromigration or by hydrostatic or pneumatic methods. After zone electrophoresis in capillaries, separated sample components are detected in real time as they pass an on-line detector. Ultraviolet absorption and fluorescence detection have proven most useful so far for CZE.

CZE is faster and easier than slab gel electrophoresis. Although CZE is still in its infancy, powerful separation methods have been already developed for amino acids, peptides, nucleic acids, and their fragments. In view of the increasing importance of biotechnology in food manufacturing, CZE is expected to play a major role in analytical food chemistry. (*See* **Amino Acids**: Determination; **Peptides**.)

Application to Food Analysis/ Authentication

Proteins and peptides are the primary targets of electrophoresis in food analysis. Electrophoretic techniques serve to characterize molecular architecture, assess homogeneity, and identify and quantify proteins.

Electrophoresis has allowed food chemists to characterize increases in protein yield, protein–protein interactions, and enzymatic protein degradation. Further studies of compositional parameters and processing treatments have highlighted the importance of these features on the flavor and texture of protein-based foods. This is particularly true in the field of dairy science and technology where the electrophoretic separation and quantification of milk proteins and peptides have always helped new developments. Figure 1 illustrates the simultaneous determination of the major milk proteins by IEF. This efficient procedure can be successfully applied to follow changes in protein distribution in cheeses manufactured by accelerated ripening and/or ultrafiltration procedures.

For studying proteins and larger peptides in complex food systems, the most popular electrophoretic techniques are isoelectric focusing and SDS (disc) electrophoresis in ultrathin, horizontal PAG slabs. Subtle differences in molecular properties such as those due to posttranslational modifications or genetic variation within protein classes can be determined with these methods. Perhaps the ultimate in protein separation is obtained when a two-dimensional electrophoretic approach is used. Truly spectacular resolution can be achieved when one-dimensional isoelectric focusing is combined with two-dimensional SDS gradient PAGE, immunodiffusion, or immunoelectrophoresis. These high-resolution techniques are used to follow proteolytic breakdown and to verify the intact primary structure of food proteins after certain processing treatments.

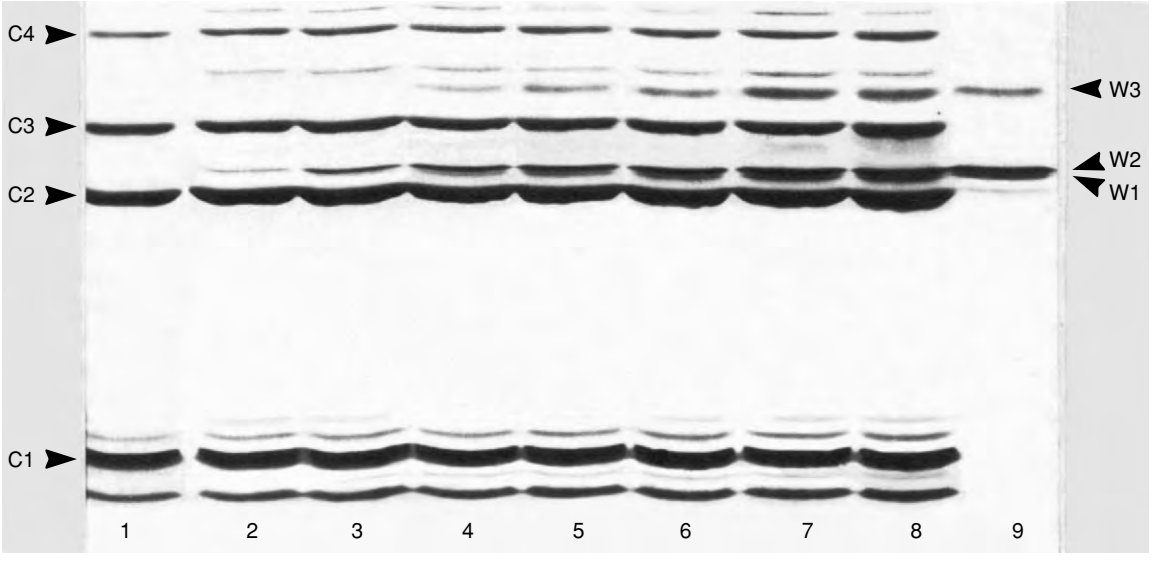

Figure 1 Simultaneous determination of the major milk proteins by isoelectric focusing in ultrathin-layer PAG. C1, α_{S1}-casein B; C2, β-casein A^2; C3, β-casein A^1; C4, α_{S2}-casein; W1, α-lactalbumine; W2, β-lactoglobuline A; W3, β-lactoglobuline B. Samples from left: recombined milk powders with casein: whey protein ratio of 100:0 (1), 98:2 (2), 95:5 (3), 90:10 (4), 80:20 (5), 70:30 (6), 60:40 (7), 50:50 (8), and 0:100 (9). Reproduced from Electrophoresis, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

It is not surprising that the discriminating power and versatility of modern electrophoretic techniques are unsurpassed in the positive identification of specific proteins and peptides. Thus, techniques such as IEF, with or without immunodetection, provide reliable methods in food authentication in order to prevent fraud and adulteration. Examples of current interest include the verification/identification of the species origin of meat, fish, milk and cheese products, the detection of nonmeat and nonmilk proteins in meat and milk products, respectively, the identification of cereal varieties, the classification of pasta into durum wheat and soft wheat types, the characterization of cultivars of crops, fruits and vegetables, and the determination of enzymes in beer and cheese. (*See* **Adulteration of Foods**: Detection.)

Isotachophoresis is the method of choice for the analysis of complex mixtures of organic acids in foods without derivatization but is also applicable to artificial sweeteners and preservatives.

EMERGING FOODBORNE ENTERIC PATHOGENS

D W K Acheson, University of Maryland School of Medicine, Baltimore, MD, USA

Background

Over the last 25 years, there have been an ever-growing number of enteric pathogens linked with foodborne disease (**Table 1**). Following some major foodborne disease outbreaks in the early 1990s, there has been increased focus on understanding the causes and pathogenesis of foodborne disease. As part of this initiative, federal agencies developed improved surveillance systems and invested in gaining a better understanding of how to prevent foodborne disease through safer food processing. During the course of this chapter, the initial section will describe the current major emerging foodborne infections in the context of our new epidemiological knowledge. This is then followed by a more detailed description of some of the principal emerging foodborne infections that are considered to be important. Clearly, different parts of the world have to deal with different enteric pathogens, but the focus of this chapter will be on issues within the USA and other developed countries. It is not the goal of this text to specifically address emerging foodborne pathogens in developing countries that not only have to deal with all the problems seen in developed nations, but also frequently have to deal with other specific pathogens.

Current Trends of Emerging Foodborne Pathogens

In 1996, the Foodborne Diseases Active Surveillance Network (FoodNet) was established. This is a

cooperative venture between the Centers for Disease Control, state health departments, the Food Safety and Inspection Service of the US Department of Agriculture, and the Food and Drug Administration. FoodNet is a sentinel network that is designed to produce national estimates of the burden and sources of specific foodborne illnesses. FoodNet currently focuses on obtaining information on nine important and emerging foodborne infection agents (Table 2). FoodNet operates by conducting population-based active surveillance for confirmed cases of the various pathogens shown in Table 2. Since the initiation of FoodNet in 1996, the population under surveillance has grown from five sites and some 14 million persons in 1996 to 29.5 million that were under surveillance during the year 2000. This number now represents over 10% of the US population and involves a number of states including Minnesota, Oregon, California, Connecticut, Georgia, Maryland, New York, and Tennessee.

During the year 2000, there were 12 631 laboratory-confirmed cases of the nine diseases listed in Table 2 at the FoodNet sites. Of these 12 631, 4640 were campylobacteriosis, 4237 were salmonellosis, 2324 were shigellosis, 631 were *E. coli* O157:H7, 484 were cryptosporidiosis, 131 yersiniosis, 101 listeriosis, 61 Vibrios and 22 cyclosporiasis. Since 1996, the levels of the major pathogens have varied amongst the five original sites, and these data are shown in Table 3. As can be seen from Table 3, there have been minor fluctuations but little major change in the nine important pathogens, although for *Campylobacter* and *Salmonella*, the general trend is downward.

One of the key criteria in relation to determining the importance of emerging (and emerged) foodborne pathogens relates to the severity and frequency of disease with which they are associated. In the past, there was a great deal of uncertainty about the morbidity and mortality associated with foodborne disease, but in 1999, a study was published by the Centers for Disease Control that specifically

Table 3 Incidence (per 100 000 population) of diagnosed infections in the original five FoodNet sites

Pathogen	*1996*	*1997*	*1998*	*1999*	*2000*
Campylobacter	23.5	25.2	21.4	17.5	20.1
Cryptosporidium	nr	3.7	2.9	1.8	2.4
Cyclospora	nr	0.4	0.1	0.1	0.1

nr, not reported.
Modified from Preliminary FoodNet Data on the Incidence of Foodborne Illness – Selected Sites, United States, 2000 (2001) *MMWR* 50: 241–246.

addressed these issues using FoodNet and other data. The overall conclusion from this study was that there was an estimated 76 million foodborne illnesses per year, resulting in 325 000 hospitalizations and 5000 deaths. An interesting outcome of this work was that known pathogens only accounted for 14 million (18%) of these cases. This obviously begs the question of what is going on in the remaining 80% of cases. Part of the answer lies in our inability to diagnose foodborne disease in all cases. This is due to a mixture of the failure of infected patients to seek medical attention, the failure of physicians to order stool cultures, and the failure of the laboratories to find foodborne pathogens, even when they are present, the latter either due to funding or technological limitations. However, it does also raise the issue of new emerging infectious foodborne agents that either we are unaware of or have not yet been linked with foodborne disease.

Whereas there are over 200 known diseases transmitted via food, including microbes, toxins, chemicals, physical hazards, and prions, there is a relatively short list of the important agents, and many of these could be considered as emerging simply because they were not recognized until recently. Mead *et al*. determined

Table 4 Ranking of the most common microbial causes of foodborne disease with an estimate of the percentage of infections that are transmitted via food, and deaths as a percentage of total foodborne disease-related deaths

Disease or agent	*Estimated total cases*	*Percentage foodborne transmission*	*Percentage of deaths*[a]
Norwalk-like viruses	23 000 000	40	7
Campylobacter spp.	2 500 000	80	5
Giardia lamblia	2 000 000	10	0.1
Salmonella	1 400 000	95	31
Shigella	450 000	20	0.8
Cryptosporidium parvum	300 000	10	0.4
Clostridium spp.	250 000	100	0.4
Toxoplasma gondii	225 000	50	21
Staphylococcal food poisoning	185 000	100	0.1
Shiga toxin-producing *E. coli*	110 000	85	1.4
Yersinia enterocolitica	100 000	90	0.1
Bacillus cereus	27 000	100	0
Cyclospora cayetanensis	16 000	90	0
Listeria monocytogenes	2 500	99	28

[a]Expressed as a percentage of the number of deaths related to foodborne pathogens.
Modified from Mead PS, Slutskev L, Dietz V *et al*. (1999) Food-related illness and death in the United States. *Emerging Infectious Diseases* 5: 607–625.

which are the important foodborne pathogens in terms of frequency of disease, and at the same time determined what proportion of illness due to those pathogens were actually transmitted via food, as opposed to some other means of transmission such as person-to-person or directly from animals. A summary of this information is presented in Table 4 and illustrates the point that some of the most common foodborne infections such as *Campylobacter* and Norwalk-like virus result in a relatively small number of hospitalizations and death compared with other pathogens such as *Listeria monocytogenes*. Another key observation was that five pathogens accounted for more than 90% of the deaths as follows: *Salmonella* – 31%; *Listeria* – 28%; *Toxoplasma* – 21%; Norwalk-like virus – 7%; *Campylobacter* – 5%; *E. coli* O157:H7 – 3%.

Generally, there is a perception amongst many that foodborne disease usually occurs as part of outbreaks (defined as an incident in which two or more persons experience an illness resulting from the ingestion of a common food). In fact, the vast majority of foodborne disease are isolated cases that are not linked to other cases. A recently published summary of documented outbreaks, which occurred between 1993 and 1997, illustrates the important emerging pathogens and foodborne agents that are most frequently linked to outbreaks. During that period, there were 2751 outbreaks investigated by the Centers for Disease Control averaging about 500 outbreaks per year. A total of 86 058 people were sick in connection with the outbreaks, and while only 32% had a known etiology, they accounted for 59% of the 86 058 infections. Table 5 summarizes some of the outbreak data and illustrates the importance of *Salmonella* and *E. coli* as causes of outbreaks and death, but also demonstrates the importance of two preformed toxins, Scrombotoxin and Ciguatoxin, as causes of outbreaks. As already stated, outbreaks account for the minority of foodborne disease. Based on previous work and assuming 76 million cases of foodborne disease per year, during the 5 years from 1993 to 1997, there would have been 380 million episodes of foodborne disease. During this time, only 86 058 cases were linked with outbreaks.

In summary, since 1996 and the inception of FoodNet, we have learnt a great deal about the foodborne agents that are responsible for disease and death in the USA. Many of these were unrecognized 20 or 30 years ago and underscore the need to remain vigilant about new agents and newly emerging pathogens.

Specific Emerging Foodborne Pathogens

In the following sections, a more detailed description of some of the specific emerging foodborne pathogens is given. It is beyond the scope of this text to discuss in detail all the emerging foodborne enteric pathogens, but readers are referred to other specific chapters in this text that deal in more detail with individual microbes.

Campylobacter

Foodborne disease due to *Campylobacter*, which was not recognized until the mid-1970s, is now one of the most frequently diagnosed causes of food-related gastroenteritis. In fact, *Campylobacter* and *Salmonella* probably account for 70% of diagnosed cases of bacterial foodborne disease in the USA.

Table 5 Major causes of foodborne disease outbreaks in the USA between 1993 and 1997, showing the numbers of outbreaks, the numbers of total cases, and the number of deaths associated with a particular etiology

Etiology	*Number of outbreaks (%)*	*Number of cases (%)*	*Number of deaths (%)*
Salmonella	357 (13.0)	32 610 (37.6)	13 (44.8)
Escherichia coli	84 (3.1)	3 260 (3.8)	8 (27.6)
Scrombotoxin	69 (2.5)	297 (0.3)	0
Ciguatoxin	60 (2.2)	205 (0.2)	0
Clostriduim perfringens	57 (2.1)	2 772 (3.2)	0
Shigella	43 (1.6)	1 555 (1.8)	0
Staphylococcus aureus	42 (1.5)	1 413 (1.6)	1 (3.4)
Campylobacter	25 (0.9)	539 (0.6)	1 (3.4)
Hepatitis A	23 (0.8)	729 (0.8)	0
Bacillus cereus	14 (0.5)	691 (0.8)	0
Clostridium botulinum	13 (0.5)	56 (0.1)	1 (3.4)
Norwalk virus	9 (0.3)	1 233 (1.4)	0
Listeria monocytogenes	3 (0.1)	100 (0.1)	2 (6.9)

Modified from Centers for Disease Control (2000) Surveillance for foodborne disease outbreaks – United States, 1993–1997. *MMWR* 49: 1–51.

There are two main species of *Campylobacter* that are responsible for most of the illness seen in humans. *C. jejuni* accounts for the vast majority ($\sim 90\%$), and *C. coli* accounts for the majority of the remainder. Other *Campylobacter* species that have been associated with gastroenteritis in humans include *C. fetus*, *C. upsaliensis*, *C. hyointestinalis*, and *C. lari*. *Campylobacter* species are fragile organisms and tend to die in transport media, so rapid plating of samples is an advantage. Enriched media are usually used that contain a variety of antibiotics to reduce competitive flora. The infectious dose of *Campylobacter* seems to be variable depending on the strain and the host, but low numbers of *Campylobacter* may be all that is needed to cause disease, and in some instances, in human volunteers, less than 100 organisms can cause disease. These organisms are more frequently associated with sporadic disease rather than outbreaks, and person-to-person spread does not appear to be common, although it can occur in a family environment, for example. This sporadic epidemiology suggests that the infectious dose may actually be higher in many situations. *C. jejuni* and *C. coli* are commensals in the intestines of many animals and birds, including domestic pets. The main vehicles for infection are raw meats, especially poultry, milk, and water. Surface water is frequently contaminated with campylobacters, and waterborne outbreaks have occurred.

Campylobacter species are invasive organisms, which means that they have the capacity to invade the epithelial cells lining the intestine. The pathogenesis of *Campylobacter* is dependent on its motility. *In vitro*, nonmotile strains are not capable of invading intestinal epithelial cells. It is assumed that invasion in the intestine is one of the principal pathogenic mechanisms of these bacteria, although the genes involved are not known. The recent publication of the *C. jejuni* genome is, however, helping with the discovery of new genes and determining the function of previously identified genes.

Following infection with campylobacters, there is typically an inflammatory response with marked inflammatory infiltration of the lamina propria resulting in leukocytes being present in the stools. Clinically, symptoms usually occur within 2–3 days following exposure, or up to 7 days after exposure. Nongastrointestinal symptoms such as fever (which may be high), headache, and myalgia may precede the onset of nausea, vomiting, and diarrhea. Diarrhea is usually the predominant symptom. This may be watery or bloody, and is usually associated with severe cramping abdominal pain. Interestingly, the disease is occasionally biphasic with an apparent settling of symptoms after 4–5 days, only to be followed by a recrudescence. A number of complications are associated with *Campylobacter*, including cholecystitis, hepatitis, acute appendicitis, pancreatitis, and focal extraintestinal infections. Longer-term complications include reactive arthritis, Reiter's syndrome, uveitis and Guillain–Barré syndrome; molecular mimicry may be involved in some of these complications. The majority of *Campylobacter* infections are self-limiting and require supportive therapy only, especially in the form of rehydration. Antibiotic therapy is not routinely required, but patients with prolonged or severe symptoms or who have other significant risk factors (AIDS, cirrhosis, diabetes, etc.) should be treated. Erythromycin is a reliable therapy, although there is a general move toward using quinolone antibiotics. Despite the use of erythromycin for many years, the resistance levels have remained low. This is not the case with the quinolones, and there are increasing reports of ciprofloxacin

resistance, which may become more of a problem in view of the expanded use of these antibiotics in agriculture.

Listeria monocytogenes

L. monocytogenes is a Gram-positive motile rod that is one of the most frightening foodborne pathogens because of the high mortality rate associated with infection. Of the seven *Listeria* species, only *L. monocytogenes* is pathogenic for humans. *L. monocytogenes* is a common environmental organism and is frequently present in soil and water, on plants, and in the intestinal tracts of many animals. It has been found in 37 different types of mammals and at least 17 species of birds. Between 1 and 10% of people are carriers of *L. monocytogenes*. This organism is associated with both sporadic disease and outbreaks. Incriminated foods include milk, cheese, raw vegetables, undercooked meat, and foods prepared for instant use such as hot dogs. The infectious dose is not really known: some studies have suggested that it may be very high (up to 10^9 organisms), and others have suggested that it may be as low as several hundred. In practice, the most critical aspect is probably individual susceptibility rather than the infectious dose *per se*. Clinically, it usually begins with nonspecific symptoms such as fever, myalgia and gastrointestinal upset in the form of diarrhea, and nausea. What makes *L. monocytogenes* exceptional as a foodborne pathogen is its very high mortality rate. Of the approximately 1800 cases per year that are estimated to occur in the USA, there are over 400 deaths. This gives a case fatality rate of over 20%. There are certain groups that are especially at risk of developing listeriosis, and these include pregnant women, the elderly, and the immunocompromised. Transplacental transmission in pregnant women is a major concern, although it does not inevitably lead to major consequences. Spontaneous abortion, prematurity, neonatal sepsis, and meningitis are all complications of transplacental transmission. Although *L. monocytogenes* is readily killed by heat and cooking, the fact that it is so ubiquitous makes recontamination a real risk. This then poses a major health problem, because the organism will grow and multiply at standard refrigerator temperatures. Thus, even minor contamination of a product may, after storage, result in high levels of bacteria, even if the product has been adequately refrigerated. Following diagnosis, *L. monocytogenes* is readily treated by penicillins or aminoglycosides. *L. monocytogenes* has also been linked with acute gastroenteritis in individuals with normal immune systems, but it is unclear how frequently this occurs.

Salmonella spp.

Salmonella are one of the most common causes of foodborne illness in humans, and although they are not as a group considered to be emerging foodborne pathogens, some types of *Salmonella* (e.g., *S. enteritidis* in eggs) have definitely emerged as a major problem in recent years. There are many types of *Salmonella*, but they can be divided into two broad categories: those that cause typhoid and those that do not. The typhoidal *Salmonella* such as *S. typhi* and *S. paratyphi* only colonize humans and are usually acquired by the consumption of food or water contaminated with human fecal material. The much broader group of nontyphoidal *Salmonella* are found in the intestines of other mammals and therefore are acquired from the consumption of food or water that has been contaminated with fecal material from a wide variety of animals and poultry.

The number of cases of nontyphoidal *Salmonella* has increased steadily over the last four decades. *S. entertidis* particularly has become a growing problem, especially in hen eggs. In the year 2000 FoodNet data, of the 4237 *Salmonella* that were isolated, 3686 were serotyped, and 23% were *S. typhimurium*, and 15% were *S. enteritidis*. Currently, the estimate is that around 1 in 10 000 eggs are contaminated with *Salmonella*. It is now known that *Salmonella* can penetrate intact eggs lying in fecally contaminated material and also infect eggs transovarially during egg development before the shell is formed. Other than eggs, common sources of nontyphoidal salmonellosis are milk, foods containing raw eggs, meat and poultry, and fresh produce. Essentially, as with many of the other foodborne bacterial infections, *Salmonella* are frequently transmitted through fecal contamination of food because of the large numbers of animals that carry the organism. The infective dose of nontyphoidal *Salmonella* may vary from < 100 to 10^6, depending on the host and on the actual type of *Salmonella*. Irrespective of the type of *Salmonella*, the most critical virulence determinant of these bacteria is their ability to invade the intestinal epithelium, following which they interact with underlying lymphoid tissue.

Clinically, nontyphoidal *Salmonella* typically presents with gastroenteritis 24–48 hours after exposure to the organisms. There is usually nausea, vomiting, abdominal cramps, and diarrhea, which may be watery or occasionally bloody. It is not unusual for there to be associated symptoms of fever, chills, headache, and myalgia. Occasionally there can be long-term consequences following *Salmonella* infection such as reactive arthritis (especially in individuals who are HLA B27-positive), endocarditis, and localized

infections such as osteomyelitis, septic arthritis, and soft tissue infections. Diagnosing infection with *Salmonella* is dependent on culturing the organism, usually from either stool or blood cultures. In the case of nontyphoidal *Salmonella*, it is also worth trying to culture organisms from the incriminated food.

Gastroenteritis from nontyphoidal *Salmonella* is usually self-limiting, and rehydration is the most critical aspect of treatment. Antibiotic therapy is not routinely required for this aspect of *Salmonella* infection and has in some instances been thought to promote chronic carriage. When there is systemic invasion with the bacteria and in cases of enteric fever, antibiotic therapy is important. Third-generation cephalosporins and quinolones are most frequently used, although chloramphenicol has been the mainstay of treatment for typhoid fever for many years and is still used in many developing countries, but chloramphenicol does carry a risk of complications.

Antibiotic resistance has become a major problem with many *Salmonella* serovars. Of particular concern is the recent emergence and spread of *Salmonella* DT104 that carries resistance to multiple antibiotics, including, in some instances, to the fluoroquinolones such as ciprofloxacin. In 2000, *Salmonella* strains that were resistant to Ceftriaxone were also reported, further raising the concern that the emergence of new antibiotic resistance profiles were occurring.

Shiga Toxin-producing *E. coli*

Shiga toxin-producing *E. coli* (STEC) are relative newcomers to the scene of foodborne pathogens. The first STEC to be associated with disease in humans was *E. coli* O157:H7 following two outbreaks of hemorrhagic colitis in 1982. Since then, it has been learned that there are in fact many different serotypes of STEC, and at least 60 different types have been associated with clinical disease. Recent studies have suggested that around 1% of samples submitted to clinical microbiology laboratories in the USA contain STEC, of which around two-thirds are O157:H7, the remainder being non O157. STEC are present in the gastrointestinal tracts of many mammalian species but appear to be especially common in ruminants (cattle, sheep, deer, and goats). Therefore, the main source of STEC in our food supply is bovine products.

Recently, there have been an increasing number of reports associating STEC infection with fresh produce (lettuce, alfalfa sprouts, apple cider) and water. This is thought to be mainly due to contamination with fecal material from cattle pasture. Clinically, STEC cause a variety of diseases ranging from diarrhea, which may or may not be bloody, hemorrhagic colitis, and the hemolytic uremic syndrome (HUS). HUS is a triad of renal failure, thrombocytopenia, and hemolytic anemia. Acutely, HUS has a mortality rate of around 5%, and up to 50% of HUS patients may have some degree of permanent renal insufficiency. The main virulence factor from STEC is the production of one or more bacteriophage-encoded Shiga toxins (Stx), which are of two main types, Stx1 and Stx2. Following ingestion of the bacteria, they colonize portions of the lower intestinal tract and produce the toxins. Stx is then thought to cross the intestinal epithelial cell barrier and damage distant target sites, especially the kidney and brain, by a direct effect on endothelial cells in the microvasculature. The infectious dose of STEC may be very low, in the region of 10–100 organisms in some instances. Symptoms typically develop 2–4 days following ingestion but may occur in as little as 1 day or in as much as 8 days. The diarrhea can be of variable type (bloody or nonbloody) and may contain leukocytes. The type of diarrhea is not a reliable indication of who will go on to develop HUS. The mainstay of treatment for STEC and its major complications is supportive. There is a degree of controversy over the use of antibiotics, and a number of studies have suggested that certain antimicrobials (e.g., trimethoprim-sulfamethoxazole) actually increase the likelihood that a patient will go on to develop serious complications.

Yersinia spp.

Of the three members of the genus *Yersinia*, *Y. enterocolitica* and *Y. pseudotuberculosis* are considered to be foodborne, whereas *Y. pestis* is not. *Yersinia* are not very commonly found as causes of foodborne illness compared with *Salmonella* or *Campylobacter*. However, they are clearly transmitted in food and can cause a significant gastrointestinal illness. The food most frequently associated with yersiniosis is pork. Swine are a major reservoir of these organisms, and although they have been found in many other animals (e.g., sheep, dogs, cats, and cattle), consumption of undercooked pork is a common association. Milk is another frequently reported source, and since *Y. enterocolitica* can survive, and indeed multiply, in milk at 4 °C, small numbers of organisms can become a significant health threat, even if the milk is refrigerated. Symptoms in *Y. enterocolitica* infection can be prolonged, lasting several weeks or even longer. Most infections are, however, self-limiting, although complications may occur such as ulceration and intestinal perforation. A classic long-term complication following yersiniosis is the development of reactive

arthritis. As with other enteric pathogens, this is more likely in patients who are HLA B27-positive.

Viral Foodborne Pathogens

Viral agents are considered to be an increasingly important cause of foodborne illness. A number of different viral agents have been associated with foodborne disease and cause a variety of illnesses varying from a simple gastroenteritis to major systemic upset such as hepatitis. Food and water are vehicles for viruses, but viruses do not reproduce in food, and nor do they produce toxins in food. Some viruses, such as Norwalk, cause large outbreaks, and others seem to be more frequently associated with sporadic disease. Overall, the difficulty in diagnosing viral illness has precluded the development of large amounts of epidemiological data. It is beyond the scope of this chapter to discuss all viral causes of foodborne disease. However, Norwalk-like viruses do deserve a specific mention.

Norwalk virus is a small round-structured virus (SRSV) and was the first virus to be clearly associated with gastroenteritis. Norwalk is a calicivirus, and this group of viruses causes disease worldwide and has been associated with some large outbreaks, often in confined environments such as cruise ships. Outbreaks have been associated with contaminated drinking water, swimming water, consumption of undercooked shellfish, ice, and salads. As with the other enteric viruses, fecal contamination of food or water is usually found to be the ultimate source. The incubation time following exposure is around 48 h, and the clinical illness usually consists of vomiting and diarrhea. The diarrhea is watery without red cells, leukocytes or mucus. The disease is usually self-limiting, settles in 24 h, and requires no specific therapy. Specific diagnosis is difficult. A number of assays are available (but not commercially), including electron microscopy, enzyme immunoassays, and reverse transcriptase–polymerase chain reaction.

Parasites

Two emerging parasitic foodbrone pathogens that cause predominantly watery diarrhea are *Cryptosporidium parvum* and *Cyclospora cayetanensis*. As can be seen from Table 4, *C. parvum* causes a lot of disease, but only 10% of it is considered to be foodborne; in contrast, *C. cayetanensis* causes a lot less disease, but 90% of it is considered to be foodborne, much of which is based on outbreak data. *Cryptosporidium parvum*, for which proven effective therapy does not exist, has gained notoriety for causing persistent chronic diarrhea in immunocompromised patients. *C. parvum* is endemic in cattle and is usually acquired in humans from contaminated water, fresh produce, unpasteurized milk, or person-to-person spread. The incubation period is typically about a week but can be as long as 28 days. *C. parvum* is known to cause large outbreaks, the largest of which was waterborne in Milwaukee, in which around 400 000 individuals became sick. *C. cayetanensis* infection has been associated in the past with consumption of imported berries most likely contaminated with fecally contaminated water. More recently, it has been linked with fresh basil. It can be diagnosed by direct acid-fast microscopy of stools, but it is important to note that most microbiology laboratories will not routinely look for *C. parvum* and/or *C. cayetanensis*, so they may be more common than we think.

Transmissible Spongiform Encepalopathies

Mad cow disease or bovine spongiform encephalopathy (BSE) was first diagnosed in the UK in 1986. BSE is a member of the family of transmissible spongiform encephalopathies (TSEs) that are linked with neurological diseases in a variety of animals, including humans, sheep, elk, and mink (Table 6). Historically, TSEs were recognized in Europe as long ago as the eighteenth century, when a neurological condition known as scrapie was first described in sheep. However, TSEs did not become a public health or food safety concern until the mid-1990s, when the link between BSE and a condition in humans, known as new variant Creutzfeldt–Jakob disease (nvCJD), was made, and it became clear that the disease was due to transmissible agents, that were given the name prions.

Although there are no clear answers as to the origins of BSE, the generally held belief is that BSE originated from feeding cattle rendered protein produced from the carcasses of scrapie-infected sheep or cattle. The rendering process involves processing carcasses by boiling at atmospheric or higher

Table 6 Types of transmissible spongiform encephalopathies (TSEs) in animals and humans

pressures, which results in the generation of an aqueous protein solution under a layer of fat. The fat can be removed and the protein solution further processed into a meat and bone meal product for use as an animal food. Changes were made in the rendering process in the UK around 1980, and it is assumed that this change allowed the survival of the etiologic agent. The recycling of cattle carcasses through the rendering process only served to concentrate the etiologic agent further that eventually led to the epidemic of BSE in the UK in the late 1980s. Thus, the current belief is that the etiologic agent can be delivered orally and is concentrated in certain parts of an infected animal's body, especially central nervous tissues.

In the year 2000, there were 1101 new cases of BSE diagnosed in the UK, so infectious cattle still remain in the UK. BSE has not been limited to the UK, and there have been several hundred cases in other European countries and elsewhere in the world, although some of these are imported rather than native cases. Since 1994, when the first case of nvCJD was recognized in the UK, there has been a steady increase in the numbers of cases. Up to November 2000, there had been 84 cases in the UK, and the trends in incidence since 1994 indicate that the number of cases and deaths per year are on the rise.

Up to the time of this writing, there have been no documented cases of BSE in the USA. The USDA and FDA have taken action to prevent the importation of BSE-contaminated material or animals into the USA. Active surveillance for BSE is underway in cattle in the USA with signs of neurological disease and cattle that are nonambulatory at slaughter. Close to 12 000 brains have been examined so far, with no evidence of BSE. Despite the lack of evidence of BSE in the USA, there is concern that it will appear at some point. The long incubation period and the difficulty in controlling all imports of potentially contaminated products from different parts of the world make it possible that BSE will appear in the USA, at some time in the future. In the general context of food safety, the risks and the likelihood of serious outcomes that are associated with bacterial pathogens such as *Campylobacter*, *Salmonella*, and *E. coli* are significantly greater than the risk of developing nvCJD from BSE. However, nvCJD is frightening, because it is incurable, inevitably leads to death, and there are currently no assays available to test food for the BSE prions, although new tests to determine the presence of nervous tissue in meat products are becoming available.

EMULSIFIERS

Contents

Organic Emulsifiers

T Kinyanjui and W E Artz, University of Illinois, Urbana, IL, USA
S Mahungu, Egerton University, Njoro, Kenya

Background

This chapter will narrowly focus on organic emulsifiers, one category in the general class of compounds called surface-active agents, rather than macromolecular stabilizers or any of the other components involved in emulsion stabilization. Some familiar emulsions include those occurring in foods (milk, mayonnaise, etc.), cosmetics (creams and lotions), pharmaceuticals (soluble vitamins and hormone products), and agricultural products (insecticides and herbicides).

The discussion will be limited to food emulsifiers, rather than the use of emulsifiers for nonfood products, such as cosmetics, paints or drug-delivery systems. Emulsifiers are substances that reduce the surface tension at the interface of two normally immiscible phases, allowing them to mix and form an emulsion. Representing one class of a broader group of ingredients called surface active ingredients or surfactants, emulsifiers assert their effects at the interface between oil, water, or air dispersed in a second immiscible fluid. They promote the formation and stabilization of emulsions as well as foams and suspensions. There are several types of emulsions, including oil in water (o/w) water in oil (w/o), oil in water emulsion dispersed in oil (o/w/o) etc.

Emulsions are a special kind of colloidal dispersion: one in which a liquid is dispersed in a continuous liquid phase of a different composition. The dispersed phase is sometimes referred to as the 'internal phase' and the continuous phase as the 'external phase.'

Structure

Food emulsifiers can be categorized (Table 1) on the basis of several characteristics, including origin, either synthetic or natural; potential for ionization, nonionic versus ionic; hydrophilic/lipophilic balance (HLB); and the presence of functional groups.

Lecithin and Lecithin Derivatives

The primary source of lecithin, the only naturally occurring emulsifier used in any significant quantities in the food industry, is soybeans. Soybean oil contains anywhere from 1 to 3% phospholipids in the crude oil. Other sources include corn, sunflower, cottonseed, rapeseed, and eggs. Lecithin is obtained by an aqueous extraction of the oil extracted from soybeans. Phase separation occurs upon hydration of the phospholipids, and the two phases are separated by

centrifugation. The crude extract, after water removal, contains about 35% triglycerols and smaller amounts of nonphospholipid materials. Extraction with acetone is used to produce an oil-free lecithin. The term 'lecithin' has been used to describe both phosphatidylcholine and mixtures of phospholipids. Current recommendations by the International Union of Pure and Applied Chemistry–International Union of Biochemistry suggest the use of 3-*sn*-phosphatidylcholine rather than lecithin to describe 1,2-diacyl-*sn*-glycero-3-phosphatidylcholine. However, a commercial, soybean-derived lecithin preparation contains several different phospholipids, primarily phosphatidylcholine, phosphatidylethanolamine and phosphatidylinositol. The structures are shown in Figure 1. (*See* **Phospholipids**: Properties and Occurrence.)

Commercial lecithin preparations can be either treated or modified chemically to provide a product with altered functional characteristics. Treatment with either hydrogen peroxide or benzoyl peroxide will produce a lighter-colored product. The chemical modification of lecithin by reaction with hydrogen peroxide, plus lactic or acetic acid and water, will produce a hydroxylated product. Hydroxylation occurs at the double bonds, altering lecithin such that its hydrophilic character is increased. The result is a product with improved oil-in-water emulsifying properties relative to unmodified lecithin.

Triglycerols are soluble in acetone, whereas phospholipids are not. Therefore, the greater the percentage of acetone-insoluble material, the greater the phospholipid content in crude lecithin. Because of this, one of the primary criteria for the evaluation of lecithin is the percentage of acetone-insoluble material. Lecithin is also evaluated on the basis of several other parameters including acid value (an indication of free fatty acids), hexane-insoluble matter (an indication of fibrous material), water, peroxide value and metallic impurities. Individual phospholipids in soy lecithin can be quantitated using HPLC.

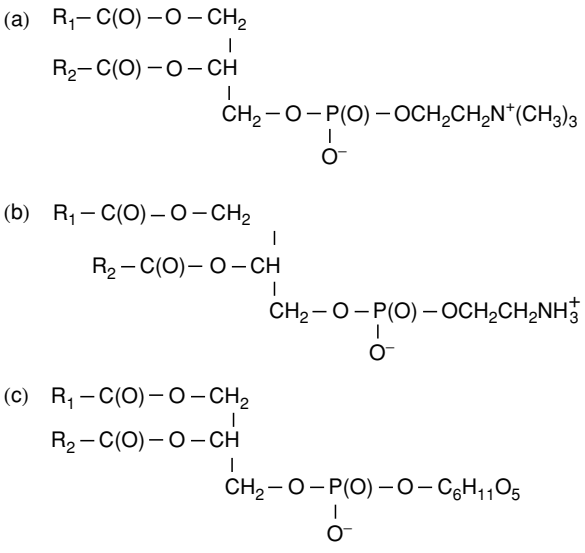

Figure 1 Primary phospholipids reported in commerical lecithin, where R_1 and R_2 are fatty acids: (a) phosphatidylcholine; (b) phosphatidylethanolamine; (c) phosphatidylinositol.

Mono- and Diglycerides

Mono- and diglycerides are the most commonly used food emulsifiers. They consist of esters synthesized via catalytic transesterification of glycerol with triglycerides, with the usual triglyceride source as hydrogenated soybean oil. Mono- and diglycerides are also synthesized directly from glycerol and fatty acids under alkaline conditions. Molecular distillation is used to prepare a purified product containing up to approximately 90% monoglycerol. Monoglycerols can be prepared from the reaction of glycidol (2,3-epoxy-1-propanol) and carboxylic acids with a yield in excess of 90%. Advantages of the process include the synthesis of difficult to produce monoglycerides and a good potential for continuous processing. Mono- and diglycerols have also been obtained from a butterfat fraction by chemical glycerolysis. The enzymatic preparation of mono- and distearin by glycerolysis of ethylstearate and direct esterification of glycerol in the presence of a lipase from *Candida antarctica* has also been reported.

Several tests are used for characterizing commercial sources of mono- and diglycerides, including total monoglycerides, hydroxyl value, iodine value, and the saponification value. With the monoesters, the fatty acid can be attached at either the alpha or beta positions, as with the diglycerides (see Figure 2).

Hydroxycarboxylic and Fatty Acid Esters

To produce an emulsifier with an increased hydrophilic character relative to monoglycerides, small organic acids are esterified to monoglycerols (Figure 3). Some

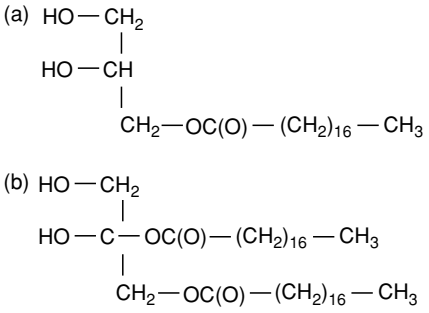

Figure 2 (a) Mono- and (b) diglycerides.

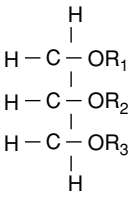

Figure 3 Organic acid ester of monoglycerol, where at least one R is a short-chain organic acid, for example, acetic acid.

of the acids used are acetic, citric, fumaric, lactic, succinic, and tartaric. Succinylated monoglycerols are synthesized from succinic anhydride and distilled. They are used by the baking industry as dough conditioners and crumb softeners. Acetic acid esters of mono- and diglycerides are synthesized from fatty acids plus acetic anhydride or by transesterification. The product is lipid-soluble and water-insoluble. Functions in food include control of fat crystallization and improvement of aeration properties of high-fat foods. They are often added to shortenings or cake mixes. (*See* **Fats:** Classification.)

To synthesize other acid esters, citric acid esters of mono- and diglycerides, glycerol is esterified with a mixture of citric acid and fatty acids. It can also be prepared by the direct esterification of citric acid with glyceryl monooleate. The product is hot water- and lipid-soluble. Functions in food include emulsification, antispattering agent in margarine, improvement of bakery product characteristics, a fat replacement in high-fat foods and a synergist and solubilizer for antioxidants.

Diacetyl tartaric acid esters of monoglycerides (DATEM) are synthesized from diacetyl tartaric acid anhydride and monoglycerides. The emulsification properties of DATEM depend primarily upon the type of fatty acid and the percentage of esterified tartaric acid. Emulsifier quality is based upon results from the analyses for tartaric and acetic acid, acid value, total fatty acids, saponification value, and metallic residues.

Lactic acid esters of mono and diglycerides consist of a mixture of lactic and fatty acid esters of glycerin. The emulsifier is dispersible in hot water. Important qualitative parameters include the percentage of monoglycerides, total lactic acid, acid value, free glycerin, and the amount of water.

Lactylate Fatty Acid Esters

Polymeric lactic acid esters of monoglycerides are also available, commonly known as sodium or calcium stearoyl-2-lactylates (see Figure 4). Typically, there are two lactic acid groups per emulsifier molecule. To produce the emulsifier, a mixture of the fatty acid, polylactic acid, and calcium or sodium carbonate is heated at about 200 °C for about 1 h with agitation in an inert atmosphere. The calcium salt is less dispersible in water than sodium stearoyl-2-lactylate.

Polyglycerol Fatty Acid Esters

Polyglycerol esters (Figure 5) of fatty acid are also used in food products, primarily in baked goods. They consist of mixed partial esters synthesized from the reaction of polymerized glycerol with edible fats. Polyglycerols will vary in degree of glycerol polymerization with an average specified. The source of fatty acids as well as the degree of polymerization can vary, providing a wide range of emulsifiers, from hydrophilic to very lipophilic.

Polyethylene or Propylene Glycol Fatty Acid Esters

Fatty acids can be esterified directly to polyethylene glycol ethers or by enzymatic preparation, which allows better control of the reaction. Propylene glycol fatty acid (C12, C14, C16, C18, and C18:1) monoesters (Figure 6) have been produced by lipase-catalyzed reactions. Propylene glycol monoesters of docosahexaenoic acid and eicosapentaenoic acid that are potentially health-beneficial w/o emulsifiers useful in the food industry have been synthesized by lipase-catalyzed esterification. The HLB of the emulsifier is altered by adjusting the degree of ethoxylation. Fatty acid polyglycol esters are good o/w emulsifiers.

Ethoxylated Derivatives of Monoglycerides

Ethoxylated mono- and diglycerides are produced from the reaction of several moles of ethylene oxide and mono- or diglycerols under pressure. Ethoxylation of monoglycerols results in a product that is much more hydrophilic relative to monoglycerols.

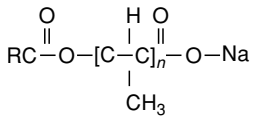

Figure 4 Sodium stearoyl-2-lactylate, where *n* normally averages 2, and R is a fatty acid moiety.

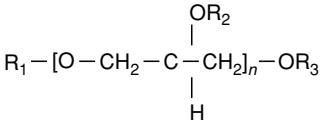

Figure 5 Polyglycerol esters of fatty acids, where R_1, R_2, and R_3 are each a fatty acid and/or a hydrogen, and where the average value of *n* is greater than 1.

The end product of the synthesis is actually a mixture with a distribution range and peak; therefore, many often vary among manufacturers.

Sorbitan Fatty Acid Esters

Polyoxyethylene sorbitan esters are synthesized by the addition, via polymerization, of ethylene oxide to sorbitan fatty acid esters. These nonionic hydrophilic emulsifiers are very effective antistaling agents and, thus, are used in a wide variety of bakery products. These emulsifiers are much more widely known as the polysorbates, e.g., polysorbate 20, 60, and 80 (Figure 7). Polysorbate 20, 60, and 80 utilize lauric, stearate, and oleate, respectively, for the fatty acid portion of the molecule. Polysorbate 60 is a monostearate, whereas polysorbate 65 is a tristearate.

Miscellaneous Derivatives

Fatty acids can be esterified directly to compounds other than glycerol, for example, sugar alcohols like sorbitol, mannitol, and maltitol, and sugars like sucrose, glucose, fructose, lactose, and maltose.

Sorbitol or sorbitan esters are formed from 1,4-anhydro-sorbitol and fatty acids (see Figure 8). Typically, the emulsifier consists of a mixture of stearic and palmitic acid esters of sorbitol and its mono- and dianhydrides. Ethoxylated derivatives can also be prepared by the addition of several moles of ethylene oxide to the sorbitan monoglycerol ester and, depending on the number of moles of ethylene oxide added, have a wide range in HLB.

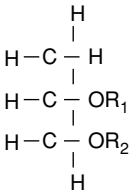

Figure 6 Propylene glycol esters of fatty acids, where R_1 and R_2 represent a fatty acid and/or a hydrogen, and where at least one R represents a fatty acid.

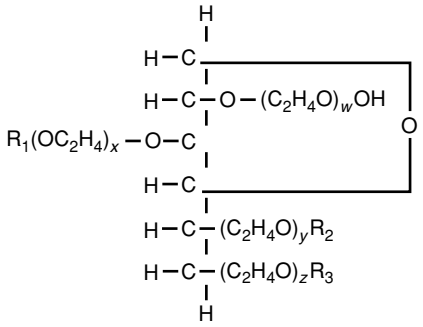

Figure 7 Polysorbates, where $w + x + y + z = 20$ (approx.) and Rs represent a single fatty acid and hydrogens for polysorbate 20, 40, 60, and 80. For polysorbate 65, each R represents a stearic acid moiety. The fatty acids are lauric, palmitic, stearic, and oleic acid for polysorbate 20, 40, 60, and 80, respectively.

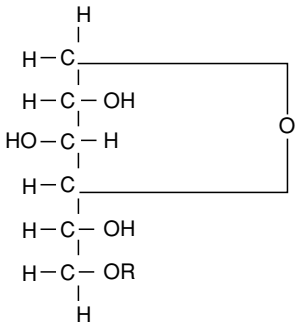

Figure 8 Sorbitan stearate, where R represents a fatty acid moiety, for example, stearic acid, oleic acid, lauric acid, or palmitic acid.

Lactitol (the hydrogenation product of lactose) palmitate is synthesized by direct esterification at a temperature of approximately 160 °C. Workers have reported the enzymatic synthesis of acetylated glucose fatty acid esters. Two immobilized lipases from *Candida antarctica* (SP 382) and *Candida cylindraceae* catalyzed the synthesis of novel acetylated glucose fatty acid esters with glucose pentaacetate and Trisun 80 (80% oleic) vegetable oil or methyl oleate as substrates in organic solvents. The incorporation of oleic acid on to the glucose ranged from 30 to 100%. It was possible to catalyze the synthesis of glucose fatty acid esters with free glucose as the sugar substrate. Other researchers have reported the synthesis of a novel nonionic surfactant, dialkyl glucosylglutamate from δ-gluconolactone, glutamic acid and alkyl alcohols. Sucrose fatty acid esters (Figure 9) can be synthesized using a variety of solvents or by direct esterification. The first description of a practical commercial process for the preparation of sucrose esters of fatty acids was reported in 1956. Enzymatic synthesis of carbohydrate esters of fatty acids has also been reported for the esters of sucrose, glucose, fructose, and sorbitol with oleic and stearic acid and fructofuranose. The reports by researchers indicate the enzymatic preparation of three different 1,6-diacyl fructofuranoses. At low temperatures (5 °C), the synthesis produces quantitative yields of the diesters by simple addition of the original sugar to a solution of the fatty acid in a solvent (acetone), which is accepted by the European Commission (EC) for use in the manufacture of additives. By varying the degree of esterification, the HLB and, hence, the functionality can be controlled. Sucrose

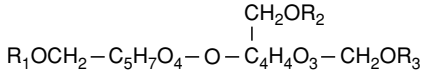

Figure 9 Sucrose fatty acid esters, where at least one of either R_1, R_2, or R_3 represents a fatty acid, and the remainder may represent a fatty acid or a hydrogen; the degree of substitution is 1–3.

monoesters have an HLB value greater than 16 while the triesters have an HLB value less than 1. Monoesters are particularly useful for the stabilization of o/w emulsions, whereas diesters are best for w/o emulsions. With esterification equal to or greater than 5 moles of fatty acid per mole of sucrose, the emulsification properties of sucrose fatty acid esters are lost. But, at that degree of esterification, the sucrose fatty acid polyester can be used as a low-calorie fat replacement since it is neither digestible nor absorbable.

The consistency of both o/w and w/o emulsions can be affected with the addition of ethylene or propylene glycol monostearate. The most common ethylene and propylene glycol esters used as emulsifiers are the monostearate and monopalmitate.

Emulsion Stability

Small droplets and the presence of an interfacial film on the droplets in emulsions make them stable; that is, the suspended droplets do not settle out or float rapidly, and the droplets do not coalesce quickly.

Emulsifiers are generally classified as: anionic emulsifiers, cationic emulsifiers, amphoteric emulsifiers and nonionic emulsifiers. Proteins (caseins) are known to stabilize emulsions, owing to their amphoteric nature. The oil phase viscosity also contributes to the stability of the emulsion stability, but this depends on the adsorption and interfacial behavior of the emulsifiers.

One basis for a theory of emulsion stability concerns the balance between the attractive and repulsive forces of the particle. In other words, attractive (Van der Waals forces or London dispersion forces) would tend toward destabilizing an emulsion, whereas the repulsive forces (electrostatic repulsion between electrical double layers of like sign) would stabilize the emulsion by keeping the droplets separated.

There are several phenomena that can cause emulsion destabilization. Each is affected by the presence of emulsifiers. To understand best the mechanism of emulsion formation and ultimately the forces stabilizing emulsions, the mechanisms of destabilization should be understood.

Mechanisms of Destabilization

Emulsion destabilization can be due to one or all of five possible mechanisms; flocculation, coalescence, sedimentation or creaming, Ostwald ripening, and phase inversion.

-Flocculation The adherence of droplets to form aggregates or clusters and the buildup of these aggregates are referred to as 'flocculation.' It occurs when the attractive forces between the droplets exceeds that of the repulsive forces, without a breakdown in the structural integrity of the interfacial film surrounding the droplets.

-Coalescence When aggregates or flocculates of the dispersed phase combine to form a single, larger drop, the phenomenon is referred to as 'coalescence.' Coalescence is really a reflection of the nature of the interfacial film on the surface of the droplet. A strong, stable film on the surface of the droplet, owing to the addition of the correct concentration of the appropriate emulsifier, will minimize this type of destabilization.

-Ostwald ripening If the two phases forming the emulsion are not totally immiscible, and there are differences in droplet size within the emulsion, larger droplets will form at the expense of smaller droplets owing to a process known as 'Ostwald ripening.' Ostwald ripening is always a factor since variations in initial droplet size always occur in macroemulsions, and both phases are never completely immiscible. The driving force for Ostwald ripening is the difference in chemical potential between droplets of difference sizes. Equilibrium will only exist when all droplets are the same size, which really means a single 'drop' or the presence of two continuous and separate phases.

-Phase inversion The viscosity of an emulsion will increase gradually as more and more of a given phase is added until a critical volume is reached. If more of that same phase is added, exceeding the critical volume, the emulsion will invert, i.e., the discontinuous phase will become the continuous phase.

Mechanisms of Stabilization by Emulsifiers

There are several factors, some of which are dependent on the emulsifiers and stabilizers added, involved in emulsion stabilization. The first is the reduction of interfacial tension by the emulsifiers. Next, is repulsion between droplets due to similar electrical charges on the surface of the droplets. A third is the formation of mesophases or liquid-crystalline phases, which will

provide the most stable configuration for a specified set of conditions. A fourth is the addition of macromolecules or particulate material, which can substantially increase emulsion viscosity and stability. An increase in viscosity of the continuous phase adds to the kinetic stability. However, without a concurrent energy barrier, viscosity will have a small effect on stabilization. Viscosity enhancers increase the stability of the energy barrier. Stable oil-in-water emulsions of argan oil with two different types of mixtures of nonionic emulsifiers have been produced. Three different types of oil (Israeli argan oil, Moroccan argan oil, and soybean oil) have been emulsified with mixtures of Span 80 and Tween 80. The optimum HLB value for argan oil is 11.0. The argan o/w emulsions are stable for more than 5 months at 25 °C. Synergistic effects have been found in enhancing the stability of emulsions prepared with sucrose monostearate. The origin of the oil and the internal content of natural emulsifiers, such as monoglycerides and phospholipids, have a profound influence on its interfacial properties and on the stability of the argan o/w emulsions.

Emulsion stability is also dependent upon the conditions under which the emulsion is formed. This includes not only the constituents of the emulsion but also the emulsifier concentration, emulsion temperature, and physical state (crystalline vs. fluid) of the emulsifier. The order of addition of the constituents is also an important factor. Addition of lecithin to the lipid phase prior to the addition of the aqueous phase can substantially alter the droplet size, liquid crystal formation, and emulsion stability. Another contributing factor is the nature of the internal and continuous phases. Both affect emulsion stability. Two types of emulsions, those prepared with unsaturated emulsifiers and unsaturated oil and those prepared with saturated emulsifiers and saturated oil, are more stable than those prepared with emulsifiers and oil of intermediate or mixed saturation.

Functions of Emulsifiers

Interfacial Tension

The reduction of interfacial tension through the addition of emulsifiers is a key factor in emulsion formation. It allows emulsion formation with considerably less energy input than would be required without the presence of an emulsifier. Once the interfacial film consisting of emulsifier is formed, it acts as an effective barrier to droplet coalescence. It has been found that, in the presence of emulsifiers, the droplet interface may acquire viscoelastic properties, which are important in the prevention of coalescence. A strong interaction between the hydrophilic portion of the emulsifier and the aqueous phase leads to a large reduction in the surface tension of the water; this also affects the type of emulsion formed. A weak interaction between water and the hydrophilic portion of the emulsifier molecule will favor a w/o emulsion, whereas a strong interaction will favor a o/w emulsion.

Electrical Charge

Ionic emulsifiers provide an additional mechanism for emulsion stabilization relative to nonionic emulsifiers, through ion–ion and ion–solvent interactions. In addition, the introduction of charged groups on the surface of the emulsion droplets increases the repulsive forces. Ionic emulsifiers will form an electrically charged double layer in the aqueous solution surrounding each oil droplet.

Liquid Crystal Stabilization

Macroemulsions, although thermodynamically unstable, can attain rather long-term stability, strongly suggesting an intermediate stability level. This was attributed to the formation of a liquid crystalline state by the emulsifier. It has been shown that the presence of a liquid crystalline state reduces the rate of coalescence, even if droplet flocculation occurs. (*See* **Crystallization**: Basic Principles.)

Stabilization by Macromolecules and Finely Divided Solids

Emulsion stability can be increased by the addition of macromolecules like gums and protein. Colloids like xanthan gum, carboxy methyl cellulose and guar gum significantly increase emulsion stability. With both a constant emulsifier and colloid concentration, emulsion stability is enhanced by increased emulsification temperature, increasing the degree of shear, and increase pH, in the range of 3–6. Colloids act by either increasing the viscosity or partitioning into the o/w interface and providing a physical barrier to coalescence.

To evaluate emulsion stability and thereby characterize the potential of an emulsifier, the rate at which the combined destabilization phenomena occur must be determined. These rates can be determined from the changes in the size and distribution of the oil droplets with time. There are several methods available for this determination. Nuclear magnetic resonance is often preferred as a better indication of stability to HLB values. Other methods, used to evaluate the effects of processing on emulsion stability, include centrifugation, turbidity light micoscopy scanning electron microscopy, etc.

Emulsifier Selection

Emulsifier selection is based upon the final product characteristics, emulsion preparation methodology, the amount of emulsifier added, the chemical and physical characteristics of each phase, and the presence of other functional components in the emulsion. Food emulsifiers have a wide range of functions. The most obvious is to assist stabilization and formation of emulsions by the reduction of surface tension at the o/w interface.

Perhaps the most important factor in preparing an emulsion is the selection of the appropriate emulsifier. Several methodologies have been developed to assist in such an endeavor. These include the HLB system of Griffin, the H/L numbers, the water number, the phase inversion temperature, and the emulsion inversion point. Even with the best of methods, selection can be very difficult, except perhaps for the few foods that are relatively straightforward emulsions, like mayonnaise and margarine. Often, one of the best sources of information is the emulsifier manufacturer. Several parameters should be considered during emulsifier selection. These parameters include: (1) approval of the emulsifier by the appropriate government agency, (2) desired functional properties, (3) end-product application, (4) processing parameters, (5) synergistic effect of other ingredients, (6) home preparation, and finally (7) cost.

Obviously, before an emulsifier can be used in a food product, it must be approved by the appropriate regulatory agency. Assuming this criterion is met, the most important considerations would be both the required functional properties of the selected emulsifier and the application. Delineating the required functional properties such as emulsification, starch complexation and crystallization control and the specific end-product application are the two major factors in emulsifier selection. An exact determination of these two parameters should focus attention on a limited number of emulsifiers. The processing methodology and equipment available in the processing facility could further limit the range of emulsifiers that are of potential use. It is at this stage that ingredient supplier(s) could begin to provide helpful assistance.

By far, the most widely used rule for the selection of food emulsifiers is the HLB number. The HLB index is based upon the relative percentage of hydrophilic to lipophilic groups within the emulsifier molecule. The assigned values range from 1 to 20. Lower HLB values indicate a more lipophilic emulsifier, whereas higher values indicate a more hydrophilic emulsifier. Emulsifiers with HLB numbers in the 3–6 range are best for w/o emulsions, whereas emulsifiers with HLB numbers in the range of 8–18 are best for o/w emulsions. Depending upon the application and the types of oils to be emulsified, there is an optimum HLB.

There is an equation that can be used to determine the HLB number for several types of nonionic emulsifiers, particularly the ethoxylated alcohols and the polyhydric fatty acid esters. To determine the HLB for the fatty acid ester type, the following equation can be used:

$$\mathrm{HLB} = 20(1 - S/A),$$

where A is the acid number, and S is the saponification number of the ester.

For the polysorbate type of emulsifier, the HLB value can be determined from the equation:

$$\mathrm{HLB} = (E + P)/5,$$

where E is the weight percentage of oxyethylene, and P is the weight percentage of polyhydric alcohol.

However, there are several factors that reduce the utility of the HLB selection system. One factor is that the HLB system does not work well for ionic emulsifiers, a problem further complicated by the fact that the charge varies with pH. Another factor is that commercial preparations usually contain two or more emulsifiers. These emulsifiers can have a significant synergistic effect that makes it very difficult to apply the HLB system. Another limitation is due to the fact that the HLB system is based upon the molecular structure of the emulsifier and does not take into account the combined oil/aqueous phase/emulsifier system. In addition, once the appropriate emulsifier has been selected, the correct concentration can not be determined from the HLB value. The concentration required is really a function of the droplet size. The smaller the droplet, the greater the surface area and, therefore, the greater the amount of emulsifier that is required for monolayer coverage of each droplet. In spite of these limitations, the HLB is still the most widely used index of emulsifier functionality.

Phosphates as Meat Emulsion Stabilizers

L Knipe, Ohio State University, Columbus, OH, USA

Introduction

The emulsifying capacity of phosphates in meat emulsions may take several approaches, depending upon the definition of emulsification. A finely chopped meat mixture is conventionally referred to as a 'meat emulsion.' However, this is now considered to be a misnomer. The so-called meat emulsion consists of solid fat particles dispersed in a mixture of water and many fibrous particles, including connective tissue and muscle fibers. A true emulsion is a stable suspension of two liquids (oil and water) which are not normally soluble in each other. It might be more appropriate to refer to a meat emulsion as a matrix, whose stability is dependent upon the water-holding capacity or binding capacity of the meat proteins in the matrix. However, a finely chopped meat mixture will be referred to as an emulsion in the remainder of this article.

If the proper combination of meat ingredients is combined with the proper processing procedures (e.g., grinding, chopping, emulsifying), a stable emulsion will be prepared which will hold up well during the cooking process. Examples of meat emulsions are bologna sausages or wieners, which have such fine meat particles that they are not distinguishable on the smooth product surface. However, if either the quantity or quality of meat ingredients or the processing methods are inadequate, the meat mixture will be unstable and result in a poor-quality product upon cooking. (*See* **Meat**: Sausages and Comminuted Products.)

If it is assumed that a meat emulsion is not a true emulsion, then phosphates are probably not true emulsifiers, but stabilizers of meat mixtures. There are many factors involved in the stability of meat emulsions which can be affected by the addition of inorganic phosphates. The main effects of phosphates in finely chopped meat systems are on the pH, ionic strength, protein extraction, divalent cation binding, and viscosity. (*See* **Colloids and Emulsions; Stabilizers**: Types and Function; Applications.)

Phosphate Classification and Nomenclature

Inorganic phosphates are classified by the number of phosphorus atoms in the phosphate molecule. The types of phosphates that are important to the meat industry include the orthophosphates, the pyrophosphates, and the straight-chain phosphates.

Orthophosphates contain only one phosphorus atom per molecule. The pyrophosphate molecule consists of two phosphorus atoms linked by a shared oxygen atom. An inorganic phosphate of such structure is referred to as a condensed phosphate. The two pyrophosphates approved by the US Department of Agriculture's Food Safety Inspection Service (USDA FSIS) are sodium acid pyrophosphate and tetrasodium pyrophosphate.

Inorganic phosphates of three or more phosphorus atoms are referred to as polyphosphates. Sodium or potassium tripolyphosphates consist of three linked phosphorus atoms. Sodium hexametaphosphate is a

misnomer for a long straight-chain polyphosphate. The 'meta' designation is correctly given to cyclic polyphosphates. Hexametaphosphate contains an average of 10–15 phosphorus atoms. The name 'sodium hexametaphosphate' has been deleted from USDA regulations and replaced with 'sodium polyphosphate, glassy' (Graham's salt) and 'sodium metaphosphate, insoluble' (Maddrell's salt).

Phosphates and pH

Phosphates affect the pH of both water and meat. The pH values of 1% solutions of the phosphates approved for use in meat products, by the USDA FSIS, appear in Table 1. Whereas meat contains 60–70% moisture, the phosphate effect on the pH of meat, as determined by standard pH measurements, is somewhat less than their effect in water, due to the buffering capacity of meat. Alkaline phosphates increase meat pH in the range 0.1–0.6 units, depending upon the phosphate chosen. The following list indicates the decreasing order of impact on increasing meat pH – pyrophosphates, tripolyphosphates, and hexametaphosphates. Hexametaphosphates are considered to be rather neutral and often have no effect in increasing meat pH. Acid pyrophosphates often, in fact, decrease the pH of meat systems. There is, however, some debate among researchers as to the true importance of meat pH changes, due to the addition of phosphates, on the stability of meat emulsions. (*See* **pH – Principles and Measurement**.)

Water-Holding Capacity of Meat Emulsions

The water-holding capacity of meat could be compared to the action of a sponge and is important to meat processing in that as proteins are able to hold more water they become more soluble. The water-holding capacity of meat is at a minimum at the isoelectric point (pI) of meat proteins. At this point, equal positive and negative charges on the protein molecules result in a maximum number of bonds between peptide chains and a net charge equal to zero. The pI of meat (where water-holding capacity is at a minimum) is in the pH range of 5.0–5.4, which is also the ultimate pH of meat or the pH of meat after it has gone through rigor mortis.

The water-holding capacity of meat is greatly affected by pH. Increasing or decreasing the pH on either side of the pI will result in an increased water-holding capacity by creating a charge imbalance. A charge imbalance is a predominance of either positive or negative charges which will result in a repulsion of the charged protein groups of the same (positive or negative) charge. This repulsion results in increased capacity for water retention and could be compared to the repulsive effect of like charges on two magnets.

An increase in predominance of negative protein charges, due to the addition of phosphates, may also cause better distribution of fat particles in emulsified products. The better fat particle distribution may prevent the clumping of fat particles that occurs during overchopping and which results in an unstable emulsion.

Table 1 pH values for 1% water solutions of US Department of Agriculture-approved phosphates

Inorganic phosphate	*pH*
Tetrasodium or tetrapotassium pyrophosphate	10.2
Sodium or potassium tripolyphosphate	9.8
Disodium or potassium orthophosphate	8.8
Sodium polyphosphate, glassy	7.0
Sodium metaphosphate, insoluble	6.5
Monosodium or potassium orthophosphate	4.4
Sodium acid pyrophosphate	4.2

From Ellinger RH (1972) *Phosphates as Food Ingredients*. Cleveland, OH: CRC Press with permission.

Phosphates and Ionic Strength

Phosphates also affect the ionic strength of meat mixtures. Inorganic phosphates ionize in water to form polyelectrolytes. This ionization causes a masking of positive sites on the meat proteins which further causes an electrostatic repulsion of the proteins. An electrostatic repulsion between meat proteins allows more space between proteins for binding water, which increases the water-holding capacity. This effect is sometimes hard to differentiate from the pH effect on the water-holding capacity of meat. In addition to the repulsion theory, the long-chain phosphates have numerous charged anions along the chains, which allows direct binding of phosphates to water molecules. This is especially true for the long-chain phosphates, such as the hexametaphosphates.

Protein Extraction and Solubilization

During the formation of a meat emulsion, meat proteins are extracted from the fibrous muscle structure and are solubilized to form a solution. This protein extraction is enhanced by the optimal ionic strength and pH of the solution in which the protein is submersed. Once solubilized, with additional chopping or mixing, the liquid proteins are dispersed around the bundles of muscle cells and fat particles. When the mixture is then cooked, the protein solution denatures and coagulates (like egg white) to form a gel around the muscle bundles and fat particles. This gel

serves to stabilize the matrix of the meat mixture or emulsion. (*See* **Protein**: Functional Properties.)

Phosphates have a very valuable role in extracting proteins from muscles. In fact, tetrasodium pyrophosphates are known to have a specific effect on meat proteins in that they are able to extract muscle proteins, and stabilize meat emulsions, to a degree much greater than normally possible considering the effects of tetrasodium pyrophosphates on ionic strength, and pH compared to other phosphates. Part of the specific effect is that pyrophosphates serve to dissociate, or separate, actomyosin into its component parts, actin and myosin. This is very advantageous, as myosin by itself is more beneficial in producing a stable emulsion than actomyosin. Phosphates are also known to extract myosin more readily from fast (white) muscle fibers than slow (red) muscle fibers.

Commercially available phosphates are ranked in the following descending order of impact on extraction of muscle proteins from meat: tetrasodium or potassium pyrophosphates, sodium or potassium tripolyphosphates, sodium hexametaphosphates. There are cases, however, where it has been shown that level of protein extraction in a meat system was not well correlated to the emulsion stability of the final cooked product.

Phosphates and Divalent Cations

Phosphates also bind divalent cations, which are native to meat proteins and which are detrimental to finished processed-meat quality. Divalent cations, such as those of calcium, magnesium, and iron, are often found in untreated or unsoftened water supplies, as well as meat, and are known to decrease the water-holding capacity of meat. This is believed to be due to bridging and binding between several groups of proteins, similar to that which occurs during rigor mortis. Another theory is that divalent cations screen the negatively charged protein groups, minimizing any repulsive effect. However, there is some evidence that increased magnesium concentration enhances the myosin-extracting ability of pyrophosphates.

There is still some debate among researchers as to whether phosphates bind cations which are already bound to the muscle or bind only to free cations in solution within muscle. In either case, the binding of cations in a meat system increases the water-holding capacity. One indication that phosphates are binding divalent cations is in the antioxidant effects of phosphates added to meat products. (*See* **Antioxidants**: Synthetic Antioxidants.)

The long-chain phosphates, such as sodium hexametaphosphates, are most active in chelating calcium ions and short-chain phosphates, such as tetrasodium pyrophosphates, bind magnesium cations most readily.

Viscosity of Meat Emulsions

Phosphates are also important in the physiochemical aspects of meat processing. For example, phosphates reduce the viscosity of meat mixtures. This is important because, in the chopping or mixing steps, meat temperatures will rise due to frictional energy produced as the chopper or emulsifier knives are cutting and moving through the meat mixture. Chopping emulsions containing a soft fat, such as pork fat, to excessively high temperatures will result in an unstable product.

However, when meat is finely chopped to make a stable emulsion-type sausage product, the fat particles need to be reduced to a small enough size so that the extracted meat proteins can coat or entrap the fat. If the fat particles are too large, a coarse, unstable emulsion will result but, if the fat is chopped too much, the fat surface area may be too large or too many fat cells may be broken, also resulting in an unstable product. By reducing the viscosity, a mixture can also be chopped or mixed longer, either to reduce fat particle size or extract more protein to stabilize the mixture further, with less temperature rise. Without phosphates, long chopping or mixing times would result in unstable products.

Phosphates and Sodium Chloride

The functionality of phosphates is greatly affected by the addition of common table salt or sodium chloride to meat emulsions. The effects of combining salt and phosphates in meat emulsions is considered to be synergistic, which means that the measurable effects of the two ingredients combined is greater than the combined effects of the two ingredients added individually. It seems that phosphates exert more effect on the pH and protein solubility and salt exerts more effect on the ionic strength and water-holding capacity. The phosphate effect on muscle proteins appears to diminish at higher salt concentrations ($> 0.6\,\mathrm{mol\,l^{-1}}$ sodium chloride).

Uses in Processed Foods

T Kinyanjui and W E Artz, University of Illinois, Urbana, IL, USA
S Mahungu, Egerton University, Njoro, Kenya

Emulsions

Natural food emulsions existed, of course, long before food processing. A good example is milk, a natural emulsion/colloid in which fat is stabilized by a milk-fat-globule membrane. The development of technologies for processing oils, such as refining, bleaching, and hydrogenation, has led to the use of food emulsifiers.

The definition of an emulsion has continued to evolve since the 1930s. Becher developed an elaborate definition from several previous authors:

> An emulsion is a heterogeneous system, consisting of at least one immiscible liquid intimately dispersed in another in the form of droplets, whose diameter, in general, exceeds 0.1 μm. Such systems possess a minimal stability, which may be accentuated by such additives as surface-active agents, finely divided solids, etc.

Liquid crystalline phases are significant in emulsion stability. This was reflected in the IUPAC-IUB definition of an emulsion: 'In an emulsion, liquid droplets and/or liquid crystals are dispersed in a liquid.' Sharma and Shah defined both micro- and macroemulsions, differentiating them on the basis of size and stability. Macroemulsions were defined as:

> mixtures of two immiscible liquids, one of them being dispersed in the form of fine droplets with (a) diameter greater than 0.1 μm in the other liquid. Such systems are turbid, milky in color and thermodynamically unstable.

Microemulsions were defined as:

> the clear thermodynamically stable dispersions of two immiscible liquids. The dispersed range consists of small droplets in the range of 100–1000 Å.

Food macroemulsions are unstable systems, even with the addition of emulsifiers. Emulsifiers must be added to increase product stability and attain an acceptable shelf-life. The function of an emulsifier is to mix the oily and aqueous phases of an emulsion, in a homogeneous and stable preparation. The main characteristic of an emulsifier is that its molecules must contain two parts. The first part must have a hydrophilic affinity, and the second part must have a lipophilic affinity. Emulsifiers are generally classified as: anionic emulsifiers, cationic emulsifiers, amphoteric emulsifiers, and nonionic emulsifiers. (*See* **Colloids and Emulsions**.)

Emulsifier selection is based upon final product characteristics, emulsion preparation methodology, the amount of emulsifier added, the chemical and physical characteristics of each phase, and the presence of other functional components in the emulsion. Food emulsifiers have a wide range of functions. The most obvious is to assist in the stabilization and formation of emulsions by reducing the surface tension at the oil–water interface.

By far the most used rule of the selection of a food emulsifier is the HLB value. The HLB value, which is

the 'hydrophile–lipophile balance,' is based on the relative percentage of hydrophilic to lipophilic groups within the emulsifier molecule. Values range from 1 to 20: a lower HLB value indicates a more lipophilic emulsifier, whereas higher HLB value indicates a more hydrophilic emulsifier.

The first step in the formation of a stable emulsion is dispersion of one phase in another. A critical factor in the emulsification process is the formation of a monomolecular layer at the lipid–water interface by the emulsifier. During emulsion formation, there is a large increase in surface area (up to several thousand-fold), which is dependent upon the number and size of the droplets. To form and disperse these droplets, a substantial amount of energy or work must be supplied. Since emulsifiers reduce the surface tension, the addition of emulsifiers reduces the amount of work that must be done to form the emulsion. The most common method of emulsion formation is the application of mechanical energy via vigorous agitation.

Emulsifier Chemistry

Schuster has written a comprehensive treatise on emulsifiers with extensive discussions on the current theories of emulsion formation, emulsifier chemistry, function, and analysis. He included a discussion covering all the emulsifiers currently used in Germany and the USA, plus applications in a wide variety of products.

Applications in Foods

Categories

Food emulsifiers can be categorized (Table 1) on the basis of several characteristics, including: origin, either synthetic or natural; potential for ionization, nonionic versus ionic; HLB; and the presence of functional groups.

Some biopolymer-type emulsifiers, such as whey proteins, will function both as an emulsifier and as a thickener. For underprocessed emulsions, the droplets may not be dispersed finely enough. Overprocessing an emulsion may reduce or eliminate the maximum networking ability of a stabilizing macromolecule colloid (protein or polysaccharide), due to the excessive mechanical or thermal treatment.

An example of an anion-type food emulsifier is sodium stearoyl lactylate. When combined with distilled, saturated monoglycerols (1:1, w/w), vesicles form that are relatively stable in food systems. These work well for such applications as aerating or texturing low-fat foods.

Table 1 Some food emulsifier categories[a]

Emulsifier
Mono- and diglycerols
Propylene glycol monoesters
Lactylated esters
Polyglycerol esters
Sorbitan esters
Ethoxylated esters
Succinated esters
Fruit acid esters
Acetylated mono- and diglycerols
Phosphated mono- and diglycerols
Sucrose esters

[a]Adapted from Zielinski RJ (1997) Synthesis and composition of food grade emulsifiers. In: Hasenhuetti GL and Hartel R (eds) *Food Emulsifiers and their Applications*, pp. 11–38. New York: Chapman and Hall.

When adding an emulsifier–water mesophase as a part of a food formulation, it is important to realize that phase changes may take place due to the effect of the food ingredients (fats, oils, proteins, salts, etc.) on the mesophase, as well as the effect of temperature during pasteurization, sterilization, or freezing of foods.

Functionality

Surface active compounds operate through a hydrophilic head that is attracted to the aqueous phase, and a lipophilic tail that partitions into the oil phase. The surfactant is positioned at the oil–water interface, where it can act to lower the surface or interfacial tension. Lipophilic tails are generally composed of C16 or longer fatty acids. Emulsifiers with shorter fatty acid chains can act as emulsifiers but may hydrolyze to cause soapy or other undesirable off-flavors.

The concentration of added emulsifiers in foods is usually too low to result in any formation of liquid crystalline phases during food processing; nevertheless, some may be formed during processing by the polar lipids present in the food ingredients. This is the case with bakery products such as bread, rolls, and buns based on wheat flour, which contains polar lipids, such as glycolipids and phospholipids. Another example is mayonnaise and salad dressings where the phospholipids from the eggyolk can form liquid crystalline structures. Acetic acid or lactic acid esters of monoglycerols or propylene glycol monostearate are used in whippable emulsions, such as creams, toppings, etc.

Emulsifiers have a wide range of functional properties in addition to the obvious property – stabilization of food emulsions. Table 2 lists the functional properties of food emulsifiers compiled from a variety of sources including product brochures from several emulsifier manufacturers.

Table 2 Functional properties of food emulsifiers[a]

Functions	*Product examples*
Starch complexer	Marcaroni, pasta
Antispattering agent	Margarines
Gloss enhancer	Confectionery coatings
Emulsification, water-in-oil emulsions	Margarine
Emulsification, oil-in-water emulsions	Mayonnaise
Aeration	Whipped toppings
Whippability	Whipped toppings
Inhibition of fat crystallization	Candy
Softening	Candy
Antistaling	Bread
Dough conditioner	Bread dough
Improve loaf volume	Bread
Reduce shortening requirements	Bread
Pan release agent	Yeast-leavened and other dough and batter products
Fat stabilizer	Food oils
Antispattering agent	Margarine and frying oils
Antisticking agent	Caramel candy
Protective coating	Fresh fruits and vegetables
Surfactant	Molasses
Control viscosity	Molten chocolate
Improved solubility	Instant drinks
Starch complexation	Instant potatoes
Humectant	Cake icings
Plasticizer	Cake icings
Defoaming agent	Sugar production
Stabilization of flavor oils	Flavor emulsions
Promotion of 'dryness'	Icecream
Freeze–thaw stability	Whipped toppings
Improve wetting ability	Instant soups
Inhibition of sugar Crystallization	Panned coatings

[a]Adapted from Hasenhuettl GL (1997) Overview of food emulsifiers. In: Hasenhuetti GL and Hartel R (eds) *Food Emulsifiers and their Applications*, pp. 1–9. New York: Chapman and Hall and Artz WE (1990) Emulsifiers. In: Branen AL, Davidson MP and Salminen S (eds) *Food Additives*, pp. 347–393. New York: Marcel Dekker.

Petroswski has compiled a good list of some of the commercial emulsifiers and described their nature, iodine, HLB values, and melting points.

Uses

-Cereal-based products Baked products without emulsifiers have been described as undesirable in terms of texture, taste, and appearance. Current processing, distribution, and storage techniques used for baked products require the use of additives that maintain quality and freshness.

Reviews by Schuster and Adams and Stampfli and Nersten cover research on emulsifiers with respect to baked goods and include excellent discussions on the mechanism of emulsification, the interaction of emulsifiers with starch, and a wide range of applications.

A series of bakery blends have been formulated for several fat-free, low-fat, or reduced-fat bakery applications, including muffins and sweet doughs, cakes and frostings. Emulsifiers function as dough conditioners, giving the product increased resistance to mixing and mechanical abuse, stronger side walls, more uniformity, and improved slicing characteristics. Several different types of bakery products, in addition to bread produced via conventional methods, benefit from added emulsifiers, including white bread produced by a highly mechanized process, buns and rolls, yeast-raised sweet rolls and doughnuts, plus variety breads that contain a significant portion of nonwheat flour components. (*See* **Biscuits, Cookies, and Crackers**: Methods of Manufacture.)

Certain emulsifiers can also function as crumb softeners, another type of dough conditioner. Soft crumb, a characteristic of freshly baked bread, can be retained longer if the appropriate emulsifiers are added. Crumb firming, associated with staling and starch retrogradation, can be delayed for 2–4 days with the addition of emulsifiers. When shortening is added to a wheat dough, it will improve the volume.

Cake volume and crumb texture are both related to the number of air bubbles present in the aerated batter. Commercially manufactured gel phases are available for use as aerating agents in low-fat cakes (Table 3.)

Investigators have attributed the effect of emulsifiers on the delay of crumb firming to the ability of emulsifiers to function as foam stabilizers.

Most investigators have found that lecithin has the same characteristics as other dough conditioners on bakery products: increased water absorption, reduced mixing time, improved machinability, and longer freshness. Lecithin can also improve the wettability of cake mixes. Phospholipids, treated with phospholipase to alter functionality, have been utilized in wheat dough to improve product characteristics. (*See* **Phospholipids**: Properties and Occurrence.)

The wheat proteins, gliadin and glutenin, form a viscous colloidal complex called 'gluten' when mixed into a dough. The properties of the dough are influenced by lipid emulsifiers. Emulsifiers interact with starch to form a complex that slows down the staling process. A blend of whey proteins, mono- and diglycerides, lactic acid fatty acid esters, and lecithin will increase the spreadability, reduce stickiness, increase creaminess, and contribute body to the baked product. (*See* **Wheat**: Grain Structure of Wheat and Wheat-based Products.)

A cake batter is a fat-in-water emulsion, where the aqueous phase contains dissolved sugar and suspended flour particles. In layer cakes, emulsifiers aid in aeration, lubrication, and crumb texture.

Table 3 Influence of emulsifiers on production and quality of baked products[a]

Process	*Influence of emulsifier*	*Advantages*
Mixing	• Improvement of wettability • Stabilization of phases • Better distribution of phases • Interaction of emulsifier/lipid • Interaction of emulsifier/starch surface • Interaction-emulsifier/protein	• Decrease of mixing and speed • Reduced shortening levels • Improvement of mixing • Greater shock tolerance • Improvement of machinability
Fermentation	• Interaction-emulsifier/protein	• Improvement of gas-retaining properties • Shorter fermentation • Greater shock tolerance
Baking	• Emulsifier–starch complex formation	• Improvement of gas-retaining properties • Improved loaf volume • Better texture • Better crumb grain • Better uniformity • Decreased water loss
Storage	• Emulsifier–starch complex formation	• Improvement of crumb softness and longer shelf-life

[a]Modified from Orthoefer FT (1997) Applications of Emulsifiers in Baked Foods. In: Hasenhuetti GL and Hartel R (eds) *Food Emulsifiers and their Applications*, pp. 211–234. New York: Chapman and Hall.

Nonflour lipid additives such as polar lipids (surfactants or emulsifiers) are commonly included in standard baking recipes today. Their effects on dough or cake batter and on the final product include an improvement in texture and an extended shelf-life. The disadvantages of using oil alone in bread include a weak dough, dull crumb, and reduced loaf volume. Emulsifiers can alter the solid fat index and the crystal polymorphism of shortening.

The deleterious effect of wheat bran on bread quality can be offset by the addition of emulsifiers and vital wheat gluten. Lecithin (0.5%) is used in shortening, but it is slightly less effective than 0.5% of ethoxylated monoglycerides, sucrose monopalmitate, or diacetyl tartaric esters for improving whole wheat bread.

A mixture of hydrophilic and lipophilic emulsifiers provides the best dispersibility for bakery products. Diacetyl tartaric acid ester of monoglycerides, a widely used emulsifier in Europe for bread products, appears to act as a dough strengthener and a crumb softener. It can also improve loaf volume and delay staling, and it shows synergistic activity with monoglycerides for some functions.

A family of starch–lipid composites, prepared by passing aqueous mixtures of starch and lipid through a steam jet cooker, offer flavor and texture advantages when combined with food products, particularly ground beef. The jet-cooked dispersions are stable and do not phase-separate, even after prolonged standing. They can be drum-dried and milled to yield dry powders that are not oily to the touch. The lipid component is dispersed within the starch or starch–water matrix as droplets, about 1–10 μm in diameter. The products, trademarked as Fantesk™, are a new type of starch–lipid composite prepared by a continuous steam jet cooking process. (*See* **Bread**: Breadmaking Processes.)

Flat bread products are consumed extensively in the Middle East, North Africa, and the Indian subcontinent. Like other bread products, the flat breads will stale upon storage. The addition of sodium stearoyl-2-lactylate and monoglycerides reduces the degree of firmness upon storage of flat breads. The addition of sucrose esters to chapaties, a flat bread product, allows the substitution of 40% of the whole wheat flour with nonglutenous flour (e.g., corn, sorghum, millet, or soy) with only a slight loss in quality. This would facilitate soy flour fortification of chapaties to improve the nutritional quality of the product.

There is a wide range of baked products, other than bread, with improved characteristics as a result of the addition of emulsifiers. Emulsifiers can be used to prevent, inhibit, or control starch gelation in macaroni, spaghetti, and snack foods, and maintain cooked rice in a dry and nonsticky condition.

Cookie characteristics (volume, top grain, and spreadability) can be improved by the addition of the appropriate emulsifier. The interaction of emulsifiers with starch alters the effect of heat on starch. Puddings, for example, have an increased freeze–thaw stability and increased resistance to retort processing, whereas starch-based sauces have an improved freeze–thaw stability and increased stability during holding at high temperatures.

Sucrose esters of fatty acids are used as nonionic food emulsifiers in nondairy based whipping cream

and dessert toppings, icecream, bread cakes and sponge products, beverage whiteners, and pasta and noodles.

-Dairy products Milk is a complex food emulsion. The emulsion component is composed of fat droplets dispersed in an aqueous phase containing protein.

Ice cream Icecream is both a foam and an emulsion, containing ice crystals and an unfrozen aqueous phase whose freezing point is depressed due to the presence of salts, sugars, and polysaccharide stabilizers.

Many emulsifiers used in icecream have a low HLB value. A number of comparisons of the effects of different emulsifiers in icecream have been made and established that emulsifiers impart desirable structural characteristics to icecream. The emulsifier enables icecream to be extruded into shapes for wrapping, or to retain its shape when it is filled into a cone from a counter freezer. Monolaurate, monooleate, and monostearate are effective in icecream emulsification destabilization, which is also enhanced by the addition of eggyolk solids and butter milk solids due to their surface-active lipid content. The function of emulsifiers in icecream may be summarized as:

1. After homogenization, a minimum amount of emulsifier is needed to prevent coalescence. The emulsion is then stabilized by adsorbed milk proteins.
2. Emulsifiers reduce the amount of protein needed, possibly through the involvement of a mesomorphic phase at the interface.
3. Saturated emulsifiers promote crystallization of the emulsified fat.
4. Emulsifiers promote the destabilization of the emulsion during freezing.

Emulsifiers are particularly useful with formed specialty products, such as icecream sandwiches, slices, and factory filled cones. Emulsifiers coat the milk fat, increasing the ability of the protein film to surround the air cells in the icecream. The results are an improved whippability, smoother texture and body, drier appearance, and slower melting rate. The smoother texture is favored since both ice crystal and air cell sizes are reduced. Two types of emulsifiers are used: (1) mono- and diglycerides and (2) polyoxethylene derivatives of sugar alcohol fatty acid esters.

The polyoxyethylene derivatives of the sorbitan fatty acid esters are particularly effective in imparting stiffness to icecream immediately upon leaving the freezer. The emulsifiers are added not to stabilize the mix, but to impart desirable end-product qualities. Selection of a suitable emulsifier should be based on HLB since optimum product characteristics are dependent on the emulsifier HLB. The optimum emulsifier HLB is 16. Icecream production has been characterized as a deemulsification process due to a combination of agitation, freezing, and the presence of an emulsifier. Emulsifiers give the icecream the dryness and stiffness required by agglomerating the finely dispersed fat globules to properly. (*See* **Dairy Products – Nutritional Contribution**.)

Other dairy products Cream liqueurs represent an unusual type of dairy emulsion that requires long-term stabilization of dispersed fat in an alcoholic environment. Soluble sodium caseinate can be used to stabilize an emulsion that shows finely dispersed fat.

Flack found that mono- and diglycerides, citric acid esters of monoglycerides, lactic acid esters of monoglycerides, and distilled monoglycerides affected the whippability and foam stability of dairy whipping cream that had been pasteurized and homogenized. Lactic acid esters produced a stable foam with a high overrun that was substantially different from a fresh whipped cream, whereas a mixture of citric acid fatty acid esters and distilled monoglycerides produced a foam similar to that of fresh whipped cream. Blends of xanthan gum, carageenan, and galactomannans act as good stabilizers for frozen and chilled dairy products, such as icecream, sherbet, sour cream, sterile whipping cream, and recombined milk.

Processed cheese consists of fat droplets dispersed in a concentrated protein gel network. The emulsion stability in the fat droplets is controlled primarily by adsorbed caseins or hydrolyzed casein fractions. Some manufacturers add mono- and diglycerols as emulsifiers. To control the structure of processed cheese, 'emulsifying' salts, such as polyphosphates, are employed. Although these emulsifying salts are not surface-active, they can play an important role in modifying the activity of the surface-active casein. Cheese yield can be increased with the addition of an emulsifier, such as lecithin. Lecithin was added in quantities of 0.001–0.066% by weight of milk. Studies have reported the use of coconut protein as an emulsion stabilizer in cheese analogs. (*See* **Cheeses: Chemistry of Gel Formation.**)

In concentrated milk products, emulsifiers can aid in emulsion formation and stabilization. Some can increase the heat stability of milks and milk proteins. Usually, low-molecular-weight emulsifiers are utilized, particularly mono- and diglycerides. With certain butter products, phospholipids can be added as antispattering agents to prevent fat spattering during pan and grill frying.

Confectionery The benefits of emulsifiers in both chocolate and sugar confectionery products have been well established. The most common example in confectionery products is the use of lecithin in chocolate to reduce product viscosity and to facilitate handling. Another emulsifier used in chocolate is polyglycerol polyricinoleate, which is used to modify the viscosity of chocolate coatings. (*See* **Sweets and Candies:** Sugar Confectionery.)

Sorbitan monostearate inhibits the migration of fat retarding bloom and extends the shelf-life of chocolate coatings. 'Chocolate bloom' may be defined as the mottled discoloration of confectioners coatings followed by a loss of the gloss. This defect occurs when the coating starts to melt, and some of the melting fat migrates to the surface. The cocoa components that impart the color are left behind inside the coating. Upon cooling, the melted fractions resolidify on the surface to form lighter colored blotches.

Emulsifiers are often used with both semisweet and milk chocolate. Emulsifiers aid in processing by reducing the weep or exudate that occurs with heavy sugar pastes during processing. For example, a marshmallow-based frozen confectionery product is prepared with 0.2–0.8% emulsifier with an HLB between 3 and 9.

Peanut butter contains about 50% peanut oil suspended in peanut fibers. Upon standing, the oil can separate from the peanut fibers, which impairs the product's appearance and palatability. Mono- and diglycerides can be added to emulsify part of the oil during processing, thereby preventing phase separation. Other benefits include an improved stability and spreadability.

Chewing gums contain fats and emulsifiers that soften the gum base and act as carriers for color and flavor. Lecithin is generally used for this purpose. Emulsifiers (sucrose fatty acid esters, sorbitan fatty acid esters, glycerol fatty acid esters, or propylene glycol fatty acid esters) have been used to improve the shelf stability of center-filled chewing gum. The emulsifiers are added to the flavored liquid center at 0.01–0.5% by weight. Some emulsifiers, such as the saturated ethoxylated monoglycerols, can be adsorbed on to starch granules. This property can be used to modify the texture of starch-based sugar confectionery.

Miscellaneous Liquid nondairy creamers (coffee whiteners) are used in the beverage industry. The nondairy whitener modified for use in a hot, acidic environment (coffee) can be prepared by pasteurizing and homogenizing a water-rich lipid emulsion consisting of 6–15% edible fat, approximately 0.6–2% mixed emulsifier (constituting approximately 0.3–1% low-HLB mono- and diglycerides). These whiteners are popular in dry powder form. Evaluation of emulsion stability for liquid coffee whiteners has revealed that if the emulsion is unstable, coagulation can occur. However, with the addition of the correct mixture of emulsifiers, optimum product characteristics are maintained.

To improve the wetting characteristics in instant cocoa drinks, the powder is agglomerated. Lecithin facilitates agglomeration during spray drying. During the spray drying process, the hydrophobic portion of the emulsifier dissolves in the cocoa butter, orienting the hydrophilic portion of the phospholipid towards the surface of the particle. This results in an increased affinity of the cocoa powder for water, thus aiding dispersion and wetting.

Margarine exists as a water–oil emulsion for only a short period of time prior to chilling, during which time, the emulsion is converted to a dispersion of water in a semisolid fat phase. Upon solidification, the product stability is greatly enhanced, since coalescence is essentially eliminated. Emulsifiers fulfill three functions in margarine: (1) assistance in emulsion formation, (2) modification of the crystal structure in the vegetable fat, and (3) antispattering during frying. Typically, a mixture of lecithin or citric acid monoglycerides and monoglycerides is used. A stable emulsion during frying reduces the coalescence of water droplets to form large drops. This facilitates gradual water evaporation, rather than explosive evolution or spattering, during frying. An additional explanation may be that the lecithin sludge formed during frying serves as nuclei for the formation of small vapor bubbles.

To reduce sandiness and 'oiling out' in margarine due to recrystallization, emulsifiers can be added. Sorbitan monostearate and citric acid esters of monoglycerides are effective in preventing recrystallization in tristearin. However, to be effective in margarine, the emulsifier must be very soluble in the oil phase. Other emulsifiers used include polysorbates and polyglyerol esters of fatty acids. To produce a low-calorie imitation dairy product, emulsifiers are usually added to the product. The caloric content can be significantly reduced by replacement of part of the fat with the appropriate emulsifier system. For low-fat margarine containing approximately 40% fat, a mixture of saturated and unsaturated monoglycerides and lecithin has been used successfully. Similarly, emulsifiers are used for partial fat replacement in low-fat, butter-flavored, liquid spreads. The stability of milk fat and water emulsions is dependent on the amount of emulsifier added.

Mayonnaise is an oil–water emulsion containing a high percentage of oil (> 70%). Owing to the high

percentage of fat, coalescence, rather than creaming, is the primary problem. Different protein sources are utilized because of their effectiveness in reducing coalescence.

The manufacturing procedure for mayonnaise is critical since the product contains a very high percentage of oil. Lecithin, contained in the added eggyolk, is usually the only emulsifier added. However, the vegetable oil may contain emulsifiers added to inhibit crystallization, e.g., ethoxylated sorbitan monooleate and monostearate. To inhibit cloud formation in salad dressings and salad oils, emulsifiers can also be added. (*See* **Dressings and Mayonnaise**: The Products and Their Manufacture.)

Emulsifiers can be used to produce emulsions that can deliver flavor, color, and a dispersed lipid phase in a cooked food product. Blending pork volatiles with the appropriate emulsifier, such as the polyglycerol ester of palmitic acid, and warming it will produce a relatively stable, flavored emulsion. The product can be used to replace part of the fat in a pork analog product. The fat level of such a product is 50% that of the regular pork product. In emulsion sausages, the product properties are dependent on a meat–protein matrix, a gel that gives the hot dog, for example, its characteristic sensory properties. The meat proteins are important in forming and stabilizing the emulsion.

Measurement of Food Energy

J C Brown, AFRC Institute of Food Research, Norwich, UK

Background

The accurate assessment of the energy value of foods and diets is essential for the study of energy metabolism and energy balance, and for dealing with problems of malnutrition and obesity. Whereas the body oxidizes the constituents of food in the process of metabolism, the bomb calorimeter determines the energy released as a result of direct oxidation of the food constituents, and so enables measurement of an energy value. The energy value obtained is the *heat of combustion*, which is the maximum potential energy present in the food and is called its gross energy. The gross energy makes no allowance for losses of energy, owing to incomplete digestion or during metabolism.

In nutritional studies, the energy values used are for metabolizable energy, which is the energy available to the body from food. These values are usually calculated using energy conversion factors applied to the fat, protein, and carbohydrate content of a food, and take into account the average energy losses in feces and urine. For greater accuracy, normal losses of energy to feces and urine can be deducted from the gross energy, which is determined by bomb calorimetry, to give a metabolizable energy. In more precise studies the metabolizable energy value is measured, rather than calculated, by determining these energy losses directly.

Principles of Bomb Calorimetry for the Determination of Energy Values of Foods

The principle that allows the determination of energy value using bomb calorimetry is based on the first law of thermodynamics. Implicit in this law is the finding termed 'the law of constant heat summation,' which appeared in a paper published by G.H. Hess in 1838. Hess showed that the heat produced in a given chemical reaction was always the same, regardless of the intermediate steps.

The major sources of energy in foods are the organic constituents fat, carbohydrates, and protein, with smaller contributions from alcohol, organic acids, and traces of other organic materials such as mineral oils. The foods are completely oxidized in the bomb calorimeter, to yield the end products: carbon dioxide, water, oxides of nitrogen and sulfur, and heat. In the process of bomb calorimetry, the sample is rapidly combusted in oxygen at increased pressure, and the heat production is measured. The apparatus is calibrated with benzoic acid, a thermochemical standard, and a heat of combustion is derived for the food.

Occasionally, when an absolute measurement of heat of combustion is required, corrections are applied to the result obtained, e.g., for (1) sulfuric acid production from sulfur in the sample, (2) nitric acid production present in the bomb during combustion, and (3) departures from the standard state, pressure, or temperature of reactants or products. For the purposes of determining the energy values of foods or biological samples, the above corrections are normally sufficiently small to be ignored.

Types of Equipment Used

There are two different types of bomb calorimeter currently in use: the adiabatic (without gain or loss of heat) and the ballistic. The adiabatic bomb is favored for accurate nutritional studies. The ballistic bomb gives more rapid determinations but with a lower accuracy.

Development of the Adiabatic Bomb Calorimeter

The structure and operation of all bomb calorimeters, from the earliest (dated around 1900) to those currently in use, are similar. The bomb chamber in which combustion of the sample takes place is typically made from noncorroding steel and submerged in a water-filled calorimeter vessel. The water is continuously stirred and its temperature recorded, before and

after it rises as a result of heat produced by the combustion of the fuel. With the early designs of bomb calorimeter, it was necessary to determine a cooling correction, since some of the heat generated during the combustion was lost to surrounding air. Assessment of cooling correction involved the recording of accurate temperature observations made at precise time intervals, commencing at least 5 min before firing and continuing until at least 5 min after a constant rate of temperature change is resumed.

Major developments in bomb calorimeter design were concerned with providing heated outer water jackets capable of minizing heat loss from the calorimeter vessel surrounding the bomb. In 1900, Richards had used a closely controlled exothermic reaction within the water jacket to control the temperature. Benedict and Higgins, in 1910, introduced the use of an electrical heating coil to control the temperature of the water jacket, but rapid and close matching of the temperatures of the jacket and calorimeter vessel containing the bomb was still impossible. In 1916, Daniels achieved this by using heating elements, making the whole jacket a conductor. This system was automated by Raymond, Canaway, and Harris, in 1957, to produce an adiabatic bomb calorimeter, which was the basis for current systems. The Berthold–Maher and Maher–Cook bomb calorimeters, produced by Gallenkamp in the early 1950s, had a simple copper water jacket to provide some insulation from the surroundings, but around the late 1950s, Gallenkamp were producing an adiabatic bomb calorimeter.

The current adiabatic bomb, produced by Sanyo Gallenkamp, is shown in Figure 1 and is an improved version of the early ones described above. It is equipped with heaters, which, using a sensitive electrical system, maintain the outer water jacket at the same temperature as that of the water in the calorimeter vessel throughout the period of operation. Employment of the adiabatic concept eliminates cooling from the calorimeter vessel and the need for a cooling correction. This gives the system advantages over previous designs: (1) determinations are more rapid and lead to less operator fatigue, since continuous readings of temperature are not necessary; (2) readings only need to be taken once the equipment has stabilized, before and after the temperature rise resulting from combustion. Further improvement in the control of the temperature of the outer water jacket has been achieved by employing a heated reservoir of water (shown in Figure 1), which injects warm water into that already circulating in the outer water jacket.

Operation of the Adiabatic Bomb Calorimeter

The energy value is determined on a homogeneous dry sample that is compacted into a preweighed crucible. The electrodes are connected by a piece of nickel/chromium fuse wire. To facilitate combustion, a piece of cotton is tied to the wire and is placed in contact with the sample below. The crucible and electrodes are sealed in the bomb chamber, and oxygen is introduced to a pressure of 3030 kPa. The bomb chamber is placed inside the calorimeter vessel, which contains a constant mass of water, and the lid of the calorimeter is closed. The temperature of the water in the calorimeter vessel is recorded, and, once stabilized, the sample is ignited. The heat produced by the combustion is liberated into the bomb, water, and calorimeter vessel. The temperature of the outer water jacket increases in parallel with that of the water in the calorimeter vessel as heating elements are activated via balanced thermistors located in the water jacket and calorimeter vessel. A new steady temperature is achieved in 5–8 min and the final temperature reading taken. The heat capacity (heat

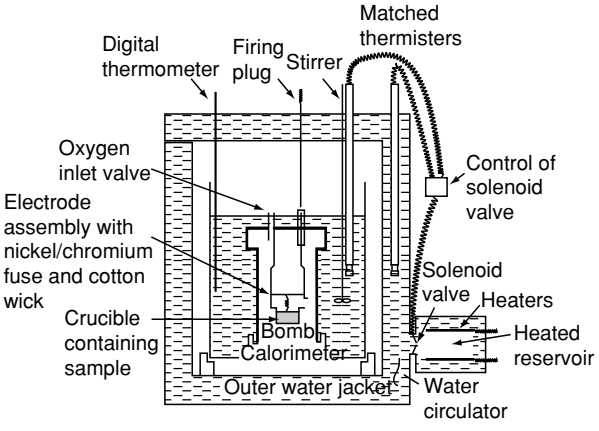

Figure 1 Adiabatic bomb calorimeter. Reproduced from Energy: Measurement of Food Energy, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

released per unit temperature rise) of the apparatus is determined using benzoic acid, and the temperature rise obtained from samples is translated into the energy released. This type of bomb allows corrections for sulfuric acid and nitric acid production to be made, if required, by collection and dual titration of the rinsings from the inside of the bomb chamber. This process is extremely tedious and is unnecessary for most purposes (unless the amount of sulfur present in the fuel leads to a significant quantity of extra heat release when it is converted to sulfuric acid rather than sulfur dioxide). Control of the adiabatic bomb calorimeter by microcomputer is also now possible, but this only controls recording measurements of temperature, and firing. The more labor-intensive parts of the operation – preparation of samples, introduction of oxygen, and cleaning and reloading of the bomb – must still be performed by the operator.

Development of the Ballistic Bomb Calorimeter

In 1959, Fox, Miller, and Payne described an alternative to the adiabatic bomb, giving quicker determinations of energy values. Their design made use of a light bomb casing and eliminated the water-filled calorimeter vessel. On combustion, most of the heat produced is transmitted to the upper parts of the bomb casing and measured using a thermocouple linked to a meter. No attempt is made to measure the equilibrium temperature of the bomb. In the modified version, a thermocouple is attached to the lid and connected to a galvanometer via a series resistance. This bomb, known as the ballistic bomb, was subsequently improved by reducing the thermal capacity of the upper casing.

The current ballistic bomb, shown in Figure 2, is directly descended from that described above. Possible sources of error involved variation in (1) the oxygen pressure, (2) the initial temperature, and (3) the crucible position in the bomb. These were standardized at the optimum level for operation.

Operation of the Ballistic Bomb Calorimeter

The sample, crucible, and electrodes are assembled in the bomb chamber, as in the adiabatic bomb. Oxygen is introduced, and, once stabilized (30 s), the sample is ignited, with maximum deflection on the galvanometer occurring after about 40 s. Deflection of the galvanometer scale is translated into the energy released by calibration with benzoic acid.

Comparison of Adiabatic and Ballistic Bomb Calorimeters

The ballistic bomb has an accuracy of $\pm 1.1\%$ on six determinations, compared with $\pm 0.1\%$ on two determinations with the adiabatic bomb. It was argued that a standard error of less than $\pm 0.5\%$ of the energy value is essential in accurate energy-balance studies. This level of accuracy would not normally be obtained with the ballistic bomb unless about 15 replicates were carried out. It was confirmed that to obtain the same precision on the ballistic bomb as that of the adiabatic, six times as many replicates would have to be carried out. Since the ballistic bomb is only two to three times faster, it is not a

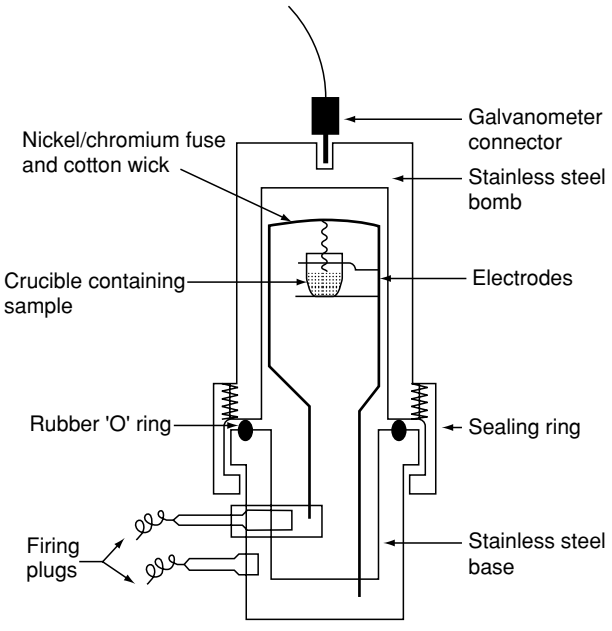

Figure 2 Ballistic bomb calorimeter. Reproduced from Energy: Measurement of Food Energy, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

serious alternative to the adiabatic system for accurate energy balance studies. Table 1 gives average heats of combustion or gross energies of some whole foods and protein, fat, and carbohydrate, determined using bomb calorimetry.

Limitations of Gross Energy Values Obtained for Diets

The energy value determined for a diet using bomb calorimetry is the energy that is released when the fuels are fully oxidized. This complete oxidation does not occur in the body. The energy value obtained for the food (gross energy) takes no account of the digestibility or metabolizability of the energy in the food by the body. Equations (1) and (2) show the relationship that exists between gross, digestible, metabolizable, fecal and urinary energy (*GE*, *DE*, *ME*, *FE*, and *UE*, respectively):

$$GE - FE = DE. \quad (1)$$

The digestibility of the energy of protein, fat, and carbohydrate is reckoned to be about 97%, 95%, and 98%, respectively.

$$DE - UE = ME. \quad (2)$$

This step sometimes involves additional energy losses owing to combustible gases produced during anaerobic fermentation.

The energy in protein is not fully metabolized, some energy-yielding nitrogenous components being present in urine. Atwater determined the heat combustion of food components and found that urine contained $5.23\,kJ\,g^{-1}$ ($1.25\,cal\,g^{-1}$) of absorbable protein, if the subject was in nitrogen equilibrium. (*See* **Protein**: Digestion and Absorption of Protein and Nitrogen Balance.)

The usual purpose of determining the energy value is to obtain a measure of the energy that the body gains from a food, its metabolizable energy value. Metabolizable energy can be measured by determination of gross energy content of diet, feces and urine (eqns (1) and (2)). Collection and analysis of these materials, however, are time-consuming and difficult, especially in humans. The alternative that is most commonly employed, but less accurate, involves the use of appropriate energy conversion factors. These can be used to calculate the metabolizable energy from the composition of the food or diet, or to correct the gross energy obtained by bomb calorimetry for the usual energy losses to feces and urine.

In 1896, Atwater put forward energy conversion factors for calculating the metabolizable energy obtained from protein, fat and carbohydrate of 17, 37 and $17\,kJ\,g^{-1}$ (4, 9, $4\,kcal\,g^{-1}$), respectively, which accounted for losses to feces and urine. These factors vary between foods, and, using the more precise system of Merrill and Watt, it is possible to use the compositional data and energy conversion factors derived for each individual food to calculate the metabolizable energy value. The British system of average factors used for most purposes are $17\,kJ\,g^{-1}$ ($4.0\,kcal\,g^{-1}$) for total protein, $37\,kJ\,g^{-1}$ ($9\,kcal\,g^{-1}$) for total fat, and $16\,kJ\,g^{-1}$ ($3.75\,kcal\,g^{-1}$) for total available carbohydrate (measured as monosaccharides).

An alternative to the use of compositional data for estimating metabolizable energy is to correct the gross energy, determined by bomb calorimetry, for usual energy losses in feces and urine. Miller and Payne assumed 95% digestibility of diets and put forward a system for estimating the metabolizable energy from determined gross energy ($kJ\,g^{-1}$) and

the nitrogen content of the diet (N; g kg^{-1}), which is shown in eqn (3). This equation is appropriate for determination of ME (kg g^{-1}) in Western diets that are low in dietary fiber:

$$ME = 0.95GE - 31.88N. \quad (3)$$

However, 95% digestibility is not always true, especially of diets high in dietary fiber. An alternative system, based on a regression equation that deducts a value of 16.7 kJ g^{-1} (4 kcal g^{-1}) for unavailable carbohydrate (UC), or dietary fiber was proposed. This equation (eqn (4)) was derived using diets of up to 30 g of dietary fiber per day; thus, it has this upper limit.

$$ME = 0.977GE - 27.6N - 16.7UC. \quad (4)$$

A further equation (eqn (5)) takes account of the lowering of digestibility of gross energy diets as the level of dietary fiber (F; %) increases. This equation is used where dietary fiber intake is above 30 g per day, and especially where the diet is high in cereals.

$$ME = (0.95 - F)GE - 31.4N. \quad (5)$$

An equation, based on a regression analysis of many diets, including those of more than 30 g of dietary fiber per day, was derived. This equation (eqn (6)) accounts for the effect of unavailable carbohydrate on the digestible energy content of the diet and can be used in all cases, except with high-cereal diets. Equations (5) and (6) therefore complement each other in terms of application.

$$ME = 0.96GE - 9UC - 30N. \quad (6)$$

The coefficient of individual variation on these equations is around 1% of GE; however, there is uncertainty about how appropriate they are for predicting ME of diets of the elderly, the very young (under 8 years), individuals in the diseased state or those of different races. Since the energy equations are intended for calculating available energy from whole foods, they are most likely to be inappropriate when used for diets including isolates, or novel ingredients, which may fall outside of the scope of the derived equations.

To obtain an accurate value of DE or ME, the heat of combustion of diet, feces, and urine must be determined by bomb calorimetry. Most of the considered variation in metabolizability of a diet or ingredient comes about as a result of a difference in digestibility of energy rather than metabolizability (except for very poorly metabolized materials such as novel sugars that are excreted in the urine). It is therefore sometimes sufficient and more practical in accurate biological studies to make a measurement of DE – which does not require collection and analysis of urine – rather than ME.

Intake and Energy Requirements

G R Goldberg, British Nutrition Foundation, London, UK

Introduction

This chapter outlines the progress that has been made in the last 10 years in the evaluation and interpretation of energy intake data, and in the use of energy expenditure data to define energy requirements. In particular, the data presented here illustrate the important contribution of doubly labelled water measurements of total free-living energy expenditure. These have provided points of reference that can be used to assess and define both energy intakes and energy requirements.

Energy Intake

Gross, digestible, and metabolizable energy obtained from food

The energy in food is provided by the four energy-yielding macronutrients, protein, fat carbohydrate and alcohol. The energy obtained from macronutrient oxidation is utilized in a number of ways. It can be used to perform mechanical, electrical, and chemical work; be deposited as new tissue; or exported from the body (e.g., as milk). The gross energy of a food is the energy obtained when it is totally combusted in a bomb calorimeter, and is the maximum amount of energy that can be extracted. However, not all the energy in food is available for use by the body. Not all the macronutrients are digested completely, not all

the products of digestion are absorbed completely, and energy is lost in urine as nitrogenous compounds (including urea, uric acid and creatinine), because the protein that is digested and absorbed is not oxidized completely.

$$\text{Gross energy}_{\text{food}} - \text{gross energy}_{\text{feces}} = \text{digestible energy}$$

$$\text{Digestible energy} - \text{protein energy}_{\text{urine and feces}} = \text{metabolizable energy.}$$

Estimates of Energy Content Using Food Tables

Tables of food composition usually list the energy content of foods not as gross, but as available or metabolizable energy, i.e., allowances have already been made for digestibility, and for the incomplete oxidation of protein by using food specific or mixed diet factors. Differences in the methods used to determine the carbohydrate content of individual foods and inclusion of the nondigestible fractions may lead to an overestimation of the energy content, particularly in fruits and vegetables. However, when calculating the total energy content of a mixed diet, these differences are of little practical significance. The inherent variability of foodstuffs and how they are prepared and cooked are greater sources of error. For example: food tables may not represent the value of foods and drinks as consumed, particularly when dietary intake is recorded in terms of composite dishes and not as separate ingredients; the energy content of foods varies with the proportions of water and fat that they contain; and recipes used by subjects for dishes such as stews, casseroles, cakes, and puddings may differ considerably from the recipe used to calculate the food table value.

Measurements of Energy Intake

-Rationale Dietary assessments form a central component of many areas of clinical and research studies. Various national and international committees make recommendations with respect to the proportions of the dietary energy intake from different food sources that are considered to be best for optimal health. Data from large epidemiological surveys provide vital information for expert committees to consider when formulating allowances and deciding issues of food policy. Energy and nutrient intakes and requirements in different groups of people need to be quantified at an individual level to determine the relationships between nutrition and health. Intakes also need to be quantified at the population level to detect and establish the prevalence of people who are not achieving adequate levels of energy and nutrient intake. Some reported energy intake data from national surveys conducted in the UK and published in the last 10 years are shown in Table 1.

-Methods used to measure energy intake Measurements of energy intake in free-living individuals are obtained by dietary surveys. A record or estimate of all food and drink consumed is collected, and the energy content is then most usually estimated using data from food tables. In some experimental settings, where very accurate measurements are required, duplicate diets comprising foods actually consumed are collected by researchers and subjected to bomb calorimetry. However, under free-living conditions, the effort required of a subject to collect duplicate diets leads to alteration of food patterns and to an underestimate of food consumption.

There are a number of different survey techniques for estimating energy and nutrient intakes. The methods used to collect data about food consumption include weighed intake records, food diaries, collection of duplicate diets, diet history, 24-h recalls, and food-frequency questionnaries. Recalls and questionnaires may also include methods of estimating quantity by reference to models or photographs. The chosen method will depend on a number of factors such as resources available, number of subjects, foods and nutrients of interest, other parameters to be measured, the purpose of study, and subject characteristics such as age, behavioral, and health indices.

Table 1 Mean reported energy intakes of free-living children and adults in the UK

Age range (years)	*Males*		*Females*	
	MJ per day	*kcal per day*	*MJ per day*	*kcal per day*
1.5–2.5	4.39	1045	4.39	1045

-Validity of energy-intake measurements It is often assumed that energy intake is the easiest and most straightforward component of the energy-balance equation to measure accurately. Whilst this may be so under strictly controlled experimental conditions, it is far more problematical in free-living subjects. Estimates of energy intake are subject to many errors, some of which have been well recognized and understood for many years. For example, food table values do not necessarily reflect the actual food as eaten (see above), inadequate descriptions of foods lead to errors in choosing appropriate foods from the food tables, and there may be errors in estimating the quantities of food and drink consumed. However, the magnitude and direction of other errors, and their implications, only began to be appreciated in the last 10 years. Up until then, the mean results for energy intake in studies of diet and health were rarely questioned. It was recognized that during a study, some individuals' reported energy intake would be lower than their habitual intake, but it was assumed that this was balanced by overestimates of intake at the other end of the distribution, thus yielding valid data for a group. Studies were based on the premise that the methods used were accurate and precise and that they provided valid estimates of habitual intake.

-Evaluation of energy-intake measurements The development in the early 1980s of the doubly labeled water (DLW) technique for measuring energy expenditure in free-living people also provided an external validation of measurements of energy intake. On a group basis, energy intake may be presumed to be equal to energy expenditure. Data from DLW measurements have, therefore, not only provided information of energy expenditure and energy requirements (see below) under many physiological, behavioral and experimentally imposed conditions, but also given important insights into the validity and interpretation of energy intake measurements. Of particular concern is that the majority of dietary surveys are significantly biased towards the underestimation of energy intake.

Invalid dietary data have serious implications for the interpretation of results. Apparent underestimates of intake will falsely inflate the prevalence of inadequate nutrient intake, and between-subject differences in qualitative or quantitative reporting creates bias that distorts the real associations between diet and health.

It is not feasible or necessary to carry out concurrent DLW measurements of energy expenditure when the prime interest of a study is the measurement of energy intake. However, the large body of DLW data yielded from many studies conducted over the last 20 years, together with statistical considerations, that take into account the number of subjects, duration of measurements, and variability in energy intake and expenditure, can be used as independent points of reference for evaluating measurements of energy intake.

-Developments in methodology of energy-intake measurements Over the past 10 years, a great deal of research has been undertaken by workers in many countries. The work includes the exploration of the statistical nature of food intakes in order to develop better study designs, and strategies for obtaining reliable and habitual-intake data. Energy intake data are now more closely scrutinized, and critically evaluated and interpreted. The subgroups most likely to provide records of poor validity are also being characterized. This is turn means that psychological assessments (dietary restraint, attitudes to food, health and other topics) as well as the more traditional elements (height, weight, assessment of occupation and leisure activities need to be incorporated into study protocols as a matter of routine. The origins and causes of misreporting due to food- and meal-specific bias, and the socioeconomic, demographic, behavioral, and psychological characteristics of subjects are all the focus of much research.

Energy Requirements

Definition of Energy Requirements

In 1985, the report of the Joint Food and Agriculture Organization, World Health Organization and United Nations University Expert Consultation stated that:

> The energy requirement of an individual is the level of energy intake from food that will balance energy expenditure when the individual has a body size and composition, and level of physical activity, consistent with long-term good health; and that will allow for the maintenance of economically necessary and socially desirable physical activity. In children and pregnant or lactating women, the energy requirement includes the energy needs associated with the deposition of tissues or the secretion of milk at rates consistent with good health.

Rationale for Defining Energy Requirements

Estimates of energy requirements are required as the basis of nutrition policy and dietary advice, to assess the adequacy of diets and evaluate nutritional status, to plan the food supplies of populations, and to plan diets for institutionalized individuals. In many countries, expert committees are charged with estimating the energy requirements of their own populations, usually divided into different age and sex groups.

The average energy requirements currently used in the UK are shown in Table 2.

Determinants of Energy Requirements

All body movements require energy in addition to that required for maintenance. Strenuous activities require more energy than sedentary activities, and the cost of weight-bearing activities increases with body weight. Whilst the gross energy costs of certain activities may be very high during that activity, e.g., during laboring tasks or very athletic recreations, these activities are rarely maintained for long periods of time. The energy costs are diluted by the time spent undertaking sedentary activities, e.g., sitting or standing around, and the average overall daily energy requirement is further reduced by the time spent asleep. The amount of physical activity due to differences in occupation, leisure pursuits, and domestic circumstances determines the overall energy expenditure, and therefore the energy requirements, of otherwise similar individuals.

In addition to the energy required for maintenance and for physical activity, the biochemical synthesis of new tissues for growth, development, repair, and milk production incurs extra energy costs, and therefore the energy requirements, for infants, children, pregnant women and lactating women, and in some clinical conditions. The energy requirements under these circumstances are difficult to quantify, and estimates are often derived from stoichiometric calculations based on rates and composition of weight gain, milk production and tissue repair, and the effects of infection, disease, trauma, and drug therapy on appetite and energy expenditure.

Table 2 Estimated average requirements for energy in the UK

Age range	*Males*		*Females*	
	MJ per day	*kcal per day*	*MJ per day*	*kcal per day*
0–3 months	2.28	545	2.16	515
4–6 months	2.89	690	2.69	645
7–9 months	3.44	825	3.20	765

Estimation of Energy Requirements

The 1985 FAO/WHO/UNU Expert Consultation heralded a significant change in the way that recommendations for dietary energy were determined and defined. It was considered that observed energy intakes, even if they were accurate, did not necessarily represent desirable levels for body weight, physical activity, and optimal health. It was concluded that estimates of requirements should 'as far as possible be based on estimates of actual or desirable energy expenditure.' The 1985 Committee also stated that 'Although, in principle, it would be desirable to determine the requirements of children in the same way as for adults, from measurements of energy expenditure, this approach involves many difficulties in practice.' It was concluded that the necessary data were not yet available to base recommendations for energy requirements of infants and children on estimates of energy expenditure, and so the use of information about normally growing infants and children has continued.

-Physical activity levels The 1985 FAO/WHO/UNU report also established the principle of calculating energy requirements for adults (although not pregnant and lactating women) as multiples of measured or predicted basal metabolic rate (BMR). Multiples of BMR are now widely referred to as physical activity levels (PALs). These are a succinct way of expressing the energy requirements of diverse groups of people, and the values provide a means of comparing activity levels between and within individuals. Because total energy expenditure is expressed as a multiple of BMR, most of the interindividual variability due to weight, height, age, and sex is removed.

-Estimates of physical activity levels using factorial calculations The PALs derived by the 1985 Consultation were based on literature values of the energy costs of various occupational and discretionary activities, and assumptions about their duration and intensity. A factorial calculation was then used to determine the theoretical overall 24-h energy requirement. For example, it was estimated that the PAL for a typical rural woman in a developing country was $1.76 \times$ BMR. This was based on the assumptions that within each 24-h period, 8 h were spent asleep ($0.33 \times 1.0 \times$ BMR); 3 h were spent on housework and preparing food ($0.13 \times 2.7 \times$ BMR); 4 h were spent working in fields ($0.17 \times 2.8 \times$ BMR); 2 h were spent on discretionary activities ($0.08 \times 2.5 \times$ BMR); and the remainder of the time (7 h), was spent on sedentary activities ($0.29 \times 1.4 \times$ BMR). A similar calculation indicated that the typical PAL of a man

employed as an office clerk was 1.54 × BMR. The survival requirement, with no allowance for energy needed to earn a living or prepare food, was considered to be 1.27 × BMR; a level of expenditure expected to be found only in totally inactive dependent persons and not compatible with long-term health (see also Table 8). The estimated average daily energy requirements of adults whose work is classified as light, moderate, or heavy, are given in Table 3.

The UK Committee on Dietary Reference Values followed the approach of the FAO/WHO/UNU panel and arrived at PALs considered to be more appropriate for UK populations. In countries like the UK, it is likely that the overall energy expenditure of an individual may be influenced more by recreational activities than by work. PAL values taking both occupational and nonoccupational activity levels into account are shown in Table 4.

-Measurements of physical activity levels from DLW measurements The development in the early 1980s of the DLW technique for measuring total energy expenditure (TEE) in free-living people revolutionized knowledge and assumptions about energy expenditure. The measurement of TEE over relatively long periods is likely, in the majority of people, to be representative of their habitual energy expenditure and, by inference, their energy requirements. TEE measured by DLW, used together with measured or predicted BMR, has allowed PALs to be measured, as well as estimated factorially. Studies conducted over the last 20 years mean that there is now a large dataset of DLW measurements of energy expenditure and PALs measured under many physiological, behavioral, and experimentally imposed conditions. Some of these data are summarized in Tables 5, 6 and 7. These tables illustrate the range of PALs depending on age, and on activity levels that are typical of populations in developed countries.

There are also data that have been obtained from individuals at the extremes of physical activity that can be used to define the upper and lower limits of human energy expenditure and, by inference, the limits of energy requirements and energy intake. Some of these data are summarized in Tables 8 and 9. It should be noted that at the upper level of energy expenditure, it is important to draw a distinction between the maximum achievable level over a limited period of time (e.g., intensive periods of sports) and the maximum sustainable as a long-term way of life given physical fitness and adequate food.

DLW data from men and women people living in rural areas in developing countries have shown that PALs for a very physically active lifestyle are about 2.5.

Low Levels of Energy Expenditure and Energy Requirements in Developed Countries

Many studies conducted in developed counties over the last 20–30 years show secular trends with respect to decreases in the levels of both energy intake and energy expenditure. The latter is due to decreases in the energy expended on physical activity because of labor-saving devices, increased use of mechanized transport for even short journeys, and changes in leisure-time activities. In many developed countries, therefore, energy requirements are falling. Low levels of physical activity are the reason why some expert committees set average energy requirements at a relatively low level. For example, in the UK, because of the inactive lifestyle of much of the population due to their light occupations and nonactive, nonoccupational activity, in the absence of other information, a PAL of only 1.4 is used to estimate energy requirements.

Implications of Low Energy Intakes and Energy Requirements

Current healthy eating guidelines in the UK, USA, and many other countries recommend that people eat a wide variety of foods. As energy requirements fall, so it becomes more difficult for a low energy diet to provide adequate intakes of macronutrients and micronutrients from all the major food groups. Low levels of energy expenditure and physical activity, or more correctly inactivity, have been identified as major risk factors for becoming overweight and obese. This applies to both developed, and increasingly to developing, countries. Low levels of physical activity are also associated with increased morbidity and mortality, and increased risk of diabetes, cardiovascular disease, and osteoporosis. Hence, there are now many health-promotion initiatives that integrate energy and nutrient intake messages with advice about physical activity.

Developments in Recommendations for Energy Requirements

Sections of the 1985 FAO/WHO/UNU report are currently undergoing expert revision by the International Dietary Energy Consultative Group. Data have been reexamined and updated. With respect to energy requirements, the topics under consideration by expert working groups include the equations used to predict BMR, physical activity levels in adults, and the energy requirements of infants, children and adolescents aged 1–18 years, pregnant and lactating women, and older individuals.

Table 9 Summary of physical activity levels (PALs) calculated from doubly labelled water measurements of total energy expenditure

Overall activity	*PAL*
Chair-bound or bed-bound	1.2
Seated work with no option of moving around and little or no strenuous leisure activity	1.4–1.5
Seated work with discretion and requirement to move around but with little or no strenuous leisure activity	1.6–1.7
Standing work (e.g., housewife, shop assistant)	1.8–1.9
Significant amounts of sport or strenuous leisure activity (30–60 min, four or five times per week)	+0.3
Strenuous work or very active leisure	2.0–2.4

Measurement of Energy Expenditure

P R Murgatroyd, University of Cambridge, Cambridge, UK
W A Coward, MRC Human Nutrition Research, Cambridge, UK

Background

The energy that drives endogenous chemical processes and the performance of external mechanical work is released from the macronutrients fat, carbohydrate, and protein by oxidation and ultimately dissipated as heat. Energy expenditure may thus be measured either directly, by estimating the energy dissipated as heat, or indirectly, by measuring the rates of macronutrient oxidation. The associated measurement techniques are termed direct and indirect calorimetry, respectively. This article describes the ways in which measurements of energy expenditure may be made and discusses the factors influencing their accuracy and precision.

The most accurate and precise primary energy measurement techniques impose constraints on the individual being studied, but these may be turned to advantage in studies that require closely controlled conditions. Where an estimate of free-living energy expenditure is required, secondary indirect techniques, lacking the quality of the primary measurements but relying on them for verification or standardization, must be used. These include the estimation of carbon dioxide production from the elimination rates of the stable isotopes ^{2}H and ^{18}O, and the estimation of energy expenditure from measurements of heart rate or from records of activity.

Direct Calorimetry

Heat is dissipated from the body by *nonevaporative* routes (by radiation, conduction and convection) and *evaporative* routes (through respiratory and perspiratory water loss). These components are estimated, together with the heat generated in external work, by measuring the fluxes of heat from a *calorimeter*, a ventilated room that contains the subject. The nonevaporative heat flux is generally measured by one of two techniques, gradient layer or heat sink calorimetry. Evaporative heat flux measurements are made either by condensing the evaporated water or by measuring the water vapor added to the ventilating air.

Nonevaporative Heat-loss Measurement

-Gradient-layer calorimetry Gradient-layer calorimetry measures the flux of heat through the walls of the calorimeter. The walls are constructed of a thin, rigid material such as glass-reinforced epoxy resin. As heat produced by a subject flows out through the wall, a temperature gradient is established across the wall. This is measured by temperature-sensing layers distributed over the inner and outer wall surfaces. These layers may be resistance thermometers, formed by etching copper films bonded to each side of the wall material, or may be in the form of a thermopile with 'hot' junctions on one side of the wall and 'cold' junctions on the other. The relationship between the mean wall temperature gradient and heat flux is found empirically by calibration with known heat inputs to the calorimeter. To ensure that the heat flux measured arises only from the subject, the rate of change of the heat content of the calorimeter must be very much less than the heat flux from the subject. This is generally achieved by fixing the outside temperature of the wall with a water jacket, the water temperature being controlled to avoid rates of change of water temperature exceeding $0.001\,^{\circ}C\,min^{-1}$.

-Heat-sink calorimetry A heat-sink calorimeter measures the nonevaporative heat lost by a subject in terms of the rate at which heat must be removed from the calorimeter to prevent air-temperature rise and associated heat loss through the calorimeter walls. The heat is removed by recirculating the calorimeter air over a water cooled heat exchanger. Thermal insulation makes the temperature gradient across the walls very responsive to changes in heat production within the calorimeter. This gradient is sensed and used to control the temperature of water entering the heat exchanger so that it removes heat at a rate which minimizes heat losses through the walls and thus equals the heat flux from the subject. The heat flux is expressed as:

$$Q_e = \frac{\Delta t_e}{\Delta t_s} x Q_s$$

where Q_e is the heat extracted from the calorimeter, Δt_e is the rise in temperature of the water flowing through the heat exchanger, Δt_s is the rise in temperature of the same water passing through a standard heater, and Q_s is the heat input to the standard heater.

As with the gradient layer calorimeter, the rate of change of heat content of the calorimeter must be minimized, but due to the higher thermal insulation of the heat sink calorimeter's walls, this can be achieved by controlling the temperature of the air surrounding it to $\pm$ 0.25 °C, avoiding the need for a water jacket.

Evaporative Heat-loss Measurement

-Condensation measurements Ventilating air is conditioned prior to entering the calorimeter. It is first saturated, then cooled to a constant dew point temperature by a water-cooled heat exchanger, then reheated to the calorimeter temperature. Air leaving the calorimeter is passed over an identical heat exchanger to return it to its initial dew point temperature. The heat extracted from the outgoing air is the evaporative heat loss plus a nonevaporative component, which may be deduced either from measurements of ventilation air flow rate and temperature or by measuring the heat added to the air after the ingoing heat exchanger to bring it to the calorimeter temperature. Corrections must be made to the evaporative heat loss measurement for the difference between the latent heats of evaporation at body temperature and the condensation temperature.

-Vapor-phase measurements The rate of evaporative heat loss can be expressed as the product of the rate of vapor production and the latent heat of vaporization. Water-vapor production within the calorimeter is calculated from measures of in- and out-going vapor pressure, total (atmospheric) pressure, and the flow rate of the calorimeter ventilating air. The vapor pressure is best deduced from dewpoint temperature, which can be measured to $\pm$ 0.1 °C using commercial instruments.

Strengths and Limitations of Direct Calorimetry

Measurements of total heat production in direct calorimeters can be of very high quality, certainly yielding results reproducible to within $\pm$ 1% of calibration standards. Response times are also very rapid, particularly for gradient-layer systems using condensation techniques to measure the evaporative heat component. The accurate partition of heat loss into evaporative and nonevaporative components is difficult to demonstrate, as some of the latent heat of vaporization may be supplied by the environment rather than the subject. Direct calorimetry can be something of an engineering *tour de force*, which in part explains the move towards indirect calorimetry in recent years. There are also operational difficulties. Heat dissipated within the calorimeter from sources other than the subject must be accurately measured. These sources, which include radiant heat exchanges through windows, heat dissipated from meals and drinks before they are consumed, and heat lost from excreta, may contribute as much as 15% of the total measured heat. Direct calorimetry still has an important role in combination with indirect calorimetry in the study of heat balance, but this is currently a relatively minor area of research interest. For studies of energy regulation, indirect calorimetry has displaced direct calorimetry because of its overriding advantage of adding to the measurement of energy expenditure the measurement of the oxidation rates of the individual energy macronutrients.

Indirect Calorimetry

Indirect calorimetry measures energy expenditure by estimating the oxidation rates of the energy macronutrients, fat, carbohydrate, and protein, from rates of respiratory exchange of oxygen and carbon dioxide and from the excretion in urine of incompletely oxidized nitrogenous compounds. The respiratory exchanges may be measured in air directly respired through a mask or mouthpiece, in the air flowing through a ventilated canopy over the subject's head or in the air ventilating a small room in which the subject may live for some time. The measurements and calculations required are essentially the same for all these cases.

Gas-exchange-rate Measurements

The variables that must be measured to calculate oxygen and carbon dioxide exchange rates at standard temperature and pressure (STP) under dry conditions are: the ventilation rate of the subject or his enclosure, the concentrations of oxygen and carbon dioxide inspired and expired by the subject or entering and leaving the enclosure, and the moisture content, temperature, and pressure of the ventilating air at the point where its flow rate is measured. It is assumed that the only gaseous variables are oxygen, carbon dioxide, and water vapor, i.e., that nitrogen and the minor components of air are not metabolically active. Rates of gas exchange in directly respired air or in small ventilated canopies are calculated in terms of the product of the ventilation rate and the gas concentration changes generated by the subject as:

$$R_G = F_o \Psi_o f_{N_2o}(f_{Go}/f_{N_2o} - f_{Gi}/f_{N_2i}),$$

where the outgoing ventilation flow rate is measured and:

$$R_G = F_i\ \Psi_i\ f_{N_2i}(f_{Go}/f_{N_2o} - f_{Gi}/f_{N_2i}),$$

where ingoing ventilation flow rate is measured. F is the ventilation rate, Ψ is the correction to STP dry conditions, and f is the fractional concentration of a gas. The subscripts i and o indicate in- and outgoing samples. N_2 refers to nitrogen and the inert components of air, deduced by the difference from O_2 and CO_2 measurements.

When measurements are made in a room, this simple approach yields results that do not immediately reflect the gas exchanges of the subject. An additional term, the product of the calorimeter volume and the rate of change of gas concentration, is needed to account for the rate at which the volume of oxygen or carbon dioxide stored within the room air is changed by the subject. With the addition of this term, and with highly precise determination of oxygen and carbon dioxide concentrations, useful measurements of macronutrient oxidation rates and energy expenditure can be made over periods as short as 30 min in a room whose volume is 150 times greater than that of the subject within it.

Measurement of Macronutrient Oxidation Rates

Protein oxidation is an incomplete process yielding nitrogenous compounds, urea, uric acid, and ammonia, which are excreted in urine. The nitrogen in urine may be measured by several techniques, but the most commonly used procedure is the Kjeldahl method (*See* **Meat**: Analysis). Protein oxidation is calculated as 6.25 × nitrogen excretion rate in grams. The oxygen and carbon dioxide exchanges associated with protein oxidation can be deduced from the coefficients in Table 1. When these exchanges are subtracted from the total respiratory gas exchanges, the 'nonprotein' exchanges remain, and from these, the rates of fat and carbohydrate oxidation are calculated. The precisions achievable for fat and carbohydrate oxidation measurements made over 30 min within a room calorimeter are typically ± 0.4 and ± 0.7 g. (Precision is estimated as ± 1 standard deviation confidence limits from 20 repeated measures of simulated gas exchange and nitrogen analysis.) The accuracies are typically ± 0.2 and ± 0.42 g, respectively, for sedentary activity in an adult subject.

Figure 1 illustrates macronutrient flux measurements made by indirect calorimetry and the oxidation rates of fat and carbohydrate measured during alternating 30-min periods of exercise and rest. Measurements were made within a whole-body calorimeter room with an internal volume of 11 m^3.

Calculation of Energy Expenditure

Once the macronutrient oxidation rates are known, energy expenditure can be calculated from the summation of the products of the macronutrients oxidized and their energy densities (Table 1). The accuracy of energy expenditure measurements achieved in this way can be ± 1% or better. Protein oxidation often accounts for a small (12–15%) and relatively constant proportion of total energy expenditure, and so energy expenditure may be estimated as:

$$EE = 15.82 \times O_2 \text{ consumption} + 5.21 \times CO_2 \text{ production},$$

where EE is in kJ min^{-1}, and gas exchanges are in 1 min^{-1}.

Table 1 Macronutrient oxidation coefficients

	Carbohydrate	*Protein*	*Fat*
Energy equivalent of oxygen (kJ l^{-1})	21.12	19.48	19.61
Respiratory quotient	1.0	0.835	0.71
Energy density (kJ g^{-1})	15.76	18.56	39.33

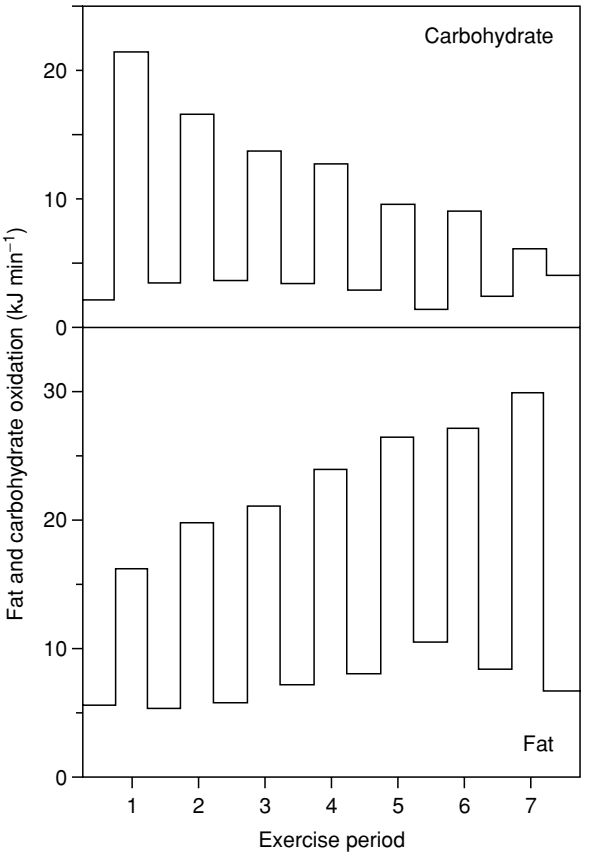

Figure 1 Oxidation rates of fat and carbohydrate measured by whole body indirect calorimetry during alternating 30-min periods of exercise and rest.

The respiratory quotient (RQ) is the ratio of carbon dioxide production to oxygen consumption and reflects the relative contributions of fat, carbohydrate, and protein to the oxidation fuel mixture (Table 1). The energy equivalent of 1 l of oxygen consumed by fat, carbohydrate, or protein oxidation is rather similar (Table 1). By assuming an RQ of 0.85 with 12.5% energy from protein oxidation, energy expenditure can be estimated from oxygen consumption alone as:

$$EE = 20.3 \times O_2 \text{ consumption}.$$

This remains accurate to within about $\pm$ 2.5% over the range of fat to carbohydrate oxidation ratios normally encountered.

Measurement of Energy Expenditure in Free-living Subjects

Doubly Labeled Water

-Principles of the method In the previous section, it was shown that energy expenditure can be estimated from oxygen-consumption measurements. Energy expenditure can also be expressed in terms of measurements of CO_2 production, and this forms the basis of the doubly labeled water method.

The energy equivalence of carbon dioxide, in contrast to that of oxygen, varies significantly with the mixture of macronutrients being oxidized. RQ could range from 0.7, if fat were the source of all energy, to 1.0, if all energy came from carbohydrate (see Table 1). In practice, sustained average RQ values outside the range 0.8–0.9 are rare, and for subjects close to energy balance, RQ may be inferred with greater confidence than this from knowledge of the subject's typical dietary composition. The energy equivalence of CO_2 for a range of RQ values is given in Table 2.

Carbon dioxide production may be measured, and hence energy expenditure estimated, from the difference between the disappearance rates of labeled hydrogen and oxygen in body water. The origin of the difference in isotope disappearance rates is the carbonic anhydrase catalyzed exchange of oxygen in water with oxygen in carbon dioxide (CO_2). Labeled oxygen can thus leave the body as either water or carbon dioxide, while hydrogen can leave only as water.

Table 2 Energy equivalence of carbon dioxide for different values of respiratory quotient

Respiratory quotient	$E_{eq}CO_2$
0.75	26.2
0.8	24.9
0.85	23.8
0.9	22.8
1.0	21.0

The volume of water in a body may be measured by the dilution of isotopes in the body water pool, a technique that has long been used for studies of body composition. In this procedure, small amounts of water labeled with stable isotopes of hydrogen or oxygen (^2H or ^{18}O) are administered, usually orally, and body-water volume calculated from the equation:

$$\text{Isotope dilution space} = \text{isotope given}/\text{isotope concentration found}.$$

This relationship assumes that isotope instantaneously distributes itself in body water in the same way that a marker dye would distribute itself in a flask of water. In practice, because body water is continually being lost and replenished by water intake, the isotope concentration falls in an exponential manner from its initial value. Because labeled oxygen can leave the body as either water or carbon dioxide, while hydrogen can leave only as water, each isotope has an individual logarithmic slope for its disappearance or rate constant (k_H and k_O) as may be seen in Figure 2. Furthermore, the isotope distribution spaces (V_H and V_O) are slightly different, principally because the hydrogen atoms in water exchange rapidly with those in proteins.

The difference between the rates of disappearance of labeled hydrogen and oxygen thus provides a measure of carbon dioxide excretion or production, r_{CO_2}, which may be expressed as:

$$r_{CO_2} = (k_O V_O - k_H V_H)/2 \text{ moles}.$$

The factor of 2 arises because 1 mole of CO_2 is equivalent to 2 moles of water.

To calculate CO_2 production rates, this basic equation is modified to allow for isotope fractionation when losses occur as water vapor or CO_2. There are several ways in which this can be done, but the simplest is to assume that water loss consists of a fractionated component (r_f) and an unfractionated component (r_i), and that r_f is related to r_{CO_2}. For adults in temperate climates, $r_f = 2.1\, r_{CO_2}$, in which case:

$$r_{CO_2} = \frac{k_O\ V_O - k_H\ V_H}{2f_3 + 2.1(f_2 - f_1)},$$

where f_1, f_2, and f_3 are fractionation factors for ^2H and ^{18}O in water vapor and ^{18}O in CO_2, respectively.

-The method in practice The procedure used in the application of this method is that the subject first provides a sample of their body water (e.g., a urine

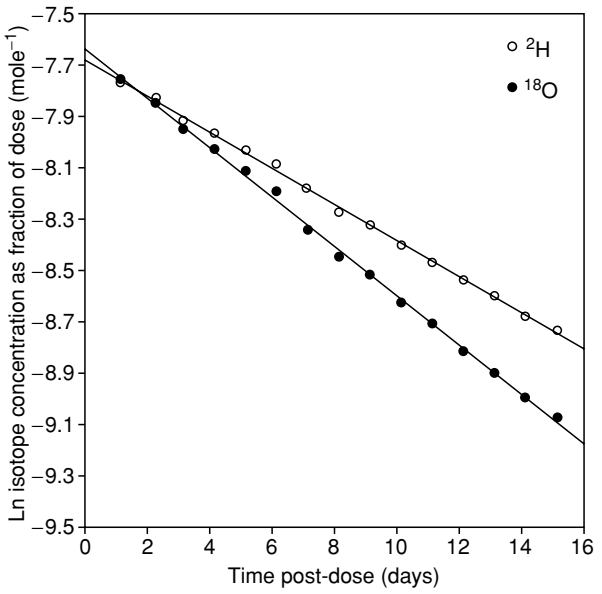

Figure 2 Disappearance of ^{2}H and ^{2}O isotopes from the body water pool in man.

sample) for the measurement of background isotope levels. The isotope dose is then drunk, and samples of urine produced over the next few days are retained for analysis. As few as two samples are required, one near the start of the experiment and one 2–3 biological half-lives of the isotopes later, though precision of the CO_2 production estimate can be improved by taking more samples during this period. The biological half-life of a tracer is the time taken for the isotope concentration to fall to half its original value. In man, this may vary from 3 days for lactating women in tropical countries to 14 days in elderly Western subjects. Average values for the accuracy of the method in comparison to CO_2 production measurements made during whole-body calorimetry studies in man range from -8.7 to $+1.9\%$, and in routine field use, the precision is better than 5%.

So far, the method has been mainly used to try to establish recommendations for energy intake of populations, to test the reliability of food intake measurements, and to assess the significance of energy expenditure in comparison to energy intake as causes of obesity.

Heart Rate

The responsiveness of heart rate to changes in activity level has led to many attempts to relate heart rate to energy expenditure and thereby to estimate free living energy expenditure. Generally, this procedure involves developing an individual relationship between a subject's energy expenditure, measured under laboratory conditions using indirect calorimetry, and simultaneously measured heart rate. The energy expenditure is modulated during this calibration process by varying the subject's activity from rest on a bed, through sitting and standing, to cycle or treadmill work over a range of intensities. The energy expenditure increases little as heart rate is increased by postural changes, but energy expenditure and heart rate both respond proportionally to the increasing intensity of dynamic exercise. A variety of techniques have been employed to describe the relationship between energy expenditure and heart rate. Many use a piece-wise linear approximation and attempt to define a point at which to make the transition from a 'rest' line to an 'exercise' line. A more elegant, though mathematically more complex, approach is to constrain a curve to fit the calibration data taking lines through the resting and exercising data as asymptotes.

The heart-rate method undoubtedly provides excellent qualitative information about energy expenditure and has been shown to be capable of predicting the mean 24-h energy expenditure of eight subjects, measured by whole body calorimetry, to better than 10%, though the accuracy of prediction for individuals varies widely. It is only with the recent development of the doubly labeled water technique that the validity of the extrapolation from laboratory calibration to field energy expenditure can be effectively tested, but heart-rate measurement is likely to remain a useful technique for comparing the relative energy expenditures of study groups when economics preclude the use of doubly labeled water.

Activity Recording

Energy expenditure may be estimated from the records in a diary of activities kept by the subject or an observer. The recordings are used to increment measurements or predictions of resting energy expenditure to provide energy expenditure estimates for each recorded activity, which can be summed to give the total energy expended over a period. As with heart rate, the estimates yield good qualitative results suitable for comparing the relative expenditures of groups.

Energy Expenditure and Energy Balance

N G Norgan, Loughborough University, Loughborough, Leicestershire, UK

Introduction

The origins of energy expenditure lie within the metabolic activities of the body. To maintain an ordered state, as opposed to randomness and chaos, requires energy. To preserve the ionic gradients across cell membranes, and to allow the activity of cells, tissues, and organs as well as their control by enzymes, hormones, and nerves, requires energy. To maintain respiration and circulation, to grow or produce new tissue, to move and to work, all require energy. The energy expenditure results from these activities and functions. However, these are not amenable to individual measurement in the free-ranging human being. Using indirect calorimetry, it is possible to measure the energy expenditure at various levels of exertion – sleeping, lying, sitting, standing, walking, occupational and nonoccupational activities, and under various influences, such as eating, hot and cold environments, disease, pregnancy, and lactation. From the duration and energy cost, the total energy expenditure in each activity under specified conditions can be determined and the total daily energy expenditure (TDEE) calculated. An example is given in **Table 1**. This is a lengthy and laborious procedure and there are doubts about the precision and accuracy of the method. The advent of a new technique based on the disappearance of a dose of doubly labeled water has enabled a measurement of TDEE with some degree of confidence in most cases. Basal metabolism can be measured with relative ease and precision, and subtraction of the basal metabolism from TDEE gives the energy expenditure resulting from physical activity and thermogenesis. Although this model of the components of energy expenditure is less informative, it is felt to be more precise and accurate and so better for investigation of energy balance and imbalance.

Energy balance can be described by the energy balance equation:

$$\text{Energy intake (EI)} - \text{energy expenditure(EE)} = \text{change in energy stores } (\Delta ES)$$

Table 1 Typical time use, energy cost of activity (physical activity ratio: PAR), and energy expenditure in a group of young male office workers of median body weight

PAR = (energy expenditure of an activity)/(basal metabolic rate, BMR).
Physical activity level (PAL) = (total daily energy expenditure)/(BMR).

Energy intakes in excess of energy expenditure will result in increased body energy stores and, conversely, when energy expenditure exceeds energy intake the deficit is drawn from the energy stores. As we eat intermittently but expend energy continuously, we regularly alternate between positive energy balance after meals and negative energy balance between or before meals. Energy balance must then be expressed over some time period, usually 24 h.

Positive energy balance is the norm over much of the life cycle as we grow and increase energy stores in childhood and adolescence, in pregnancy, and during adulthood. However, the extent of positive energy balance is quite small in most of us. The energy deposited in growth in the newborn may be one-third of the energy intake but by 6 months it is less than 5%. The fat gain of 10 kg experienced by many between the ages of 20 and 50 years requires only 0.001% of the energy intake.

The existence of energy balance, neither gaining nor losing energy, fat, and weight, is not by itself a sign of good energy nutritional status. The obese and the undernourished are often in a static state of neither gaining nor losing energy. It is only during the dynamic phase that the expected perturbations in energy balance are manifest.

The regulation of energy balance has been a subject of some controversy. Do we eat to meet the requirements for energy expenditure and energy gain, or do we modify expenditure according to the level of intake in order to maintain appropriate energy stores and energy gain? These are questions considered below.

Components of Total Daily Energy Expenditure

Basal Metabolism, Activity, and Thermogenesis

The basal metabolic rate (BMR) is defined as the energy expenditure at complete bodily rest, in a thermoneutral environment, 12–18 h after the last meal. These are conditions which rarely exist or persist in ordinary daily life. They are most commonly met on waking in the morning, when BMR is best measured. BMR amounts to about 4.2 kJ (1 kcal) kg^{-1} body weight h^{-1} in men and 3.8 kJ (0.9 kcal) kg^{-1} h^{-1} in women, i.e., about 4.2 kJ min^{-1}. BMR is not the lowest rate of energy expenditure of the day but its ease of measurement, relative precision, and the size of the existing database of information render it a suitable index for study. The resting metabolic rate (RMR) is measured with the less rigorous exclusion of the effects of previous eating and physical activity and is 3–5% higher than BMR. It shows a circadian (daily) rhythm of amplitude 5–10% with a peak at around 16.00–18.00 h and a trough in the early hours of the morning. Many women show a 5% variation over the menstrual cycle, being lowest 1 week before ovulation and highest 1 week after ovulation.

The energy expenditure at rest is determined to a large extent by the body weight and, in particular, by the lean body mass (*See* **Body Composition**). Men have higher resting energy expenditures than women do. The difference persists when energy expenditure is expressed per kg body weight because men tend to be leaner and each kg has more lean tissue that is more metabolically active than adipose (fat) tissue. Metabolic rate tends to fall with age too as lean body mass declines associated, in part, with a fall in level of activity.

Size is an important determinant of the energy expenditure in activities too, but to this must be added the extent to which the body weight is moved, horizontally and, in particular, vertically. The energy expenditure of walking and running can be estimated reliably from data on body weight, speed, incline, and the nature of the surface, e.g., tarmac, soft sand. Not surprisingly, walkers freely choose stride lengths and step frequencies associated with the lowest net energy cost of travel. Unfortunately, there are few other groups of activities where energy costs can be summarized by simple equations.

Comparisons of the energy expenditure of activities can be made by the physical activity ratio (PAR), i.e., the energy expenditure of an activity divided by BMR. This makes an approximate adjustment for age, sex, body weight and, in some cases, body composition so that values are more easily comparable in the different members of the population. The PAR of sitting quietly is about 1.2; for standing it is 1.7, but for walking at 5 km h^{-1} it is 3–4 and for walking at 5 km h^{-1} up a 25% incline it is 5 or more. The PARs of some everyday activities are shown in **Table 1**. These are values obtained during continuous activity but in everyday life we usually interpose pauses and breaks or a mixture of activities. If a task is hard, e.g., PAR 4–6, as in laboring and construction work, rest pauses are essential if the activity is to be maintained for any length of time. In the fraction of a second it takes to jump upwards, the rate of energy expenditure may be 25–50 times that at complete rest. However, we are only able to maintain activities of PAR 4–5 over the whole of a working day by introducing more rest and recovery pauses into the work pattern. (*See* **Exercise**: Metabolic Requirements).

The third component of energy expenditure has been called thermogenesis. This is an unfortunate term as most of the energy expended (strictly speaking, transduced) appears as heat anyway. Here, thermogenesis refers to the extra heat production

arising from energy expenditure associated with the ingestion and metabolism of food and with the extra heat required to maintain body temperature constant, by shivering or other mechanisms, as opposed to the waste heat which usually has this effect. Each of these components of thermogenesis have been further subdivided, in the case of diet-induced thermogenesis (DIT), into obligatory and facultative or adaptive DIT, while cold-induced thermogenesis has been subdivided into shivering and nonshivering thermogenesis (NST).

Obligatory DIT has several synonyms, e.g., thermic effect of food, heat increment of food. It represents the energy cost of digestion and absorption and the handling of absorbed nutrients, particularly the cost of synthesis. It is some 5–10% of dietary energy but may be higher for single food constituents such as protein. The thermic effect of food is normally included in measurements of energy expenditure and is not assessed separately. Facultative DIT and NST have been examined closely as possible components of energy expenditure that could be altered to allow energy balance to be maintained on widely different levels of energy intake. This is described more fully below. Extremes of climates may affect energy expenditure at rest and volitional physical activity. In everyday life in temperate parts of the world, behavioral and technological adjustments of and to clothing and control of the built environment ameliorate these climatic effects. Over the years, views about whether BMR are lower in the tropics, in particular the South Asia Indians, and raised in indigenous circumpolar populations for their body size and composition have tended to fluctuate more according to the zeal of the investigators rather than the quantity and quality of the evidence.

The TDEE is less variable than the daily energy intake. This is because whereas we may choose to eat a little or a lot, we can never expend no energy, and fatigue can reduce the extent to which we can raise expenditure. With our modern, sedentary lifestyles, resting energy expenditure makes up 70% of TDEE for most of us. Expressed in another way, physical activity levels (PAL = TDEE/BMR) for men and women in light occupations with nonactive leisure time are 1.4–1.5 (Table 1 and Figure 1). Values of up to 2.0 have been recorded in some occupations and 2.5–3.5 in athletes in training and competition, but to reach values of 4 it is necessary to work at the level of Tour de France cyclists. In mammals and birds, the maximum seems to be 7. The existence of a ceiling is a consequence of the need for increased mass of energy-supplying organs with high maintenance and operating costs in very active species matching the high levels of activity.

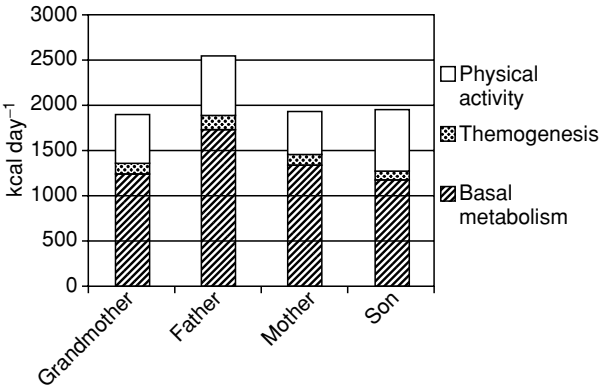

Figure 1 Total daily energy expenditure (TDEE) and its main components in a family: the grandmother is 70 years and weighs 65 kg, the father is 40 years and weighs 75 kg, the mother is 40 years and weighs 62 kg and the 10-year-old son weighs 30 kg. The physical activity levels (TDEE/basal metabolic rate) are 1.52, 1.47, 1.44, and 1.66 respectively.

High TDEE may be achieved by occupations or activities performed at a moderate level for many hours a day or by a shorter period of intensive activity. The physiological characteristics necessary for these two activity patterns are very different. Much higher levels of fitness and work capacity are needed for intense activity without excessive strain. Conversely, fitness improvement and health promotion require activity above a threshold intensity. More time at a lower level may not have the conditioning effect sought. For most of the population, however, exercise such as brisk walking may be of sufficient intensity. Common exercise regimes of three to four times per week for 30–60 min do not alter TDEE significantly. The benefits of exercise lie elsewhere.

Variation and Trends in Energy Expenditure

Individuals differ in their levels of energy expenditure. Much of this may be attributed to their size and composition (the proportions of actively metabolizing lean tissue and the less metabolically active adipose tissue). Men have higher rates than women do because of both size and composition differences. Different patterns of physical activity are the next most likely or important origin of differences in TDEE. Even with the same pattern of activity, individuals may select different rates, unless the activity is paced, as in treadmill walking.

TDEE increases throughout childhood and adolescence. In adulthood, TDEE declines where stable body weight and falling levels of activity are found. More commonly, increases in weight may balance falls in activity such that TDEE may not alter much

between 25–45 years. Thereafter, less child care and career progression, leading to desk-bound work and retirement, may further curtail activity. In addition, BMR falls 2% per decade as lean tissue mass decreases. In very old age, incapacity restricts the ability to be active and PAL levels may be only 1.2. Ill health at other parts of the life cycle may also affect activity and TDEE. In many parts of the world, infection not only causes personal misery but also seriously affects subsistence and occupational activity. Pregnancy has the twin characteristics of an increasing body size plus a customary fall in activity, particularly in the last trimester. Therefore the total extra cost of pregnancy may be less than expected, unless the woman does not reduce activity.

The contribution of genetic factors to differences in energy expenditure is very difficult to investigate and whether any genetic differences are actually expressed in the individual or population depends on a multitude of factors. Results from twin and other studies suggest that variations in RMR, thermic effect of food, level of physical activity, and energy cost of light exercise have a low to moderate genetic component. There are frequent reports in the literature of low BMR in tropical populations, particularly from the Indian subcontinent. Whether these arise from differences in size and composition and nutritional status, or ethnic differences *per se*, is controversial. Some groups have a renowned propensity for fatness, and a hypothesis of a thrifty genotype has been put forward to explain massive overweight and obesity in, for example, Polynesians and the Pima Indians of Arizona, USA, apparently as they altered their traditional lifestyle and took up western habits. The hypothesis suggests that, in response to chronic food shortages over many generations, individuals with more efficient energy utilization survived and bred selectively. Now that high energy intake can be achieved with low energy expenditure, the superior efficiency results in high energy stores. To support the hypothesis, evidence of a lower energy turnover or increased efficiency is required. In Pima Indians some families do have lower RMR than others and these show higher rates of obesity. But, a major problem in human energetics is how to compare the rates of energy expenditure in individuals of different sizes, whether the small, thin individuals in India with apparently low BMR or these large, obese individuals, where low BMR is also being sought. The problem is less difficult for physical activity as the net mechanical efficiency (NME = work done divided by energy expended) is an appropriate index of efficiency. Although NME varies between individuals for reasons that are not entirely clear, there is no consistent pattern of evidence suggesting that the body can alter NME in response to varying planes of nutrition in the short term or over many generations. This attractive hypothesis of a thrifty genotype spread throughout the population appears evolutionarily sound but remains a hypothesis.

Owing to the pervasiveness of modern communication, all societies and populations experienced changes in lifestyle in the 20th century. For many this has meant a shift from subsistence lifestyles, where all material needs were met by 2–3 days' work per week, to long hours of repetitive, often hard, poorly paid labor. In the developed economies, the trend has continued towards increased mechanization, a fall in the length of the working week, and increased holiday entitlements, which have reduced the effort in work, particularly the peak- and high-intensity efforts. The effect of this on TDEE is difficult to gauge. Surprisingly, analyses suggest there are no differences in levels of habitual physical activity, as evidenced by PALs, between the developed and the developing world. This might be explained, in part, by the curtailment of physical activity as a behavioral adaptation to the presence of chronic energy deficiency. It does highlight, however, the pitfalls of taking as self-evident beliefs about energy expenditure and physical activity. There have been few representative national studies of current-day activity and expenditure patterns, let alone studies for earlier periods of the last century. One way round this is to ignore the small effect of the greater energy stores in modern populations and to assume that energy intakes reflect energy expenditure. Again, there are no national representative intake data from earlier years but the evidence suggests that levels of energy expenditure have fallen, albeit only in the last 10–20 years.

Control of Energy Expenditure and Regulation of Energy Balance

There are several types of factors operating at different levels. At the primary level, the setting of regulatory centers in the brain or mechanisms at the cellular level may ultimately determine the level of energy balance. These respond to changes in energy intake and expenditure, at a secondary physiological, biochemical, or neurophysiological level. Traditionally, the regulation of energy balance has been seen as energy intake being controlled to match antecedent levels of energy expenditure. It has been argued recently that regulation of energy balance is less accurate when the energy intake is high in fat, as characterizes many contemporary diets, than for diets with low-fat energy and that this contributes to the modern rise in the prevalence of obesity. In contrast, attention has also been paid to the possibility of the

regulation of energy expenditure to maintain energy balance. In this case, energy expenditure rises when intakes are high and would otherwise lead to an increase in energy stores, and decreases when intakes are low and stores need to be conserved or used efficiently. A consistent effect of high energy intakes or low energy intakes is a change in body size. This tends to buffer the effects of the inequality by altering expenditure in the same direction as intake. However, this is more of an obligatory response in energy expenditure and less the facultative or adaptive response, mentioned earlier. The main mechanism of inefficient energy disposal in overeating has been suggested to be uncoupled oxidative phosphorylation in brown adipose tissue. The most recent suggestion is that the role of the facultative response in the regulation of energy balance may be secondary to its function in regulating the supply of essential nutrients in nutrient-deficient or unbalanced diets.

In undernutrition and during slimming the activity of the sympathetic nervous system, essential for brown adipose tissue thermogenesis, and protein synthesis – an energetically expensive process – may be reduced. However, in humans, by far the majority of the savings in energy expenditure with undernutrition occur owing to the smaller body size and reduced volitional physical activity. The effect of reductions of the metabolic rate of cells is less than 15% of the total reduction. Similarly, the magnitude of DIT of overfeeding at the rates seen in our societies and with our diets is almost certainly low and unlikely to exceed 10% of the extra energy ingested.

A multitude of tertiary-level factors – behavioral, social, and psychological – influence intake and expenditure and, ultimately, energy balance. These include the lifestyle factors referred to earlier, labor-saving devices, availability of private transport, shorter working hours, and inactive leisure. At the same time, the constant availability of food, its variety, and increased palatability and acceptance may easily override control mechanisms evolved for other diet types and nutritional circumstances. Median weights and weights for height or age are increasing in both Europe and North America, illustrating the increased incidence of positive energy balance. Reduced physical activity and increased sedentary behaviors, such as watching television, contribute to lower energy expenditure and are widely regarded as having a role in the increased prevalence of overweight and obesity, but exactly what, it is difficult to uncover. Longitudinal studies in the UK do not consistently show falls in physical activity over the last 10 years, particularly in nonmanual households. There are several dimensions to physical activity, which affect different segments of the population differently.

It has been suggested that to avoid obesity populations should be physically active throughout life at a PAL of 1.7–1.8. As present levels in adults may be nearer 1.55, this would involve the adoption of 20 min vigorous activity per day, such as running or team ball games, or 60 min per day of moderate activity such as brisk walking or cycling. These are clearly difficult to fit into most people's daily lives and a more appropriate strategy would be to perform everyday activities in a more energy-expensive manner, to walk instead of using fuelled transport, to do activities standing instead of sitting, etc. Recently, it has been suggested that fidgeting may play a more important role in energy expenditure than was previously thought. Training studies of the overweight but not obese suggest that increased physical activity plus dieting is associated with weight loss of only some 3 kg over 6 months. Women tend to be less successful than men in reducing body weight and fatness through exercise. It is not known if these differences have physiological or behavioral origins.

One tenet of health and fitness is that body weight should not increase in the adult years. However, data from cross-sectional studies of 7000 male runners, young and old, suggest that in modern society to achieve this requires increasing physical activity with age. Age-neutral body mass index (body weight allowing for height) is not compatible with age-neutral physical activity. Running distances needed to increase 2 km $week^{-1}$ for each increase of 1 year of age. Again, such increases are not easy to adopt and against the trend in the majority of even ardent runners and joggers.

One objection to physical activity as a means of achieving a more favorable energy balance that has been raised is that physical activity and increased energy expenditure cause energy intake to increase with no net effect on energy balance and body weight. The evidence suggests there often is compensation in energy intake but not beyond the amount of energy expended in exercise.

Although weight gain with age is commonplace, the increment in body energy represents only a tiny proportion of the energy throughput. Looked at in this way, regulation and control are still quite accurate.

Energy Expenditure *See* **Metabolic Rate**

ENERGY METABOLISM

S Rubinstein-Litwak, Clarksville, MD, USA

Introduction

All living organisms need energy to perform the most basic of natural functions, that is, they need energy to survive. Humans consume energy from the moment they are conceived to the moment they cease to exist, and considering that, according to the First Law of Thermodynamics, 'energy is not created or destroyed, just transformed,' where do humans obtain this much needed energy? The answer to this question lies within each cell of each individual organism.

The group of chemical and biological reactions involved in the process of obtaining and spending energy is known as energy metabolism. There are two major sources of free energy: food oxidation and light absorption.

The input of energy needs to be constant and must be converted into a highly accessible form to be used for three major purposes:

- performance of mechanical work in muscle contraction and other cellular movements;
- active transport of molecules and ions;
- synthesis of biomolecules that originate from simple precursors, including macromolecules.

Metabolism

Metabolism is defined as the series of physicochemical reactions that take place in cells with the purpose of synthesizing, converting, utilizing, and catabolizing substrates. The primary goal of metabolism is to form adenosine triphosphate (ATP), nicotinamide adenine dinucleotide (NADH) and building blocks for biosynthesis (i.e., amino acids, fatty acids, and sugars). It is through this constant generation and

consumption of metabolic substrates (i.e., ATP, NADH,) that living organisms transform free energy into channeled energy. Metabolism includes catabolic and anabolic pathways that are almost always distinct. During anabolic or degradative pathways, ATP is utilized, whereas during catabolic or biosynthetic pathways, ATP is generated. Most reactions of the human metabolism are performed in the presence of enzymes, which are protein molecules highly adapted and regulated that catalyze said reactions. Many reactions also require cofactors or coenzymes, most commonly vitamin molecules. The amount of enzymes, the catalytic activity of the enzymes, and the accessibility of substrates present at the time of the reactions regulate the metabolic process. The energy charge, defined as the energy status of the cell based on the relative amounts of ATP, adenosine diphosphate (ADP), and adenosine monophosphate (AMP), plays a central role in metabolic regulations. A low energy charge stimulates ATP-generating pathways, while inhibiting ATP-utilizing pathways. ATP is the only form of energy that can be used directly by the cells; energy released as heat is lost and cannot be utilized.

ATP–ADP Cycle

The ATP–ADP cycle is the basis for energy exchange in biological systems. ATP acts as the principal donor of energy and has a very high turnover. When energy is needed, ATP is hydrolyzed to ADP and orthophosphate (Pi). If more energy is needed, ADP can be further hydrolyzed to AMP and pyrophosphate (PPi). ATP can also be regenerated from ADP during oxidation of fuel molecules or when light is trapped (i.e., photosynthesis) (Figure 1).

Metabolism of Food Molecules

The energy in food becomes available only after the macromolecules contained in it (carbohydrates, fat, or protein) are transformed into less complex structures by undergoing a series of reactions. After adjustment for net absorption and urinary losses, the energy value of these substrates is estimated as 4 kcal g^{-1} for carbohydrates, 4 kcal g^{-1} for proteins and 9 kcal g^{-1} for fat (16.8 kJ g^{-1}, 16.8 kJ g^{-1}, and 37.8 kJ g^{-1}, respectively). Three stages in the generation of energy from food oxidation have been described (Figure 2).

- Stage 1: Large molecules in food are broken down into smaller units. No useful energy is generated in this step.
  - Proteins → Amino acids
  - Polysaccharides → Simple sugars (i.e., glucose)
  - Fats → Glycerol + fatty acids
- Stage 2: The recently formed smaller units are degraded once again, to yield a few simple units that

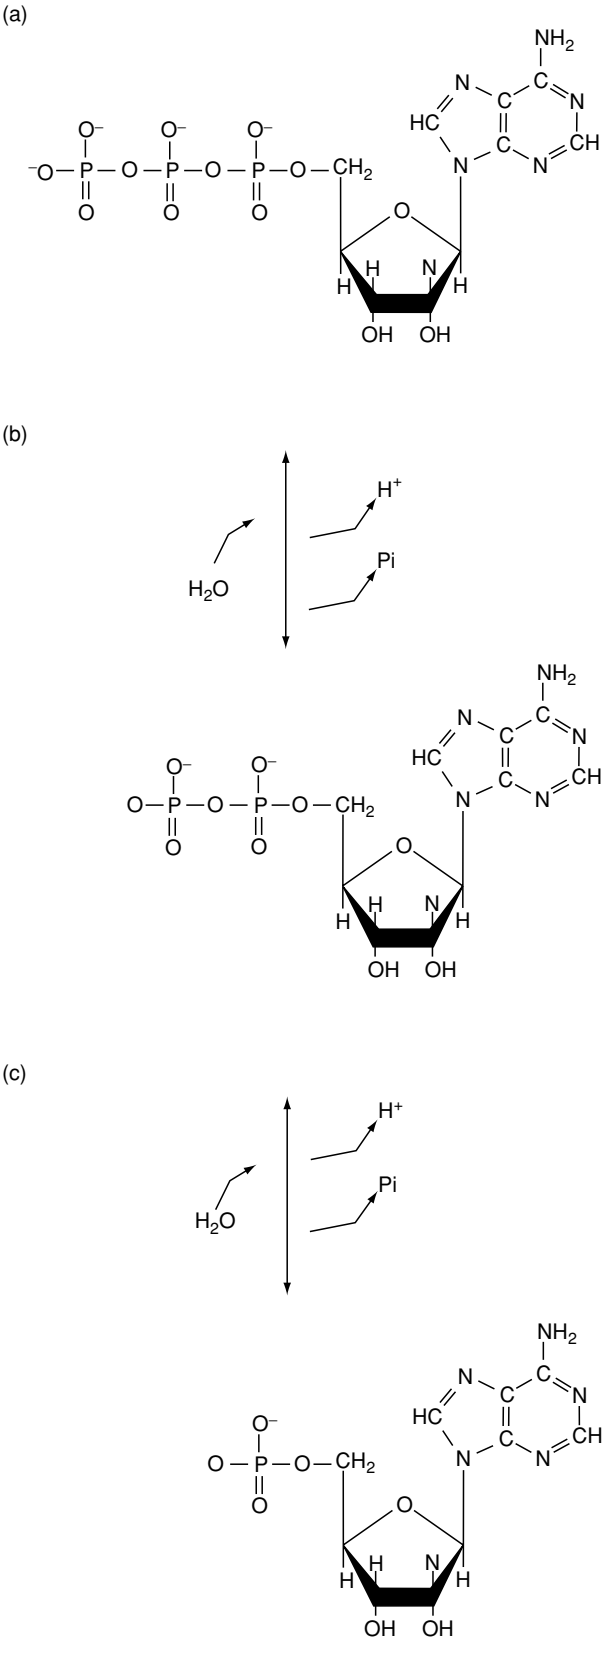

Figure 1 ATP metabolic path. (a) Adenosine triphosphate (ATP); (b) adenosine diphosphate (ADP); (c) adenosine monophosphate (AMP).

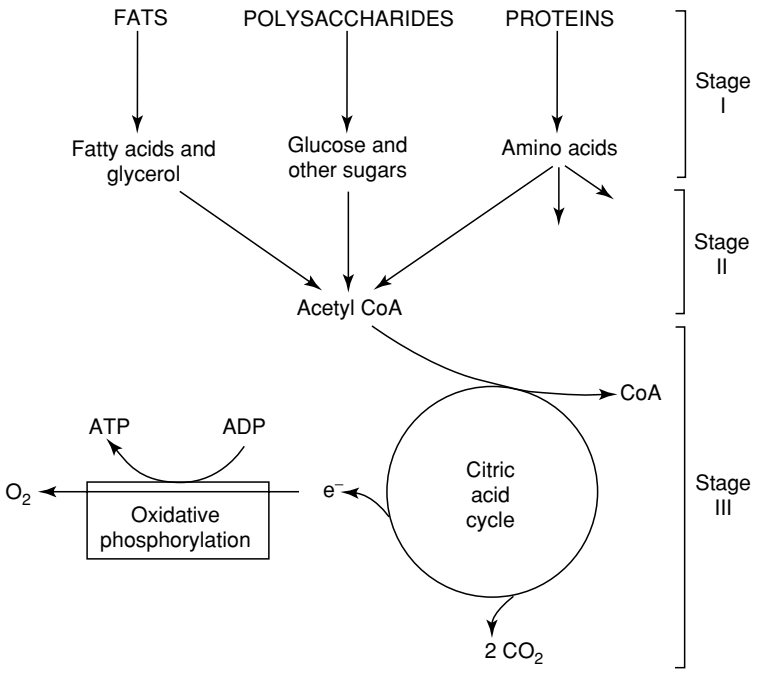

Figure 2 Stages in the extraction of energy from food. From Stryer L (1995) *Biochemistry,* 4th edn. New York: W.H. Freeman, with permission.

play a central role in metabolism. Most molecules are converted into acetyl coenzyme A (acetyl CoA). During this step, some ATP is generated.

- Stage 3: During this step, 90% of the ATP is generated. It includes the citric acid cycle and oxidative phosphorylation.

Carbohydrates

Carbohydrates serve as energy stores, fuels, and metabolic intermediates. When ATP is needed, polysaccharides can be rapidly mobilized to yield glucose, which acts as a prime fuel for the generation of ATP. Phosphorylated sugars are greatly involved in energy production by acting as intermediate substrates in the metabolic pathways. Glucose is the major form of carbohydrate substrate and the preferred energy source for the brain, the renal cortex, and red blood cells.

-Glycolysis Glycolysis includes a series of reactions that convert glucose into pyruvate with a small production of ATP. Reactions occur in the cytosol of the cell. It represents the initial steps that lead to the tricarboxylic acid cycle and the electron transport chain. The glycolytic pathway has a dual role. On one side, it degrades glucose to generate ATP, and on the other, it provides building blocks for the synthesis of cellular components. Glycolysis can be divided into three stages that are presented in Figure 3.

- In the first stage, the substrate is trapped in the cell to form a compound that can be readily cleaved into phosphorylated three-carbon units from where ATP is subsequently extracted. This consists of two phosphorylations and one isomeration to convert glucose into fructose 1,6-bisphosphate. In this step, no energy is extracted, and two molecules of ATP are used.
  - Glucose enters the cell through specific transport proteins. Once in the cell, it is phosphorylated by ATP to form glucose 6-phosphate.
  - Glucose 6-phosphate is isomerated into fructose 6-phosphate
  - Fructose 6-phosphate is phosphorylated by ATP, forming fructose 1,6-bisphosphate.
- In the second stage, some energy is generated. This involves the conversion of fructose 1,6-bisphosphate into 3-phosphoglycerate and a molecule of ATP.
  - Fructose 1,6-bisphosphate is split into glyceraldehyde 3-phosphate (which can be used in the direct pathway) and dihydroxyacetone phosphate. With the help of an isomerase enzyme, *triose phosphate isomerase*, the molecule of dihydroxyacetone phosphate can be converted into a second molecule of glyceraldehyde. The result is the formation of two molecules of glyceraldehyde 3-phosphate from one molecule of fructose 1,6-bisphosphate.
  - Glyceraldehyde 3-phosphate is converted into 1,3-bisphosphoglycerate (1,3-BPG), which is combined with ADP to generate 3-phoshoglycerate

plus ATP. This step represents the first ATP generating reaction in glycolisis.
- In the last stage, 3-phosphoglycerate is converted into pyruvate, and a second molecule of ATP is formed.
- The phosphoryl group in 3-phosphoglycerate is rearranged to form 2-phosphoglycerate.
- 2-Phosphoglycerate is dehydrated to form phosphoenolpyruvate.
- Phosphoenolpyruvate is converted into pyruvate. During this reaction, the phosphoryl group is transferred to ADP to form a molecule of ATP.

The net reaction in the transformation of glucose into pyruvate is:

$$\text{Glucose} + 2\,\text{Pi} + 2\,\text{ADP} + 2\,\text{NAD}^+ \rightarrow$$
$$2\,\text{pyruvate} + 2\,\text{ATP} + 2\,\text{NADH} + 2\,\text{H}^+ + 2\,\text{H}_2\text{O}.$$

Fat

Dietary fat is primarily distributed as triacylglycerols, which are highly concentrated stores of metabolic energy. To be able to use fat as energy, triacylglycerols need to be broken down to fatty acids and glycerol. This is achieved by hydrolysis with the help of a lipase, an enzyme that aids in the degradation of fat molecules. Oxidation of fatty acids takes place in mitochondria. Before entering the mitochondrial membrane, long-chain fatty acids in the outer membrane need to bind to coenzyme A to form acyl CoA. The activated fatty acids are carried across the inner membrane with the help of carnitine. Once in the mitochondria, Acyl CoA goes through a four-step process, called β-oxidation. First, acyl CoA goes through oxidation by flavin adenosine dinucleotide (FAD), then through a hydration, a second oxidation by nicotinamide adenine dinucleotide (NAD), and finally a thiolysis by CoA. The result is the reduction of the carbon chain of the fatty acid by two carbon atoms and the formation of acetyl CoA, NADH and $FADH_2$. Acetyl CoA then enters the tricarboxylic acid cycle by binding to oxaloacetate, while $FADH_2$ and NADH transfer their electrons to molecular oxygen by means of the electron transport chain.

The glycerol moiety that was liberated in the degradation of triacylglycerols can also be further metabolized by entering the glycolitic pathway as a three-carbon compound yielding eventually pyruvate.

Proteins

Proteins need to be degraded to amino acids so the body can use them. Most of the amino acids are used for the synthesis of new proteins, while the remaining amino acids are used for metabolic fuel. Amino acids can be used as the precursors for the synthesis of glucose, ketone bodies, and fatty acids. After the amino group is removed and converted to urea, the carbon chain of ketogenic amino acids is degraded to acetyl CoA or acetoacetyl CoA, to form ketone bodies. At the same time, glucogenic amino acids are degraded to pyruvate or one of the intermediates of the TCA cycle; α-ketoglutarate, succinyl CoA, fumarate, or oxaloacetate to synthesize glucose.

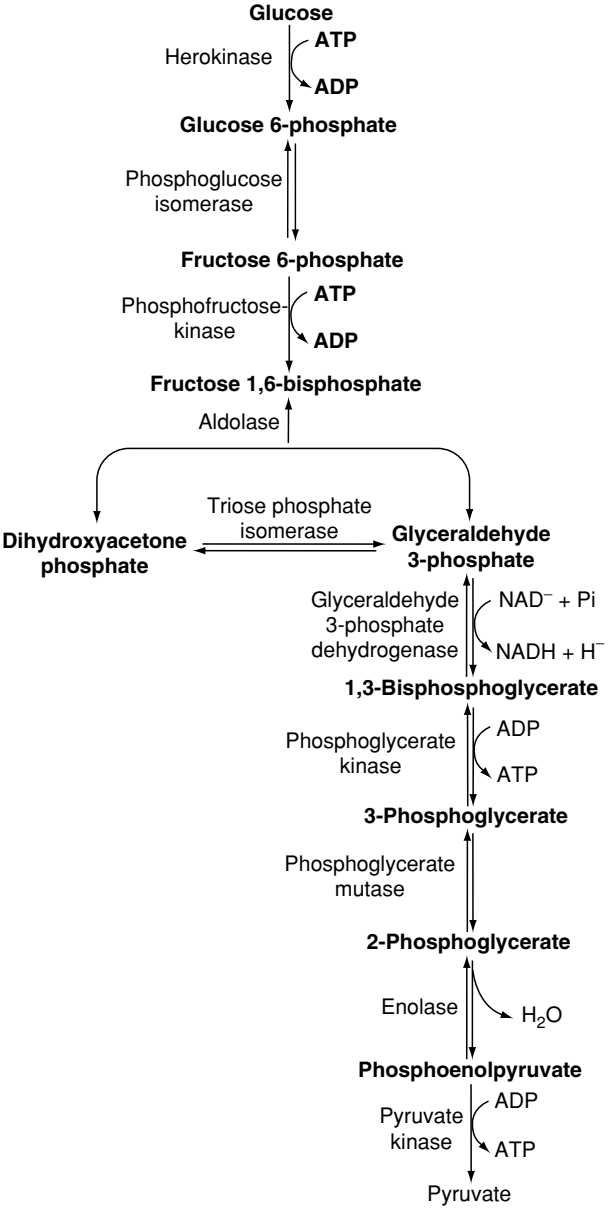

Figure 3 Glycolysis. From Stryer L (1995) *Biochemistry*, 4th edn. New York: W.H. Freeman, with permission.

Tricarboxylic Acid Cycle

The tricarboxylic acid (TCA) cycle is also known as the citric acid cycle or the Krebs cycle. It constitutes a series of reactions that involve the decarboxylation of pyruvate to form acetyl CoA, which in turn is fully oxidized to carbon dioxide (CO_2) and water (H_2O). These reactions take place in the mitochondria. The TCA cycle represents the final common pathway for the oxidation of fuel molecules.

The link between glycolysis and the TCA cycle is the oxidative decarboxylation of pyruvate to form acetyl CoA. Coenzyme A is a heat-stable cofactor that plays a central role within the molecule in metabolism. It can deliver activated acyl groups for degradation and energy generation as well as for biosynthetic purposes.

$$\text{Pyruvate} + \text{CoA} + \text{NAD}^+ \rightarrow \text{Acetyl CoA} + \text{CO}_2 + \text{NADH}.$$

The TCA cycle is graphically represented in Figure 4. The start of the cycle includes the union of oxaloacetate (a four-carbon unit) with the acetyl group of acetyl CoA (a two-carbon unit) to form citrate and CoA. Citrate is then isomerized into isocitrate, which undergoes the first oxidative decarboxylation of the cycle to become oxalosuccinate and then α-ketoglutarate. There then follows a second oxidative decarboxylation that yields a molecule of succinyl CoA. Succinyl CoA becomes attached to guanosine diphosphate (GDP), resulting in the formation of succinate, guanosine triphosphate (GTP) and CoA. This is the only step in the cycle that directly yields a high-energy phosphate bond.

Succinate is oxidized to fumarate, which in turn is hydrated to form malate. The final step in the cycle is the regeneration of oxaloacetate from malate. The electrons that are released during the cycle are transferred to NAD^+ and FAD to be transported in oxidative phosphorylation.

The net reaction of the TCA cycle is:

$$\text{Acetyl CoA} + 3\,\text{NAD}^+ + \text{FAD} + \text{GDP} + \text{Pi} + 2\,\text{H}_2\text{O} \rightarrow 2\,\text{CO}_2 + 3\,\text{NADH} + \text{FADH}_2 + \text{GTP} + 2\text{H}^+ + \text{CoA}$$

Oxidative Phosphorylation

Oxidative phosphorylation is also known as the electron transport chain. It includes the reactions that result in the synthesis of ATP from ADP + Pi. Heat can also be generated when ATP production is uncoupled from the respiratory chain.

Synthesis of ATP

Oxidative phosphorylation constitutes the major source of ATP in aerobic organisms. During the oxidation of fuel molecules, $FADH_2$ and NADH play a central role as the major electron carriers taking the electrons to the ultimate acceptor, oxygen (O_2). The transfer of electrons from NADH and $FADH_2$ to O_2 takes place in the inner membrane of the mitochondria. During this transfer, a number of protons are pumped out of the mitochondrial matrix, forming a proton gradient. Finally, with the help of ATPase, an ATP-synthesizing complex, the protons flow back into the matrix generating the necessary energy to generate ATP.

The electrons are transferred from NADH to O_2 through a chain of three large protein complexes. Each complex is an electron-driven proton pump that contains multiple oxidation–reduction centers. The electron carrying groups that take the electrons from NADH and $FADH_2$ to O_2 are flavins, iron–sulfur clusters, hemes and copper ions (Figure 5).

Complex I, also known as NADH-Q reductase, involves the first process through which the electrons from NADH are transferred. NADH binds to a flavoprotein, flavin mononucleotide (FMN), transferring its two high potential electrons and losing its hydrogen molecules. The result is $FMNH_2$ and NAD^+. From there, the electrons are transferred to coenzyme Q, also known as ubiquinone Q, on their way to complex III. Coenzyme Q is also the entry point for the electrons of $FADH_2$ to the chain. While some energy is lost as heat, ATP is also formed in a coupled reaction by bonding ADP + Pi. Complex III, also known as cytochrome reductase or cytochrome b, is the second proton pump in the electron transport chain. In this step, the electrons from coenzyme Q are transferred to cytochrome b and then to cytochrome c, a water-soluble protein, on their way to complex IV. During the transfer, some protons are once again pumped out of the mitochondrial membrane. A second coupled reaction results in the formation of ATP. Complex IV, also known as cytochrome oxidase or cytochrome a, plays a role in the transfer of the electrons from cytochrome c to O_2. In the final step, the electrons bind to O_2 to form H_2O.

The net reaction from each glucose molecule that enters glycolysis and proceeds through the TCA cycle and oxidative phosphorylation is:

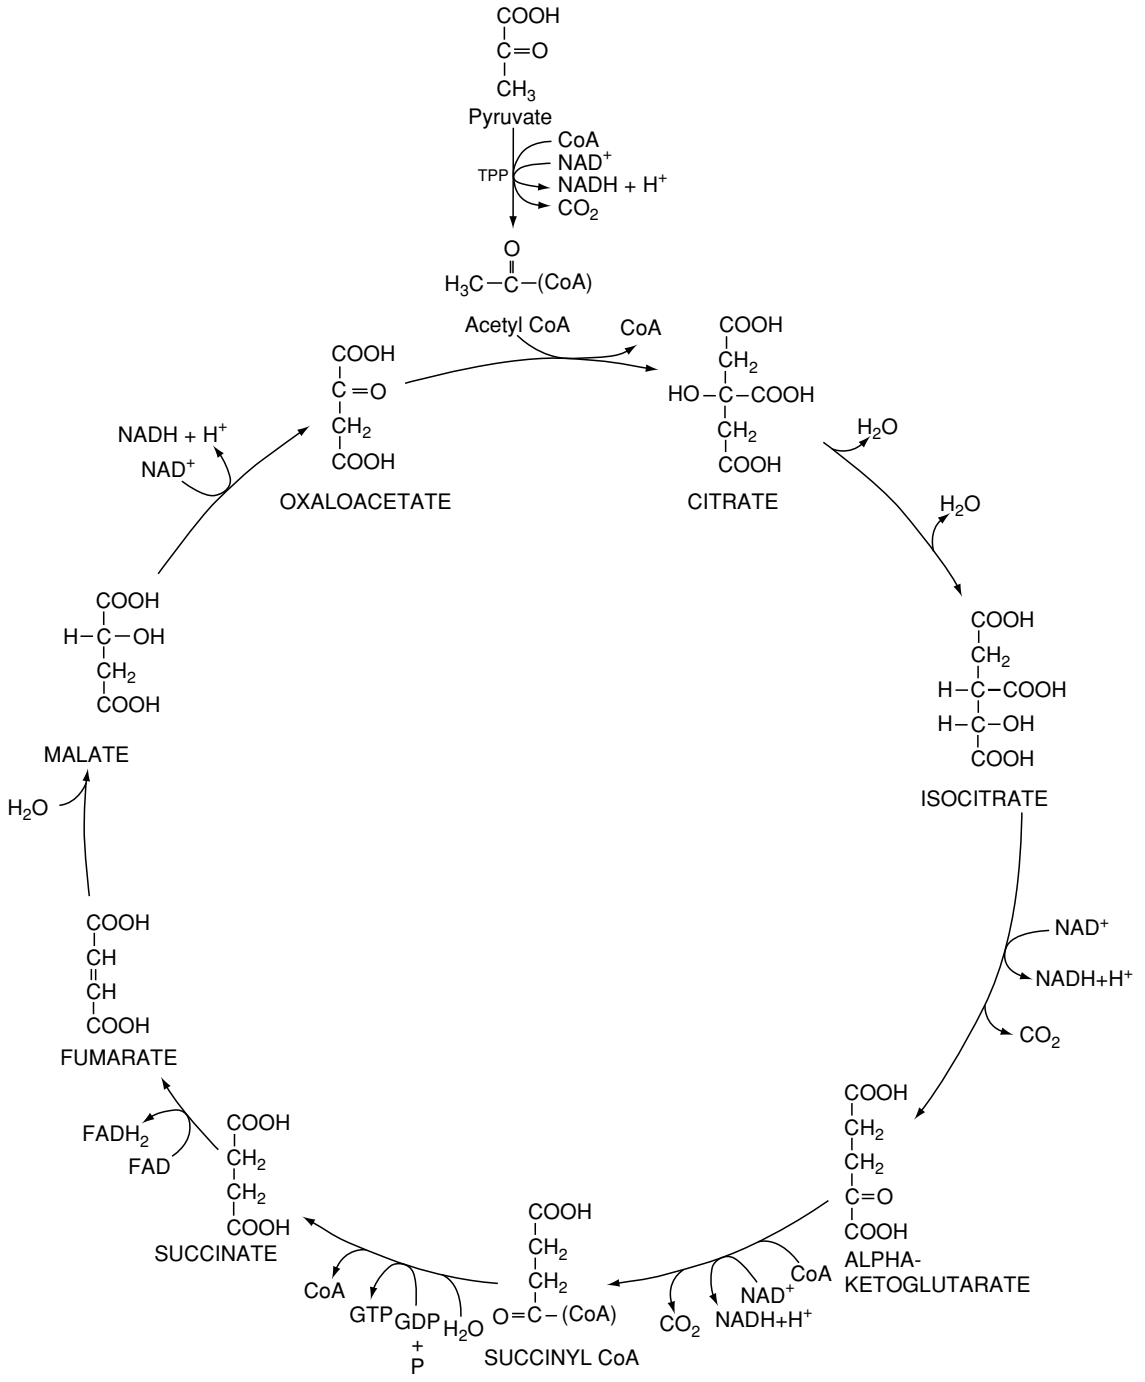

Figure 4 Tricarboxylic acid cycle.

$$\text{Glucose} + 6\,O_2 + 36\,\text{ADP} + 36\,\text{Pi} \rightarrow 6\,CO_2 + 36\,\text{ATP} + 6\,H_2O.$$

Generation of Heat

When there is not enough energy to transform ADP into ATP, mitochondrial electron transport is uncoupled from ATP synthesis by a proton leak. The result is the release of energy as heat. Uncoupling proteins (UCP) are known to be responsible for the leak that sometimes occurs during oxidative phosphorylation. Three uncoupling proteins have been identified. Thermogenin or UCP1 present in brown adipose tissue, UCP2 present in several tissues, and UCP3 mainly present in skeletal muscle. UCP

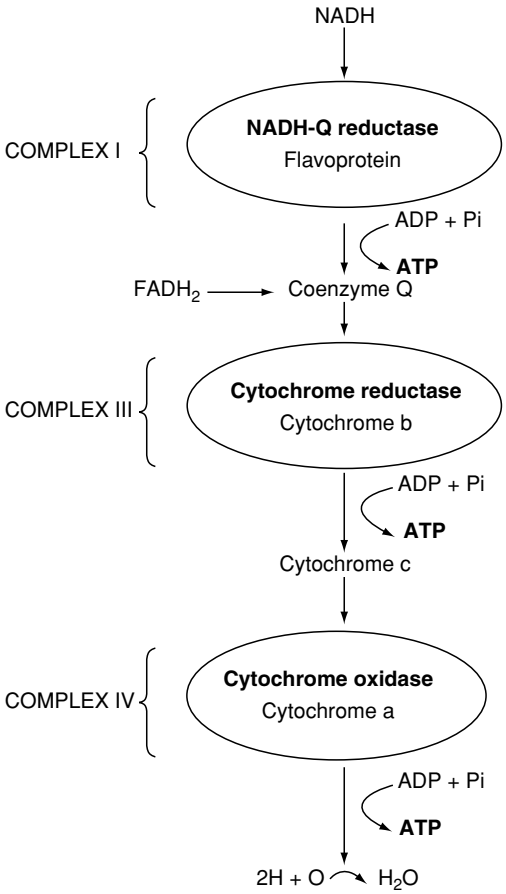

Figure 5 Oxidative phosphorylation.

play a role in energy metabolism by limiting the synthesis of ATP and dissipating energy as heat, thus reducing the efficiency of energy production.

Summary

As described in the previous paragraphs, humans obtain their energy from food. Once in the body, the macromolecules found in food undergo a series of degenerative reactions that yield the necessary substrates to promote the continuation of a process known as energy metabolism. The result of this very precise series of chemical and biological reactions is the transformation of energy in its free form into energy that can be fully utilized by the human body. Carbohydrates are degraded to simple sugars, fat to fatty acids and proteins to amino acids. Eventually, the complete oxidation of these molecules yields acetyl CoA, which acts as a link to the TCA cycle.

In the TCA cycle, acetyl CoA is fully oxidized to CO_2 and H_2O. Throughout the cycle, hydrogen atoms and their electrons are released. The hydrogen atoms are then bound to other compounds, resulting in the production of three molecules of NADH, one $FADH_2$, and one GTP. These new molecules contain the energy originally found in acetyl CoA. For the production of ATP, NADH and $FADH_2$ carry the electrons from the TCA cycle through an electron transport chain known as oxidative phosphorylation. The process ends with the production of ATP and H_2O. An alteration in oxidative phosphorylation can impair the production of ATP and dissipate energy as heat instead. Uncoupling proteins are responsible for this.

ENTERAL NUTRITION

V A Stallings, The Children's Hospital of Philadelphia, Philadelphia, PA, USA

Enteral Feeding

The nutritional status of hospitalized patients has received much interest since studies in the 1970s and 1980s indicated that up to 50% of surgical and medical pediatric and adult patients have some clinical or biochemical evidence of malnutrition. (*See* **Protein**: Deficiency.)

The four main groups of patients who generally require nutrition support are:

1. Patients with existing moderate-to-severe malnutrition indicated by weight loss in excess of 10%, muscle wasting, peripheral edema and/or albumin less than $30\,g\,l^{-1}$.
2. Patients with mild-to-moderate malnutrition who are at-risk of becoming further nutritionally compromised as a result of their medical condition.
3. Patients with a normal nutritional status but who, as a result of their medical condition, would not be able to commence normal feeding of adequate nutrient intake for a length of time appropriate for age and disease status, thereby potentially leading to a state of malnutrition.
4. Pediatric patients who are unable to maintain a normal pattern of growth and development, or who require nutrition support to promote an increased rate of growth (catch-up growth).

In order to prevent and treat malnutrition, the early identification of the 'at-risk' patient is very important. (*See* **Malnutrition**: The Problem of Malnutrition.)

Providing Enteral Nutrition Support

Oral Feeding

Patients who cannot safely consume solid food may take blenderized food. Patients who are able to take some amount of food but cannot maintain an adequate nutritional status may require oral dietary supplements. There are two main types of dietary supplements:

1. Modular, i.e., single nutrient supplements such as protein, fat, carbohydrates, vitamins, or minerals. There are several formulations of each type of nutrient. For example, protein may be provided as intact proteins, protein hydrolysates, or individual amino acids, and fats as long-chain fats, including essential fatty acids and medium-chain triglycerides.
2. Complete, i.e., balanced nutrient supplements which contain all the nutrients and may be taken as the whole meal, part of a meal, or a snack.

There are a vast number of liquid and semisolid commercial nutritional products that may be used for enteral feeding. These products may be designed for a specific age group (i.e., infant, adult) or specific medical condition (i.e., premature infant, pulmonary failure, renal failure).

Enteral Tube Feeding

Enteral tube feeding is the preferred route of diet administration for all patients with a functioning gastrointestinal tract who, for a variety of reasons, do not take adequate nutrition from food and/or oral dietary supplements. In recent years, research and clinical experience has led to many technical advances in the formulation and presentation of enteral formulas and feeding equipment. As a result, technology-assisted enteral support is now widely used. The most commonly used routes for providing enteral nutrition are via nasogastric and gastrostomy feeding tubes.

-Nasogastric feeding Fine-bore feeding tubes are the tubes of choice as they are narrow, softer, flexible, and more comfortable for the patient than the previously used large-bore nasogastric tubes. The use of fine-bore feeding tubes has reduced many of the common nasal tube complications such as rhinitis, esophagitis, pharyngitis, esophageal strictures, and erosions.

Fine-bore feeding tubes are inserted per nasally with a wire stylet to facilitate passage. The correct position of the tube may be confirmed by aspiration of the gastric contents and testing for acidic pH, or by auscultation of the epigastrium as air is injected into the stomach via the feeding tube. Radiological confirmation of the correct position of the nasogastric tube is required in patients who have an impaired gag reflex, those who are semiconscious or unconscious, and other high-risk patients including infants.

Nasogastric feeding may not be suitable for patients who are at-risk of regurgitation and/or pulmonary aspiration of the feed, and nasoduodenal or nasojejunal feeding tubes should be considered for these patients. Enteral feeding tubes with small weighted tips (3–5 g) are available to facilitate tube passage postpylorically for feeding directly into the

Figure 1 Fine-bore nasoenteral tubes (courtesy of Corpak Medsystems, USA).

duodenum or the jejunum. Figure 1 shows weighted fine-bore nasoenteral tubes (Corpak Medsystems, USA) and two types of unweighted nasogastric feeding tubes. In some patients, endoscopic placement of the feeding tube may be undertaken to ensure rapid and correct placement.

-Gastrostomy feeding Patients who require long-term or permanent enteral feeding should be considered for gastrostomy feeding tube or gastrostomy button (a smaller appliance which is almost flush with the skin) placement. The technique of percutaneous endoscopic gastrostomy (PEG) is a well-established procedure for providing enteral nutrition support. Although the feeding gastrostomy may be placed surgically, PEGs compare favorably, with a lower morbidity and cost; the surgical gastrostomy requires a laparotomy and a general anesthetic, whereas the PEG is performed under local anesthesia using a fiber-optic endoscope. A range of PEG kits are available for infants, children, and adults. A feeding jejunostomy may be considered as the means of providing early postoperative nutrition support in selected patients and may be used for short- or long-term support.

Techniques of Administration of Enteral Tube Feeding

Enteral formulas are usually given from a reservoir (plastic bag) via appropriate tubing to connect to the feeding tube (nasogastric, gastrostomy, jejunostomy). The formula is infused either by gravity or by mechanical peristaltic pump to ensure a selected and steady delivery rate. The enteral feeding administration set should be changed at least every 12 h to minimize the risk of infectious complications. The method of continuous feeding by a pump saves nursing time and ensures that the prescribed amount and rate of formula are provided. Bolus feeding is considered more physiological, but this method of enteral nutrition has a greater incidence of side-effects, such as regurgitation, distention, and diarrhea.

Intermittent enteral tube feeding during the day or the administration of continuous overnight (8–12 h) infusion can be of benefit to patients who may be able to take small quantities of food. This is common practice when patients are being transitioned for total intravenous nutrition support for conditions such as short-bowel syndrome.

Enteral Formulas Tube Feeding

In the past, regular hospital food was blenderized, but these preparations were too viscous for most feeding tubes. Further dilutions lowered the nutrient density, and the resulting blended feed was often nutritionally inadequate. The problems of ensuring nutritional quality while avoiding microbial contamination of these feeds, along with the time taken for their preparation, has led to the increased use of commercially prepared 'ready-to-feed' enteral formulas in most hospital and home care settings.

Types of Enteral Formulas

The four main groups of commercially available enteral diets are polymeric, predigested, disease-specific, and modular. The selection of the most appropriate enteral formulas requires consideration of the patient's age, nutritional status, disease process, and the specific nutritional requirements.

-Polymeric formulas Polymeric formulas are indicated for the majority of patients with normal or near-normal gastrointestinal function. The dietary constituents in polymeric enteral formula generally are as follows: *energy* – carbohydrate as glucose polymers, fat as long-chain triglycerides; *nitrogen* – whole protein; *vitamins*; *minerals*; and *trace elements*. (*See* **Carbohydrates**: Requirements and Dietary Importance; **Energy**: Measurement of Food Energy; **Fats**: Requirements; **Minerals – Dietary Importance**; **Protein**: Requirements; **Vitamins**: Overview.)

Most standard polymeric diets have an energy density of 4.2 kJ (1 kcal) ml^{-1} and a nitrogen concentration of 5–7 g l^{-1}. Some patients may require the energy and nitrogen-dense formulations which contain 8–10 g of nitrogen per liter and possess an energy density of 6.3 kJ (1.5 kcal) ml^{-1} or more. Polymeric diets containing dietary fiber are available and may promote the regulation of bowel function in some enterally fed patients. The use of enteral formulas containing fiber has been suggested in the elderly, those who require long-term nutritional support, and patients with neurological conditions and enteral

inactivity. (*See* **Dietary Fiber**: Physiological Effects; Effects of Fiber on Absorption.)

-Predigested, chemically defined formulas Predigested, chemically defined formulas are also called elemental formulas or diets. These preparations are used in the nutritional management of patients with impaired gastrointestinal function, such as severe impairment of luminal nutrient hydrolysis or substantially reduced functional absorptive capacity (e.g., short-bowel syndrome, exocrine pancreatic insufficiency). Predigested diets contain carbohydrate in the form of glucose polymers, peptides and amino acids as the nitrogen source, fat, usually as a mixture of medium-chain and long-chain triglycerides, and the full complement of vitamins and minerals.

-Disease-specific formulas Specific dietary formulations have been developed for patients with conditions such as liver disease, renal disease, or respiratory disease.

Liver disease Patients with encephalopathy and cirrhosis have abnormal plasma amino acid profiles characterized by raised levels of aromatic amino acids (i.e., tyrosine and phenylalanine) and depressed levels of branched-chain amino acids (i.e., leucine, valine, and isoleucine). These changes in the pattern of amino acid levels have been implicated in the pathogenesis of hepatic encephalopathy. Enteral feeding preparations containing low levels of aromatic amino acids and higher levels of branched-chain amino acids are available for oral or tube feeding: the administration of these diets may be of benefit to patients with encephalopathy associated with acute or chronic liver disease. (*See* **Liver**: Nutritional Management of Liver and Biliary Disorders.)

Renal disease Formulas containing all of the essential amino acids plus histidine, without the nonessential amino acids, have been developed for patients with impaired renal function. It is suggested that these diets reduce urea production and promote the reutilization of nonessential amino acids in the liver by transamination. At present, there is little evidence to support their chronic use to delay progression of chronic renal disease.

Respiratory disease The level of energy from carbohydrate in enteral formulas can result in further increased production of carbon dioxide and respiratory distress in some patients. In order to reduce the production of carbon dioxide, the use of enteral formulas which have a higher fat:carbohydrate ratio has been suggested for patients with respiratory disease. These formulas may facilitate more rapid weaning from ventilatory support.

-Modular diets Modular diets allow specific components of a diet to be altered according to the individual patient requirement. These include products that provide various types of isolated carbohydrate, protein, and fat compounds.

Initiation and Contraindications of Enteral Feeding

Some care teams administer small volumes of diluted enteral feeds during the initial stages of nutrition support in order to minimize any gastrointestinal side-effects. Some studies report that the use of dilute 'starter regimens' does not decrease the frequency of gastrointestinal side-effects but may result in reduced energy and nutrient intake and thus may adversely affect the nitrogen balance. Enteral nutrition is contraindicated in patients with an inaccessible or nonfunctioning gastrointestinal tract (e.g., paralytic ileus, intestinal obstruction).

Complications of Enteral Nutrition

Malposition of enteral feeding tubes may occur, but this can usually be avoided by strict adherence to the protocol for the insertion of feeding tubes, and confirmation of the position of the tube. Unintentional removal of feeding tubes is commonly noted in agitated, disoriented patients. Blockage of tubes can occur unless they are flushed regularly.

Diarrhea is the most commonly reported side-effect, and the factors implicated are high osmotic loads, concomitant antibiotic therapy, and excessively rapid infusion. Problems of lactose intolerance are limited, since the majority of commercial enteral formulas are low in lactose or lactose-free. Tube-feeding-related diarrhea occurs in up to 30% of patient, but its etiology is unclear. Nausea, vomiting, bloating, cramps, and abdominal distension can occur in some patients, especially following bolus feeding or when the feed is infused at a high flow rate. Pulmonary aspiration and regurgitation may be reduced by elevating the head of the patient's bed. Duodenal (transpyloric) feeding may be beneficial in patients at risk for aspiration.

Abnormalities of liver function tests are generally minor and reversible with an enteral feeding regime. Regular monitoring of patients enables early detection of biochemical imbalances, including electrolyte and fluid balance abnormalities. Drug–nutrient interactions can occur with many medications, including theophylline, warfarin, methyldopa, and digoxin.

Monitoring Patients Receiving Enteral Nutrition

Monitoring enterally fed patients is an essential aspect of providing safe and effective nutrition support.

Fluid Balance Charts and Weight

Continuous fluid-balance records enable an accurate review of the patient's actual intake of enteral formula compared to the prescribed regimen, as well as other fluid intake. The prescribed regimen and the actual intake may not be the same, and without records, patients may receive suboptimal (inadequate or excessive) levels of nutrition support. All patients receiving enteral nutrition support should be weighed regularly. The frequency of the weight assessment depends upon the patient's age, nutritional status, and medical condition.

Biochemical and Hematological

Plasma glucose, electrolytes, calcium, phosphate, and magnesium should be monitored regularly, and more frequently in severely malnourished patients. Plasma proteins are useful markers of nutritional status, transferrin and prealbumin in the short-term, and albumin in the long-term. Hemoglobin and the white blood cell and lymphocyte count should be monitored regularly and often. (*See* **Nutritional Assessment**: Biochemical Tests for Vitamins and Minerals.)

Anthropometric and Dynamometric

Measurements of mid-arm circumference and triceps and subscapular skinfolds should be taken regularly and are commonly used for research purposes. (*See* **Nutritional Assessment**: Anthropometry and Clinical Examination.)

Ending Enteral Tube Feeding

As the patient is able to increase oral intake of regular food, the administration of the enteral tube feed is decreased. Oral and enteral tube intake should be monitored using food record charts to document the nutritional quality of the total intake. Enteral feeding should not be discontinued until adequate nutrition can be taken from food and/or oral dietary supplements, and normal hydration and weight maintained.

Nutrition Team

Team management of enterally fed patients reduces associated morbidity and optimizes nutrition support. This interdisciplinary team usually includes a dietitian/nutritionist, nurse, and physician.

ENZYMES

Contents

Functions and Characteristics

J R Whitaker, University of California, Davis, CA, USA

Introduction

Enzymes are absolutely essential for life. They occur in all animals, plants, and microorganisms. Nearly all chemical reactions in living organisms are a result of enzyme activities. Enzymes cause reactions to occur rapidly at ambient temperatures with a high degree of specificity. As an example, it takes 24–72 h at 100–110 °C and 6 N hydrochloric acid to hydrolyze a protein. Gastrointestinal-tract enzymes accomplish this in 2–4 h at 37 °C. There are thousands of different enzymes in living organisms.

Definition of an Enzyme

An enzyme is a protein with catalytic properties due to its power of specific activation. Some enzymes also require cofactors for activity. The properties and characteristics of enzymes are described below. A few ribonucleic acids, called ribozymes, also act as catalysts for a limited number of hydrolytic reactions, but they do not fit the definition of an enzyme as defined above.

History

Although the effects of enzymes, such as fermentation, digestion, milk clotting and meat tenderization, were known for centuries, the first clear recognition of an enzyme as a unique compound was in 1833, when Payen and Persoz reported that an alcohol precipitate of malt extract contained a thermolabile substance 'diastase' (now known as amylase) because of its ability to separate starch from insoluble envelopes of starch grains. They identified some characteristics of enzymes – precipitation with alcohol, thermolability, and specificity – and designed a naming system (stem of substrate name plus the suffix '-ase') that is used universally today. Schoenbein, in 1855, discovered peroxidase in plants that, in the presence of hydrogen peroxide, causes a brown solution of gum guaiac to turn blue. Later (1856), Schoenbein also discovered polyphenol oxidase in mushrooms, which causes them (and many other plant tissues) to turn brown. Berthelot in 1860

discovered invertase in yeast, which causes an inversion in the optical rotation of a sucrose solution. Several thousand enzymes are now well known.

The relationship between enzymes and living cells was a controversial topic between 1875 and 1900. Pasteur, a microbiologist and enologist, argued that fermentation was inseparable from living cells. Liebig, a chemist who demonstrated the action of pepsin on proteins, held that enzymes are chemical substances, active in the absence of cells. Büchner, in 1897, separated broken yeast cells from liquid, showing that the cell-free extract carried out fermentation, thereby ending the controversy. In 1878, Kühne proposed the name 'enzyme' (Greek for 'in yeast') for the substance transforming one compound to another. (*See* **Fermented Foods**: Origins and Applications.)

Protein Nature of Enzymes

Enzymes are proteins. This was generally accepted in the late 19th and early 20th centuries. However, this idea was challenged in the late 1920s by Willstätter. He purified peroxidase until no protein was detectable, but appreciable activity remained. Therefore, he concluded that enzymes could not be proteins. Sumner, in 1926, crystallized urease from Jack Bean meal and showed it to be a protein. This set off a polemic debate between Willstätter and Sumner that involved many scientists. In 1930, the famous biochemist Haldane indicated that, with the single exception of urease, almost nothing was known about the chemical nature of enzymes. However, soon thereafter, scientists at the Rockefeller Institute in New York, led by the distinguished biochemist, John Northrop, crystallized pepsin, trypsin, chymotrypsin, and carboxypeptidase A, among others. All were proteins. More than 600 enzymes, all proteins, have now been crystallized.

As proteins, enzymes have specific structures. Each has a fixed molecular size and a specific amino acid sequence (primary sequence), as determined by the gene for that enzyme. The primary structure is folded, via α-helices, β-pleated sheets, β and γ bends and random-coil segments, to give secondary structure. Further folding, giving a tertiary structure, results from thermodynamic and kinetic requirements that most of the hydrophobic amino acid residues must be inside the protein, away from water, and most of the hydrophilic amino acid residues must be on the surface. (*See* **Protein**: Chemistry.)

Many enzymes consist of single polypeptide molecules. Others have two or more subunits (identical or different) per molecule, giving rise to a quaternary structure. Some enzymes associate to form macromolecular structure systems to convert substrate to product(s) more efficiently. *Escherichia coli* pyruvate dehydrogenase is a complex of three different enzymes and five cofactors (M_r of 4.44×10^6 Da).

Early on, researchers investigated water-soluble enzymes. Now, much emphasis is on structurally bound enzymes.

Solvation of Enzymes

Water is an important factor in determining native enzyme structure, as well as activity. Hydrophobic amino acid residues are largely inside the enzyme molecule, away from water, and most of the hydrophilic amino acid residues are on the outside. Enzymes contain 30–40% (w/v) of bound surface water (170–220 mol of water per 10 000 gram of protein). The relatively high surface hydrophobicity of a folded polypeptide chain, and its lack of hydration by water molecules, determines whether an enzyme has a quaternary structure or not. In less polar solvents than water, but miscible with water, an enzyme probably would not fold in the same way, and is most likely inactive. Enzymes can be more stable suspended in immiscible organic solvents than in water. (*See* **Water Activity**: Effect on Food Stability.)

Size

Enzymes are large molecules. Ribonuclease ($M_r =$ 13 683) and lysozyme (14 100) are small enzymes, alkaline phosphatase (80 000) and mushroom polyphenol oxidase (128 000) are of intermediate size, and β-galactosidase (520 000) and glutamate dehydrogenase (2 000 000) are large enzymes.

Catalytic Nature of Enzymes

The most unique feature of enzymes is their ability to bind compounds (called substrates) stereospecifically and to convert them to other compounds (called products) very efficiently. Two measures of enzyme efficiency are turnover number and rate enhancement. Example turnover numbers are 10^2–10^7 mol of substrate converted to product per second per mole of enzyme active site for chymotrypsin and catalase, respectively. Some examples of rate enhancement (based on the same temperature and concentration) are: hydrogen peroxide is converted to water and oxygen by catalase 3.5×10^8 times faster than noncatalytically; invertase hydrolyzes sucrose to glucose and fructose 5.6×10^{10} times faster than does 1 M hydrochloric acid; urease hydrolyzes urea to carbon dioxide and ammonia 4.2×10^{11} times faster than does 1 M hydrochloric acid. This remarkable rate enhancement makes life possible at ambient temperatures.

Enzymes increase rates of conversion of substrate to product by lowering the activation energy, E_a. E_a is the minimum energy that a substrate must acquire above the ground-state energy to go to product. In two of the examples above, catalase lowers E_a from 18.0 to 6.4 kcal mol^{-1} (3.5×10^8 rate enhancement) for the oxidoreduction of hydrogen peroxide to products and urease lowers E_a from 24.2 to 8.7 kcal mol^{-1} (4.2×10^{11} rate enhancement) in the hydrolysis of urea.

Enzymes convert substrates to products by well-known chemical mechanisms. Because of their efficiency, it was once considered that they must have magical qualities. We now know that several well-known factors can account for this efficiency. These are: (1) conversion from inter- to intramolecular reaction; (2) proximity and specific orientation of substrate in the active site of the enzyme; (3) catalysis by distortion of bonds; (4) general acid–general base catalysis; and (5) nucleophilic–electrophilic catalysis. These will be explained below.

Active Sites of Enzymes

Reactions occur at active sites of enzymes. The active site is a small area, a cavity or hole on the surface of the enzyme. The active site consists of 10–15 amino acid residues brought together by folding from different parts of the primary structure of the protein. One part of the active site is responsible for stereospecific binding of the substrate in proximity to the (second) transforming part of the active site. In α-chymotrypsin, residues Ser189, Gly216, and Gly226 are responsible for binding the peptide substrate, and residues His57, Ser195, and Asp102 are responsible for catalyzing hydrolysis of the scissile peptide bonds. The amino group of Ile16 and the carboxyl group of Asp194 assist in maintaining the shape of the active site. The binding site recognizes L-Tyr, L-Phe or L-Trp residues of the substrate. Peptide bonds involving other L-amino acids or D-amino acids are not hydrolyzed. There must be very close complementarity, following any induced fit, between the shape of the substrate and the active site for binding to occur. (*See* **Amino Acids**: Properties and Occurrence.)

Proximity and Orientation Effects

Proximity and orientation effects include (1) intra- vs intermolecular catalysis, (2) reaction entropy, and (3) effective concentration of reactive groups. An absolute requirement for catalysis is that the substrate must bind stereospecifically in a correct orientation at the active site to form the enzyme–substrate complex, as

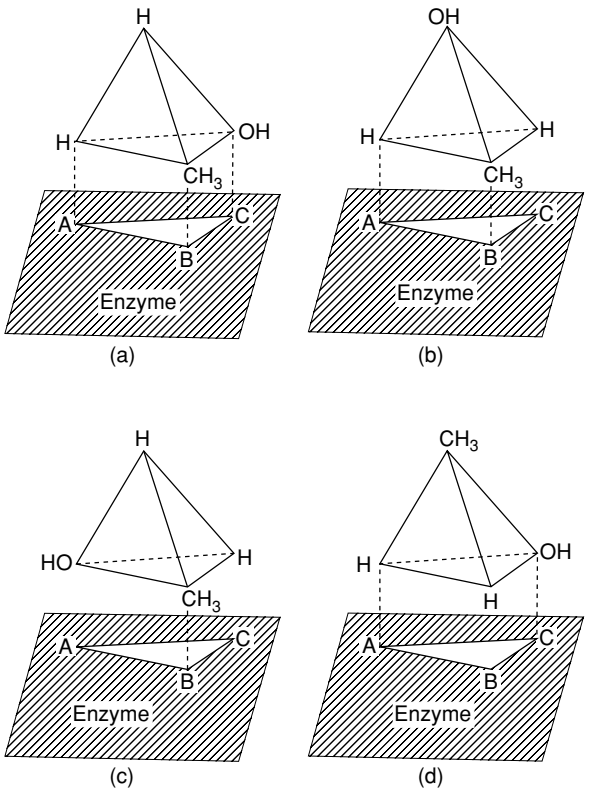

Figure 1 Schematic representation of several possible modes of orientation of ethanol on the surface of alcohol dehydrogenase. A, B, and C are binding points for two Hs, OH, and CH_3 of ethanol on the surface of the enzyme. Only (a) shows the ethanol bound properly with the enzyme surface.

shown in eqn (1), where E is the enzyme, S is the substrate, E·S is the enzyme–substrate complex, E·P is the enzyme–product complex, and P is the product. The obligatory E·S complex converts an intermolecular reaction to an intramolecular reaction. This increases the rate of an enzyme-catalyzed reaction compared with a noncatalyzed reaction by 10^3, 10^{15}, and 10^{22} times for bimolecular, trimolecular, and termolecular reactions, respectively.

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{E{\cdot}S} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{E{\cdot}P} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \mathrm{E} + \mathrm{P}. \qquad (1)$$

Binding of the substrate at the active site involves multiple (a minimum of three and up to 12) contacts between the substrate and the enzyme (Figure 1).

As a result of E·S, catalytic groups of the enzyme are 0.1–0.2 nm from the substrate bond to be transformed, usually by general acid–general base or nucleophilic–electrophilic catalysis (Figure 2). This proximity effect is equivalent to about a 10 M concentration of the corresponding intermolecular catalyst (His57 in Figure 2).

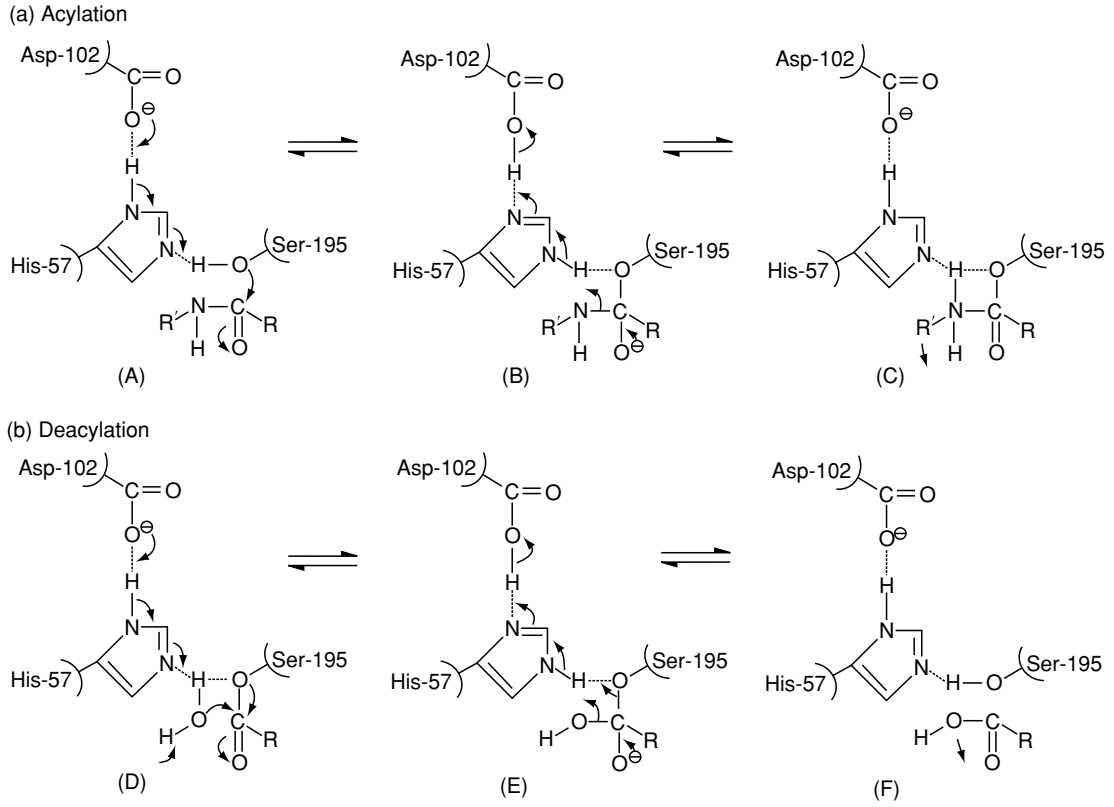

Figure 2 Proposed mechanism for α-chymotrypsin-catalyzed reactions. (a) Acylation. (b) Deacylation.

Table 1 Factors responsible for the rate enhancement of chymotrypsin-catalyzed hydrolysis of *N*-acetyl-L-tryptophanamide relative to the hydroxide ion and imidazole[a]

(1)	Rate constant for hydroxide ion catalysis	3×10^{-4} m^{-1} s^{-1}
(2)	Rate constant for imidazole catalysis	4.8×10^{-10} m^{-1} s^{-1}

	(d) General acid catalysis by imidazole (10^2) (see **Figure 2**)	4.8×10^{-2} s^{-1}

[a]At 25 °C; data from Bender ML, Kezdy FJ and Gunter CR (1964) The mechanism of action of proteolytic enzymes. XXXIII. The anatomy of an enzymatic catalysis. α-Chymotrypsin. *Journal of the American Chemical Society* 86: 3714–3721.

Catalysis by Distortion

There is a close complementarity between the structure and shape of a substrate and its binding position in the active site. This led Emil Fischer to the 'lock and key' analogy for the fit between a substrate and an enzyme. Later data established that enzymes permit some (small) latitude in the structure and shape of a substrate, leading to the 'rack mechanism' (Lumry) or the 'induced-fit' concept (Koshland). This results in a decrease in the activation energy needed, with a rate enhancement of 10^2–10^3.

Based on the factors above, an enzyme increases rates of reactions by 10^8–10^{28}, depending on how many substrates are involved in the reaction. Bender *et al.* in 1964 experimentally and theoretically determined rates of hydrolysis of *N*-acetyl-L-tryptophanamide by the three catalysts hydroxide ion, imidazole, and α-chymotrypsin (Table 1). There is remarkable agreement between the rate calculated by theory (Table 1, 4d) and determined experimentally (Table 1, 3).

Effect of Environmental Factors on Rates of Enzyme-catalyzed Reactions

Time, enzyme concentration, substrate concentration, nature of the substrate (including physical state), pH, temperature, solvent, activators, and inhibitors all affect rates of enzyme-catalyzed reactions.

Time

Enzyme-catalyzed reactions are time-dependent. Initially, the concentration of product, $[P]$, formed is linearly related to reaction time. How long the linear relation holds depends on the initial substrate concentration, $[S]_0$, in relation to the Michaelis constant K_m ($[S]_0$ at which $v_0 = 0.5\ V_{max}$; see eqn (2)), enzyme stability, pH, temperature and activators and reversibility of reaction. A tangent drawn to the initial part of the curve gives the initial velocity, v_0 ($= dP/dt$), an invaluable experimental parameter in enzymology.

Enzyme Concentration

For most enzyme-catalyzed reactions, v_0 is directly proportional to the enzyme concentration, $[E]_0$. Doubling $[E]_0$ doubles v_0. This is analytically very convenient since enzyme concentrations in biological systems are based on determination of v_0 under standard conditions. However, there are several cases where direct relations do not hold, as described by Whitaker in 1994.

Substrate Concentration

Because of the obligatory E·S (eqn (1)), the relation between $[S]_0$ and v_0 gives a right-hyperbolic plot (Figure 3). The extent of saturation of an enzyme with a substrate, to form E·S, is dependent on the relation of $[S]_0$ to K_m. At $[S]_0 << K_m$, the reaction rate is first order with respect to $[S]_0$ ($dP/dt = k[E]_0[S]_0/K_m$). At $[S]_0 >> K_m$, the reaction rate is zero order with respect to $[S]_0$ ($dp/dt = k[E]_0$), thereby giving the maximum velocity, V_{max}, under the conditions used. At $[S]_0 = K_m$, $v_0 = 0.5V_{max}$. When $[S]_0 \geq 0.01K_m \leq 100K_m$, the reaction rate is a mixture of first and zero order.

Enzyme-catalyzed systems that follow Figure 3 obey Michaelis–Menten kinetics

$$v_0 = k[\mathrm{E}]_0[\mathrm{S}]_0/(K_m) + [\mathrm{S}]_0). \qquad (2)$$

Substrate activation and inhibition and allosteric behavior cause deviations from this relation.

A plot of $1/v_0$ vs $1/[S]_0$ gives a linear relationship (Lineweaver–Burk equation), permitting V_{max} and K_m to be determined readily (Figure 3 insert).

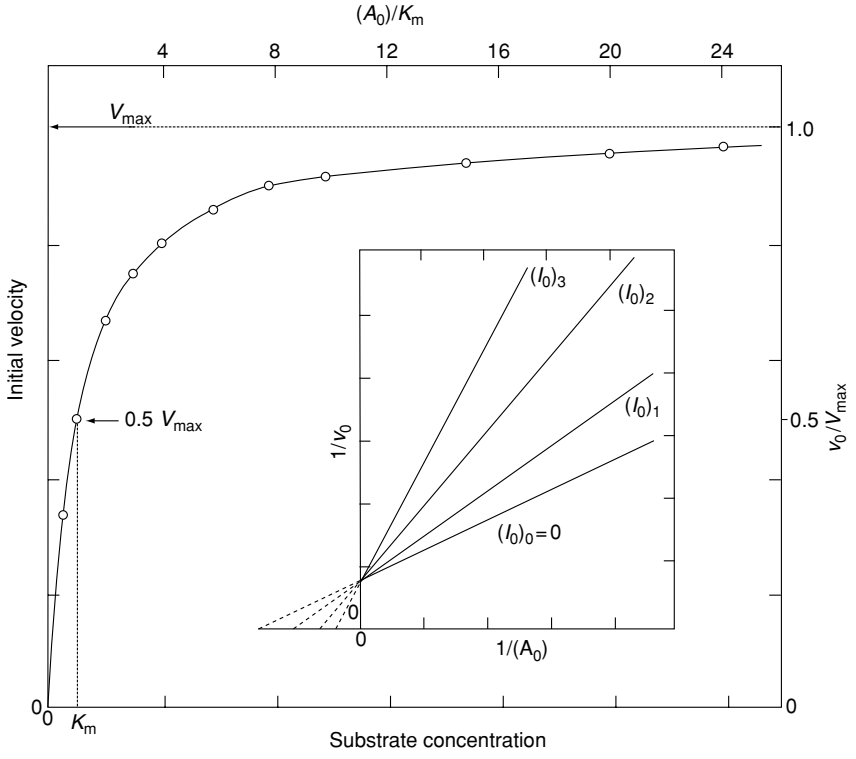

Figure 3 Relation between initial velocity, v_0, and initial substrate concentration, $[S]_0$, for an enzyme-catalyzed reaction. Insert: effect of three different concentrations of a competitive inhibitor on $1/v_0$ versus $1/[S]_0$ plot. $[I_0]_0$, $[I_0]_1$, $[I_0]_2$, and $[I_0]_3$ are 0, 0.5, 1.5, and 3.0 times K_i, respectively.

pH

Enzyme-catalyzed reactions are sensitive to the pH of the reaction, resulting in a pH optimum (maximum v_0). Examples of pH optima are: porcine pepsin, pH 2; horse-radish peroxidase, pH 6; bovine trypsin, pH 8; bovine milk alkaline phosphatase, pH 10; catalase, pH 4–9. The relation between pH and v_0, bell-shaped or sigmoidal, results from the effect of pH on the ionization of essential catalytic or binding groups in the active site of the enzyme and the effect of pH on stability of the enzyme as a protein. (*See* **pH – Principles and Measurement.**)

Temperature

Temperature affects enzyme-catalyzed reactions by influencing v_0, the stability of the enzyme as a protein and various equilibria, including K_m and pK_a of catalytic groups. There is a logarithmic effect of temperature on the rate of reaction (Figure 4, curve A), as predicted by the Arrhenius relation:

$$k = A_e^{-E_a/RT}, \qquad (3)$$

where k is a rate constant, A is a proportionality constant, T is temperature (degrees Kelvin), R is the universal gas constant, and E_a is the Arrhenius activation energy. At higher temperatures, depending on the specific enzyme, enzymes lose activity because of instability (see curve B, Figure 4), resulting in a decrease in activity. The temperature at which the maximum v_0 is obtained is the temperature optimum (apex of curve C, Figure 4) under the conditions used.

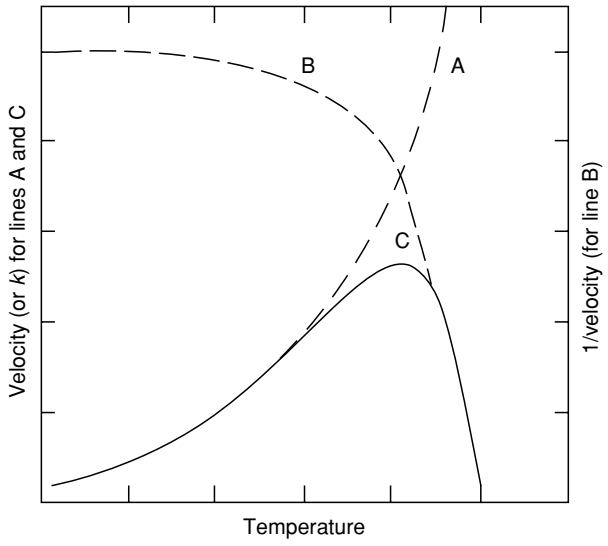

Figure 4 Effect of temperature on v_0 of an enzyme-catalyzed reaction. Curve A shows the effect of temperature on the velocity of substrate conversion to product. Curve B shows the effect of temperature on the stability of the enzyme. Curve C shows the actual effect of temperature on the velocity of substrate conversion to product.

Enzyme Activation

Any compound that increases v_0 when added to an enzyme–substrate system is an activator. These compounds can be cofactors (coenzymes or prosthetic groups), allosteric effectors, conformational effectors, or converters of proenzymes to enzymes (by proteolysis, usually).

Cofactors are small organic or inorganic molecules essential for enzyme activity. Organic cofactors are often built around the B vitamins (pyridoxine, thiamin, riboflavin, niacin, and pantothenic acid), whereas inorganic cofactors include Zn^{2+}, Mn^{2+}, Mo^{5+}, Mo^{6+}, Cu^{2+}, Mg^{2+}, Co^{2+}, Ca^{2+}, Fe^{2+}, Fe^{3+} and Cl^-. For example, more than 150 enzymes require Zn^{2+} as a cofactor. Coenzymes are bound via noncovalent bonds, whereas prosthetic groups generally are covalently bound to the protein. (*See* **Coenzymes.**)

Enzyme Inhibition

Any compound that decreases v_o when added to an enzyme–substrate system is an inhibitor. Inactivation caused by adverse pH, temperature or solvents is not included. Inhibitors occur naturally in many biological materials, may be produced synthetically, or may be metal ions (particularly Hg^{2+}, Pb^{2+}, Ag^+, Cu^{2+}). Enzyme inhibitors are important in pathogenic microorganism control, food storage, and food-quality preservation. Many pharmaceuticals are designed to inhibit specific microbial enzyme systems. Fungicides, herbicides, and insecticides are targeted to specific enzymes. Products of enzyme reactions are often inhibitors, since they resemble substrates. (*See* **Fungicides**; **Pesticides and Herbicides**: Types, Uses, and Determination of Herbicides; **Storage Stability**: Mechanisms of Degradation.)

Naming of Enzymes

Enzymes are named by adding the suffix '-ase' to the stem of the substrate name, e.g. *amylum* (Latin for 'starch')/*amylase*, *maltose/maltase*, *carbohydrate/carbohydrase*, *lipid/lipase*. However, there are several enzymes that act on a carbohydrate, for example, or a single enzyme may act on several substrates. Other trivial names are derived from the source of the

enzyme or the color of the purified enzyme. In 1955, the International Union of Biochemistry appointed members from many countries to a commission on enzymes, with the charge to develop a systematic method of naming enzymes. In 1961, a classification was adopted, based on dividing 'the enzymes into groups on the basis of the type of reaction catalysed and this, together with the name(s) of the substrate(s), provided a basis of naming individual enzymes'. Retention of the trivial name (already in general use) and addition of a four-digit numbering system were also adopted.

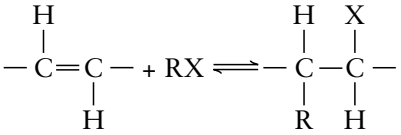
All enzymes fit one of six types of chemical reactions. These are (with the first digit of the number and a generalized reaction):

EC 1. *Oxidoreductases*
$AX + B \rightleftharpoons A + BX$, where X is H or e^-; B is oxygen etc.

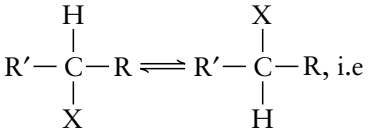
EC 2. *Transferases*
$AY + B \rightleftharpoons A + BY$, where Y is methyl, acyl, glycosyl, etc.

EC 3. *Hydrolases*
$AB + H_2O \rightleftharpoons AH + BOH$, where water is a substrate.

EC 4. *Lyases*



EC 5. *Isomerases*



D– $\rightleftharpoons$ L–, cis $\rightleftharpoons$ *trans*, keto $\rightleftharpoons$ enol, etc.

EC 6. *Ligases (synthetases)*
$A + B + AJP \rightleftharpoons AB + ADP + P_i$ (or AMP + PP), where P_i is inorganic phosphate.

The first digit of the EC number indicates the class to which the enzyme belongs, the second digit the subclass, the third digit the subsubclass, and the fourth digit serial number of the enzyme in its subsubclass. For example, the trivial name of the enzyme catalyzing the reaction shown in eqn (4) is alcohol dehydrogenase, the systematic name is alcohol:NAD^+ oxidoreductase, and the number is EC 1.1.1.1. The first digit indicates that it is an oxidoreductase, the second that the donor is a primary alcohol, the third that the acceptor is NAD^+ or $NADP^+$, and the fourth that the enzyme is alcohol dehydrogenase.

$$CH_3CH_2OH + NAD^+ \rightleftharpoons CH_3CHO + NADH + H^+. \quad (4)$$

The naming of an enzyme is complete when the organism, organ, and isozyme (if present) are indicated. For example, one of the two pig pancreas α-amylases is porcine pancreatic α-amylase-1, and the other is porcine pancreatic α-amylase-2. The isozyme number is assigned consecutively, on the basis of the fastest moving isozyme towards the anode by electrophoresis, as '1', and so on.

Uses in Food Processing

G B Quaglia and L Gennaro, Istituto Nazionale di Ricerca per gli Alimenti e la Nutrizione, Rome, Italy

Introduction

Enzymes play important roles in various aspects of food processing. In some cases they have made possible the development of new products and, in other cases, the improvement of traditional products. At least 75% of all industrial enzymes are hydrolytic in

action, and they are used for the depolymerization of natural substances. Proteinases remain the dominant type because of their wide use in dairy products processing (as coagulants); carbohydrases, used in baking, brewing, distilling, and especially in starch processing, represent the second largest group. The conventional distribution of the current world sales of enzymes is to assess them by their application sectors (dairy, detergent, starch, textiles, and other; **Figure 1**) This has been the practice for many years but it is important to consider the composition of section listed as other in **Figure 1**, in order to develop a view of future markets. The section covered by 'others' includes the following: alcohol, baking, fats and oils, flavor, fruit, and wine. The distribution of sales for 2005 is expected to be very different, because 'other' sectors will become the single largest part of enzymes sales, up to approximately 47% (**Figure 2**).

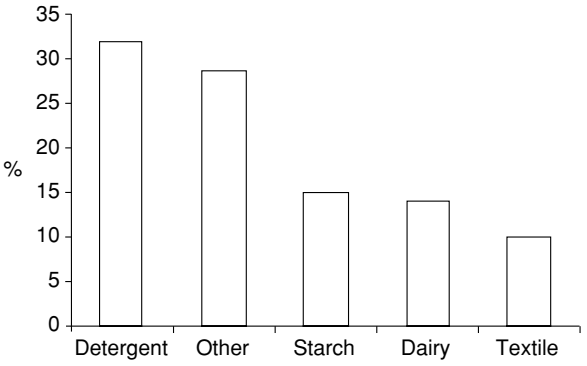

Figure 1 Distribution of enzymes sales. Data from Godfrey T and West SI (1996) Introduction to industrial enzymology. In: Godfrey T and West SI (eds) *Enzymology*, pp. 1–8. London: MacMillan Press.

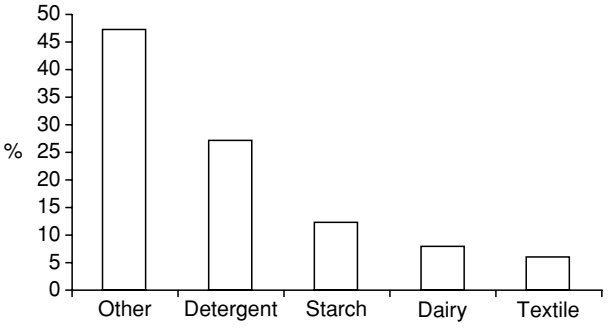

Figure 2 Forecast distribution of enzyme sales. Data from Godfrey T and West SI (1996) Introduction to industrial enzymology. In: Godfrey T and West SI (eds) *Enzymology*, pp. 1–8. London: MacMillan Press.

The advantage of using enzymes in food technology is primarily derived from two intrinsic properties: catalytic rate enhancement and specificity. The ability of enzymes to enhance reaction rates by many orders of magnitude may seem obvious, but it is particularly significant when these rates are achieved under very mild conditions. For most enzymes, this means an aqueous environment at atmospheric pressure, a pH within the range 3–9, and a temperature between 15 and 50 °C. In this way, the formation of chemically induced byproducts is vastly reduced. For example, in starch processing, chemical degradation yielded a product containing up to 6% of residual polysaccharide, as well as colored degradation products, the removal of which required a further purification step; the most recent enzymatic process produced a clean product containing at most 0.1% oligosaccharide. Moreover, the mild processing conditions facilitate the handling of sensitive substrates (such as foodstuffs) where extremes of temperature, pH, or pressure would be undesirable. Enzyme specificity is the other great advantage. Specificity, in fact, not only reduces interference by undesirable substrates but also minimizes the problem of unwanted byproducts, which are always a costly inconvenience in industrial processing. Finally, enzymes can be easily inactivated by thermal or chemical means once the desired degree of conversion has been achieved.

The versatility of enzymes in food processing will be evident by the numerous examples cited in this work. There are a number of ways in which an enzyme preparation can be presented to the market: as an amorphous or microcrystalline powder, in solution, or in some immobilized form. The nature of the preparation will be determined largely by the requirement of every industry. Liquid preparations are often preferred, because volume measurements are simple, but preparing the enzyme in an insoluble form would not only facilitate recovery of enzymes, but also permit reuse, which has obvious economic advantages. For this reason immobilized or bound enzymes have been developed by physically or chemically binding the enzyme to an insoluble support. The main cases of food processing in which immobilized enzymes are used are the conversion of glucose to fructose by glucose isomerase in the production of high-fructose syrups, and the clarification of fruit juices by means of pectic enzymes.

Any organism, whether plant, animal, or microorganism, is a potential source of enzymes. However, the nature of the source dictates the availability, the cost of source material, the ease of recovery, and many other factors (**Table 1**). The majority of enzymes used on an industrial scale are from microbial sources (**Table 2**). One exception was that of rennin, the protease derived from calf stomach, which is used in cheese-making. Even here a microbial substitute,

Mucor rennin, is now being used in a significant proportion of the dairy industry worldwide, and a recombinant chymosin (the main rennet enzyme) will be produced on a large scale. The application of genetic engineering, particularly recombinant DNA technology, is in fact having a major impact on the development of new sources of industrial enzymes for food industry, even if in western countries there is an increasing tendency among consumers not to approve the application of genetically engineered organisms to food and food ingredients.

Selected examples of enzymes used in food processing are mentioned below, and some of these will be discussed in detail:

- Meats are tenderized using the enzymes papain, ficin, and bromelain.
- Invertase is added to the fondant centers of chocolate-covered cherries. This enzyme hydrolyzes some sucrose, thereby decreasing the number of sugar crystals in the fondant, and softening the chocolate center.
- Glucose isomerase is used to convert glucose to the sweeter fructose. This process is carried on commercially with an immobilized enzyme system.
- Pectinases are used commercially to break down pectin molecules in certain fruit juices such as apple juice in order to avoid a hazy appearance; clear, sparkling juice is the final product.
- Rennet is the crude extract of the protease rennin. It is widely used to clot milk in the making of cheese.
- An enzyme system involving glucose oxidase and catalase has been used to remove traces of oxygen in tightly packaged food products. This system is also used to remove small amounts of glucose from white eggs before drying them. Browning may occur during storage if white eggs contain even small quantities of glucose.

Table 1 Sources of major industrial enzymes

Enzyme	*Process*	*Source*
Proteases – alkaline	Detergents	Bacterial
Proteases – acid	Cheese-making	Animal, fungal
Proteases – neutral	Various	Bacterial
Amylases	Starch industry	Bacterial, fungal
Isomerases	High-fructose syrups	Fungal
Pectinases	Wine, beer, condiments	Fungal
Lipases	Various	Bacterial, fungal, animal

Use in Tenderizing Meats

The Structure of Meat

It has been established beyond doubt that the consistency of meat is governed by two principal factors: the quantity and the properties of the muscle tissue collagen and the mechanically contractile state of the muscle. (*See* **Meat**: Structure.)

Collagen fiber consists of triple-helix tropocollagen molecules that are linked by covalent bonds, providing a structure of high mechanical tenacity. In muscle tissue collagen both thermolabile and thermostable bonds have been identified. The thermolabile linkages are prevalent in the collagen of young animals, and are readily broken when the meat is cooked. In older animals the thermostable bonds predominate, with the result that the meat has harder collagen fibers when cooked, i.e., tougher meat. Both the amount of collagen and the type of bond are thus important in determining meat consistency. A further important factor is the state of contraction of the muscle protein.

Once the animals have been slaughtered, chemical bonds form between the thick and the thin filaments

Table 2 Various sources of enzymes

General source	*Specific source*	*Advantage/disadvantages*	*Example*
Animals	Human blood	No longer a viable source. Available in vast quantities	Pancreatic lipase
	Bovine, porcine, and ovine tissues	Enzymes are often of low stability	Rennin
		Purification often complex	Trypsin
Plants	Leaves, fruit	Purification can be a problem	Papain
Microorganism	Bacterial, algal, fungal, and yeast	Large-scale production	Protease
		Technology advanced	Amylase
		Purification often simple	Lipase
		High yields	
		Wide variety of unusual enzymes available	
		Limited range of microorganism approved for use in food industry	

From Cowan DA (1994) Industrial enzymes. In: Moses V and Cope RE (eds) *Biotechnology*, pp. 311–340. UK: Harwood Academic Publisher with permission.

that make up the mobile part of the muscle. It is these bonds that make the muscle hard and reduce its stretching properties. Hardness is most noticeable in highly contracted muscle, where a compact and inelastic structure forms.

In order to make it tender, meat is subjected to 'ripening' ('hanging') once rigor mortis (a stiffness of the muscle resulting from glycolysis) ceases. The process is widely exploited to make the meat not only tender, but also tasty and more digestible. This process takes place when the carcass is cut into sides and quarters. Hanging entails keeping the sides for several days in controlled temperature and humidity chambers. The mode of action of the tenderizing process during this ripening and conditioning is not entirely understood. It is suggested that during this period there is a partial dissolution of the Z-lines, whose function is to anchor the thin filaments (myofibrils) of the muscle tissue. During such a process, dissociation of the thin filaments from the Z-lines leaves the entire muscle structure more stretchable and tender. However, the partial degradation of the Z-lines is due to the action of a specific proteolytic enzyme, which has been given the name of calcium-activated sarcoplasmatic factor (CASF). (*See* **Meat**: Structure.)

Artificial Tenderizing

The normal tenderization process thus seems to involve one or more specific proteases present in the muscle cells; and it is reasonable to expect that the process can be reproduced artificially with the use of proteases. This practice was already in use among the pre-Columbian inhabitants of the Americas. According to Hernan Cortés, the conquistador of Mexico, these people would wrap up pieces of meat in papaya leaves. The papain (a proteolytic enzyme) naturally present in the leaves acted on the structure of the meat, making it tender.

Artifical tenderization is achieved by resort to various sulfhydryl proteases of vegetable origin, such as papain (from the papaya plant), bromelain (from pineapple), and ficin (from the fig tree) or microbial proteases. Factors such as pH, the concentration of the enzyme, and temperature also influence the enzyme action and the degree of tenderization.

Since the enzymes employed in this field are inactive at low temperature (0–10 °C) but increase in activity as the temperature rises (65–80 °C), becoming inactive again at 82 °C, the tenderization process, for all practical purposes, begins and ends with cooking. The problem, then, is to cause the enzyme to act in such a way as to produce a controlled and homogeneous tenderizing, since excessive action during the cooking process would produce a formless lump of tissues.

Tenderization by enzymes is achieved through the action of the enzyme on the connective tissue (collagen and elastin) of the meat, and cannot be compared, in terms of its mechanism, with the natural tenderizing process described earlier.

Enzymes come in powder form, for dusting on the surface of the meat, or in liquid form; in this case the meat is either immersed in solutions of known concentrations or (a more effective method) by injecting the enzyme into the blood stream a short time before slaughtering. This is known as pretenderizing. The method in this case relies on the fact that (1) the animal's vascular system offers an excellent means of distribution among the body tissue; (2) the heart is an efficient pump; (3) blood acts as a diluent and insures uniform distribution of the enzyme; and (4) the enzymes used are safe food ingredients.

The time elapsed between pretenderizing and slaughtering – from 2 to 20 min – allows adequate distribution in the tissues. The amount of solution will vary with the weight, age, and sex of the animal. The enzyme does not act immediately upon introduction into the animal, since the temperature is below optimum, but begins to do so when the meat is cooked.

Apart from the difficulty of achieving homogeneous distribution throughout the tissues, artificial tenderizing with enzymes is further limited by the fact that the enzymes used are of low specificity, in that they act on both connective tissue (collagen and elastin) and on contractile (myofibrillary, muscle structure) protein. These two aspects make it difficult to control the tenderization process.

To overcome these constraints, collagenases are now starting to be used. Crude collagenases are highly specific proteases which act on native or denaturated collagen but not on muscle tissue, so that the dissolution of the actomyosin and Z-line proteins is restricted, while the connective tissue network is weakened. Collagenases are obtained from aerobic bacteria (*Achromobacter* spp.) and *Clostridium* strains. The outlook is promising for their application in this field.

Use in Hydrolyzing Starch

The conversion of native starch, which is the basic constituent of many vegetable products, such as maize, and potatoes, to soluble sugars is the most important application of enzymes in food industry; and in fact the process has almost entirely supplanted that of acid hydrolysis for glucose production. (*See* **Starch**: Structure, Properties, and Determination.)

In the last 30 years, as new enzymes have become available, starch hydrolysis technology has been

transformed. There has been a big move away from acid and today the vast majority of starch hydrolysis is performed using enzymes. Furthermore, in the 1970s, an enzyme technique made possible the production of syrup sweeter than glucose – high-fructose syrup. The production of this syrup has significantly boosted the growth of the starch industry in certain countries.

Depending on the enzymes used, syrups with different compositions and physical properties can be obtained from the starch (Table 3). The dextrose equivalent (DE) value is used as an indication of the degree of hydrolysis of a syrup. The DE value of starch is zero, and that of dextrose is 100. Syrup with DE values from 35 to 43 are still widely produced by acid hydrolysis, despite the drawbacks mentioned here. However, due to the formation of byproducts, it is difficult to produce low- and high-DE syrups of high quality in this way.

There are essentially five groups of enzymes involved in the hydrolysis of starch: the endo-amylases (Enzyme Commission (EC) 3.2.1.1) act primarily on the α-1,4 linkages, and products of reactions are oligosaccharides of varying chain lengths.

The exo-amylases (amyloglucosidases or glucoamylases; EC 3.2.1.3) act on the same substrates as endoamylases, but they are also able slowly to cleave α-1,6 linkages. They act externally on substrate bonds from the nonreducing end and produce low-molecular-weight products.

The debranching enzymes (such as pullulanase, EC 3.2.1.41, and isoamylase, EC 3.2.1.68) act exclusively on the α-1,6 linkages.

A fourth group, the isomerases (EC 5.3.1.5), act on glucose syrups to convert them to fructose syrup.

Finally, cyclodextrin glycosyltransferase (CGTase, EC 2.4.1.19) is an enzyme capable of hydrolysing starch to a series of nonreducing cyclomaltooligosaccharides referred to as cyclodextrins.

There are three basic steps in enzymatic starch conversion to glucose: gelatinization, liquefaction, and saccharification. In the first step, the raw starch is heated to above 40 °C to disrupt the starch granules and expose the polymer to enzymatic action (Figure 3). In its native granular form, starch resists attack from hydrolytic enzymes, so that the application of these (enzyme hydrolysis) calls for acid or enzyme pretreatment in order to bring about depolymerization and consequent reduction in the viscosity typical of gelatinized starch. The starch slurry (pH 6.5) is gelatinized by cooking at high temperature with α-amylase. The gelatinized starch is then liquefied by thermostable α-amylase to a soluble dextrin hydrolysate with a DE of 5–15. After liquefaction, the pH of slurry is adjusted

Table 3 Classification of enzymes involved in the commercial production of starch syrups, maltodextrins, and cyclodextrins

Type	*Common name*	*Source*	*Substrate specificity*	*Optimum*	
				pH	*Temperature (°C)*
Endoamylase	Bacterial amylase	*Acillus subtilis*	α-1,4-Glycosyl	6.0	65–70
		Bacillus licheniformis	α-1,4-Glycosyl	5.0–7.0	90
	Fungal α-amylase	*Aspergillus oryzae*	α-1,4-Glycosyl	4.5	50–60
Exoamylase	Amyloglucosidase	*A. niger*	α-1,4-Glycosyl α-1,6-Glycosyl	4.0–5.0	60
	Bacterial β-amylase	*Bacillus* spp.	α-1,4-Glycosyl	5.0	55–60
		Clostridium spp.	α-1,4-Glycosyl	5.5–6.0	75–85
α-1,6-amylase	Pullulanase	*Klebsiella aerogenes*	α-1,6-Maltotryosyl	5.0	60
	Isoamylase	*Pseudomonas* spp.	α-1,6-Heptasacch	4.0	50–55
Exo-α-amylases	Exomaltotriohydrolase	*Streptomyces griseus*	α-1,4-Glycosyl		
		B. subtilis	α-1,4-Glycosyl		
	Exomaltotetrahydrolase	*B. circulans*	α-1,4-Glycosyl		
		Pseudomonas stutzeri	α-1,4-Glycosyl		
	Exomaltopentahydrolase	*Pseudomonas* spp.	α-1,4-Glycosyl		
	Exomaltoexahydrolase	*B. subtilis*	α-1,4-Glycosyl		
		B. circulans	α-1,4-Glycosyl		
Isomerase	Glucose isomerase	*B. circulans*	Aldo/keto pentose Aldo/keto hexose	8.2	65
Glucanotransferase	Cyclodextrinase	*B. macerans*	α-1,4-Glycosyl	5.0	50
		Thermoanaerobacter	α-1,4-Glycosyl	4.5	90
Endo-/exocellulase	Fungal cellulase	*Trichoderma reesei*	β-1,4-Glycosyl		
Endoprotease	Bacterial protease	*B. licheniformis*		6.5	90
		B. subtilis		6.5	65.70

Data from Guzman-Maldonado H and Paredes-Lopez O (1995) Amylolytic enzymes and products derived from starch: a review. *Critical Reviews in Food Science and Nutrition* 35: 373–403.

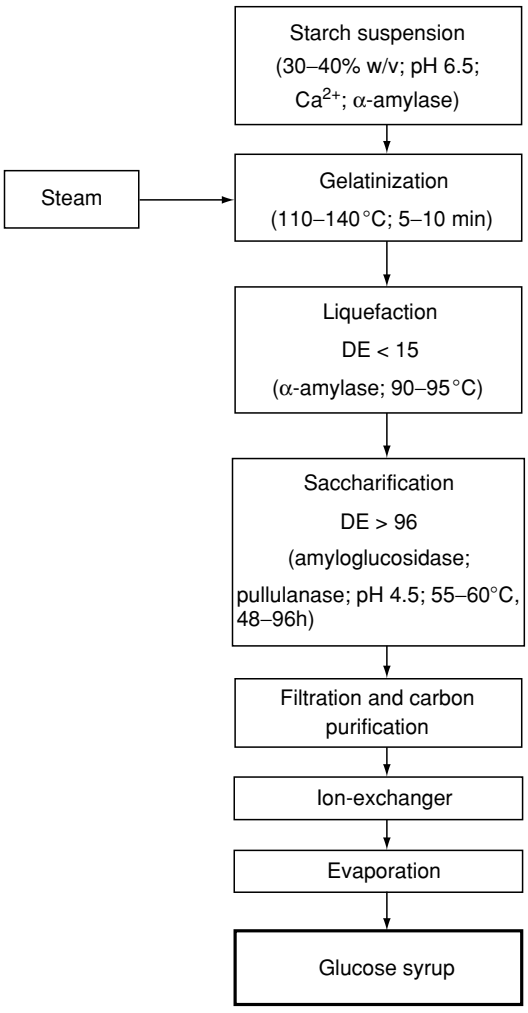

Figure 3 Production of glucose syrups. DE, dextrose equivalent.

to 4.5 and the temperature lowered to 60 °C. Amyloglucosidase is now added and the saccharification reaction is allowed to continue for 48–96 h in a stirred tank until the maximum level of glucose is reached.

Replacing soluble amyloglucosidase with its immobilized form allows for using the same enzyme batch several times in order to shorten the hydrolysis period and to apply a continuous process. However, the use of immobilized amyloglucosidase is less efficient in the production of glucose syrups than the soluble enzyme, giving a maximum DE value of 96% instead of 98%. The reason for this lower maximum DE is the increased formation of isomaltose and the decreased hydrolysis of the high-molecular-weight oligosaccharides.

The carbohydrate composition of typical glucose syrup is as follows:

- 94–98% glucose
- 1–3% maltose
- 0.3–0.5% maltotriose
- 1–2% higher saccharides.

It is possible, in industrial processing, to raise the sweetening power of glucose syrup by converting part of the glucose to fructose by isomerization with immobilized glucose isomerase obtained from a selected strain of *Bacillus coagulans*. This catalyzes the conversion of the glucose syrup in a fructose syrup containing at least 42% fructose.

Finally, it is worth mentioning cyclodextrins, which have been studied for nearly a century but not utilized for food applications until the 1990s because they were too expensive and there was insufficient information to declare them nontoxic. Now, their use is permitted in a variety of food applications.

In a so-called nonsolvent process a reactor is filled with starch and the selected enzyme under sterile conditions (because no chemicals are present to prevent microorganism growth); after the completion of the reaction, heat or acid inactivates the CGTase, and water is evaporated.

Cyclodextrins can stabilize volatile materials, such as flavors and spices, and can also stabilize emulsions of fats and oils, shielding them from oxidation and preventing rancidity. They can be used to debitter citrus juices, and can be widely used in the solubilization of organic compounds. Their market is still limited, because of their cost, but a novel production of cyclodextrins in transgenic potatoes has been developed at lower production costs.

Use in Baking

The use of wheat and other cereals as a source of flour for baking (particularly in the production of bread, probably the major staple food item in the western world) provides a demonstration of a natural enzymatic process which can be artificially modified to optimize product quality. Amylases are a natural constituent of flour. The levels of amylase activity in flour are strongly influenced by the climatic conditions in which the grain was grown. A high amylase content, the result of a moist climate, results in high dextrin production during baking. The resulting dough has low water retention and tends to be 'sticky,' while the loaf is crumbly and dry. A dry environment yields flour with a low amylase content. As a consequence, the dextrin yield is low, fermentative gas production is poor and loaf size is small. (*See* **Bread**: Breadmaking Processes.)

Normal flour, milled from sound wheat, contains significant amounts of β-amylase, but little or no α-amylase. β-Amylase can produce some maltose to aid fermentation without the presence of α-amylase,

but the amount produced is relatively small. The supplementation of dough with α-amylase affects the functional properties of the dough and may determine characteristics that are critical for automated manufacturing processes. Largely for this reason, α-amylase, sometimes in conjunction with protease, is commonly used by the baking industry.

Malted barley has traditionally served as the primary source of added α-amylase. This was the practice years ago when bread formulations were quite lean and contained relatively little sugar. Today, the primary reason for adding amylases to baked products is to improve the processing conditions as well as the overall quality of the baked product. Although barley malt is still used, supplementation with fungal and, to a lesser degree, bacterial amylases has become more common.

Cereal amylases remain active until the temperature reaches about 70 °C. They can cause some additional starch hydrolysis after the starch has gelatinized. Thus, cereal amylases, whether added to the flour (as a supplement) or native (due to sprouting), can produce excessive hydrolysis in high-moisture bread products if too much is present in the formulation.

Bacterial amylases (from *Bacillus* species) are generally the most heat-stable (> 100 °C); some remain active all the way through the bread baking cycle. They must be considered to be most problematic in bread production since they can continue to hydrolyze the starch throughout the baking process. In fact, some bacterial amylases are capable of continuing working even after baking and packaging and while sitting on the grocery shelf. Excessive starch hydrolysis results in poor loaf characteristics, including low loaf volume and dense, gummy crumb texture. The heat stability of bacterial α-amylase is of less concern in products such as cookies and crackers, which have a higher baking temperature and contain little water.

Fungal α-amylases, usually from *Aspergillus oryzae, A. niger, A. awamori*, or species of *Rhizopus*, is normally used to supplement the amylolytic activity in flour. Enzymes from these sources can raise the levels of fermentable monosaccharides and disaccharides of dough from a native level of 0.5% to concentrations that promote yeast growth. The sustained release of glucose and maltose by added fungal and endogenous enzymes provides the nutrients essential for yeast metabolism and gas production during panary fermentation. The *A. oryzae* α-amylase is sometimes favored for baking applications since this fungal enzyme is heat-labile at 60–70 °C and does not survive the baking process. Its thermolability prevents enzymatic action on the gelatinized starch in the finished loaf, which would cause a soft or sticky crumb.

Even proteolytic action on the gluten component is vital to the quality of the product. The protein component makes up a relatively small percentage of the flour, compared to starch, but it is responsible for the formation of gluten, the unique viscoelastic protein network peculiar to wheat. Because gluten protein is primarily responsible for the mixing and sheeting behavior of dough, it is an obvious candidate for enzymatic modification by protease. In particular, supplementation with proteases helps to break down the gluten protein so that the dough is softer and more extensible. Since cereals usually have low proteinase levels, supplementation with fungal (*A. oryzae*) proteinase is routine. The more thermostable bacterial proteases are generally used only in biscuit and pizza dough where the higher cooking temperature rapidly inactivates the enzymes and prevents overproteolysis and stickiness. While most commercially available proteases contain relatively nonspecific endo- and exoproteolytic activity, the units of activity will have been determined on nongluten substrate protein. This can make it difficult to choose the more efficient enzyme to hydrolyze the gluten protein in a particular process. The ability of any protease to hydrolyze the gluten effectively must be determined by experimentation in an appropriate formulation and processing scheme. Because the majority of the effects desired on wheat doughs involve altering the viscosity or rheology of the dough, an endoprotease is more effective than an exoprotease. Furthermore, protease treatment improves crumb characteristics, and the improved flow properties of the dough contribute to better, more uniform product shape.

Enzymes in the group of disulfide reductase/disulfide isomerase are being investigated as possible contributors to controlled and effective gluten modification.

Finally, it was seen that, in bread making, treatments with fungal (or bacterial) enzymes lower the viscosity of bread dough, improving the ease of manipulation by manual workers or machines. Furthermore, favorable effects on taste and crust properties are observed, and the storage characteristic of breads change, giving a product with a softer, more compressible crumb that firms more slowly and keeps longer.

Use in Juice Clarifying

The Fruit Juice Production Process

With certain fruit juices, an initial phase consists of the transformation of plant tissue into a semifluid system made up of cells, fragment of cell walls, and cellular liquid, and a second phase where the juices

are extracted by mechanical separation (pressing, straining, centrifugation).

Once extracted, the juice can be clarified further. Where problems arise in the production process, especially where demand is for limpid (clear) juices, they are for the most part due to the presence of cell wall material, of variable composition, during the ripening process – cellulose, hemicellulose and, at a high degree of esterification, pectin (polymethylgalacturonic acid). In unripe fruit, pectin is present in an insoluble form whereas, on ripening, it is in part broken down into a more soluble form and the fruit becomes soft.

As a result of this partial solubility, some of the pectin passes into the fruit juice, which becomes viscous and hard to separate from the pulp. This explains the low yield from extraction of the juice and of its soluble components, and the fact that juice so extracted is difficult to filter and clarify.

Enzymes in Fruit Juice Clarification

The use of enzymes (Table 4) to overcome the difficulties described is becoming more widespread today with a twofold aim (Figure 4):

- In the treatment of the ground pulp – to raise the juice yield, to improve the extraction rate for certain flavor and color components, and to obtain a partial or total liquefaction of the tissue (for homogenized foods, nectars, juice, and pulp concentrates);
- In the treatment of the juice – to reduce viscosity and facilitate concentration, to clarify in order to obtain a limpid product; and to increase the speed of filtration and thus prevent the formation of precipitates in the juice.

Commercial pectolytic enzymes, commonly referred to as pectinases, are a mixture of pectin esterase (EC 3.1.1.11), which triggers the deesterification of the pectin to pectic acid and methanol; polygalacturonase (EC 3.2.1.15), which hydrolyzes the internal bond of pectic acid; and pectin lyase (EC 4.2.2.10), that splits the glycosidic bonds or either pectate or pectin. These enzymes are chiefly produced from molds of the *Aspergillus* genus. They are used to clarify apple and grape juices and wine. All these preparations contain traces of other enzymes as well, such as cellulase, amylase, protease, and xylanase: when added to the product they bring about the hydrolysis of the soluble pectin and the elimination of its colloidal properties. The process is accompanied by the flocculation and then the removal by filtering or centrifugating of any particles so formed. Traditionally, the industrial utilization of pectic enzymes in fruit juice processing has been conducted in conventional batch reactors using soluble enzymes. Unfortunately, after each cycle of operations the enzymes cannot be recovered for further use, and are inevitably present in the final product, altering organoleptic properties. In this context, the immobilization of pectolytic enzymes has proven to be very advantageous for continuous processing.

Another aspect of using enzymes in fruit juice processing is wine-making; the ideal enzyme preparations for wine-making are different from those for fruit juice processing. In fruit juice processing the enzymes are inactivated very shortly after they have done their job, for example by pasteurization. In wine-making no such heat treatment is imparted. The enzymes therefore maintain their activity over a longer period, and side activities may adversely influence wine quality during storage. During wine-making, enzymatic reactions begin during the ripening of the grapes and continue through the harvest, alcoholic and malo-lactic fermentations, clarification, and even after bottling. The wine-makers still have the power to influence a few of the reactions with the tools of pectinolytic and glycosidic enzymes. These speed up the natural process of wine-making, make the fullest use of facilities and equipment, and improve the quality of wine. Pectic enzymes (from fungi, typically *A. niger, Penicillium notatum* or *Botrytis cinerea*) are used to reduce haze or gelling of grape juice at various stages of the wine-making process. A β-glucanase prepared from a selected strain of *Trichoderma* is now being used in wine-making as an adjuvant for filtering and clarifying purposes of wines made from grapes attacked from the fungus *B. cinerea*. In fact, the *Botrytis* fungus produces β-glucans (polymers of glucose with a high molecular weight), which pass into the wine. These large molecules hinder clarification and rapidly clog filters.

Finally, an improvement of our knowledge of grape composition and of *Saccharomyces cerevisiae* would allow the creation of a 'superyeast strain' by genetic manipulation to depectinize the grape must, to extract and release specific components such as color (especially in the case of red wine) or aromas, or to make the malo-lactic fermentation by heterologous cloning of enzymes from other microorganism.

Use in Cheese Production

Milk Clotting

The entire cheese-making process is based on milk clotting. Clotting can be brought about by natural or induced acidification to pH 4.6 (the isoelectric point for casein) or by enzyme action (Figure 5). The preparation most frequently used for this purpose is rennet, a crude proteolytic extract obtained

Table 4 Classification of pectic enzymes acting on pectins or pectic acids

EC suggested name	*Common name*	*EC number*	*Substrate*	*Action pattern*
Deesterifying enzymes				
Polymethylgalacturonate esterase (PMGE)	Pectinesterase	3.1.1.11	Pectin	Random
Depolymerizing enzymes				
Hydrolases				
Endopolygalacturonase (endo PG)	Polygalacturonase	3.2.1.15	Pectate	Random
Exopolygalacturonase 1 (exo PG1)	Polygalacturonase	3.2.1.67	Pectate	Terminal
Exopolygalacturonase 2 (exo PG2)	Polygalacturonase	3.2.1.82	Pectate	Penultimate bonds
Endopolymethylgalacturonase (endo PMG)	Pectin hydrolase		Pectin	Random
Exopolymethylgalacturonase (exo PMG)	Pectin hydrolase		Pectin	Terminal
Lyases				
Endopolygalacturonate lyase (endo PGL)	Pectate lyase	4.2.2.2	Pectate	Random
Exopolygalacturonate lyase (exo PGL)	Pectate lyase	4.2.2.9	Pectate	Penultimate bonds
Endopolymethylgalacturonate lyase (endo PMGL)	Pectin lyase	4.2.2.10	Pectin	Random
Exopolymethylgalacturonate lyase (exo PMGL)	Pectin lyase		Pectin	Terminal

Pectic enzymes acting on oligogalacturonates have not been included in this table because they are not very abundant and are of little interest for industrial pectin degradation. Enzymes have been classified and named according to the Enzyme Commission (EC) (IUPAC-IUB recommendations). Data from Alkorta I, Garbisu C, Liama MJ and Serra JL (1998) Industrial applications of pectic enzymes: a review. *Process Biochemistry* 33: 21–28.

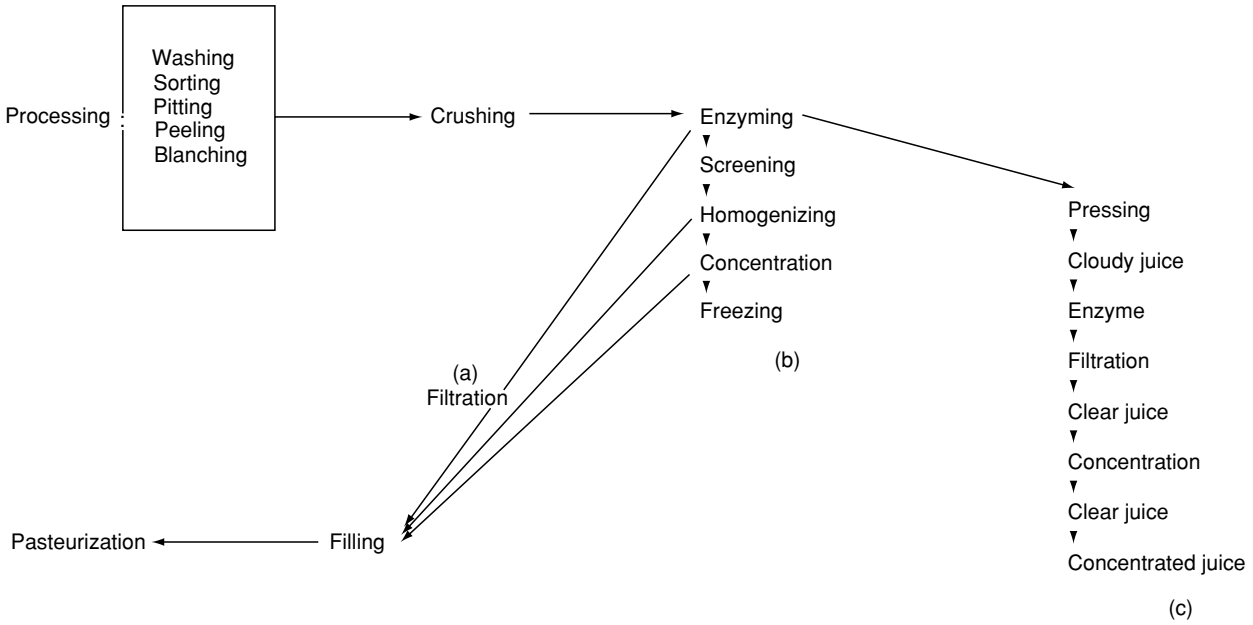

Figure 4 Use of enzymes in the preparation of (a) juices, (b) homogenates, and (c) clear juices.

from the fourth stomachs of calves, piglets, lambs, and kids and containing 85–95% chymosin and 10–15% pepsin.

In milk, primary soluble proteins are the whey proteins α-lactalbumin and β-lactoglobulin. The insoluble proteins found in the colloidal particles include casein micelles. κ-Casein is a calcium-insensitive protein which forms a protective layer around the calcium-sensitive caseins (α_s1-, α_s2-, β-, and γ-), resulting in stable casein micelles.

Chymosin, or rennin (EC 3.4.23.4), triggers the clotting of milk once the equilibrium of charges in the casein micelle has been destabilized. It causes the cleavage of κ-casein at the Phe 105–Met 106 bond, which results in a release of hydrophilic glycopeptide which passes into the whey, while the *para*-κ-casein remains in the micelles, forming the coagulum needed to produce cheese. (*See* **Milk**: Physical and Chemical Properties.)

Milk-Clotting Enzymes

With the marked expansion in world cheese production registered since the 1960s, it has become increasingly difficult to obtain stomachs of young ruminants

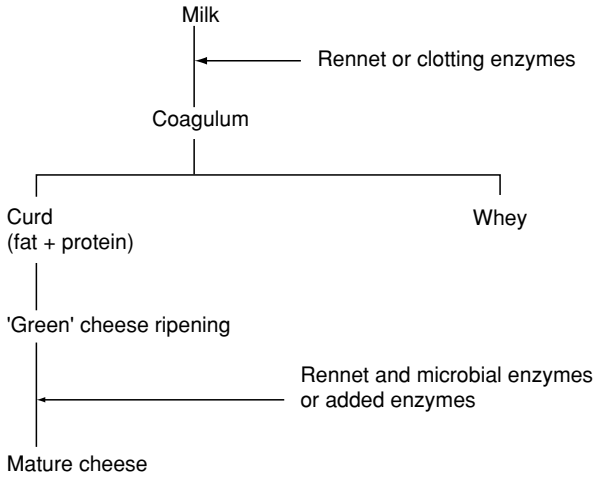

Figure 5 Flow diagram for cheese manufacturing.

from which chymosin can be extracted. In the USA in particular, a general reduction in the number of calves available for slaughter has reduced the supply of rennet, increased the price, and stimulated interest in developing rennet substitutes. Several rennet substitutes have been developed, including bovine rennet from adult cows, fungus proteinase, and other proteolytic enzymes. However, they have a much greater level of nonspecific proteolytic activity, and higher thermostability, which more completely degrade the milk proteins to peptides, leading to a reduction in yield and poor flavor development in some types of cheese. Consequently, there have been numerous attempts to produce chymosin in microorganisms.

Several of these substitute preparations (Table 5) are a mixture of rennet and pepsin but newly developed recombinant DNA techniques have led to their use in cloning the calf chymosin gene in *Escherichia coli*. Recombinant chymosin contains only the protein resulting from the expression of the sequence of one gene and thus contains one variant only. Patents have been taken out for the production of milk-clotting enzymes from *Endotia parasitica, Mucor pusillus* var. Lindt and *Mucor miehei*. Varieties of cheese have been made from recombinant chymosin and evaluated in comparison with cheese produced using the natural enzyme. No significant differences could be detected between them, with regard to the recovery of milk solids, the rate of proteolysis during ripening, or in the characteristics of the final cheese product. Under US law, these enzymes may be used for making any type of cheese.

Cheese Ripening

Although some varieties of cheese are consumed fresh, most varieties that have been subjected to rennet clotting are ripened for periods ranging from 4 weeks to 2 years, the actual duration being in an approximately inverse relation to the humidity content. During the ripening process, a series of chemical and biological changes takes place, in the course of which proteins, lipids, and residual lactose break down into primary and secondary products, such as peptides and fatty acids (lactic, propionic, etc.).

In the right combination, all these components converge to produce the characteristic flavor of the respective cheeses. The cost entailed in the ripening operation has a considerable influence on the cost of the finished product. Accordingly, if it is possible to shorten the ripening time without adversely affecting quality, the capital outlay required can be contained, not to mention the risk of freak retarded fermentation phenomena. (*See* **Fermented Milks**: Types of Fermented Milks; Other Relevant Products.)

Accelerated Ripening Enzymes and Use of Lipases

The ripening time can be reduced by:

- adding, during the manufacturing process, enzymes which are not produced by lactic bacteria;
- introducing additional lactic bacteria (as starters) or extracts of lactic bacteria (as starters) or extracts of lactic bacteria cells;
- using slurry techniques.

Directly incorporating enzymes into the milk undergoing treatment can be costly but has the advantage of insuring their homogeneous distribution. Proteases, peptidases, lipases, and decarboxylases are used for this purpose (Table 6). While the ripening of certain varieties (blue, Parmesan, etc.) is markedly influenced by lipase action, proteolysis is in all types of cheese the primary biochemical event in determining flavor and texture. Neutral proteases of bacterial origin such as neutrase (a metal protease, effective in speeding up the ripening process whether or not inserted into positively charged liposomes) or, again, a serine protease obtained from *Brevibacterium linens* (the main component of surface microflora on cheese), have proved to yield an acceptable product even if elasticity is somewhat sacrificed at times. Moreover, if the crude enzyme containing the protease (but amino peptidase as well) is used, better results can be achieved in terms of the release of peptides and amino acids without any bitter taste developing.

Studies on food and analytical-grade commercial lipase have shown that these have a different specificity in the hydrolysis of short-chain fatty acids and a different specificity in the release of the free fatty acids among them. In fact, depending on the chain-length specificity of a given lipase, its addition to a milk product may enhance the flavor of the cheese,

accelerate the cheese ripening, or assist in the preparation of enzyme-modified cheese (EMC), an important commercial flavor used in the USA for the manufacture of dips, sauces, dressings, and crackers. EMC is produced from cheese curd by the addition of lipases at elevated temperatures, increasing the content of free fatty acids about 10-fold. Depending on the chain-length specificity of the lipases used, there is either predominant liberation of short-chain fatty acid (C4–C6), which results in a sharp, tangy flavor, or of medium- and long-chain fatty acids (>C12), which convey a soapy taste and are readily metabolized to other flavor ingredients. Addition of lipase to pasteurized cows' milk can generate flavors similar to goat, sheep, or raw milk if used with the appropriate microbial consortia.

Currently, lipase technology is so advanced that the production of compounds such as flavors or emulsifiers are regarded as an old application. Commercially available lipases are usually derived from microorganisms, but since the advent of genetic engineering techniques, an increasing number of lipases are being commercially manufactured from recombinant bacteria and yeast. Some industrial applications of microbial lipases are reported in Table 7.

Use in Brewing

Traditionally, beer is produced by mixing crushed barley malt and hot water in a large circular vessel called a mash copper. This process is called 'mashing.' Besides malt, other starchy cereals such as maize, sorghum, rice, and barley, or pure starch itself, are added to the mash. These are known as adjuncts. After mashing, the mash is filtered in a lauter tun. The liquid, known as 'sweet wort,' is then run off to the copper, where it is boiled with hops. The 'hopped wort' is cooled and transferred to the fermenting vessels where yeast is added. After fermentation, the so-called 'green beer' is matured before the final filtration and bottling. (*See* **Beers**: Biochemistry of Fermentation.)

This is a much-simplified account of how beer is made. Brewing can quite happily proceed without any added enzymes, relying entirely on the natural enzymes from the ingredients and the yeast to

produce good-quality beer. From time to time, however, problems occur that cannot be easily identified or rectified. Enzymes can often provide a useful diagnostic tool, giving the immediate remedy as well as suggesting the long-term solution. Table 8 shows some of the problems that can occur during brewing and recommends some of the possible enzyme treatments that can be used to solve the problem. It also serves as a summary of the application of enzymes in brewing, together with Figure 6, which shows where the appropriate enzymes are usually used in the brewing process. Supplementation can in fact occur at various stages during the process. During the initial step of decoction and mash formation, in which probably 80% of the original starch is converted into fermentable sugars (glucose, maltose, maltotriose), bacterial and fungal α-amylases are often added, together with bacterial and fungal glucanases. The latter are important in the removal of β-glucans, β-1,3, and β-1, 4-linked polymers, which are viscous gum-like substances. Failure to hydrolyze the glucans introduces problems in the efficiency of wort filtration and in the later production of hazes. Further amylase and glucanase addition may occur during the filtration of the wort. During subsequent fermentation, particularly for low-calorie beers, where soluble polysaccharide levels need to be minimized, fungal α-amylases and glucoamylases are added.

A typical example of the use of enzymes to resolve a brewing problem is when a haze appears in the bright filtered beer (this includes the enigmatic invisible haze, which cannot be detected by the naked eye, but is recorded as a machine haze). The haze is usually ascribed to three probable causes: proteins, starch/polysaccharides, or nonstarch polysaccharides. It may result from other factors such as the passage of diatomaceous earth, oxalic acid crystals, microorganisms, or filter fibers, which can be easily identified under a microscope or using an enzyme system. In fact, adding β-glucanase, papain, and fungal

Table 7 Industrial application areas for microbial lipases

Industry	*Effect*	*Product*
Dairy	Hydrolysis of milk fat	Flavor agents
	Cheese ripening	Cheese
	Modification of butter fat	Butter
Bakery	Flavor improvement and shelf-life prolongation	Bakery products
Beverages	Improved aroma	Beverages
Food dressing	Quality improvement	Mayonnaise, dressings, and whipped toppings
Health food	Transesterification	Health foods
Meat and fish	Flavor development and fat removal	Meat and fish products
Fat and oil	Transesterification	Cocoa butter, margarine
	Hydrolysis	Fatty acids, glycerol, mono-, and diglycerides

Use of Transglutaminase in Functional Properties of Food

Transglutaminase (EC 2.3.2.13) catalyzes *in vitro* cross-linking in whey proteins, soya proteins, wheat proteins, beef myosin, casein and crude actomyosin refined from mechanically deboned poultry meat. In recent years, on the basis of the enzyme's reaction to gelatinize various food proteins through the formation of cross-links, this enzyme has been used in attempts to improve the functional properties of food. The modification of food proteins by transglutaminase may lead to textured products, help to protect lysine in food proteins from various chemical reactions, encapsulate lipids and/or lipid-soluble materials, form heat- and water-resistant films, avoid heat treatment for gelation, improve elasticity and water-holding capacity, modify solubility and functional properties, and produce food proteins of higher nutritional value through cross-linking of different proteins containing complementary limiting essential amino acids.

An overview of the application possibilities for microbial transglutaminase in food processing is given in Table 9. In meat and fish processing it is of great interest to maximize the yield of marketable products, particularly by restructuring low-value cuts and trimmings to improve their appearance, flavor, and texture. In vegetables and fruit transglutaminase is used to maintain freshness, by coating them with a membrane containing transglutaminase and proteins. Literature reports also cite a method developed for reducing the allergenicity of some food proteins and/or peptides: α_{s1}-casein was treated

Table 9 Overview of application of microbial transglutaminase in food processing

Source	*Product*	*Effect*
Meat	Hamburger, meatballs, stuffed dumplings	Improved elasticity, texture, taste, and flavor
	Canned meat	Good texture and appearance
	Frozen meat	Improved texture and reduced cost
	Molded meat	Restructuring of meat
Fish	Fish paste	Improved texture and appearance
Krill	Krill paste	Improved texture
Collagens	Shark-fin imitation	Imitation of delicious food
Wheat	Baked foods	Improved texture and high volume
Soya bean	Mapuo doufu	Improved shelf-life
	Fried tofu (aburaage)	Improved texture
	Tofu	Improved shelf-life
Vegetables and fruits	Celery	Food preservation
Casein	Mineral absorption promoters	Improved mineral absorption in intestine
Gelatin	Sweet foods	Low-calorie foods with good texture, firmness, and elasticity
Fat, oil, and proteins	Solid fats	Pork-fat substitute with good taste, texture, and flavor
Plant proteins	Protein powders	Gel formation with good texture and taste
Seasonings	Seasonings	Improve taste and flavor

with transglutaminase to manufacture cross-linked casein, which was less allergenic.

In developing countries, many people are still suffering from starvation and efforts are being focused on producing acceptable protein foods from nonanimal protein, to solve the problem of protein deficiency. On the other hand, in addition to their awareness of health problems caused by obesity, people in developed countries are increasingly aware of the environmental burden caused by surplus livestock. When presented with a novel food product, consumers are very sensitive to properties such as flavor, nutritional value, appearance, shelf-life, and palatability. In this respect, protein modification by enzymes, especially by microbial transglutaminase, the mass production of which can be achieved by fermentation from cheap substrates, is one of the most promising alternatives in developing novel protein foods.

Up to now, commercial transglutaminase has been merely obtained from animal tissues. The complicated separation and purification procedure results in an extremely high price for the enzyme. The production of transglutaminase derived from microorganisms was not reported until the late 1980s, and recently a modified downstream process for purifying microbial transglutaminase was described. The microbial process no doubt has an advantage in its independence from regional and climatic condition, in addition to its reasonable cost. But it is still of great interest to improve fermentation and downstream processing to reduce production cost. Modification of strains by genetic engineering is one of the alternatives.

Cleaning

A major use of enzymes as proteases has been in the production of detergents. These are used widely in the food industry, especially for cleaning-in-place applications, where the equipment is sensitive to heat. (*See* **Cleaning Procedures in the Factory**: Types of Detergent.)

Pancreatin (extracted from the pancreatic glands of animals), which contains the protein-degrading enzyme trypsin, was used as early as 1913 in laundry detergents. The detergent, being mainly composed of ordinary washing soda (sodium carbonate), had an excellent softening effect on water and helped to dissolve dirt. The trypsin, however, had only a limited effect.

During the 1960s, there was a significant new development in the detergent industry when a mixture of serine and microbial proteases, which appeared to be less degradable by soaps, alkalis and temperature, replaced trypsin. These enzymes have a serine-histidine active site and produce their effect in the pH range 6.5–10.0 and a temperature range of 30–60 °C.

There was a temporary setback in the early 1970s when it was realized that enzymes could cause allergic reactions among the staff working in the enzyme plant, in detergent factories, or the end users.

The introduction of encapsulated proteases in the 1980s and the withdrawal of the US Federal Trade Commission's restrictions were followed by a resurgence in the demand for proteases in detergents. Proteases remove protein stains and deposits from a wide range of food sources. These organic stains have a tendency to adhere strongly to textile fibers and equipment surfaces. The proteins act as glues, preventing water-borne detergent systems from removing some of the other components of the stain/deposit, such as pigments and particulate material. Nonenzymatic detergents are inefficient in removing proteins and can result in permanent stains due to oxidation and denaturing caused by bleaching and drying.

Proteases hydrolyze proteins and break them down into more soluble polypeptides. Through the combined effect of surfactants and enzymes, stubborn stains/deposits can be removed. Though protein stains can be easily digested by enzymes, oil and fatty stains have always been troublesome to remove. The trend towards lower cleaning temperatures has made the removal of grease spots an even greater problem.

Amylases are also used to remove residues of starchy foods, such as mashed potato, spaghetti, oatmeal porridge, custard, gravy, and chocolate.

Uses in Analysis

J R Whitaker, University of California, Davis, CA, USA

Introduction

Enzymes are ideal for analyses because of their high specificity and sensitivity. Any compound that affects the activity of an enzyme, i.e., substrate, inhibitor, or activator, can be determined rapidly and quantitatively by adding such compounds to a controlled enzyme reaction and comparing the results without the compound (control). Also, measurements of activities of selected enzymes in a biological specimen under standard conditions are useful in medicine for the diagnosis and prognosis of almost all diseases. More recently they have been used for determining specific genetically related diseases. They are also used for assessing nutritional deficiencies, physical damage to organs, suitability for and adequacy of processing and quality of foods, identifying subcellular organelles and membrane structures, and structural configurations of molecules. Enzymes are ideal reporters for measuring antigens to specific antibodies (enzyme immunoassays).

Enzyme usage in analyses is not new. Peroxidase was used for hydrogen peroxide analysis as early as 1845. Enzymatic carbohydrate determination in biological materials was an accepted method by the end of the nineteenth century. But most progress in using enzymes analytically has occurred in the last 20 years as a result of readily available pure enzymes, better understanding of the factors which affect enzyme activity, enzyme kits for specific determinations, easily usable sensitive techniques, and instrumentation matching the specificity and sensitivity of the enzymes. The rapid progress in sequencing genes, including the human genome, is due to two specific types of enzymes: the restriction endonucleases and the polymerases.

Principles and Applications

Compounds to be measured must bind stereospecifically at the active site of an enzyme or another specific location on the enzyme such that the activity of the enzyme is affected (eqn 1).

$$\begin{array}{ccccccccc} E & + & S & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & E{\cdot}S & \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} & E{\cdot}P & \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} & E + P \\ \Big\| X & & \Big\| K_d & & \Big\| X & & \Big\| K_d & & \\ E{\cdot}X & + & S & \underset{k'_{-1}}{\overset{k'_1}{\rightleftharpoons}} & E{\cdot}S{\cdot}X & \underset{k'_{-2}}{\overset{k'_2}{\rightleftharpoons}} & E{\cdot}P{\cdot}X & \underset{k'_{-3}}{\overset{k'_3}{\rightleftharpoons}} & E{\cdot}X + P \end{array} \quad (1)$$

E, enzyme; *S*, substrate; *E·S,* enzyme-substrate complex; *E·P,* enzyme-product complex; *P,* product; *X,* inhibitor or activator; *E·X,* enzyme-inhibitor (or activator) complex; *E·S·X,* enzyme-substrate-inhibitor (or activator) complex; *E·P·X,* enzyme-product-inhibitor (or activator) complex; K_d, dissociation constant; k_1, k_2, k_3, k'_1, k'_2 and k'_3 are forward rate constants.

There must be a predictable relationship between the concentration of a compound and its effect on enzymatic activity. Standard curves for compounds and

their products, including enzymes, to be determined are required in order to obtain absolute concentrations. In preparing the standard curve of initial velocity, v_o, versus compound or product concentration, purity of the analyte is essential and exact reproduction of experimental conditions is required. In the total change method (below), strict adherence to experimental conditions (such as rate of reaction) is not required, but it is essential to have pure standard compounds and products and to insure the reaction has gone to completion.

Determination of Substrate Concentration

The concentration of any compound that serves as a substrate, S, for an enzyme can be determined quantitatively by its effect on the initial velocity, v_o, of the reaction, provided K_m and V_{max} are known, as shown in eqn 2, and provided $[S]_o < 20\,K_m$:

$$v_o = V_{max}[S]_o/(K_m + [S]_o) \qquad (2)$$

Best results are obtained at $[S]_o < 5\,K_m$. This is called the rate (or kinetic) assay method.

The concentration of a compound that is a substrate can also be determined by a total change method when all the substrate is converted to product, which is then measured. It is essential to insure that all substrate has been converted to product, which may take several hours at the concentration of enzyme used in rate assays. Therefore, higher concentrations of enzymes are used in total change method assays than in rate assays. The total change method cannot be used for reactions that reach an equilibrium between substrate and product unless the product is trapped, forcing the reaction to completion. An example is alcohol dehydrogenase (alcohol:NAD^+ oxidoreductase, EC 1.1.1.1) acting on ethanol and NAD^+, as shown in eqn 3. Hydroxylamine is used to trap ethanal as the oxime, forcing the reaction to completion (eqn 4). The NADH concentration is measured spectrophotometrically.

$$CH_3CH_2OH + NAD^+ \rightleftharpoons CH_3CHO + NADH + H^+ \qquad (3)$$

$$CH_3CHO + NH_2OH \rightleftharpoons CH_3CHNOH + H_2O \qquad (4)$$

Special care must be taken in determining concentrations of substrates which exist in more than one anomeric form, in equilibrium with each other. An example is the mutarotation of reducing sugars. Glucose at equilibrium exists in the α, β, and open-chain forms in the ratio of 33:66:1, respectively. Glucose oxidase, often used to determine glucose concentrations, has strong preference for the β-D-glucose anomer, versus the α-D-glucose anomer (156:1 relative rate of oxidation). Therefore, both the total change method and the rate assay method may not give the correct concentration, unless a standard curve for glucose is established under the exact same conditions.

Some examples of compounds that can be quantitatively determined because they are enzyme substrates are shown in Table 1. Only a very few examples are given, since, with more than 1000 enzymes with individual specificities, at least that number of compounds can be uniquely determined. (*See* **Fructose**; **Lactose**; **Starch**: Structure, Properties, and Determination.)

Advantages of enzyme analyses for substrates, versus other types, include: (1) the very high specificity, permitting isomers to be distinguished; (2) no need for partial purification; and (3) the ability to work at room temperature, or below, with thermolabile compounds. An example will illustrate this. Reducing sugar methods, such as alkaline copper solutions, ferricyanide or 3,5-dinitrosalicylic acid for glucose, will determine all reducing sugars in the solution, plus other reducing compounds. However, glucose oxidase, which catalyzes the reaction

Table 1 Analytical determination of compounds that are substrates[a]

Compound	*Enzyme used*	*Analysis method*
Ammonia	Glutamate dehydrogenase	S; NADH → NAD^+
Ethanol	Alcohol dehydrogenase	S; NAD^+ → NADH
D-Fructose	Hexokinase	S; $NADP^+$ → NADPH, in coupled assay
D-Glucose	Glucose oxidase	S; H_2O_2 with peroxidase
L-Lactic acid	L-Lactate dehydrogenase	S; NAD^+ → NADH
D-Lactic acid	D-Lactate dehydrogenase	S; NAD^+ → NADH
Lactose	β-Galactosidase	S; H_2O_2 with peroxidase and glucose oxidase
Starch	Amyloglucosidase	S; NADH → NAD^+, in coupled assay through glucose and glucose oxidase
Urea	Urease	E; NH_3 electrode

[a]S, spectrophotometric method; E, electrometric method.

Adapted from Guilbault GG (1984) *Analytical Uses of Immobilized Enzymes*. New York: Marcel Dekker.

shown in eqn 5, will only determine glucose. Furthermore, it is absolutely specific for D-glucose versus L-glucose and oxidizes β-D-glucose 156 times more rapidly than α-D-glucose. The reaction shown in eqn 6 is not catalyzed by glucose oxidase. The rate is slower than that of eqn 5 and therefore cannot be used to determine glucose concentration by the rate method. Therefore, the H_2O_2 concentration is determined by use of peroxidase and a chromagen that gives a colored compound that is measured spectrophotometrically (coupled reactions). The peroxidase and chromagen concentrations must be high enough so that the rate of reaction shown in eqn 5 is rate-determining, not the reaction shown in eqn 7.

$$\beta\text{-D-Glucose} + O_2 \underset{\text{oxidase}}{\overset{\text{Glucose}}{\rightleftharpoons}} \beta\text{-D-Glucone-}\delta\text{-lactone} + H_2O_2 \quad (5)$$

$$\beta\text{-D-Glucone-}\delta\text{-lactone} + H_2O \longrightarrow \beta\text{-D-Gluconic acid} \quad (6)$$

$$H_2O_2 + \text{Chromagen} \xrightarrow{\text{peroxidase}} \text{Colored compound} \quad (7)$$

Determination of Inhibitor Concentration

Any compound that decreases v_o when added to an enzyme–substrate system is an inhibitor. Compounds that are reversible inhibitors can only be determined by rate assay methods, while irreversible inhibitors can be determined by either rate assays or total change assays. When X in eqn 1 binds only to E, so as to decrease enzyme activity (i.e., both $E{\cdot}S$ and $E{\cdot}X$ are formed), it is a competitive inhibitor; k'_1 is zero. Therefore, the concentration of the compound can be determined from the ratio of v'_o/v_o, where v'_o is the initial velocity determined in the presence of a fixed concentration of inhibitor, [I], and v_o is the initial velocity determined in the absence of inhibitor provided K_m, [S], and K_i (= [E][I]$_o$/[EI]; K_d in eqn 1) for the inhibitor are known. This relationship is shown as:

$$v'_o/v_o = (K_m + [\mathbf{S}]_o)/\{(1 + [\mathbf{I}]_o/K_i)/K_m + [\mathbf{S}]_o\} \quad (8)$$

If X binds to E and $E{\cdot}S$ equally well (eqn 1) and k'_1 and k'_2 are zero, the X is a linear noncompetitive inhibitor. [I]$_o$ can be determined from:

$$v'_o/v_o = 1 + [\mathbf{I}]_o/K_i \quad (9)$$

provided K_i for the inhibitor is known.

If X binds only to $E{\cdot}S$ (eqn 1) and k'_2 is zero, then X is a linear uncompetitive inhibitor. [I]$_o$ can be determined from:

$$v'_o/v_o = (K_m + [\mathbf{S}]_o)/\{K_m + [\mathbf{S}]_o(1 + [\mathbf{I}]_o/K_i)\} \quad (10)$$

provided K_m, [S]$_o$, and K_i are known.

If X reacts chemically with E to form an irreversible product, E-X, then the extent of inhibition is linearly related to the concentration of X as long as [X] < [E] and the reaction is allowed to go to completion (total change method). The concentration of X can be calculated, provided [E]$_o$ is known by:

$$v'_o/v_o = ([\mathbf{E}]_o - [\mathbf{E\text{-}X}])/[\mathbf{E}]_o \quad (11)$$

where [E-X] = [X] and [E]$_o$ is concentration of total active enzyme used. Table 2 gives a few examples of compounds that can be determined enzymatically because they are enzyme inhibitors, thereby decreasing v_o when added to an enzyme–substrate system.

Theoretically, any compound that is a substrate can be determined by inhibition kinetics since two substrates (one at a fixed concentration, while the unknown substrate concentration is variable) in the system compete for binding at the active site of the enzyme, based on their relative K_m values. One need only determine v_o for one of the substrates (control), and treat the second substrate as a competitive inhibitor to determine v'_o. (*See* **Aluminum (Aluminium)**: Properties and Determination; **Ascorbic Acid**: Properties and Determination; **Lead**: Properties and Determination; **Mercury**: Properties and Determination.)

Determination of Activator Concentration

Any compound that increases v_o when added to an enzyme-substrate system is an activator. Compounds

Table 2 Analytical determination of compounds that are inhibitors[a]

Compound	*Enzyme used*	*Analysis method*
Pesticides	Cholinesterase	E; H^+; thiocholine
DDT	Carbonic anhydrase	S; H^+ with indicator
Heparin	Ribonuclease	S; degradation of RNA
Ascorbic acid	Catalase	S; uric acid
Ag^+	Alcohol dehydrogenase (yeast)	S; $NAD^+ \rightarrow$ NADH
Al^{3+}	Alkaline phosphatase	S; *p*-nitrophenol
Hg^{2+}	Alcohol dehydrogenase	S; $NAD^+ \rightarrow$ NADH
Pb^{2+}	Peroxidase	F; fluorescent product
F^-	Liver esterase	E; H^+
S^{2-}	Peroxidase	F; fluorescent product

[a]The methods listed for the anions may not be absolutely specific: similar types of ions may interfere.
DDT, dichlorodiphenyltrichloroethane; E, electrometric method; F, fluorescent method; S, spectrophotometric method.
Adapted from Guilbault GG (1984) *Analytical Uses of Immobilized Enzymes*. New York: Marcel Dekker.

that form a rapid equilibrium complex with an enzyme (and/or $E{\cdot}S$) as shown in eqn 1 can only be determined by rate assay methods. This is characteristic of coenzymes, such as NAD^+, $NAD(P)^+$, nucleotide triphosphate coenzymes adenosine triphosphate (ATP), uridine 5′-triphosphate, cytidine 5′-triphosphate) and some metal ions. At a fixed concentration of enzyme and substrate, the concentration of activator, A, can be determined from:

$$v_o^o = v_o^2 - v_o = V_{\max}[\mathbf{A}]/(K_d + [\mathbf{A}]) \qquad (12)$$

provided $K_d\,(=[\mathbf{E}][\mathbf{A}]/[\mathbf{E}{\cdot}\mathbf{A}])$ and $V_{\max}$ are known. v_o^2 is initial velocity in the presence of the activator. In most cases, v_o in the absence of coenzyme is zero, so that $v_o^0 = v_o^2$ is observed; this is the increase in activity in presence of a given concentration of A. (*See* **Coenzymes**.)

Activators that form tight complexes ($K_d < 10^{-9}$ mol l^{-1}) with enzyme, such as prosthetic groups and some metal ions, increase activity of the enzyme in a linear fashion (v_o^o is directly proportional to $[\mathbf{A}]_o$). Therefore, only a total change method is useful.

It is essential to prepare a standard curve of v_o versus $[\mathbf{A}]_o$ in order to convert measured v_o values to absolute concentration. Purity of the standard activator and reproduction of experimental conditions are essential.

Table 3 gives a few examples of compounds that activate enzymes. Several inferences may be drawn from the examples presented. With the exception of O_2, all the compounds listed are cofactors. They are absolutely required for enzymatic activity.

One enzyme may be used to analyze for several compounds. For example, luciferase can determine luciferin (substrate), ATP, Mg^+, and O_2 concentrations, since all affect the activity of the enzyme (eqn 13).

Table 3 Analytical determination of compounds that are activators[a]

Compound	*Enzyme used*	*Analysis method*
ATP	Luciferase	S; NADH → NAD^+, in coupled reaction
FAD	D-Amino acid oxidase	E; O_2 electrode
K^+	Phosphofructokinase	S; activation of enzyme
Mg^{2+}	Luciferase	F; chemiluminescence
Zn^{2+}	Aminopeptidase apoenzyme	S; *p*-nitrophenol
O_2	Luciferase	F; chemiluminescence

[a]A few examples of many. There are alternative methods, depending on instruments, substrates, and enzymes available.
ATP, adenosine triphosphate; FAD, flavin adenine dinucleotide; E, electrometric method; F, fluorescent method; S, spectrophotometric method.
Adapted from Guilbault GG (1984) *Analytical Uses of Immobilized Enzymes*. New York: Marcel Dekker.

$$\text{Luciferin} + O_2 \xrightarrow[\text{ATP, } Mg^{2+}]{\text{Luciferase}} \text{Oxidized luciferin (+ phosphorescence)} \qquad (13)$$

Determination of Enzyme Concentration

Determining enzyme concentration by measuring the initial velocity, v_o, at which a substrate is converted to product seems straightforward. Yet it is fraught with difficulties unless careful attention is given to the design of the experiment, as time, substrate, pH, temperature, activators, and inhibitors all affect v_o for a fixed concentration of enzyme. Therefore, if the enzyme concentration, $[\mathbf{E}]_o$, is to be measured accurately and precisely, all these other parameters must be controlled exactly among experiments. It is important to determine the initial velocity, v_o, so that changes in substrate concentration, stability of the enzyme, approach to equilibrium, and/or inhibition by the product are not factors. The substrate concentration does not need to be much greater than K_m when v_o is measured. Any substrate concentration, when precisely reproduced, will give a linear relationship between v_o and $[\mathbf{E}]_o$, with a few exceptions. The temperature should be below optimum temperature so the enzyme is stable and the pH must be close to the optimum pH for maximum sensitivity.

Determination of absolute concentration of enzyme based on v_o requires a standard preparation of the enzyme with known purity, based on activity. For example, if it is known that a 5 µl aliquot containing 1 µg of 100% active pure enzyme has a v_o of 30 µmol of product formed per minute, while a 5 µl aliquot of an unknown sample has a v_o of 6 µmol of product formed per minute under the same conditions, then the unknown aliquot contains 0.2 µg of the enzyme.

Table 4 gives a few selected examples of analytical determinations of enzyme concentration. (*See* **Spectroscopy**: Fluorescence; Overview.)

Structural Analysis

Because of their high specificity, enzymes are ideal probes of molecular structure. They can distinguish between: D/L, *cis/trans*, α/β, and other stereospecific configurations; nature, location, and sequence of monomeric units in heteropolymers (proteins, carbohydrates, nucleic acids); and secondary, tertiary, and quaternary structures of polymers. They are useful in determining location of enzymes and substrates in organs (histochemistry) and in identifying subcellular organelles (based on enzyme composition), cell walls and membranes. The restriction enzymes and ligases are essential tools in recombinant DNA

Table 4 Analytical determination of enzyme concentration[a]

Enzyme	*Substrate used*	*Analysis method*
Catalase	H_2O_2	E; O_2
β-Galactosidase	*o*-Nitrophenyl-β-D-galactoside	S; *o*-nitrophenol
Invertase	Sucrose	S; use of glucose oxidase/peroxidase coupled assay
Lipase	Tributyrin	E; H^+
Pectin methylesterase	Pectin	E; titrate H^+ formed
Peroxidase	H_2O_2, 4-aminoantipyrine, *p*-hydroxybenzoate	S; oxidized, conjugated 4-aminoantipyrine
Phosphatase, alkaline	*p*-Nitrophenyl phosphate	S; *p*-nitrophenol
Polyphenol oxidase	Pyrocatechol	S; benzoquinone
Xanthine oxidase	Hypoxanthine	S; uric acid

[a]There are several methods available for each enzyme. Availability of instruments and substrates often determine choice of method.
E, electrometric method; F, fluorescent method; S, spectrophotometric method.
Adapted from Guilbault GG (1984) *Analytical Uses of Immobilized Enzymes*. New York: Marcel Dekker.

technology and genetic engineering, being highly specific for nucleotide primary and secondary structures. As probes of structure, unequivocal determination of activity, or lack of activity, is more important than the absolute velocity of product formation (v_o).

Determination of v_o

Determination of v_o for formation of product (dP/dt), disappearance of substrate ($-dS/dt$), change in energy (as heat), or change in pH is required for analytical use of enzymes, as indicated by the preceding discussion. This requires the ability to detect a change during the reaction. Changes in absorbance, fluorescence, phosphorescence, electrical properties including pH, or heat are appropriate monitors. Excellent instrumentation is available for detection of all these changes. The best methods are those where a continuous recording of the change is possible, often with software to convert the measured rate of change directly to concentration of the compound being measured. Data accumulation and analysis are easy when the change is continuously recorded. However, sometimes an aliquot of the reaction must be removed periodically, another reagent added to give a colored derivative (for example) of product or substrate and then the concentration of the derivative determined. Sometimes v_o can be measured only after chromatographic separation of the products. These are lengthy, laborious assays that frequently lead to one-point assays. v_o, based on one-point assays, must be accepted with great caution.

Often, solutions to difficult analyses are possible via coupled enzyme assays. A coupled enzyme assay involves two or more enzymes, in which the product of the last enzyme is measured as shown in eqn 14. The intent is to measure the concentration of A (or E_1). However, the product B is analytically very difficult to determine, while D is very easy to determine:

$$A \xrightarrow{E_1} B \xrightarrow{E_2} C \xrightarrow{E_3} D \qquad (14)$$

A specific example will illustrate this better (eqns 15–17).

$$\text{Sucrose} + H_2O \xrightarrow{\text{Invertase}} \text{Glucose} + \text{Fructose} \qquad (15)$$

$$\text{Glucose} + O_2 + H_2O \xrightarrow[\text{Oxidase}]{\text{Glucose}} \text{D-Gluconic acid} + H_2O_2 \qquad (16)$$

$$H_2O_2 + \text{Chromagenic substrate} \xrightarrow{\text{Peroxidase}} \text{Fluorescent product (or colored)} \qquad (17)$$

Coupled reactions often involve terminal enzymes requiring NAD^+ (NADH) or $NADP^+$ (NADPH), since the extinction coefficient at 340 nm is 6.22×10^3 mol l^{-1} cm^{-1} for NADH (or NADPH) versus NAD^+ (or $NADP^+$), a very large change.

Coupled reactions require enzymes with similar pH optima and that v_o ($= k_2$ [E][S]$_o$/ (K_m + [S]$_o$)) be at least 100 times larger for reactions catalyzed by E_2, E_3, etc., than for E_1. This is usually met by using high concentrations of E_2, E_3, etc. The rationale for this is the concentrations of final product measured (D in eqn 14; hydrogen peroxide in sucrose determination eqns 15–17) must be a stoichiometric reflection of concentration of substrate A (or E_1) being determined. The examples in Tables 1–4 illustrate how frequently coupled reactions are used.

Soluble enzyme systems are not required for determining v_o (and analyte concentration). In fact, present emphasis is on the use of immobilized enzyme systems in columns, electrodes, biosensor chips and antibody–enzyme conjugates (enzyme-linked immunosorbent assay (ELISA), for example). Immobilized enzymes are more stable than nonimmobilized enzymes and may be used repeatedly. Dozens of enzyme electrodes are available (several

commercially) that have response times equivalent to a hydrogen (pH) electrode and can be used repeatedly for several months. Biosensors involving multiple microchips are being developed, which may determine up to eight or more enzymes, substrates, or other compounds simultaneously when a drop of blood, urine, or other biological fluid is added. EPIDEMIOLOGY

P C Elwood, Llandough Hospital, Penarth, South Glamorgan, UK

Aims of Epidemiology

Epidemiology is the study of health and disease in the community. There are two groups of aims: first, to describe the distribution, the pattern, and the natural history of disease in the general population, and second, to identify factors that may be causal in a disease process, and to evaluate strategies for the control, management, and prevention of a disease.

In nutritional research, epidemiology aims to identify associations between nutrients or food items and the risk of a disease, and then test these associations to verify whether they are likely to be causal. In practice, epidemiology is multifaceted and a number of preliminary considerations will help to put it into context within general medical and biological research.

Epidemiologists rarely generate hypotheses. Most ideas about the causation of disease arise from clinical observations, metabolic studies, or other intensive investigations. The role of the epidemiologist is to take these ideas and test them in representative samples of the general community or, if appropriate, in representative series of patients. In doing this the epidemiologist not only tests the relevance of a factor to the disease, but also seeks to obtain an estimate of the relative importance of the mechanism or factor. Furthermore, in a well-designed comprehensive study, the extent to which the effect of any particular factor of interest is independent of the effects of other factors is established. This generally requires large complex and long-term studies, based on samples of subjects that truly represent the population.

The interest of the epidemiologist is therefore on communities and his or her attention focuses ultimately on lifestyles, on nutrition, and on environmental factors. Thus the recent finding that certain thrombosis-related factors, such as plasma fibrinogen, are very strongly predictive of future ischemic heart disease events leads the epidemiologist on to search for the dietary and lifestyle determinants of fibrinogen. The likely relevance of antioxidants to cancer and other conditions leads the laboratory worker to study free radicals and their cellular and other effects, while the epidemiologist studies the relative protection given by diets rich in natural antioxidants, and the effects of dietary antioxidant supplements. The

hypothesis that the regular consumption of fish is associated with a low incidence of vascular disease leads the biochemist to study the metabolism of fish oils and mechanisms linking fish oils to blood pressure and other cardiovascular risk factors, while the epidemiologist sets up a randomized controlled trial of fish eating and the incidence of vascular disease. The different research approaches – clinical, laboratory, and epidemiological – are complementary and all are needed.

Only the epidemiologist, however, can estimate, from studies based upon representative population samples of individuals, the relative importance of one particular factor to a disease, in comparison with a host of other relevant factors. Thus, magnesium is a key element in many enzymes and is known to be involved in a large number of metabolic and other biological mechanisms. Only the epidemiologist can however estimate the importance of magnesium to health and disease in the population, and the part played by magnesium deficiency, if any, in, say, cardiovascular disease within a community.

The Concept of Risk Factors

Epidemiologists were probably the first to use the term 'risk factor,' applying it to any factor which identifies an individual who is at increased risk of a disease.

The term is however vague and its limitations should be understood. Thus the term is used to cover factors which are inherent in a subject and cannot be altered (such as sex and race, etc.), factors which are likely to be causal and which can be changed (such as dietary fat intake, blood pressure, and plasma fibrinogen) and factors which confound relationships of interest (such as age and social class). Factors in this last group are perhaps the most difficult to identify and deal with. For example, in examining the relationship between a nutrient and a disease, calorie intake can often be a confounding variable, in that it is probably related to the intake of the nutrient of interest (for most nutrients, the more food that is eaten, the greater the intake of any nutrient), and calorie intake, or total energy, is a good surrogate measure for exercise level which, in turn, is strongly related to the incidence of vascular and other diseases.

Another suggested modification of the concept of 'risk factor' is to refer to 'predictors' of a disease (such as cholesterol level, blood pressure, plasma fibrinogen and other biochemical and hematological factors) and 'determinants' of those predictors (such as dietary fat intake, salt intake, smoking habit, and other lifestyle and dietary factors). This last grouping has the great advantage that it acknowledges the difference between factors involved at the level of metabolic processes, and extrinsic factors, upon which preventive strategies which are under the control of subjects themselves, and population-based intervention initiatives, can be focused.

Epidemiological Methods

A variety of strategies are used in epidemiology. Basically these can be divided into prospective and retrospective, and into observational and experimental. Every combination of these is possible: changes over time; comparisons between communities; individual case-control comparisons; cross-sectional surveys; prospective cohort studies; and the randomized controlled trial (RCT) with intervention. Another way in which the various strategies can be classified is by the degree of certainty of the conclusions drawn from them. This last is so important that the various study designs which are described below are listed in the order of the likely certainty of the conclusions that can be drawn from the evidence they yield.

Trends with Time

There have been great changes in the mortality of many diseases, including many cancers and coronary heart disease (CHD), in most countries during the past century and it is possible to look for dietary changes which parallel these changes in disease incidence. Great difficulties arise, however, because information on past disease is uncertain and knowledge of past dietary intakes is very poor. Diagnostic criteria change, and the attributions of certain causes to deaths have changed markedly over the years. In addition, estimates of the nutrient content of food change, as reflected in food composition tables. The MONICA study, set up by the World Health Organization in about 40 countries to study changes over time in CHD, and in relevant risk factors, is probably the most ambitious study of this kind ever mounted.

Even if reliable data on both diets and disease were available, the two cannot be linked with certainty because many other relevant factors may have changed concurrently. Diet is only one aspect of lifestyle and it should never be considered in isolation.

Cross-community Comparisons

There are differences in disease rates in different communities and some of these are large. Relating these to differences in dietary intakes has generated a number of interesting hypotheses. There are difficulties however in that the dietary data available for the different

communities may not be truly representative for those communities, and the disease data may not be truly comparable. The biggest stumbling block is the virtual impossibility of linking differences in disease incidence to dietary differences since many other factors – genetic, behavioral, and environmental – will almost certainly be different and may well be far more important in determining disease risk than dietary differences.

Case-control Studies

The identification of patients with evidence of a disease and the comparison of possible risk factors in these with the same factors in disease-free subjects is a basic research strategy. Difficulties arise, however, because the 'cases' are often patients with advanced disease, who may not be representative of all such patients. Furthermore, the observer cannot always be 'blind' with regard to whether a subject is a 'case' or a 'control,' and so that bias can easily be introduced into the data on risk factors. Further difficulties arise in the selection of suitable control subjects without the disease, and though some of these difficulties can be overcome by matching for factors such as sex, age, and area of residence, uncertainties remain about comparability between the cases and the controls with respect to factors other than those believed to be relevant to the disease.

In nutritional research the case-control strategy has only a very limited place because it necessitates inquiries about dietary intakes before the onset of the disease, and it is very difficult for a patient to separate out this information from dietary changes which have been made since symptoms of the disease commenced. Furthermore, the case-control approach has very little place in diseases with a high case fatality, such as cancer and heart disease, because only a selected subsample of all cases survive to be included in any case-control study and these will certainly not be representative of all patients with the disease. (*See* **Cancer**: Epidemiology.)

Cross-sectional Survey

One of the most common activities in epidemiology and in social science is the conducting of surveys. These can give estimates of the prevalence of a disease, the distribution of dietary intakes, and the levels of risk factors, and associations between these can be examined. For such purposes, it is essential that the population sample selected for the study is truly representative of the community being studied, and that a high response rate is achieved because otherwise representativeness will be compromised. Attention has also to be given to the reproducibility of measurements made. INTERSALT, an international collaborative study coordinated by WHO, was a good example of a cross-sectional study. In this, about 40 research centers obtained data on blood pressure and on salt excretion from 24-hr urine collections (a surrogate for salt intake) in about 200 subjects per center.

Cross-sectional studies have the great advantage that all the data collected are contemporaneous, that is, there is no dependence upon the memories of subjects, nor is there any waiting for disease to develop. On the other hand, surveys have the great disadvantage that causal factors which predated the onset of the disease cannot always be distinguished from a factor which has been affected by the disease itself. Thus, in a cross-sectional survey, differences in dietary intakes between subjects with CHD and other subjects, could equally well be the result of changes in diet made by patients after their heart attack, or the onset of angina, as the cause of the disease process.

One valuable role for cross-sectional surveys is the identification of determinants of risk factors for disease. Thus the associations between dietary and other lifestyle factors and, for example, serum cholesterol, blood pressure, or serum fibrinogen can be examined.

Prospective Studies

The prospective, cohort, or longitudinal study is the classic tool of the epidemiologist. In this, a representative population sample of subjects (a cohort) is examined and then followed forward in time. The association between the levels of the various factors measured at baseline, and the development of the disease, is examined. In other words, the predictive power for subsequent disease of dietary, lifestyle, biochemical, hematological, and other factors is examined. The great advantage of this strategy is that the suspected causal factors are measured before the disease becomes evident, and causal factors can therefore be distinguished from factors which represent effects of the disease.

The identification of factors showing greater than chance associations with subsequent disease is however not the final answer. The degree to which the predictive power of a factor for the disease is independent of other factors must be examined. Thus, on first analysis the dietary intakes of many dietary factors is likely to be found to be predictive of a range of diseases. It must be examined whether or not such relationships are simply a consequence of an age effect (older subjects having an increased risk of most diseases and, probably, a reduced intake of most nutrients) or due to confounding by smoking

(smokers having intakes of many nutrients which are different from nonsmokers, and smokers having an increased risk of a wide range of diseases). In practice it is found that most factors, dietary and other, which are predictive for a disease, are interrelated to a whole network of other factors relevant to that disease. Unscrambling these relationships presents great difficulties, especially when the different factors are estimated with different degrees of precision. Other difficulties arise because of the possibility of overcontrol for confounding, and because errors in the measurement of an independent factor, such as a dietary factor, lead to the underestimation of an association.

Intervention Trials

There are two broad uses of intervention trials in dietary research. First, there is the small, short-term intervention trial that examines a mechanism or tests the association between factors. Thus, the intake of a food item, such as salt, saturated fat, fatty fish, and vitamin C, or the intake of dietary fiber, fruit and vegetables, or dairy produce can be changed and changes observed in biochemical or hematological factors known to be relevant to disease. Possible determinants of platelet function, oxidized lipoproteins, and blood pressure can be thoroughly evaluated using this strategy.

The second, and ultimately far more important use of intervention trials is to test the relevance of a factor to the incidence of a disease. The rules for such RCTs have been well worked out and if an RCT is to yield reliable evidence then there must be no compromise on certain cardinal aspects. These last include random allocation of subjects to the intervention ('treatment') or the 'control' group; the follow-up of all subjects admitted to the trial, whatever their level of compliance, is essential if bias is to be avoided ('intention-to-treat analysis'); and the assessment of outcome events must be made 'blind' with regard to whether the subject was in the treated or the control group. Unfortunately, in dietary RCTs it is rarely possible to comply with a further point which is regarded as important in RCTs, namely 'blindness' of the participants as to whether they are receiving the intervention measure or not. This last is easily achieved in drug trials, but the use of a dummy placebo is seldom possible in dietary trials.

While RCTs give evidence with a high level of certainty, they still have limitations. First, they usually have to be large and long-term. For example, even with the inclusion of thousands of subjects, and prolongation for several years, almost all RCTs so far reported have failed to give conclusive evidence on the relevance of dietary fat intake to survival. Hence there needs to be overviews of all available and relevant evidence, as described below.

Other limitations of dietary RCTs include the difficulty in persuading subjects to make a change in their diet which is of sufficient size, and is maintained for a sufficient time, to be likely to affect the incidence or the progression of a disease. In fact, setting-up a trial with random allocation to an intervention group often leads to 'contamination' of the control group, either through contact between subjects themselves, or through reports in the media. At the very least, dietary and other changes in the two groups, intervention and control, must be carefully monitored. Then it is important to avoid as far as possible changes in dietary factors other than the one of interest, and those changes that do occur should be monitored and recorded. Thus an increase of, say, fish consumption is likely to lead to a decrease in meat intake, and an increase in wholemeal bread may lead to an increase in the use of spreading fats.

Limitations of Approach

Difficulties in epidemiological approaches to research on nutrition and disease include the following:

1. The etiology of most diseases is complex and for very few diseases is there a single cause. Not only are food items likely to interact together, and not only is a change in one dietary item likely to be accompanied by changes in other food items, but other lifestyle factors are likely to be related to the dietary intake of any particular nutrient. Smoking and exercise level are two nonnutritional factors that confound almost every possible nutritional relationship. Social class and education are also relevant to most nutritional factors and to the risk of almost every disease.
2. The difficulties in adequately characterizing the diet of any individual subject are enormous and in most nutritional epidemiological studies this is necessary for thousands of subjects. Methods of estimating dietary intakes are dealt with elsewhere and it has to be accepted that even the most careful and exacting of these give at best only a crude estimate of what is required: that is, the usual or the average dietary intake of subjects over a very long period of time. This is a most important limitation because uncertainties in the measurements of independent variables will reduce the power of a study and true effects may escape detection.
3. Third, the effects of food items or dietary patterns are likely to be very long-term, and in the

study of relationships with disease it is possible that the diet at the time the disease is diagnosed is no longer of any relevance, yet the estimation of dietary intake of an individual in the past – perhaps 10 or 20 years previously – is clearly almost impossible.

4. There are often difficulties in recruiting enough subjects to give power in a study to test a hypothesis adequately. Recruitment can be especially difficult in nutritional studies in which the collection of dietary data, or the making of a change in diet, can be quite disruptive. In estimating the power of a proposed study it is important that a realistic estimate is made of the likely size of the predicted effects. It is all too easy to overestimate this, just as it is easy to overestimate the validity of estimates of dietary intakes. The power of a study to detect a real effect depends ultimately on the size of the effect, and this is usually smaller than one would like, and the size of the effect, or intervention, being studied.
5. In uncommon diseases, and in diseases with a long 'incubation' period, a case-control study may be all that is possible, and this strategy has the greatest limitations. On the other hand, while RCTs yield the most conclusive evidence, they are the most difficult of all the strategies and, as has been indicated, they raise additional difficulties in nutritional research.

Progression in Epidemiological Research

There is a logical sequence in epidemiology, from the observation perhaps of area differences in the prevalence of a disease, or a change over time, to cross-sectional studies that determine prevalence and test associations with dietary or other factors, to intervention trials which examine a preventive strategy focused, for example, on a nutritional factor. A progression such as this will of course be governed to some extent by findings in clinical and in laboratory research and the different approaches are not in any way totally independent.

Such a sequence is seldom seen, and opportunistic studies which explore some aspect are often all that are feasible. However, research on magnesium does illustrate a logical but incomplete sequence. The demonstration of magnesium as an essential element in many enzymes and its involvement in many biological mechanisms led to studies of tissue magnesium in samples taken postmortem. These have led to long-term prospective studies of dietary Mg intakes and the incidence of vascular disease. These led to RCTs of the benefit of Mg infusions given immediately after a myocardial infarction. The sequence will not be completed, and the relevance of dietary Mg to disease will not be apparent until long-term RCTs of an increased Mg intake have been completed and examined in a metaanalysis.

Interpretation of Data

A clear distinction must always be made between the testing of a hypothesis which was defined before a study was set up, and the generation of new hypotheses from data collected for another purpose. This latter, which is often termed 'fishing' or 'dredging,' is permissible only if it is recognized for what it is and if the further associations detected are tested in new *ad hoc* studies. The dangers inherent in generating multiple hypotheses, and in then treating those that achieve an acceptable level of statistical significance as if they were prior hypotheses, are very great in dietary studies because of the number of independent variables.

Firm conclusions should only be based on evidence drawn from a number of studies. The play of chance can never be ruled out, whatever the level of statistical significance, and consistency in a number of studies is a better guide to truth than the results of a single study. Hence the importance of 'overviews' of studies, or metaanalyses of data from a number of different studies. It is most important that data from every relevant study is included in an overview. Unfortunately, certainty on this last is impossible, as there is always a 'publication bias,' that is, reports which confirm a null hypothesis are far less likely to be published than those which show an effect.

There is another aspect of this last point. Not only does one look for consistency in the results of different studies using the same design strategy; one should also look for consistency in the results of studies with different approaches. This is necessary even when there is convincing evidence from, say, a number of RCTs, because an increase in the consumption of one nutrient or one foodstuff is usually accompanied by a change in the consumption of some other nutrients or food items. Confidence is enhanced, however, if prospective studies demonstrate an association between a food item and a disease, if RCTs show a change in the disease incidence, and if these effects are consistent with the results of metabolic studies. Examples of such consistency are rare in dietary research but the benefit of fatty fish in heart disease has been shown in historical studies, in comparisons between communities, in laboratory-type studies of fish oil and vascular risk factors, and in (admittedly only one) intervention RCT.

The Cochrane Collaboration

There have been a number of basic advances in research methodology and foremost among these must be the introduction of the RCT. Another, of perhaps equal importance, has been the development of the overview or metaanalysis. The recognition of the need for these throughout clinical practice led to establishment of the Cochrane Collaboration. This is now an international organization that seeks to identify every acceptable RCT within medical care, makes these available within selected diseases or disease groups as databases, and organizes systematic reviews within different health care interventions.

The Collaboration is an exceedingly valuable research resource. For example, a recent search under the headings 'heart disease' and 'diet' produced, within a minute or two, 328 references to RCTs.

ESCHERICHIA COLI

Contents

Occurrence

K S Venkitanarayanan, University of Connecticut, Storrs, CT, USA
M P Doyle, University of Georgia, Griffin, GA, USA

Introduction

Escherichia coli was first described by Dr. Theodore Escherich in 1885. The natural habitat of *E. coli* is the large intestine of warm-blooded animals, including humans. The bacterium is Gram negative, rod-shaped, and can be easily grown on laboratory culture media. However, most strains generally do not survive very well outside of the host's gastrointestinal tract. Therefore, its presence in the environment is considered as evidence of recent contamination with mammalian or avian feces. Because many fecal-borne microorganisms are pathogenic in animals and humans, the presence of *E. coli* in water and foods is indicative of a potential hazard.

Environmentally, *E. coli* is most often associated with fecally contaminated waters. Sources of contamination include animal feces and discharge of untreated sewage. This has become a cause of concern

in recreational areas and beaches, as such areas are often closed when populations of *E. coli* increase. *E. coli*-contaminated water is also of concern to the food industry. Shellfish, through their filter-feeding apparatus, can concentrate in their tissue *E. coli* and other bacteria present in water. Many shellfish are eaten raw or poorly cooked whereby contaminating bacteria are ingested. In addition, the use of fecal-contaminated water for irrigation of crops and the use of animal manure as a fertilizer can cause contamination of vegetables and other foods of plant origin. Not only is *E. coli* an indicator of the possible presence of fecal-borne pathogens, but some strains are themselves pathogenic. Most strains of *E. coli* are harmless commensals and appear to be avirulent in healthy humans. However, a few strains, with well-characterized traits that are known to be associated with pathogenicity, cause infections of the urinary tract, peritoneum, central nervous system, wounds, and gastrointestinal tract. Those of greatest concern in water and foods are the intestinal pathogens, which are classified into five major groups: the enterotoxigenic *E. coli* (ETEC), the enteroinvasive *E. coli* (EIEC), the enteropathogenic *E. coli* (EPEC) the enterohemorrhagic *E. coli* (EHEC), and the enteroaggregative *E. coli* (EAEC).

Entry into the Food Chain

Since *E. coli* is naturally occurring in the intestinal tract of animals, its entry into foods most often occurs by direct or indirect contact with fecal material. Since humans are the principal source of ETEC, EPEC, EIEC, and EAEC, contamination with human feces is the principal factor in transmission of these pathogens. *E. coli* O157:H7, the predominant serotype among the EHEC, can colonize cattle and other ruminants such as sheep and deer. In cattle, *E. coli* O157:H7 localizes primarily in the rumen and colon, and is shed in feces. Studies have revealed that *E. coli* O157:H7 can survive in bovine feces for many months but also retains its ability to produce toxins. Two important routes by which foods may become fecally contaminated with *E. coli* include:

1. Contamination from food handlers. This can be prevented by education of food handlers in proper hygienic practices, e.g., washing hands thoroughly after defecation.
2. Contamination of animal products with feces from the animal. During slaughter and subsequent processing operations, contamination of carcasses with *E. coli* O157:H7 from the digesta or feces of cattle can occur. Hygienic slaughter practices and treatments to clean and disinfect carcasses may be inefficient in completely removing bacteria from carcasses. During milking of dairy cattle, milk can become contaminated with *E. coli*. One study has found that 46% of raw milk samples and 29% of milk products contained *E. coli*.

Water can also serve as a vehicle for contamination of foods by *E. coli*. Water-borne outbreaks of *E. coli* O157:H7 infection have been reported in the USA, Scotland, Canada, and Japan. *E. coli* O157:NM was implicated in a water-borne outbreak in South Africa. At least four water-borne outbreaks of *E. coli* O157:H7 infection in the USA were associated with swimming water in lakes. Since natural waters often contain *E. coli* of animal origin, and may be contaminated with animal feces and untreated human sewage, their use in food harvesting or processing can cause contamination of the food products, e.g.:

1. Direct contamination of seafood. This is especially a problem with filter feeders such as shellfish, also but also has been observed in many other types of seafood.
2. Contamination of plants during irrigation or fertilization. In some areas, raw human sewage is used to fertilize crops intended for human consumption. Fruits and vegetables grown on soil fertilized with cattle manure or irrigated with water contaminated with cattle manure have the potential of being a vehicle of *E. coli* O157:H7. An outbreak of disease caused by *E. coli* O157:H7 occurred after handling potatoes that had been fertilized with cow manure.
3. Contamination of food-processing equipment or food contact surfaces.

Occurrence in Foods

Since raw foods of animal and plant origin are subject to potential fecal contamination, *E. coli* has been isolated from a wide variety of foods. Foods that have been associated with outbreaks of *E. coli* infections include meat and meat products, fish, poultry, milk and dairy products, vegetables, and water. The incidence of *E. coli* in foods varies greatly in different countries. Investigators in India isolated enterotoxigenic *E. coli* from 33–52% of uncooked chicken sausages and 10–43% of uncooked pork sausages. *E. coli* was detected in 4–7% of 597 retail seafood products in San Francisco, USA. A survey of retail meats revealed that *E. coli* O157:H7 was isolated from 1–2% of beef, pork, poultry, and lamb samples in Madison, USA. A study in Mexico revealed that 74 of 75 Mexican cheeses contained *E. coli* over acceptable levels, whereas seven of 25 non-Mexican cheeses contained unacceptable levels. In Egypt, 28% of fresh

soft white cheese samples contained *E. coli*, of which half the isolates were enterotoxigenic. Twenty-nine percent of dairy products tested in the former Yugoslavia contained *E. coli*. *E. coli*, including some pathogenic serotypes, was isolated from 82 of 105 milk samples from various sources in India. However, a survey of commercially available cheese and milk samples for enterotoxigenic *E. coli* in the United States revealed that none of the *E. coli* isolates recovered was enterotoxigenic. A 1997 survey conducted on the occurrence of *E. coli* in ready-to-eat food products in the UK revealed that the bacterium was present in 2.2% of beef products, 2.8% of chicken products, 1.9% of ham products, 1% of pork products, 5% of plant products, and 2.8% of turkey products. A study of retail foods in Seattle, USA, found Shiga toxin-producing *E. coli* in 18% of pork, 12% of chicken, 7% of turkey, 10% of fish, and 5% of shellfish samples. A recent survey of ground beef for *E. coli* O157:H7 conducted by the United States Department of Agriculture found only 59 positive samples out of 7009 specimens, indicating that the prevalence of this pathogen in US ground beef is about 0.8%.

Fate of *E. coli* in Foods

The behaviour of *E. coli* in foods is similar to that of other Gram-negative bacteria. They are generally sensitive to heat and are killed in foods that are adequately cooked. Studies with *E. coli* O157:H7 have revealed the organism to be slightly more heat-sensitive than *Salmonella* spp., with *D*-values in ground beef at 57.2, 60, 62.8, and 64.3 °C of 270, 45, 24, and 9.6 s, respectively. Heating apple juice at 60 °C for 1.6 min reduced the *E. coli* O157:H7 population by 4−$\log_{10}$. *D*-values of *E. coli* in shrimp paste were 5.8 and 0–3 min at 57 and 65 °C, respectively. Hot-water sprays are useful for reducing the bacterial load on animal carcasses. Treating sides of beef with water at 83.5 °C for 20 s can reduce *E. coli* populations 3 $\log_{10}$ without any detrimental effects on meat color. *E. coli* O157:H7 is as sensitive to radiation as most other enteric pathogens. For example, in chicken, the *D*-values of *E. coli* O157:H7 at 5 and −5 °C were 0.27 and 0.42 kGy, respectively. In ground-beef patties at 4 and −16 °C, the *D*-values for *E. coli* O157:H7 were 0.24 and 0.30 kGy, respectively, compared with 0.62 and 0.80 kGy, respectively, for *Salmonella*.

E. coli O157:H7 can grow in a variety of foods, including meat, milk, cantaloupe, and watermelon cubes, and salad vegetables such as lettuce and cucumber. A study on the survival and growth characteristics of *E. coli* O157:H7 in unpasteurized milk revealed that the pathogen survived at 5 °C for 28 days, and increased in populations at 8 and 15 °C, with rapid growth growth observed at the latter temperature. In pasteurized milk samples held at 22 °C, *E. coli* O157:H7 populations increased by approximately 5.0 $\log_{10}$ colony-forming units (CFU) ml^{-1} in 7 days, and then decreased to undetectable levels by day 28. When inoculated in large populations, *E. coli* O157:H7 could survive in mayonnaise (pH 3.6–3.9) for 5–7 weeks at 5 °C and for 1–3 weeks at 20 °C. *E. coli* O157:H7 also can survive for extended periods of time in several acidic foods such as cheese, yogurt, and apple cider. *E. coli* O157:H7 survived in cottage cheese for more than 60 days. The pathogen can survive the fermentation process in yogurt for 5 h at 42 °C, and for 7 days in yogurt held at 4 °C.

Freezing can kill approximately 1 $\log_{10}$ of *E. coli* in foods. Prolonged frozen storage will not completely kill *E. coli* unless the organism goes through several freeze/thaw cycles. However, such conditions would normally destroy the palatability of food. *E. coli* O157:H7 survived for up to 9 months with no decrease in population in ground beef held frozen at −20 °C with no freeze/thaw cycles. *E. coli* is more resistant to sodium chloride and sodium nitrite than *Salmonella*. *E. coli* in brain–heart infusion broth can grow in 4% sodium chloride and 400 μg of sodium nitrite per milliliter at 15 and 35 °C.

Several studies have determined the fate of *E. coli* in a variety of dairy products. Generation times of *E. coli* in skim milk were 28–35 min at 32 °C and 66–109 min at 21 °C. When lactic starter cultures were included in the milk, growth of *E. coli* was inhibited at both temperatures. A study of the fate of *E. coli* during the manufacture of Camembert cheese revealed that *E. coli* grew slowly until the curd was cut and hooped, then increased rapidly. During overnight storage at 10 °C, as the pH of the cheese decreased to 5.0 or below, the viable *E. coli* population decreased sharply. Depending on the strain tested, *E. coli* was not detectable in the cheese after 0–9 weeks of storage at 10 °C. Inoculating *E. coli* directly onto the surface of ripening Camembert cheese resulted in rapid growth and subsequent survival for up to 7 weeks of storage.

Parameters that influence the growth of *E. coli* in foods roughly parallel those of other Gram-negative bacteria. The minimum water activity (a_w) for growth ranges from 0.94 to 0.97. The optimum pH for growth is approximately 7.0, with a minimum and maximum pH for growth of 4.5 and approximately 9.0, respectively. Growth for some strains can occur from 7 to 46 °C, with maximal growth rates occurring at 35–37 °C. *E. coli* O157:H7 grows very poorly or not at all in many media at temperatures at and

above 44 °C. *E. coli* is capable of very rapid growth in high-nutrient foods. Populations can double within 30–40 min under optimal conditions.

Acid Tolerance of *E. coli* O157:H7

E. coli O157:H7 has an unusual acid tolerance, as evidenced by involvement in outbreaks associated with high-acid foods such as apple cider, yogurt, and fermented meat sausage. *E. coli* O157:H7 can survive for extended periods of time in synthetic gastric fluid. Further, exposure of *E. coli* O157:H7 to mild or moderate acidic environments can induce an acid-tolerance response, which enables the pathogen to survive extreme acidic conditions. For example, acid-adapted cells of *E. coli* O157:H7 survived longer in apple cider, fermented sausage, and hydrochloric acid than nonacid-adapted cells. However, *E. coli* O157:H7 is not unusually heat-resistant or salt-tolerant unless cells are preexposed to acid to become acid adapted. Acid-adapted *E. coli* O157:H7 cells also have increased heat tolerance.

The effect of diet and gastrointestinal acidity in cattle on *E. coli* O157:H7 and its acid tolerance has received recent attention from microbiologists. A study published in 1998 evaluated the role of diet (grass vs grain) and the resulting volatile fatty acids (VFA) levels and pH in the rumen and colon on induction of acid tolerance in *E. coli*. The study revealed that the rumen and colon fluids of grain-fed cattle had higher VFA concentrations and lower pH values than those of cattle fed only grass. Further, larger populations of *E. coli* and acid-resistant *E. coli* were found in rumen and colonic fluids of cattle fed a high-grain diet than that in cattle fed grass only. A following study by a different group of investigators evaluated the effect of diet (high grain vs hay-rich diets) on the duration of shedding of *E. coli* O157:H7 by cattle and the acid resistance of the pathogen shed by the animals. However, these investigators observed that hay-fed cattle shed *E. coli* O157:H7 longer than grain-fed animals, and the acid resistance of *E. coli* O157:H7 was similar, irrespective of the diet.

Prevention of *E. coli* Contamination

The most important considerations for preventing *E. coli* contamination are:

1. preventing fecal contamination by use of clean water supplies, avoiding fecal material during slaughter and milking, and practicing hygienic food handling techniques;
2. thorough cooking of all foods, especially foods of animal origin, including seafood, and pasteurization of milk and fruit juices;
3. avoiding cross-contamination of cooked foods with raw foods of animal origin and unsanitized surfaces of food-processing equipment;
4. proper cleaning and sanitizing of food-processing equipment;
5. practicing good personal hygiene;
6. storing cooked or perishable food at 4 °C or lower.

Use of *Escherichia coli* as Indicator Organism

Escherichia coli is the predominant member of the facultatively anaerobic portion of the human colonic normal flora. The bacterium's only natural habitat is the large intestine of warm-blooded animals and, since *E. coli*, with some exceptions, generally does not survive well outside of the intestinal tract, its presence in environmental samples, food, or water usually indicates recent fecal contamination or poor sanitation practices in food-processing facilities. The population of *E. coli* in these samples is influenced by the extent of fecal pollution, lack of hygienic practices, and storage conditions. The mere presence of *E. coli* in food or water does not indicate directly that pathogenic microorganisms are in the sample, but it does indicate that there is a heightened risk of the presence of other fecal-borne bacteria and viruses, many of which, such as *Salmonella* spp. or hepatitis A virus, are pathogenic. For this reason, *E. coli* is widely used as an indicator organism to identify food and water samples that may contain unacceptable levels of fecal contamination.

Most testing done to isolate *E. coli* from food samples is undertaken to assess the acceptability of manufacturing practices, including sanitation regimes, used in food-processing facilities. Several methods have been developed to achieve this. The traditional cultural approach is a three-step procedure. The first step estimates the number of coliforms in the sample, the second step estimates the number of fecal coliforms, and the final step isolates *E. coli*. The coliform group is defined as members of the family Enterobacteriaceae that produce acid and gas from lactose at 37 °C. Included in this group are *E. coli* and other species of the family such as *Citrobacter*, *Enterobacter*, and *Klebsiella*. Many of these genera are not primarily of fecal origin, and so the presence of coliforms in a sample does not necessarily indicate fecal contamination. The fecal coliforms group includes those coliforms that produce acid and gas from lactose when grown at temperatures between 44 and 45.5 °C. These organisms are typically of fecal origin. *E. coli* is usually the dominant bacterium of the fecal coliform group. The two most commonly used methods for enumerating coliforms, fecal coliforms, and *E. coli* in foods both utilize the most probable number (MPN) technique of statistically estimating the number of bacteria in the sample. In the method recommended by the American Public Health Association, the Association of Food and Drug Officials of the USA, and the Association of Official Analytical Chemists (AOAC), the food or water sample is decimally diluted, and 1 ml of each dilution is transferred into each of three separate tubes containing 10 ml of lauryl sulfate tryptose (LST) broth with inverted Durham tubes. These tubes are incubated at 35–37 °C for 24 h. From each tube with growth and gas production, a loopful of culture is transferred into a tube containing 10 ml of brilliant green lactose bile (BGLB) broth and an inverted Durham tube. These tubes are incubated at 35–37 °C for 24 h. Gas production is indicative of lactose fermentation by coliform bacteria. The number of positive tubes in each dilution should be recorded and an MPN table consulted to determine the number of coliforms in the sample. Both LST and BGLB tubes should be reincubated for an additional 24 h to detect slow lactose fermenters.

For the quantitation of fecal coliform bacteria, a loopful from each gas-producing LST culture is transferred into a tube containing 10 ml of *E. coli* (EC) broth and an inverted Durham tube. These tubes are incubated at 44.5 °C for 24 h. Gas production is indicative of fecal coliform bacteria. To continue with the isolation of *E. coli*, gas-producing cultures in EC broth are streaked onto plates of eosin-methylene blue (EMB) agar or Endo agar and incubated for 24–48 h at 35–37 °C. Representative colonies are chosen and biochemically tested (Table 1).

Another method of detecting *E. coli*, recommended by the UK Ministry of Health, and more commonly used in European countries, also uses the MPN procedure. Decimal dilutions of food or water samples

are inoculated into tubes of MacConkey broth containing inverted Durham tubes, with triplicate tubes receiving 1 ml of each dilution. These tubes are incubated for 24–48 h at 35–37 °C, and the MPN of coliforms is determined using the number of tubes in each dilution showing gas production. To detect fecal coliforms, a loopful from each tube of MacConkey broth showing gas production after 24 h is transferred into a tube containing 10 ml of BGLB broth and an inverted Durham tube, and into a second tube containing 10 ml of peptone water. These tubes are incubated at 44 °C for 24 h. The indole test is performed on the peptone–water culture. Samples showing gas formation in BGLB broth and indole production are considered positive for fecal coliforms. These cultures can then be streaked onto EMB or Endo agar, and representative colonies are biochemically confirmed as *E. coli*.

Several agar media can be used for isolation of *E. coli*. EMB agar contains eosin Y and methylene blue to inhibit Gram-positive bacteria, and lactose for differentiation of lactose-fermenting colonies. Strong lactose fermentation by *E. coli* will cause formation of a typical green sheen over dark colonies. A medium commonly used for isolation of *E. coli* from clinical specimens is MacConkey agar, which contains crystal violet and bile salts to inhibit Gram-positive organisms. *E. coli* will form bright pink to red colonies, surrounded by zones of precipitated bile salts/neutral red complexes. There has been a great interest in recent years in the use of substrates of β-glucuronidase in the detection of *E. coli*. Studies have indicated that 94–99% of *E. coli* strains produce this enzyme, whereas few other species do. Two substrates that have garnered the greatest attention are 5-bromo-4-chloro-3-indolyl-β-glucuronide (BCIG), which forms a blue-colored compound when hydrolyzed by the enzyme, and methylumbelliferyl glucuronide (MUG), which forms a fluorescent compound upon hydrolysis. Of the two, BCIG may be more desirable because it does not require the use of an ultraviolet light, and the color remains more localized. Many investigators have suggested the addition of one of these compounds to standard media to further differentiate between *E. coli* and other bacterial species. Researchers in one study filtered water samples through membrane filters, incubated the filters on Endo agar, and transferred filters onto nutrient agar containing MUG. They demonstrated that 98% of *E. coli* isolates hydrolyzed MUG to produce fluorescent colonies within 4 h at 35 °C with no false positives. It is indicated by the AOAC that incorporation of MUG in LST broth in the MPN technique may enhance the specificity of the method for detecting *E. coli*. The AOAC is currently studying the use of a hydrophobic grid membrane/β-glucuronidase method for detection of *E. coli*. However, the β-glucuronidase test is not 100% sensitive or specific. *Shigella* spp. typically also produce the enzyme. Several β-glucuronidase-positive *Salmonella* strains have also been identified. Some *E. coli* strains do not produce the enzyme. One study has shown that a mean of 34% and a median of 15% of human fecal isolates of *E. coli* were β-glucuronidase-negative when grown in LST containing MUG. Among the consistently β-glucuronidase-negative *E. coli* strains, there are some pathogenic isolates, including the enterohemorrhagic *E. coli* O157:H7 strains.

Isolation of Pathogenic *E. coli*

Methods used to isolate *E. coli* as an indicator organism from foods have not proved to be efficient for isolating pathogenic strains of *E. coli*. This is largely because pathogenic strains often differ considerably from nonpathogenic *E. coli* in growth patterns. Pathogenic strains frequently show delayed growth at 44 and 45.5 °C, particularly when initially present in low populations. Some pathogenic strains will not produce acid and gas from lactose in LST, BGLB, or EC broths within 48 h. It has also been shown that growth in media containing sodium lauryl sulfate and growth at 44.5 °C can cause a loss of plasmids, known to encode many virulence factors associated with pathogenic *E. coli* strains. One study indicated that up to 95% of *E. coli* cells lost plasmids during selective enrichment cultures. Therefore, the methods commonly used for detection of *E. coli* as an indicator organism should not be used to attempt isolation of pathogenic strains from foods or water.

The US Food and Drug Administration Bacteriological Analytical Manual describes a procedure for isolating pathogenic *E. coli* that overcomes many of the problems associated with the MPN procedures. This method is not quantitative. Its goal is the isolation, but not enumeration, of pathogenic *E. coli* from foods. A 25-g sample of food is transferred into a flask containing 225 ml of brain heart infusion broth and is incubated for 3 h at 35 °C to allow for resuscitation of injured cells. The culture is mixed with 225 ml of double-strength tryptone phosphate broth and incubated at 44 °C for 20 h. Representative colonies are picked and tested for biochemical characteristics.

Isolation of Pathogenic *E. coli* from Clinical Specimens

The standard methods for detection and isolation of *E. coli* from foods are generally not practiced in clinical laboratories. The numbers of viable *E. coli* cells in

clinical specimens are generally much higher than in foods. Clinical specimens are usually streaked directly onto selective-differential media such as MacConkey or EMB agar without any enrichment or selective enrichment cultures. Typical lactose-fermenting colonies are picked and tested with a battery of biochemical tests (Table 1).

Detection of *E. coli* Virulence Factors

The major problem in isolating pathogenic strains of *E. coli* is that most *E. coli* possess no characteristics that have been directly associated with production of disease, such as production of toxins or invasiveness. Therefore, it is assumed that most *E. coli* strains are avirulent in healthy humans. Hence, when attempting to isolate pathogenic strains, isolated colonies of *E. coli* must be assayed for characteristics related to pathogenicity. This is particularly a problem in fecal specimens where large numbers of nonpathogenic *E. coli* are usually present.

The process of screening *E. coli* isolates most often involves determining the serogroup (O antigen) by agglutination in O-specific serum. Polyvalent sera containing antibodies against somatic (O) antigens frequently associated with enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), and enterohemorrhagic (EHEC) strains are commercially available. This test is easy and quick to perform. However, the disadvantages are that the procedure does not specifically test for disease-producing potential (e.g., not all strains of an ETEC-associated serogroup are ETEC), and serological cross-reactions can occur between serogroups.

Other tests to determine the virulence potential of *E. coli* isolates include assays for toxicity. Among the best known is the ligated rabbit ileal loop test, in which cell suspensions are injected into a ligated segment of rabbit intestine. Heat-labile enterotoxin (LT)-producing bacteria will cause fluid accumulation within the segment. LT can also be detected by vascular permeability in animals and by inducement of morphological changes in tissue culture cell lines Y–I and Chinese hamster ovary (CHO). Culture filtrates of heat-stable enterotoxin (ST)-producing ETEC strains cause fluid accumulation in the intestines of infant mice. Identification of EIEC and *Shigella* spp. may include the Sereny test for invasiveness. This involves applying a suspension of bacteria to the eye of a guinea-pig. If the bacteria are capable of cellular invasion, ulceration and opacity will occur in the eye within 3 days. This test has been replaced to some extent with invasiveness assays in tissue culture cells.

The advent of molecular biological techniques has provided methods to test directly for virulence factors known or believed to be involved in pathogenesis, often without the need for bacterial isolation at all. Factors for which such tests have been developed include toxins and adhesins. Polymerase chain reactions (PCR) targeting heat-labile toxin genes of ETEC and Shiga toxin genes of EHEC have been reported. An *E. coli* species-specific PCR based on the *malB* operon (gene encoding maltose permease) that detects all *E. coli* strains was developed and applied for detecting *E. coli* in water and soft cheese. Another *E. coli*-specific PCR was also developed using primers specific for 16S ribosomal RNA genes of the organism. Recently, a multiplex PCR that can simultaneously detect ETEC, Shiga toxin-producing *E. coli*, and attaching and effacing strains of *E. coli* was also reported. These methods have been widely researched because they allow confirmation of the presence of a particular microorganism faster and more accurately than cultural methods. However, they often require special equipment or reagents that most clinical, public health, and food-microbiology laboratories do not possess. This is particularly true in developing countries, where there is a greater need for *E. coli* detection systems. Another molecular method becoming commonly used for rapid and specific detection of various types of *E. coli* involves the use of genetic probes. Radiolabelled or chemiluminescent-labelled segments of DNA complementary to regions of genes encoding toxins or other virulence factors are hybridized with the sample, and the presence of the target gene is indicated by the amount of bound radioactivity. This procedure is very sensitive; the specificity is dependent on the structure of the probe and the conditions used during hybridization. Note that genetic probes detect the genes for virulence factors, and therefore presumably the organism itself, whereas ELISA detects the virulence factor that is expressed by the organism. Genetic probes have been used to detect LT- and ST-producing bacteria in food, water and stool, adhesins of ETEC, and the invasiveness proteins of EIEC. DNA probes that utilize chemiluminescent substrates such as streptavidin/biotin system eliminate the need for radioactivity, with little reduction in sensitivity.

Enzyme-linked immunosorbent assay (ELISA) is an immunological method used for detection of *E. coli* strains. There are several forms of ELISA, but all are variations on a single theme. The advantages offered by ELISA methods include rapidity of diagnosis with little or no decrease in sensitivity from tissue culture or animal methods. ELISA has been used to detect LT and ST, adhesins of ETEC, and invasiveness-related outer-membrane proteins of EIEC in stool specimens and culture filtrates. While having great utility in detection of *E. coli* virulence factors in clinical

samples, ELISA methods often do not perform as well in food samples, due to interference from food components.

Detection of *E. coli* O157:H7

Isolation of enterohemorrhagic *E. coli* O157:H7 must be approached differently than using the methods for isolating other *E. coli* strains because *E. coli* O157:H7 grows poorly or not at all at 44 °C in many media used to isolate *E. coli*. None of the methods described above can dependably isolate *E. coli* O157:H7. However, *E. coli* O157:H7 has some biochemical differences from most other *E. coli* strains that can be exploited in isolation and identification methods (**Table 1**). *E. coli* O157:H7 ferments sorbitol slowly or not at all, and does not produce functional β-glucuronidase, whereas most of the other *E. coli* strains are positive in both tests. Further, *E. coli* O157 strains do not ferment rhamnose on agar plates, whereas 60% of non-sorbitol-fermenting *E. coli* belonging to other serogroups ferment rhamnose on agar plates. Clinical laboratories that test for *E. coli* O157:H7 usually streak fecal specimens onto plates of sorbitol MacConkey agar (SMAC) (which contains sorbitol instead of lactose). Sorbitol-nonfermentative colonies are chosen and serologically tested for the O157 and H7 antigens. Positive colonies should then be tested for Shiga toxin production. (*See* **Immunoassays**: Principles.)

Several methods for isolation of this organism from foods have been suggested. Media that can be used to test both sorbitol fermentation and β-glucuronidase activity have been developed. For example, Sorbitol MacConkey agar containing MUG is commonly used for differentiating *E. coli* O157:H7 from other *E. coli* strains. In this medium, *E. coli* O157:H7 strains form colorless and nonfluorescent colonies due to their inability to ferment sorbtiol and break down MUG. However, non *E.coli* O157:H7 strains in Sorbitol MacConkey agar containing MUG, form pink colonies that are fluorescent under UV light. The recovery rate of *E. coli* O157:H7 on Sorbitol MacConkey agar can be improved by previous enrichment in trypticase soy broth supplemented with cefixime ($0.5\,mg\,l^{-1}$) and vancomycin ($8\,mg\,l^{-1}$). Another method for improving the selectivity of Sorbitol MacConkey agar for isolating *E. coli* O157:H7 is inclusion of cefixime and potassium tellurite ($2.5\,mg\,l^{-1}$) that permit growth of *E. coli* O157:H7 but inhibit most of the other *E. coli* strains. Another study indicated that addition of novobiocin can increase the selectivity of the medium for isolating *E. coli* O157:H7. Injured or stressed cells of *E. coli* O157:H7 do not grow well on selective media such as Sorbitol MacConkey agar, especially in the presence of selective agents such as novobiocin, cefixime, and potassium tellurite. A study published from the UK reported that delaying the exposure of injured *E. coli* O157:H7 cells to selective agents by inclusion of a recovery step such as resuscitating the cells on a membrane placed on the surface of tryptic soy agar followed by transfer of the membrane onto Sorbitol MacConkey agar increased the detection of stressed cells of the pathogen without sacrificing specificity. Another medium, called Rainbow agar, has been reported to be superior to Sorbitol MacConkey agar in recovering heat-injured cells of *E. coli* O157:H7. Rainbow agar contains chromogenic substrates specific for β-galactosidase and β-glucuronidase, and produces a spectrum of colored colonies ranging from black to gray to red to blue to violet, which differentiates *E. coli* O157:H7, *E. coli* O26:H11, other Shiga toxin-producing *E. coli*, and Shiga toxin-negative *E. coli*. Enterohemolysin agar is a nonselective, differential medium used for detecting enterohemolysin expressed by about 90% of Shiga toxin-producing *E. coli*. (*See* ***Salmonella***: Detection; ***Shigella***.)

DNA probes and polymerase chain reaction (PCR) provide powerful and rapid tools for specific and sensitive detection of *E. coli* O157:H7. Most probes are directed against genes encoding Shiga toxins for detecting *E. coli* O157:H7 and other Shiga toxin-producing *E. coli* (STEC) strains. Shiga toxin production is the only trait shared by all STEC that is not found in other *E. coli* strains. Probes against all Shiga toxins of strains producing human illness, including Shiga toxin 1 (Stx1) and Shiga toxin 2 (Stx2), would be necessary to detect all STEC strains, because some strains produce only one Shiga toxin. Specificity would not be 100%, because probes against Stx1 genes would also be expected to react with Shiga toxin-producing *Shigella* strains. Additionally, it is not known if all STEC are human pathogens. Many studies have shown the capability of such Shiga toxin gene probes to detect STEC strains in colony blots and enrichment broth cultures. The probes have also been successful at detecting the Shiga toxin-producing bacteria in feces and in foods, including ground beef, raw milk, and salads. Further, a variety of PCR assays specific for attaching and effacing (eae), hemolysin, plasmid pO157, and 60-Mda plasmid genes have been developed for detecting *E. coli* O157:H7. Finally, a number of immunoassays based on somatic (O) and flagellar (H) antigens specific for *E. coli* serotype O157:H7 have been reported. An ELISA procedure utilizing a monoclonal antibody (4E8C12) specific for an outermembrane protein of *E. coli* O157:H7 was capable of detecting *E. coli* O157:H7 in foods in less than 20 h.

Food Poisoning

K S Venkitanarayanan, University of Connecticut, Storrs, CT, USA
M P Doyle, University of Georgia, Griffin, GA, USA

Introduction

Pathogenic strains of *E. coli* cause more types of infections in humans than any other Gram-negative bacterium. They are a frequent cause of urinary tract infections and meningitis, and also have been associated with wound infections and pneumonia. As early as 1923, *E. coli* was suspected to be associated with infantile diarrhea. The first documented outbreak of foodborne *E. coli* infection in the United States occurred in 1971. The implicated food was imported French Camembert and Brie cheeses. *E. coli* strains that cause gastrointestinal disease have been classified into five groups: the enterotoxigenic *E. coli* (ETEC), the enteroinvasive *E. coli* (EIEC), the enteropathogenic *E. coli* (EPEC), the enterohemorrhagic *E. coli* (EHEC), and the enteroaggregative *E. coli* (EAEC). Each of the five groups of gastrointestinal pathogenic *E. coli* consists of certain serotypes that are commonly associated with that group (**Table 1**).

Enterotoxigenic *E. coli* (ETEC)

ETEC produce at least one of two types of enterotoxins, namely heat-stable enterotoxin (ST) or heat-labile enterotoxin (LT). Originally, ETEC were recognized as the etiological agents of diarrhea in piglets. Subsequently, ETEC were isolated from diarrheal stools of children and adults. ETEC cause a watery diarrhea similar to that produced by *Vibrio cholerae*, although usually not as severe in intensity. Diarrhea is usually accompanied by a low-grade fever, abdominal cramps, malaise and nausea. The mechanism of ETEC infection is similar to that of *Vibrio cholerae*. Following ingestion, ETEC cells using fimbriae attach to epithelial cells lining the ileum. The fimbriae are proteinaceous filaments that specifically recognize carbohydrate receptors on the intestinal cells. Adherence allows the bacteria to resist removal by the peristaltic movement of intestinal contents.

After adhering to the intestinal wall, ETEC produce one or more toxins (i.e., LT and ST) that induce a diarrheal response. LT is a heat-labile protein with a native molecular weight of about 86 000. LT consists of an enzymatically active 28-kDa A subunit and five identical 11.5-kDa subunits B. The A subunit, consisting of A_1 and A_2 peptides linked by a disulfide bond, is responsible for the enzymatic activity of the toxin. The B units are arranged in a ring form, and bind strongly to the ganglioside GM_1 and weakly to the ganglioside GD_1. Following binding to intestinal mucosal cells, LT is endocysted and translocated through the cell by a process involving trans-golgi vesicular transport. The A_1 peptide transfers ADP-ribosyl moiety from NAD to the α-subunit of the GTP-binding protein, G_s, which in turn stimulates adenyl cyclase activity. LT ADP ribosylates the adenylate cyclase regulatory subunit, causing the accumulation of cyclic AMP (cAMP) in the intestinal cell. This leads to an increased secretion by crypt cells and decreased absorption by villous tip cells. There are two distinct classes of LT: LT-I is immunologically related to cholera toxin; LT-II is similar to cholera

toxin in function but is not serologically cross-neutralizable. LT-I is produced by *E. coli* strains that are pathogenic for both humans and animals, whereas LT-II is mainly produced by strains of animal origin. Two antigenic variants of LT-II, namely LT-IIa and LT-IIb have been reported. Similar to LT-I, LT-II also increases intracellular cAMP level; however, the receptor for LT-II is GD_1, instead of GM_1.

ST is a heat-stable protein that is much smaller than LT, with a molecular weight of less than 5000. There are two forms of ST, i.e., STa and STb, but only STa is involved in human infection. STb-producing strains are usually of animal origin and do not infect humans. STa consists of 18–19 amino acids with a molecular weight of 2 kDa. Two types of STa have been reported, which include STp (ST porcine or STIa) and STh (ST human or STIb). Each of these two variants contains 13 identical amino acids. STa is produced from its precursor containing 72 amino acids, as a result of cleavage by a signal peptidase. The primary receptor of STa is guanyl cyclase C (GC-C). Stimulation of GC-C occurs once STa binds to it, resulting in the production of increased levels of intracellular cyclic guanosine monophosphate (cGMP). This ultimately results in the inhibition of sodium chloride transport and increased secretion of water from intestinal cells.

Both LT-I and ST are plasmid-encoded, whereas LT-II is chromosomally encoded. The large plasmids, approximately 50–70 MDa in size, that encode LT-I and ST usually encode the fimbriae used for adherence as well. ST genes are located inside a transposon-like element. The presence of these genes on plasmids has contributed to their spread throughout homoconjugative strains.

In developed countries with good hygiene, ETEC is not an important cause of disease. Patients typically have a mild, uncomplicated, watery diarrhea that requires only symptomatic treatment. In these countries, ETEC is most often associated with 'traveler's diarrhea', contracted while travelling in another country with lower hygienic standards. Occasionally, when food or water becomes contaminated, extensive outbreaks of ETEC diarrhea can occur. In 1975, over 2000 staff and visitors at a national park in the USA developed an infection after the park's water supply became contaminated with an ETEC strain that produced both LT and ST. Outbreaks of ETEC have been mainly associated with drinking contaminated water, but examples of foods that have been implicated in outbreaks include crab meat, curried turkey mayonnaise, raw vegetable salad, and Brie and Camembert cheeses. A recent study published by the Centers for Disease Control and Prevention, USA, reported an estimated 79 000 cases of ETEC diarrhea in the United States, with about 70% of the cases foodborne.

In developing countries, ETEC can be a major cause of dehydration and death, particularly among children under 5 years of age. This higher incidence of ETEC infection with higher mortality rates is associated with lower hygienic standards and poor nutrition. In many countries, children are believed to have two to three ETEC infections per year during the first 3 years of life. The disease caused by ETEC in these situations can be severe, and is often indistinguishable from cholera.

Enteroinvasive *E. coli* (EIEC)

EIEC strains are biochemically, genetically, and pathogenically related to *Shigella* spp. Similar to *Shigella* spp., EIEC are nonmotile, lactose negative, and lysine decarboxylase-negative. Further, serologically, EIEC and *Shigella* spp. demonstrate numerous cross-reactions. The mechanisms by which they cause disease are also very similar.

The pathogenesis of EIEC involves cellular invasion and spread, which are mediated by chromosomal and plasmid-borne virulence genes. Like *Shigella* spp., EIEC strains infect the colon by invading epithelial cells, a phenotype mediated by both plasmid and chromosomal loci. Moreover, EIEC elaborate endotoxins, which are believed to play a role in the development of diarrhea. The events that occur in the

pathogenesis of EIEC involve epithelial cell penetration, lysis of the endocytic vacuole, intracellular multiplication, movement through the cytoplasm, and extension into adjacent epithelial cells. Severe infections result in a strong inflammatory reaction leading to ulceration of the mucosa. The resulting symptoms are typical for bacillary dysentery: fever and diarrhea, with some blood and mucus in the stools. Some patients will also demonstrate chills, headache, muscle pain, and abdominal cramps.

The genes mediating invasion are carried on a 140-MDa plasmid. Another plasmid-borne gene (designated as *sen*) in EIEC, which codes for a novel 63-kDa protein (enterotoxin) has been cloned and sequenced. A mutation in the *sen* gene has been reported to cause a significant loss in the enterotoxic activity of the EIEC. Although the role of enterotoxins in EIEC pathogenesis is unclear, toxins are believed to play a critical role in the development of watery diarrhea.

EIEC strains have caused outbreaks of disease world-wide, with most reported outbreaks taking place in countries with high hygienic standards, such as the USA, the UK, France, and Australia. Despite these outbreaks, EIEC is not a common cause of gastrointestinal disease. Outbreaks have resulted from the consumption of contaminated Brie and Camembert cheese and potato salad, but water remains the most commonly implicated vehicle of infection.

Enteropathogenic *E. coli* (EPEC)

The EPEC group has historically been a collection of serogroups associated with infantile and neonatal diarrhea. Until the mechanism by which EPEC cause disease was elucidated, the group was defined principally on the basis of O and H serotypes. However, with a better understanding of the mechanism of EPEC's pathogenicity, this group of pathogens is currently defined on the basis of pathogenesis characteristics. EPEC strains do not produce LT or ST enterotoxins that are associated with ETEC. They are also noninvasive when evaluated by the Sereny test, but some strains are capable of invading tissue culture cells. Some strains do produce Shiga toxin, but these strains have since been reclassified as Shiga toxin-producing *E. coli* (STEC).

EPEC are capable of producing attaching and effacing lesions on host cells. EPEC strains harbor a characteristic large plasmid that confers adherence on the surface of cells. A three-stage model has been proposed in the pathogenesis of EPEC. The first stage involves localized adherence of EPEC to host cells, which is mediated by a type IV fimbria known as bundle-forming pilus (BFP) encoded by fourteen *bfp* genes present on the large plasmid. Studies have shown that mutations in *bfp* genes prevent expression of BFP, resulting in a failure of localized adherence of EPEC to cells. The second stage involves infliction of attaching and effacing lesions on cells, which are mediated by a 35 637-bp pathogenicity island known as the locus of enterocyte effacement (LEE). The attaching and effacing lesions consist of localized destruction of microvilli and the formation of a cup-like pedestal composed of cytoskeletal proteins at the site of EPEC binding to host cells. In the third stage, EPEC attaches intimately to host cells via a receptor followed by cellular alterations in the cytoskeleton. The *eae* gene located in the locus of enterocyte effacement encodes an outermembrane protein intimin, which confers strong attachment of EPEC to cells. Studies of mutations induced in the *eae* gene have revealed that EPEC mutants not only lack the ability to attach intimately to host cells, but also have a diminished ability to cause diarrhea in experimental human infections.

EPEC infections are most commonly associated with infantile diarrhea, which can last for as long as 14 days. Other symptoms can include fever, vomiting, and abdominal pain. When adults are affected by EPEC, symptoms are usually diarrhea, nausea, abdominal cramps, headache, and chills. EPEC infantile diarrhea most commonly occurs in tropical countries with poor hygiene. In Brazil, EPEC is the most common cause of diarrhea in children under 6 months of age. In temperate countries, EPEC are not an important cause of diarrhea, although occasional outbreaks do occur. Foods implicated in outbreaks include pork, meat pies and water.

Enterohemorrhagic *E. coli* (EHEC)

The observation that some strains of *E. coli* produce toxins that kill Vero (African green monkey kidney) tissue culture cells by Shiga toxin provides a basis for the STEC group of *E. coli*. Shiga toxins (also known as Vero toxins) inhibit protein synthesis by cleaving rRNA at a specific nucleotide, in a manner identical to the action of Shiga toxin produced by *Shigella dysenteriae*. Two major Shiga toxins have been characterized. Shiga toxin I (Stx1, VT1) is structurally practically identical to Shiga toxin, and can be neutralized by antiserum raised against Shiga toxin. Shiga toxin II (Stx2, VT2) is structurally similar to Stx1, having at least 74% nucleotide homology with Stx1, but cannot be neutralized by antiserum raised against Shiga toxin or Stx1.

The STEC group as a whole has not been associated with foodborne illnesses. However, a subdivision of

the STEC, known as enterohemorrhagic *E. coli* (EHEC), has been associated with outbreaks and sporadic cases of hemorrhagic colitis following the consumption of contaminated foods. EHEC is a more prevalently recognized cause of illness in developed countries than developing countries. Interestingly, a principal reservoir of EHEC is cattle and possibly other ruminants, whereas humans are the principal reservoir of EIEC and ETEC strains involved in human illness. For this reason, EHEC infections in humans are more often associated with foods of animal origin, or those contaminated with feces of animals than the other types of pathogenic *E. coli*. Additionally, the illnesses caused by EHEC strains are far more likely to lead to death or long-term disabilities than those caused by other *E. coli* gastrointestinal pathogens.

The two major virulence factors in the pathogenesis of EHEC infections include the production of Shiga toxins, and attaching and effacing lesions which are similar to those incurred by EPEC. The Shiga toxins are composed of a single catalytic subunit A, and five receptor-binding B subunits. The B subunits form a pentamer with a center pore through which the carboxyl terminus of the A subunits extends. The B pentamer of Shiga toxins binds to a specific glycolipid receptor known as globotiosyl ceramide (Gb_3), which is present on the cell surface. This is followed by entry of the A subunit into the cell by endocytosis and transport into the Golgi apparatus, and then to the endoplasmic reticulum. The A subunit translocates into the cytoplasm, where it catalyses the N-glycosidation of adenine 4324 of 28S ribosomal RNA, leading to a failure of peptide chain elongation and inhibition of protein synthesis. The block in protein synthesis results in the death of renal endothelial cells and intestinal epithelial cells, or any cells containing Gb_3 receptor. Both Stx1 and Stx2 are encoded by a bacteriophage related to the lambda phage.

Similar to EPEC, EHEC possess the entire LEE, encoded by a 35-kb pathogenicity island. Although the classical attaching and effacing histopathology has been observed in gnotobiotic piglets, infant rabbits, and cultured epithelial cells infected with *E. coli* O157:H7, such lesions have not been reported in clinical biopsy specimens from patients with EHEC infection. The cellular responses leading to attaching and effacing histopathology in EHEC infections include high concentrations of polymerized actin on mucosal lesions, increased levels of IP_3 and intracellular calcium. In addition to Shiga toxins, and attaching and effacing lesions, a plasmid-encoded fimbria has been identified among *E. coli* O157:H7 strains, but its importance in adherence and pathogenesis has not been demonstrated.

Most EHEC isolates belong to the serotype O157:H7, although other serotypes, such as O26:H11, and O111:NM, also have been reported in human illnesses. Hemorrhagic colitis is characterized by a watery diarrhea that progresses to grossly bloody diarrhea, indicative of significant amounts of gastrointestinal bleeding. Severe abdominal pain also results, although fever is usually not present. The illness typically lasts from 2 to 9 days. It is rarely fatal, except among the elderly and young children. However, hemorrhagic colitis and other gastrointestinal infections caused by EHEC strains are often antecedants to more serious conditions, presumably caused by action of Shiga toxins on kidneys and other organs. Hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP) occasionally result from a few days to a few weeks after acquiring a gastrointestinal infection with EHEC, especially among the very young and the elderly. Both are manifestations of damage to kidneys, which can lead to kidney failure and death. The clinical features of TTP are similar to HUS, but TTP also involves damage to the central nervous system. Patients often develop blood clots in the brain, frequently leading to death.

EHEC was first implicated as a cause of human illness following two outbreaks of hemorrhagic colitis in the USA in 1982. Forty-seven people became ill after eating contaminated ground-beef sandwiches. Several outbreaks have since been reported from the USA, Canada, and UK. A chain of outbreaks involving more than 40 *E. coli* O157:H7 cases was reported from Scotland in 1996. In the UK, the number of laboratory isolations of EHEC O157 from human infections increased from 76 in 1986 to 1087 in 1997. A massive outbreak of *E. coli* O157:H7 involving more than 9500 cases and nine deaths occurred in Japan in 1996. A study published by the Centers for Disease Control and Prevention, USA, in 1999 reported an estimated 62 500 foodborne cases of *E. coli* O157:H7 annually in the United States. Outbreaks of hemorrhagic colitis have been associated frequently with inadequately cooked ground beef. Outbreaks have also been associated with consumption of a variety of other foods such as salami, roast beef, venison jerky, unpasteurized milk, apple juice, coleslaw, and contaminated municipal water. Moreover, vegetables such as lettuce, alfalfa and radish sprouts, and potatoes have also been associated with outbreaks of *E. coli* O157:H7 outbreaks.

Enteroaggregative *E. coli* (EAEC)

First described in 1987, EAEC are now recognized as a cause of infantile diarrhea, especially in cases that persist for more than 14 days. EAEC are especially a

problem in developing countries; however, an increasing number of cases have been reported in industrialized countries. EAEC are characterized by their ability to adhere to cultured cell monolayers with an aggregative or 'stacked brick' pattern.

The pathogenesis of EAEC has not been fully elucidated; however, a characteristic histopathologic pattern and a number of virulence factors have been identified. A surface fimbrial structure designated as Aggregative Adherence Fimbriae I (AAF/I) that mediates adherence to Hep-2 cells and erythrocyte hemagglutination has been identified in EAEC. A 60-MDa plasmid containing two separate gene clusters encodes AAF/I. A second fimbriae, AAF/II, that is morphologically and genetically distinct from AAF/I has also been reported in EAEC. Although EAEC is reported to produce a 4100-Da homolog of the heat-stable enterotoxin (EAST1), its role *in vivo* in pathogenicity is not clear. EAEC also produces a 108-kDa cytotoxin that incurs destructive lesions in a rat ileal loop, and is believed to be responsible for mucosal damage in patients. Lesions such as shortening of villi, hemorrhagic necrosis of villous tips, edema, and mononuclear infiltration of submucosa are observed in EAEC infection.

Typical clinical manifestations of EAEC infection include watery, mucoid diarrhea, and low-grade fever with no vomiting. In some patients, grossly bloody stools are observed. In studies with volunteers, the mean incubation period of EAEC infection was 14 h, with a range of 7–22 h. The duration of diarrhea is typically longer than 14 days. Although outbreaks of EAEC were commonly reported from developing countries such as Brazil, Chile, Mexico, India, and Bangladesh, some of the recently reported outbreaks occurred in industrialized countries, including Japan and the UK. A massive outbreak of EAEC involving 2697 schoolchildren was reported from Japan in 1993. Four outbreaks of EAEC occurred in the UK in 1994. Although foods have not been implicated as vehicles in any EAEC outbreaks, the role of food and water in the transmission of EAEC merits investigation. Diagnosis of EAEC infection involves isolation of *E. coli* from stool specimens and a demonstration of aggregative adherence pattern in HEp-2 cells. A DNA probe and a PCR assay specific for EAEC have also been reported.

Treatment

In developed countries, medical intervention in cases of gastrointestinal *E. coli* infections is rarely required. The illness typically is of short duration and resolves without any significant incident. Antibiotic therapy is usually not necessary, with the exception of newborn children with severe EPEC infection. In most other cases, treatment with antimicrobial agents does not appear to have a substantial effect on the duration or intensity of disease. A principal concern is to prevent dehydration, especially among infants. Diarrheal episodes in developing countries are generally considerably more severe than in developed countries. Oral rehydration with aqueous solutions containing sodium, potassium, chloride, bicarbonate, and glucose has substantially decreased mortality. The World Health Organization recommends a rehydration solution containing 90 mM sodium, 20 mM potassium, 80 mM chloride, 30 mM bicarbonate and 111 mM glucose.

Infection by *E. coli* O157:H7 is usually self-limited as well, although patients with severely bloody diarrhea, HUS, or TTP are hospitalized. Care must be taken to prevent dehydration and excessive blood loss. Patients who develop HUS or TTP will often require extensive treatment, including dialysis and blood transfusions.

Control and Prevention

Strains of ETEC, EIEC, and EPEC that cause human disease are usually not associated with animals. The principal source of these bacteria is believed to be feces of human carriers. Therefore, the primary step in preventing these infections is avoiding fecal contamination of foods and water. Water used for cleaning of food contact surfaces should be chlorinated to ensure absence of viable *E. coli* cells. Untreated human sewage should not be used to fertilize vegetables or crops intended for human consumption. Food handlers should be educated in proper personal hygiene and in techniques of handling food safely. Foods should be heated thoroughly to kill *E. coli* and stored under refrigeration conditions to prevent bacterial multiplication. *E. coli* O157:H7 and other EHEC serotypes differ from other *E. coli* gastrointestinal pathogens in that the strains that cause human illness are also found in the intestinal tract of domestic animals used in food production. Consumers should be certain that all foods of animal origin are thoroughly cooked or pasteurized before consumption, and care should be taken to prevent contamination of ready-to-eat foods with uncooked material. Food producers and processors should avoid contamination of animal products with feces during slaughter or milking.

Vaccination of cattle is one potential method for reducing carriage of *E. coli* O157:H7. Although a number of studies have attempted to develop a vaccine targeting various colonization factors such as intimin, an effective vaccine against *E. coli* O157:H7 in cattle has not been reported. However,

an alternative strategy involving administration of probiotic bacteria to cattle that reduce colonization of *E. coli* O157:H7 was recently reported. Protection against ETEC infection has been demonstrated in animals immunized with fimbrial antigens used by these organisms to adhere to intestinal epithelium, and in the litters of pigs immunized with these fimbriae while pregnant. Several studies aimed at inducing immunogenicity against ETEC in humans have been reported. A recent study revealed that peroral administration to children of inactivated, whole cells ETEC coupled with the B subunit of cholera toxin was effective in eliciting an IgA response against ETEC colonization factor antigen I.

Occurrence and Epidemiology of Species other than *Escherichia coli*

P Guglielmetti, Università di Siena, Siena, Italy
A Bartoloni, Università di Firenze, Firenze, Italy

Background

The Enterobacteriaceae are a large family of microorganisms, widely distributed in nature, that may have either saprophytic or pathogenic interactions with the host. In this article, some members of the Enterobacteriaceae, other than *Escherichia coli, Salmonella* spp., *Shigella* spp., and *Yersinia enterocolitica*, are reviewed, with particular reference to their occurrence, isolation, and identification procedure and their role in foodborne poisoning. (*See* ***Shigella***; ***Yersinia enterocolitica***: Properties and Occurrence.)

Characteristics and Occurrence

The very large group of Gram-negative bacteria in the Enterobacteriaceae family are among the most important organisms in the field of human health. The bacteria included in this family share properties. They are Gram-negative, nonsporing, straight rods (0.3–1.0 μm by 1.0–6.0 μm), motile by peritrichous flagella, or nonmotile. They grow well on peptone, meat extract, and usually MacConkey's media, both aerobically and anaerobically, often with gas production by fermentation, rather than oxidation. They are catalase-positive and oxidase-negative, reduce nitrate to nitrite, and have a 39–59% guanine and cytosine (G + C) content of deoxyribonucleic acid (DNA).

The family of Enterobacteriaceae includes 26 genera and more than 60 species. Enterobacteriaceae are widely distributed on plants, fruits, vegetables in

the soil, and water, and in the intestine of humans and animals. Some strains occupy a limited ecological niche (e.g., *Salmonella typhi*); others (e.g., *Klebsiella* and *Proteus*) are widely distributed in the environment.

Only organisms in four genera – *Escherichia, Salmonella, Shigella*, and *Yersinia* – have been clearly documented as enteric pathogens. The occurrence and characteristics of genera potentially implicated in intestinal disease, but for which a definitive role has to be confirmed, are discussed here with special reference to food poisoning.

Citrobacter

There are three species in the *Citrobacter* genus that may have some importance. *Citrobacter freundii* is isolated from human and animal feces, as well as from extraintestinal specimens. It is also commonly found in soil water and food. *Citrobacter diversus* is a rare but important agent of neonatal meningitis and infections in compromised hosts. *Citrobacter amalonaticus*, widely distributed in the environment, is found in a variety of human clinical specimens as an opportunistic pathogen.

Edwardsiella

The most frequently identified species in the *Edwardsiella* genus is *E. tarda*, which is rarely isolated but a well-documented cause of extraintestinal infections. It is suspected, but not firmly established, to be an enteric pathogen. Other species in the *Edwardsiella* genus are extremely rare.

Enterobacter

All *Enterobacter* species are found in water, sewage, soil, and vegetables. *Enterobacter cloacae* is the most frequently isolated *Enterobacter* species from humans and animals. Its role as an enteric pathogen has not been demonstrated. However, it may be an opportunistic pathogen and has an increasing importance in hospital-acquired infections (intensive care units, emergency units, urology). *Enterobacter cloacae* is less susceptible to chlorination than *Escherichia coli*. It may also be isolated in meat, hospital environments, and on the skin of man as a commensal.

Enterobacter sakazakii has no importance as an enteric pathogen, but it is a rare cause of neonatal meningitis and sepsis; it occurs in the environment and in food.

Enterobacter agglomerans is occasionally isolated from clinical specimens and has no conclusive importance as an enteric pathogen. *Enterobacter aerogenes*, phenotypically very similar to *E. gergoviae*, has been identified in dairy products and water.

Hafnia

The only species in the *Hafnia* genus is *H. alvei*, previously known as *Enterobacter alvei*. It is frequently found in clinical specimens, especially in feces from healthy individuals. This organism has been reported by some authors as a potential causative agent of intestinal disease. It has also been isolated from water and dairy products.

Moellerella

The genus *Moellerella* has been recently described (1984), and it includes only one species, *M. wisconsensis*, which has been reported by some authors as a potential agent of gastroenteritis. *Moellerella wisconsensis* has been mainly isolated from human feces.

Morganella

Morganella morganii is the only species in the genus *Morganella*. This organism was once assumed to be a cause of diarrhea, but confirmation about its role in intestinal disease has been lacking in recent years. It is now considered an opportunistic pathogen, and has been isolated from blood, sputa, and pus in patients with bacteremias, respiratory tract, and wound infections. *Morganella morganii* is widely distributed in nature and is commonly identified from the intestines of humans, dogs, other mammals, and reptiles.

Proteus

Among the species in *Proteus* genus, *P. mirabilis* and *P. vulgaris* may cause infections in humans. The former is more frequently identified in clinical specimens than *P. vulgaris*, mainly in human urinary tract infections. *Proteus* urinary tract infections are more commonly found in hospitalized and compromised hosts. Approximately 25% of the healthy population are intestinal carriers. The patients may infect themselves by acquiring the environmental strains or with their own flora. *Proteus* urinary tract infections may give rise to bacteremias that are often fatal.

Proteus mirabilis has been suggested as a possible causative agent of outbreaks of gastroenteritis, resulting from the consumption of contaminated food. Its role as a causative agent of acute gastroenteritis is very difficult to assess because of the high carrier rate in healthy individuals.

Providencia

Among the species in the *Providencia genus, P. alcalifaciens* may be isolated from human and animal feces. The role of *P. alcalifaciens* in disease production is not known.

Serratia

Serratia marcescens is an important opportunistic pathogen, is responsible for many nosocomial infections, and is not an intestinal pathogen. Many other *Serratia* species have been described, all of which are widely distributed in the environment (soil, water, plants, intestine of different species).

Klebsiella

Klebsiellae are opportunistic pathogens that may give rise to several extraintestinal infections. An increase in *Klebsiella* species infections has been reported, particularly in those hospitals where the strains isolated were multiple-antibiotic-resistant. The main reservoir of these strains is considered to be the human intestinal tract, whereas hands are the main vehicles for transmission. Enterotoxin-producing strains have been described.

Klebsiellae are widely distributed in nature, occurring in botanical, aquatic, and soil environments. The two species *K. terricola* and *K. planticola* are thought to be pure environmental strains. *Klebsiella pneumoniae* and *K. oxytoca* are normally found in human and animal intestinal tracts, but in lower numbers, if compared with *E. coli*. *Klebsiella oxytoca* may also be isolated from plants and aquatic environment. Klebsiellae are not considered enteric or foodborne pathogens, but their role in determining intestinal disease is not excluded.

Many other genera and species are included in the large family of Enterobacteriaceae, but only those genera that may be important in food contamination and as opportunistic pathogens are described here.

Growth Factors, Isolation, and Identification

In common with all Enterobacteriaceae, the bacteria listed above grow very well on a broad variety of culture media. The isolation depends on the origin of the specimen. In clinical microbiology laboratories, specimens from a normally sterile body site are cultured on blood or chocolate agar. These media are very rich in nutrient elements and allow the growth of many strains. All the Enterobacteriaceae grow well on such media. Specimens that are likely to be a mixture of microorganisms (feces and vomitus) are generally cultured on selective media to enhance the recovery of the Enterobacteriaceae. A preliminary grouping of enteric bacteria and other Gram-negative organisms may be carried out using media such as MacConkey agar or eosin methylene blue agar. The characteristic appearance of the most common organisms described on blood agar or MacConkey agar allows a preliminary identification of these bacteria. (*See* **Food Poisoning**: Tracing Origins and Testing.)

When a small number of Enterobacteriaceae are thought to be present in the specimen, enrichment techniques in liquid media may be of value to isolate them. This is generally the case for the bacteria previously reviewed, which are present in lower numbers when compared with *E. coli*. Enrichment techniques are associated with subcultures in appropriate selective media in which the presence of antibiotics and other substances makes the isolation of the suspected microorganism easier. For example, the selectivity of the media for *Klebsiella* isolation is based upon the high resistence of this genus to carbenicillin, in contrast to other Enterobacteriaceae. Selective media are routinely used in clinical microbiology laboratories to isolate Enterobacteriaceae from feces. Commonly used selective media for Enterobacteriaceae are MacConkey agar, xylose–lysine–deoxycholate agar, or Hektoen enteric agar. Most of these media inhibit the growth of Gram-positive and commensal organisms and differentiate between lactose fermenters and nonlactose fermenters. Special enrichment and selective media are often available according to the species investigated. These kinds of media are very efficient for isolating *Morganella, Serratia, Proteus*, and *Providencia*. For example, when feces are examined for *Proteus*, the rate of isolation is increased from 8.2 to 23.6% for *P. mirabilis*, when primary plating is preceded by enrichment with tetrathionate or selenite broth. Selective or enrichment methods are not available for *Citrobacter, Enterobacter*, and *Hafnia*, and for *Edwardsiella*, little information exists on selective isolation. Although klebsiellae are usually present in the intestinal tract in low numbers, their elevated and mucoid appearance in agar media is very characteristic and easy to identify. However, the isolation of this microorganism from polymicrobic sources can be facilitated by using selective media.

The identification of Enterobacteriaceae at the genus and species level is based on several conventional biochemical tests. The suspected colony is inoculated, from a pure culture in nonselective media, into a series of tubes with different media for each biochemical test; the tests are read after 24 and 48 h. At present, the procedure is simplified by using a series of miniaturized and standardized tests that are available commercially. These identification procedures are utilized in the large majority of clinical microbiology laboratories.

To isolate and identify these bacteria from food, enrichment procedures are normally performed.

Role in Foodborne Poisoning

In general, the microorganisms reviewed are part of the normal intestinal flora. Mainly for this reason, it is very difficult to establish their role in intestinal disease. More than the isolation and identification of a single species in feces of patients with diarrhea and/or in a suspected food, it is the epidemiological analysis of the episode that is important, especially in the case of a foodborne outbreak. Moreover, some of these organisms, mainly *Enterobacter, Proteus, Serratia*, and *Klebsiella*, may be isolated from food without any evidence of a concomitant intestinal pathology in consumers. The high frequency of recovery and count of the *Klebsiella–Enterobacter–Serratia* group indicates that these bacteria are natural flora of some foods, such as vegetables, and are not necessarily contaminants from humans.

In general, proof of their role in causing illness and their mode of transmission is lacking. For this reason, the reports on foodborne poisoning caused by these Enterobacteriaceae are sporadic and lack definitive confirmation.

Nevertheless, some authors have reported the association of these bacteria with human intestinal disease. Furthermore, the evidence of the production of an enterotoxin by some of these bacteria suggests their hypothetical role as agents of intestinal disease.

Reports are available for *Citrobacter, Edwardsiella, Enterobacter, Hafnia, Moellerella, Proteus, Providencia*, and *Klebsiella*.

Citrobacter has been isolated from feces of patients with diarrhea and from apparently normal persons. The same observations were obtained in animals. In adults with diarrhea, the microorganism was more often found than in asymptomatic controls; *Citrobacter* in symptomatic patients was above all isolated in pure culture. Unfortunately, the lack of data concerning serotypes and biological activity of the isolated strains did not allow the formation of a consensus opinion concerning their pathogenicity. *Citrobacter* has also been isolated from feces of patients and from implicated food in a few foodborne disease outbreaks. Patients had mild to serious diarrhea; symptoms were abdominal cramps, fever, chills, headache, tenesmus, vomiting, nausea, dizziness, and fainting. The documented incubation period in one of these outbreaks was 10–15 h, and the duration of the illness was 12 h. Strains potentially implicated in these outbreaks were isolated from corn pudding, spoiled milk, raw milk, macaroni, meat, liver sausage and smoked meat.

After an outbreak in a nursery, *Proteus mirabilis*, serotype 09:H2, was isolated from spaghetti with cheese, and from the feces of symptomatic children who had eaten the implicated food. The role of *Proteus* species has been suspected in other foodborne outbreaks, but the lack of information about other intestinal pathogens, particularly staphylococci and *Clostridium perfringens*, or in some cases the association of well-known agents of gastroenteritis, does not permit a final conclusion.

A well-documented role of *Proteus* spp. and *Klebsiella* spp. in the genesis of foodborne infections is that of histamine fish (scombroid) poisoning. Scombroids, in common with many other Atlantic and Pacific fish, contain high levels of histidine in their flesh. When the fish are inadequately cooled, *Proteus* and *Klebsiella* may multiply rapidly, decarboxylating histidine into histamine and other related products. These substances are responsible for an allergy-type illness, which starts within an hour of ingestion of the implicated fish. (*See* **Fish**: Spoilage of Seafood.)

Organisms belonging to the *Providencia* genus have been isolated more frequently in children and adults with diarrhea, compared with asymptomatic subjects. In a foodborne disease outbreak, *Providencia*, associated with *Proteus mirabilis* and *Providencia rettgeri*, has been isolated from patients with watery diarrhea and from the suspected food (chicken fricassee).

Klebsiellae are considered normal inhabitants of the human intestinal tract. Nevertheless, occasional reports suggest their potential role as agents of gastroenteritis. Several strains of *K. pneumoniae* gave positive responses in rabbit ileal loop, and a heat-stable enterotoxin, similar to the *E. coli* toxin, has been purified and characterized. A foodborne disease outbreak that involved 190 people has been associated with *Klebsiella* contamination of food, but no definitive evidence was produced. *Klebsiella* is a well-established cause of opportunistic infections, particularly in hospitalized patients. Food prepared and supplied by hospital kitchens is at risk of colonization by Enterobacteriaceae. *Klebsiella* was identified in high numbers from 12 foods in a hospital kitchen and has been isolated from vegetables and seeds, sugar, and milk. The most probable origin of these contaminants is the incoming food, but spread of these microorganisms in the hospital environment may also occur by means of colonized subjects. In addition, other Enterobacteriaceae, such as *Enterobacter, Serratia, Citrobacter*, and *Proteus*, are commonly found in vegetables.

Like *K. pneumoniae, Enterobacter cloacae* in the rabbit ileal loop is strongly positive in certain strains, and a heat-stable toxin, resembling the heat-stable enterotoxin of *E. coli*, has been partially purified and described. The presence of such toxins may be

the *in-vitro* evidence of the potential pathogenicity *in vivo*. Nevertheless, there are few reports of foodborne outbreaks associated with *Enterobacter*.

Hafnia alvei has been associated with an outbreak of mild gastroenteritis among hospitalized individuals and staff members. It has been isolated from the feces of patients with diarrhea and from milk that was implicated as the vehicle of the outbreak.

Edwardsiella has been identified in the feces of both patients with diarrhea and asymptomatic subjects. The role of this genus in intestinal disease is unknown.

Food Poisoning by Species other than *Escherichia coli*

P Guglielmetti, Università di Siena, Siena, Italy
A Bartoloni, Università di Firenze, Firenze, Italy

Background

Enterobacteriaceae other than *Escherichia coli*, *Salmonella* spp., *Shigella* spp., and *Yersinia enterocolitica* have rarely been reported as causes of food poisoning. This article analyzes the role, clinical features and characteristics, detection, treatment, and prevention of foodborne disease associated with this large group of Enterobacteriaceae. (*See* ***Shigella***; ***Yersinia enterocolitica***: Properties and Occurrence.)

Role in Foodborne Poisoning

Among the members of the large Enterobacteriaceae family, *E. coli*, *Salmonella* spp., *Shigella* spp., *Yersinia enterocolitica*, and pathogenic strains of *E. coli* are well-established agents of bacterial food poisoning and foodborne infections. Although other genera in this family (*Citrobacter*, *Edwardsiella*, *Enterobacter*, *Hafnia*, *Moellerella*, *Proteus*, and *Klebsiella*) have rarely been reported as the cause of foodborne outbreaks, their definitive role has not been demonstrated.

It is extremely difficult to evaluate these organisms as causative agents of intestinal disease for many reasons. First, these Enterobacteriaceae are part of the normal intestinal flora, and their presence in both symptomatic and asymptomatic individuals rules out their role as causative agents of intestinal disease. Moreover, the higher prevalence of certain species in stool culture in subjects with diarrhea, compared to that in healthy people, could be caused by overgrowing of these nonpathogenic bacteria as a result of changing conditions associated with the diarrheal disease.

Some of these organisms are well-established opportunistic pathogens but only under certain circumstances, such as in hospitalized patients or in compromised hosts. Although the susceptibility of the individuals ingesting the potential pathogenic microorganism may have a very important role, until now, no significant association has been reported between these Enterobacteriaceae and intestinal disease in infants, old people, malnourished people, and immunocompromised patients.

Other conditions specifically linked to the strains may have an importance in transforming these harmless commensals into facultative intestinal pathogens. Such conditions include the virulence or enterotoxigenicity of the ingested strains and the number of the organisms ingested. That certain strains among the *Klebsiella* and *Enterobacter* genera might be responsible for some outbreaks is suggested by reports of the production of heat-labile (LT) and heat-stable (ST) enterotoxins, which are similar to the enterotoxins produced by *E. coli*.

Another problem in interpreting the role played by these Enterobacteriaceae in outbreaks of food poisoning is that they are widely distributed in the environment and are commonly found as commensals and contaminants of food. Under favorable growth conditions, they multiply and may be isolated in large numbers in food implicated in outbreaks.

To strengthen the hypothesis, the suspected strain isolated from the feces of symptomatic individuals might be identified in implicated food to which

outbreaks have been attributed. Its concurrent recovery in vomitus of patients and in feces of subjects who had eaten the implicated food, even if asymptomatic may be important for a better understanding of the outbreaks. (*See* **Food Poisoning**: Tracing Origins and Testing.)

A factor that may cause ambiguous interpretations is that samples of the suspected food are generally contaminated after they were eaten, and the rapidly growing cultures can outgrow and completely mask the causative organism.

Information about the diffusion of these Enterobacteriaceae in nature may be found in the preceding article.

Members of genera *Citrobacter*, *Edwardsiella*, *Enterobacter*, *Hafnia*, *Moellerella*, *Proteus*, and *Klebsiella* have been associated with food poisoning.

Clinical Features and Characteristics

Citrobacter

In a few food-poisoning epidemics, *Citrobacter* has been isolated from symptomatic patients with diarrhea, from food handlers, and, occasionally, from implicated food.

In the cases where the suspected organism has been identified, the clinical picture of the disease varied from mild to intense diarrhea, with abdominal cramps, nausea, vomiting, fever, chills, headache, tenesmus, dizziness, and fainting.

Citrobacter has been identified as a suspected agent of outbreaks in milk, meat, spaghetti, vegetables, and liver sausage.

Edwardsiella

Edwardsiella tarda has been isolated from the feces of both asymptomatic and symptomatic individuals with diarrhea. This organism has also been identified from the feces of food-industry workers, but its role in foodborne disease outbreaks is unknown.

Enterobacter and *Hafnia*

In 1923 and 1932, two food-poisoning epidemics were associated with organisms of the *cloacae–aerogenes* group, but the symptoms and incubation periods were consistent with staphylococcal intoxications.

Hafnia alvei, previously known as *Enterobacter alvei*, has been associated with an outbreak of mild gastroenteritis where milk was suspected as the vehicle. Other contemporary cases have been reported in the same city where the hospital was located, and a common source that served the implicated food has been identified. In this investigation, the analysis of the serotype showed that the strains isolated from the hospital and urban cases were identical.

A fatal case of food poisoning has been reported in which a man became ill after eating a stew. The incubation period of illness was 4 days. *Hafnia alvei* was isolated from the patient but not from the suspected food, which was discarded.

The role of the organisms in the *Enterobacter* and *Hafnia* genera as potential intestinal pathogens is supported by, besides clinical and epidemiological reports, the observation that *Enterobacter cloacae* has given a positive response in the isolated rabbit ileal-loop test. The toxin implicated has been purified, and the analysis has reported its similarity to the heat-stable enterotoxin (ST) produced by *Escherichia coli*.

Moellerella

Moellerella wisconsensis, from the newly described genus *Moellerella*, has been frequently isolated from the feces of symptomatic individuals. Most of the isolates have been from children with diarrhea. Its role in foodborne disease outbreaks is unknown, but it seems to be an intestinal potential pathogen for humans.

Proteus

The presence of strains belonging to the *Proteus* genus is normal in human and animal intestinal tracts. In the past, many cases of food poisoning, in which *Proteus* was suspected as potential causative agent, have been reported before the role of staphylococci and *Clostridium perfringens* in determining acute gastroenteritis was known. Nevertheless, foodborne disease outbreaks have been reported where *P. mirabilis* has been isolated from feces of subjects with diarrhea in the absence of *Salmonella* spp. and staphylococci.

The clinical features included nausea, vomiting, diarrhea, abdominal cramps, collapse, cyanosis, and sleepiness. Fever was reported in only a few cases. The incubation period was 3–5 h after eating the implicated food. In one of these epidemics, *P. vulgaris* has been isolated from inadequately cooked brawn prepared from brine-pickled meat. Another reported outbreak involved a suspected *P. mirabilis* strain that was isolated in large numbers from the vomitus and feces of symptomatic subjects and from a suspected baked ham. The clinical features and incubation periods suggested the hypothesis of staphylococcal intoxication, but the suspected food was not analyzed for staphyloenterotoxin.

Histamine fish poisoning was responsible for 182 among 2745 (6.6 %) foodborne disease outbreaks

of known etiology reported to the Centers for Disease Control (USA) from 1972 to 1986. (*See* **Histamine**.)

In one outbreak, a strain of *Klebsiella pneumoniae*, capable of producing large quantities of histamine, was isolated from tuna. In general, *Proteus* spp. are responsible for histamine food poisoning.

The clinical features of the illness are characterized by symptoms resembling those of a histamine reaction within 5–60 min of eating the implicated fish. Burning of the mouth and throat, headache, dizziness, and flushing are common. Other symptoms in descending order of frequency are abdominal cramps, nausea, vomiting and diarrhea. Urticaria and bronchospasm may also occur. Symptoms of intoxication are self-limiting and usually resolve in a few hours; in general, no therapy is required. Histamine fish poisoning is reported all the year round primarily from coastal areas.

Klebsiella

Klebsiellae are well-established opportunistic pathogens and are not normally considered as causative agents of intestinal disease. Nevertheless, these organisms have been occasionally reported as potential pathogens in acute gastroenteritis. *Klebsiella pneumoniae*, like *Enterobacter cloacae*, causes a positive rabbit ileal-loop response, and a heat-stable enterotoxin similar to that produced by *E. coli* has been purified and characterized.

A possible outbreak of foodborne *Klebsiella* infection has been reported in which 190 people who had eaten at a boarding school developed gastroenteritis. The suspected food was eaten during lunch. All the subjects developed watery diarrhea with violent abdominal pain 10–15 h after eating the implicated meal. Fever was not reported, and all the subjects recovered within 24 h without antibiotic therapy. Klebsiellae were identified from the soup and beef cooked in rice. *Klebsiella* was the predominant organism in stool culture and has been also identified in high numbers from the suspected food. However, these observations cannot establish these organisms as primary causative agents of the outbreak because the food was improperly stored prior to sampling.

Klebsiellae are very important agents of opportunistic infections in hospitalized patients. Food prepared and supplied by hospital kitchens is at risk of colonization by Enterobacteriaceae. Klebsiellae were identified in high numbers from 12 foods in a hospital kitchen and have been isolated from vegetables, seeds, sugar, and milk. The more probable origins of these contaminants are the incoming foods, but spread of these microorganisms in the hospital environment may also occur by means of the colonized subjects. Other Enterobacteriaceae, such as *Enterobacter*, *Serratia*, *Citrobacter*, and *Proteus*, are also commonly found as contaminants in food prepared in hospital kitchens. Hospitalized patients may be colonized by these organisms and may have a higher risk of developing opportunistic infections.

Detection

The detection and identification of Enterobacteriaceae in suspected specimens are not difficult. Appropriate specimens for laboratory diagnosis include feces, vomitus, gastric contents, and suspected and nonsuspected food. Cultures of the food preparation environment and food handlers may also be useful.

The laboratory should be alerted to investigate also the organisms considered part of the normal flora, as well as the common agents of food poisoning. The quantity of the isolate per gram from the incriminated food item is important, but the specimen analyzed may be derived from properly stored food after it was served. The count of the organism in feces of the patients is not significant; it is more important to demonstrate the common source of origin of the isolates. Serotyping, susceptibility to a series of antibiotics, and bacteriocin analysis (as well as other methods) are utilized in confirming that isolates are derived from a common source. Plasmid analysis may also be useful.

Detailed information about isolation and identification procedures is given in the preceding article. (*See* ***Escherichia coli***: Occurrence and Epidemiology of Species other than *Escherichia coli*.)

Treatment

The food poisoning associated with these strains of Enterobacteriaceae is generally self-limiting. Supportive measures are the mainstay of therapy in these cases. Fluid replacement is the major consideration in all of these illnesses.

Antibiotics play no role, either in therapy or in prophylaxis. Antiperistaltic agents are of little benefit in controlling diarrhea and are contraindicated in patients with symptoms that suggest the responsibility of an invasive pathogen (fever, or leucocytes in feces).

The syndrome associated with histamine fish poisoning may be relieved by antihistamines.

Prevention and Control

The mainstay of food-poisoning prevention is the proper selection, preparation, and storage of food. Inadequate refrigeration is the single most frequent factor responsible for foodborne disease outbreaks.

Enterobacteriaceae grow very well in food at temperatures ranging from 4 to 60 °C. Growth may be prevented if cold food is properly refrigerated and if hot food is held at temperatures above 60 °C before serving.

Poor personal hygiene by food handlers frequently contributes to contamination. Education of the public, nurses, physicians, and those working in eating establishments is crucial in preventing food poisoning by these Enterobacteriaceae, as well as by all the other pathogens implicated in intestinal disease. (*See* **Catering:** Nutritional Implications.)

Reporting all the suspected episodes to public health authorities is essential both in investigating an outbreak and in preventing additional cases.

ESSENTIAL FATTY ACIDS

R Shireman, University of Florida, Gainesville, FL, USA

Essentiality of Polyunsaturated Fatty Acids

In the late 1920s, the polyunsaturated fatty acid (PUFA) linoleic acid (18:2*n*-6) was first described as necessary in the diet of rats to promote normal health. Soon, it was apparent that both 18:2*n*-6 (α-linoleic) and 18:2*n*-3 (α-linolenic) are essential in the diet because animals require these for growth and function of all tissues but lack the capacity for inserting double bonds in the *n*-6 and *n*-3 positions. In the 1930s, G. O. Burr and M. N. Burr described nutritional essential fatty acid deficiency (EFAD) in a variety of animals, and A. E. Hansen demonstrated its existence in children. In ensuing years, work in the laboratories of R. T. Holman and S. B. Johnson established normal levels of total serum fatty acids (FA) in humans of different ages, as well as the distributions in various serum lipid classes (e.g., triacylglycerols, phospholipids). These data allowed comparisons of serum fatty acids of the *n*-9, *n*-6, and *n*-3 series in normal and disease states. The single best index of essential fatty acid status was reported first to be the total serum *n*-6 concentration. Later, it was realized that in deficient states, endogenous synthesis of the 20:3*n*-9 from 18:1*n*-9 occurs; thus, the serum level of 20:3*n*-9 provides another index of status. Essential fatty acids (EFAs) may be classified in two ways: (1) those essential in the diet because animals cannot synthesize *n*-6 and *n*-3 FA *de novo* and (2) PUFA with essential functions. As pointed out by A. A. Spector, linoleic acid appears to be essential not so much because of an immediate cellular function, but because it is the precursor of 20:4*n*-6, which has numerous essential functions. Likewise, the importance of dietary 18:3*n*-3 is that it is the precursor of 22:6*n*-3, which is found in membrane phosphatidylethanolamine (PE) and phosphatidylserine (PS) in large proportions in nervous tissue. Animal cells are able to elongate and desaturate dietary 18:2*n*-6 and 18:2*n*-3 to form two long-chain fatty acids, arachidonic (AA, 20:4*n*-6) and docosahexaenoic (DHA, 22:6*n*-3). Since these are essential for cellular growth and function, they are usually listed as EFA. However, 10:5*n*-3 (eicosapentaenoic, EPA) has many effects in cells, but it has no proven essential functions. DHA (22:6*n*-3) has been recognized as especially important for premature and newborn infants. Some experts suggest using the terms 'indispensable' and 'conditionally dispensable'; for example, if 20:4*n*-6 is present in the diet, there is an absence of deficiency symptoms in healthy adults who have little or no dietary 18:2*n*-6. Thus, the 'true' linoleate requirement depends greatly upon the intake of other FA.

Essentiality is based on biochemical evidence and functional measures associated with deficiency. Numerous experiments with nonhuman primates and other animals have shown that functional development of the retina and occipital cortex in the fetus and neonate is abnormal in α-linolenic acid (18:3*n*-3) deficiency because of a subsequent lack of 22:6*n*-3 production. Such studies are difficult to perform because two or more generations of animals usually have to continue on the deficient diet before definitive effects are seen. Biochemical interactions and various conversions of dietary PUFA make it difficult to state an exact requirement for the EFAs. PUFA intakes among adults are highly variable, but the average estimated current intake is shown in Table 1. Major sources of individual PUFAs are shown in Table 2. Most diets contain much more *n*-6 than *n*-3, unless supplemented with products such as fish oil or flaxseed oil.

Essential Fatty Acid Deficiency

Human EFAD of dietary origin is not common in Western countries, and most EFAD research has been conducted on rats. It may occur in patients on long-term total parenteral nutrition (TPN) when EFAs are not included in the TPN formulation. In countries where protein malnutrition occurs, EFAD may occur because of either very low dietary EFA or lack of enzyme synthesis. Originally, it was thought that 18:3*n*-3 could substitute for 18:2*n*-6, but this proved not to be so because the products of the metabolism of these PUFA differ in function. Dietary 18:3*n*-3 does not alleviate the dermatitis of EFAD nor promote growth to the same extent as 18:2*n*-6. The estimated minimal 18:3*n*-3 dietary requirement for children is 0.54% of calories, whereas that for 18:2*n*-6 is about 1.1%. The estimated minimal requirement of 18:3*n*-6 for adults is 1–2 energy percent, with an optimum of 3–6% (approximately 1 tablespoon of oil); the optimum for 18:2*n*-3 is about 2%. The estimated ideal intake range of *n*-3/*n*-6 is 1:2 or 1:3. In both children and adults, the ratio of the two should be considered, because an overabundance of either suppresses some of the desaturation/elongation reactions for the other.

Primary (dietary-related) and secondary etiologies of EFAD in humans are listed in Table 3. There may be other conditions that are secondary to gastrointestinal (GI) pathology or enzyme defects. In cases such as chronic liver disease or hereditary enzyme deficiencies, the EFAD is not due to a lack of 18:2*n*-6 and 18:3*n*-3 in the diet but is due to an inability to metabolize them further to the necessary end products (20:4*n*-6 and 22:6*n*-3). Some experts contend that if 18:2*n*-6 is sufficient in the diet, typical symptoms of EFAD do not occur, but it is accepted by most that *n*-3 FA are needed for normal neuronal development and visual acuity, based on animal studies. The importance of the long-chain 20:4*n*-6 and 22:6*n*-3 in humans is illustrated by the effects of genetic enzyme deficiencies such as Sjogren–Larsson syndrome and acrodermatitis enteropathica; despite normal intakes of 18:2*n*-6, there are severe symptoms of EFAD including mental retardation, ichthyosis, and very abnormal prostaglandin metabolism (Table 4).

In the past, a serum triene/tetraene ratio of 1 was considered a biochemical indication of serious EFAD. An EFA-deficient diet results in insufficient 18:2*n*-6, 20:4*n*-6, and 22:6*n*-3 in tissues, but there is also marked enrichment in eicosatrienoic acid (20:3*n*-9)

Table 1 Estimated average intake of PUFA in Western diets

Polyunsaturated fatty acid	*Intake (g per day)*
18:2*n*-6	22.5
18:3*n*-3	1.2
20:4*n*-6	0.6
20:5*n*-3	0.05
22:6*n*-3	0.08
Total *n*-6/*n*-3 ratio	16.7

Table 2 PUFA major sources and functions

Fatty acid	*Major sources*	*Major functions*
18:2*n*-6 α-Linoleic	Safflower, sunflower, sesame, soybean, and corn oils	Component of epidermal permeability barrier; precursor of 20:4*n*-6
18:3*n*-3 α-Linolenic	Linseed, canola, flax and other seed oils	Precursor of EPA, DHA
20:4*n*-6 Arachidonic	Meats, dairy products	Precursor to bioactive eicosanoids; signal transduction; gene expression
20:5*n*-3 Eicosapentaenoic (EPA)	Marine fish oils	Competitive inhibitor of 20:4*n*-6
22:6*n*-3 Docosahexaenoic (DHA)	Marine fish oils, marine algae	Neuronal membrane structure; gene expression; prevention of apoptosis
18:3*n*-6 γ-Linolenic (GLA)	Evening primrose oil, borage seed oil	Precursor to 20:3*n*-6
20:3*n*-6 Dihomo-γ-linolenic (DHLA)	Milk (small amount)	Competitive inhibitor of 20:4*n*-6

Table 3 Etiology and characteristics of primary and secondary EFAD

Etiology	*Result*	*Effect*
Chronic malnutrition, especially in children	Lack of dietary fat and protein Decreased enzyme synthesis	Very abnormal serum FA patterns Low total serum PUFA
Long-term fat-free TPN	Lack of dietary EFA	Abnormal serum 20:3*n*-9/20*n*-6
Various fat malabsorption conditions	Secondary to pancreatic insufficiency, bowel cancer, or other serious GI diseases	Low total serum PUFA
Sjogren–Larsson syndrome	Genetic enzyme defect in desaturation and elongation	Low serum levels of C20 and 22 PUFA
Acrodermatitis enteropathica	Genetic defect in ε5 and ε6 desaturase activity	Very low levels of 22:6*n*-3
End-stage liver disease	Impairment in desaturase and elongase activities	Very low serum levels of LCPUFA

Table 4 Characteristics of EFAD in humans

Known clinical manifestations
- Dermatitis; dry, scaly skin; impetigo; eczema; generalized erythema
- Coarse, sparse hair
- Increased frequency of stools
- Decreased growth rate
- Cellular hyperproliferation in skin, alimentary tract, and urinary tract
- Possible immune impairment
- Slow wound repair

Suggested manifestations associated primarily with 22:6n-3 deficiency
- Slower early learning behavior (based on animal studies)
- Visual perturbations (based on animal studies)
- Mental retardation in human genetic defects involving desaturases and elongases

Known biochemical aberrations
- Serum 20:3*n*-9/20:4*n*-6 greater than 0.4
- Increased serum 16:1*n*-7, 18:1*n*-9, and 20:3*n*-9; decreased 18:2*n*-6, 20:3*n*-6, and 20:4*n*-6

in blood and liver. Status is now usually measured more accurately as the 20:3*n*-9/20:4*n*-6 ratio in serum phospholipids. A normal value is considered to be about 0.1–0.2. Occasionally, when abnormalities are due to an enzyme deficiency rather than to diet, some other index may be more useful. For example, the normal conversion of 18:2*n*-6 to 20:4*n*-6 results in a ratio of 18:2*n*-6/20:4*n*-6 of about 1.6, but in severe dietary EFAD, it may be 1.2. In achrodermatitis enteropathica, however, very little arachidonic acid is synthesized, and this ratio may be 10 or larger.

Serum FA patterns and symptoms that resemble EFAD occur in a variety of disorders. Marginal or frank EFAD is somewhat common in young cystic fibrosis (CF) patients, but whether this is a consequence of decreased fat absorption or a defect in FA metabolism, or both, is not known. While all serum FA levels are decreased in some CF patients, the fact that fewer desaturation products are present has led to the speculation that there is an enzymatic defect in FA metabolism. Oxidative stress disorders tend to show FA patterns characteristic of EFAD. The reason is unknown. Perhaps reactive oxygen species or products of oxidative damage act to decrease the activity of desaturases. Whereas high amounts of PUFA in the diet are said to increase the requirement for vitamin E, in studies on concomitant EFAD and vitamin E deficiency, measures of autooxidative susceptibilty in rat red blood cells indicated that EFAD actually potentiated the vitamin E deficiency. Patients with malabsorption syndromes or long-term depressed oral intake or TPN may exhaust stores of EFA and exhibit clinical signs of EFAD, especially dermatitis. Also, TPN formulations with very high ratios of *n*-6 to *n*-3 have resulted in symptoms of *n*-3 deficiency, including neuropathy and immune impairment in animals.

Nervous tissues in primates and other animals are rich in *n*-3 PUFAs and their products. There have been numerous reports of learning deficits and other effects on nervous tissue in animals deprived of all *n*-3 PUFAs. If 22:6*n*-3 is not added to the media of retinal photoreceptor cells in culture, they degenerate and die, presumably because of activation of an apoptotic pathway. But reports of effects in humans have been less convincing, largely because long-term controlled dietary experiments cannot be conducted. Episodic numbness, weakness, pain in the legs, and blurring of vision occurred in children on TPN formulas that did not contain *n*-3 PUFA. These effects were reversed after inclusion of *n*-3 FA in the formula. Researchers have noted that some of the physical symptoms of attention-deficit hyperactivity disorder are similar to those of EFAD and that many of the diagnosed children have decreased serum 20:4*n*-6 and 22:6*n*-3 levels. Conversion of 18:2*n*-6 and 18:3*n*-3 requires

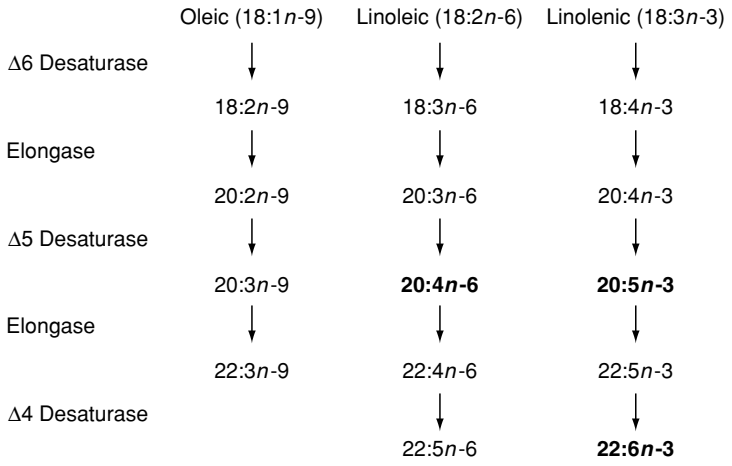

Figure 1 Metabolic pathways for fatty acid elongation and desaturation. Bold type designates major end products of the pathway.

desaturase and elongase enzymes, which may not be fully active in the preterm infant and neonate. Long-chain PUFAs (LCPUFAs), especially 22:6*n*-3, are particularly important for brain and nerve cell development *in utero*, but the fetus does not synthesize the long-chain EFA to any extent. Thus, maternal intake may be more important than has generally been recognized. Many investigators support the inclusion of *n*-3 PUFA, especially 22:6, in formulas for both premature and term infants. There remains some controversy over whether the inclusion is needed, since several studies have shown no detectable benefits for breast-fed infants whose mothers took supplemental dietary 22:6*n*-3. While there is some evidence of the efficacy of *n*-3 long-chain PUFA in increasing early visual maturation in preterm infants, there is no demonstrated long-term benefit. Six randomized trials with supplementation of infant formulas with LCPUFA were reviewed by Simmer, who concluded that there is little evidence to support the hypothesis that supplementation with 20:5*n*-3 and 22:6*n*-3 conferred any benefit on visual or cognitive development or influenced the growth of term infants.

Metabolism of PUFAs

In general, cells try to maintain a balance of FA of different chain lengths and degrees of desaturation to control membrane fluidity. PUFAs can be oxidized for energy, but the functional and structural roles of EFA depend largely on their metabolic products. All 20 carbon FA are referred to as eicosanoids, and 20:3*n*-6, 20:4*n*-6, and 20:5*n*-3 can all be used for prostaglandin synthesis. The metabolism of the *n*-9, *n*-6, and *n*-3 families can occur along the same pathways but normally does not, at least to the same extent (Figure 1). Furthermore, major products of the pathways may differ among cells, depending on enzyme activities. For example, the end product of 20:4*n*-6 in endothelial cells is prostacyclin (PGI_2), whereas the end product in platelets is thromboxane (TXA_2). The balance of LCPUFAs in the cell is regulated largely by induction or suppression of the relevant desaturases and elongases. In EFAD, there is increased desaturation of both 18:0 and 18:1. Negligible amounts of oleic acid (18:1*n*-9) are normally converted via the pathway in Figure 1, but in EFAD, cells try to produce long-chain PUFA needed for structure and functions by conversion of 18:1*n*-9 (oleic acid) to 20:3*n*-9. The ratio of 20:3*n*-9 to 20:4*n*-6 can be used as an index of deficiency.

In the presence of excess PUFA, the Δ9, Δ6, and Δ5 desaturases are suppressed, in part at the level of gene expression. Experiments with cultured endothelial cells have shown that added *n*-3 FA will be mostly elongated to C22 products, thus effectively removing competitors of 20:4*n*-6. But such experiments are lacking in many other types of cells. A. A. Spector has pointed out that even though cells can produce 22:5*n*-6, very little is normally produced possibly because most of the precursor, 20:4*n*-6, leaves the pathway for later prostaglandin synthesis. In *n*-3 PUFA deficiency, more 22:6*n*-6 is produced, but it does not fully replace the function of 22:6*n*-3. EFA desaturation and elongation occurs mainly in the liver and is then delivered to other cells. DHA (22:6*n*-3) is not synthesized in neurons, despite its high concentration there; however, it can be synthesized from 18:3*n*-3 and 20:5*n*-3 in the surrounding astrocytes. It is hypothesized that astrocytes synthesize DHA and release it as a trophic factor for neurons. EFA retroconversion, or shortening of the chain, can occur but its metabolic significance, if any, is not known.

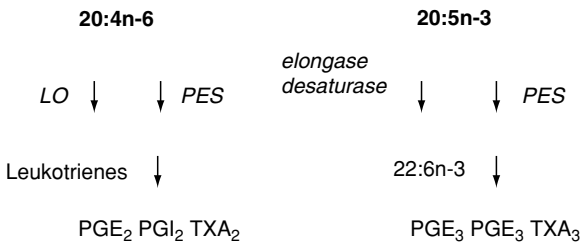

Figure 2 Summary of arachidonic and eicosapentaenoic acid metabolism.

Arachidonic acid undergoes metabolism to the series-2 prostaglandins (i.e., two double bonds) and to the leukotrienes of series-4 (four double bonds), as simplified in Figure 2. The oxidation of eicosaenoic acids (20:4*n*-6, 20:3*n*-6, and 20:5*n*-3) is catalyzed by the enzyme prostaglandin endoperoxide synthetase (PES), which has two separate activities usually referred to as cyclooxygenase (CO) and peroxidase. Figure 2 shows the difference in the products in the pathways that involve the same enzymes. Cyclooxygenase converts 20:3*n*-6 to PGG_1, 20:4*n*-6 to PGG_2, and 20:5*n*-3 to PGG_3. Subsequent conversion to hydroxy analogs occurs next via peroxidase activity. Metabolism of these endoperoxides to characteristic products depends largely on the cell type. For example, in arterial endothelial cells, PGG_2 is largely converted to PGI_2, prostacyclin, which causes vessel vasodilation and also inhibits platelet aggregation. In platelets, however, PGG_2 is converted to TXA_2 which is important to normal blood clotting, since it causes vasoconstriction and platelet aggregation. These metabolites must be continuously synthesized as they have a very short half-life. The various products tend to act in a 'balanced antagonistic' way; while TXA_2 is the most potent proaggregatory agent known, it is normally counteracted by prostacyclin. When the balance is altered, excess thromboxane leads to abnormal platelet adhesion and aggregation and therefore it may be implicated in coronary thrombosis. Although 20:3*n*-6 and 20:5*n*-3 can be used to form similar products that have one or three double bonds, respectively, the series-1 and series-3 prostaglandins do not have the same biological activity as the series-2. In addition, the precursors (18:3*n*-6 and 20:5*n*-3) compete with 20:4*n*-6 for cyclooxygenase action. This is why EPA (20:5*n*-3) in fish oil is said to be beneficial in preventing thrombosis.

Lipoxygenase (LO) catalysis of 20:4*n*-6 forms hydroxy fatty acids known as leukotrienes (e.g., LTA_4, LTB_4) These are compounds that have four double bonds, at least three of which are conjugated double bonds. Other eicosanoids can compete with 20:4*n*-6 for LO activity and thereby reduce the amounts of series-4 leukotrienes formed.

Functions of EFAs and their Metabolites

There are numerous known and some purported functions of PUFA. The major function of both α-linoleic acid (18:2*n*-6) and α-linolenic acid (18:3*n*-3) is as a precursor to other essential long-chain fatty acids, although 18:2*n*-6 itself may be important in membrane and lipoprotein structure and may have some cellular functions. The functions of the metabolites are very different, except that both 20:4*n*-6 and 22:2*n*-3 are components of membrane phospholipids and are involved in signal transduction. Also, both are known to modulate or regulate gene expression for several enzymes. All LCPUFAs suppress transcription of genes encoding several lipogenic enzymes including fatty acid synthetase and S14 protein and induce certain genes encoding peroxisomal and cytochrome P_{450} enzymes. The net result is that at a high PUFA, suppression of lipogenesis and triacylglycerol synthesis occurs. They regulate the expression and/or activity of the acyl desaturases and perhaps some of the enzymes of the glycolytic pathway. Otherwise, the effects of 20:4*n*-6 and 22:2*n*-3 are quite different. The various products of 20:4*n*-6 metabolism also have very diverse, sometimes antagonistic, functions. In addition, the competition of the other 20C*n*-6 and *n*-3 FA for the same enzymes makes it difficult to assign cause-and-effect functions. General functions are shown in Table 5.

Among the lesser known effects of EFA are the effects on lipoprotein metabolism. Normal EFA status is necessary for overall lipoprotein metabolism and especially for efficient high-density lipoprotein processing by the liver. In dietary deficiency with normal liver function, there is decreased incorporation of phosphatidylcholine into bile and decreased chylomicron production. Altered partitioning of available EFA has been noted in animals and increased hepatic conversion of linoleic to arachidonic acid occurs. Also, hepatic Δ6 and Δ5 desaturases are upregulated. More eicosanoid precursors are distributed into hepatic phosphatidylethanolamine than

Table 5 Some general functions of arachidonic acid, docosahexaenoic acid, or their metabolites

Modulation of gene expression	Lipoprotein synthesis and metabolism

usual. The *n*-3 PUFA decrease serum triacylglycerol through reduced very low density lipoprotein production. The precise biochemical nature of these effects has not been established. Another less known effect of EFAs is that they enhance the effects of vitamin D in increasing calcium absorption and help decrease urinary excretion of calcium. EFA-deficient animals develop severe osteoporosis and ectopic calcification.

The effects of PUFAs on cell proliferation, tumors, and cancers are highly variable, depending on the cell type and proportions of FA. They may be modulators of carcinogenesis with distinct tissue-specific pro- or anticancer effects. LCPUFAs activate the peroxisomal proliferation activator receptor, which may mediate their purported effects on gene expression, cellular growth and differentiation, and apoptosis. Both 18:2*n*-6 and 20:4*n*-6 are said to inhibit mitogen-stimulated proliferation of lymphocytes in culture, but they may have no effect or a stimulatory effect in other cell types. In EFAD in animals, diminished immunity occurs because 20:4*n*-6 metabolites are needed for normal immune responses. However, the *n*-3 PUFAs suppress immune response and may be of benefit in inflammatory and autoimmune disorders. As mentioned above, the prostaglandin and thromboxane derivatives of 20:4*n*-6 are bioactive molecules that act as paracrine hormones and have many well-known, important functions on blood clotting, smooth muscle contractions, and immune responses. When released from phospholipids, 20:4*n*-6 activates protein kinase C and therefore modulates the activation of growth factor receptors such as EGH receptors. It is thought to have other cell-signaling functions as it can inhibit GTPase activated protein.

The *n*-3 PUFAs are said to inhibit endothelial activation. This may occur in at least two ways; 20:5*n*-3 competes with 20:4*n*-6 for conversion to the prostaglandin, which normally stimulates this activity, and 22:6*n*-3 decreases expression of endothelial leukocyte adhesion molecules. Usually, prostacyclin-mediated cytokine stimulation of expression of adhesion molecules is a normal physiologic protective function, but in pathological states, this leads to an undesirable sequence of events that may result in atheroma formation. These *n*-3 PUFAs may help confer a protective effect against atherogenesis. Also, *n*-3 FA promote an antiarrhythmic action, apparently owing to a slight hyperpolarization of heart muscle membranes that prevents 'easy' induction of action potentials.

Leukotriene metabolites have profound effects on white blood cell chemotaxis and phagocytosis, regulation of neutrophil and eosinophil function, smooth muscle contraction and bronchoconstriction in the pulmonary system, and changes in capillary permeability. In neutrophils, 20:4*n*-6 is metabolized primarily by the 5-LO pathway leading to the formation of LTA_4, which is a precursor for a potent chemotactic factor. Thus, a decrease in 20:4*n*-6 concentration can result in an antiinflammatory response. Since 20:5*n*-3 and 20:3*n*-6 compete with 20:4*n*-6 for the LO pathway, the result is similar because less conversion to LTA_4 occurs. Although the prostanoids and leukotrienes formed from 20:4*n*-6 have many extremely important physiologic functions, overproduction of some of these compounds appears to be involved in certain disease processes or states, including thrombosis, myocardial infarction, cardiac arrythmia, arthritis, asthma, inflammatory conditions, and autoimmune disorders. Reduction of tissue levels of 20:4*n*-6, competition for enzymes by other FA, or inhibition of the enzymes by drugs may in some cases ameliorate some of the symptoms associated with the disorder(s). For example, aspirin, ibuprofen, and several other drugs inhibit the activity of cyclooxygenase, and steroidal antiinflammatory compounds such as hydrocortisone inhibit the enzyme phospholipase A_2 that releases 20:4*n*-6 from membrane phospholipids. All of these result in less prostaglandin synthesis. Inhibition of phospholipase A_2 also reduces leukotriene synthesis.

DHA (22:6*n*-3) is the major PUFA in neuronal membranes; it is especially enriched in PS. PS is important structurally and functions in translocation of specific proteins, such as Raf-1 and protein kinase C, to the plasma membrane. Also, it is hypothesized to be involved in cellular apoptosis. Raf-1 translocation is a first step in the transduction of growth factor signaling. Depletion of 22:6*n*-3 leads to a decrease in the synthesis of PS and lower levels of PS in brain cell membranes. PS levels are much higher in nerve tissues than in other tissues, and *n*-3 deficiency results in a dramatic reduction of PS only in nerve cells. Thus, *n*-3 deficiency seems to have profound effects on PS-related signaling events in the nervous system. In animals, a decrease in 22:6*n*-3 may be associated with compensatory increased levels of 22:5*n*-6 leading to: modification of neural membrane composition and functional changes in enzyme activities, suboptimal retinal and brain development, and a poorer performance in learning tasks. It may also be correlated with peroxisomal disorders associated with neuronal deterioration. Brain concentrations of 22:6*n*-3 plateau with 18:3*n*-3 intake of about 0.7% energy, but this is influenced by the 18:2*n*-6 intake. Several studies have shown adverse effects on growth and function of animals with high intakes of 22:6*n*-3.

The amount, type, and balance of dietary FA along with antioxidant nutrients impact the immune system. The amelioration of symptoms of autoimmune diseases in some studies with high doses of fish oils

was attributed to effects of 20:5*n*-3 suppression of T-lymphocyte proliferation, apoptosis of autoreactive lymphocytes, and decreased proinflammatory cytokine production. Long-term effects of such treatment on host immunity require further study. T-cell proliferation was shown to be decreased after administration of 2.4 g per day 18:3*n*-6 (γ-linolenic) in borage seed oil, but not with 18:3*n*-3 or 18:2*n*-6. The effect therefore appears to be a competitive effect of 20:5*n*-3 and 20:3*n*-6 with 20:4*n*-6. Dietary 20:5*n*-3 and 18:3*n*-6 also appear to inhibit arachidonic induced production of thromboxane (TBB_2) by platelets.

Recent Advances

In the past decade, much research has focused on fish oil supplementation, with high levels of 20:5*n*-3 and 22:6*n*-3. The fatty acid content of menhaden oil is shown in Table 6, and possible benefits and concerns of supplementation in Table 7. Three areas have been of special interest: effects on immune responses, coronary heart disease, and behavior. In all of these areas, there have been inconsistencies in the reported results, some of which may be due to different diets and conditions.

Some researchers have suggested a role for EPA as well as DHA in normal nerve cell membrane structure. This is based largely on reports of lower than normal levels of EFA in some patients with schizophrenia and the moderately positive effect observed with EPA supplementation. However, since EPA can undergo further metabolism to DHA, it is unclear whether EPA has anything other than a precursor role in these cells. There are trials in progress on the use of EPA in the treatment of schizophrenia.

Rats with decreased brain levels of 22:6*n*-3 show an impaired performance in learning tasks compared to rats fed 22:6*n*-3 and increasing the amount of 22:6*n*-3 to a 10:1 ratio *n*-6/*n*-3 in infant formula of primates was associated with greater accretion of 22:6*n*-3 in neonatal brain and retina. Patients with moderately severe dementia of thrombotic cardiovascular disorder and Alzheimer's dementia supplemented with fish oil were followed for one year and showed improved scores on a psychometric test as well as better red blood cell (RBC)-deformation scores. It was unclear whether the improvement was a direct effect on neuronal cells or due to improved RBC function. Low-serum 22:6*n*-3, along with the associated decrease in phosphatidylcholine, is now considered to be a significant risk factor for Alzheimer's dementia. Of concern is the reduction in Δ6 desaturase activity that occurs with aging and possible lack of adequate 22:6*n*-3 synthesis, even with adequate intake of 18:3*n*-3. This FA comprises more

Table 7 Possible beneficial effects vs. safety concerns related to dietary *n*-3 PUFA

Possible benefits of supplementation in selected individuals
Decrease in serum triacylglycerols
Decrease in myocardial infarctions in persons with diagnosed CHD
Decreased inflammation and relief of certain conditions, as rheumatoid arthritis, psoriasis, lupus and inflammatory bowel syndrome
Decreased cardiac arrhythmias (animal studies, not very definitive in human studies)
Possible safety concerns related to excess intake (based on animal or human studies)
Increased bleeding times and associated risk of hemorrhagic stroke
Increased peroxidation of fatty acids
Inhibition of immune cell function and decreased resistance to infection
No change or increase in serum LDL-cholesterol
Imbalance of PUFAs (very low *n*-6/*n*-3) with resultant behavioral abnormalities
Concerns related to interactions with drugs
Interactions with drugs that affect eicosanoid metabolism and clotting mechanisms
Interactions with drugs that affect eicosanoid metabolism and immune responses
Potentiation of cytotoxicity of some anticancer drugs
Possible cases for 'special' supplementation
Chronic liver disease – may require supplementation of 20:4*n*-6 and 22:6*n*-3
Cystic fibrosis – may require supplementation of 20:4*n*-6 and 22:6*n*-3 in addition to 18:2
Inherited desaturase and/or elongase deficiencies, as in some peroxisomal disorders
Subnormal 20:6*n*-3 serum levels associated with certain types of depression, dementia, attention-deficit disorder, adrenoleukodystrophy, long-chain hydroxyacyl-CoA dehydrogenase deficiency, and dyslexia

than 30% of the structural lipid of neurons and is very enriched in retinal rod outer segments. Subnormal levels are associated with neurological conditions, including depression, attention deficit hyperactivity disorder, and dementia. Dietary intervention to increase plasma 22:6*n*-3 levels has been associated with improvements in visual or neurological deficits in adrenoleukodystrophy, long-chain hydroxyacyl-CoA dehydrogenase deficiency, dyslexia, and Alzheimer's dementia. Intervention trials are now underway to determine the effects of dietary 22:6*n*-3 from algal sources on development of Alzheimer's dementia. This source, which contains much less 20:5*n*-3, will be evaluated for safety and efficacy in hopes of reducing the side-effects of high levels of 20:5*n*-3, including immune suppression and bleeding tendencies.

Diets rich in *n*-3 PUFAs have been associated with suppression of cell-mediated immune response. Although this accounts for the reported beneficial effects of fish oil in arthritis, suppression of immune response is of great concern in some individuals. Fish-oil diets suppress lymphocyte proliferation, monocyte and neutrophil chemotaxis, and tumor necrosis factor, interleukin-2, and interleukin-6 production, and also reduce expression of adhesion molecules on the surface of endothelial cells, monocytes, and lymphocytes. This is the basis of its antiinflammatory effect. LTB_4, which is a potent chemoattractant for monocytes, important in regulation of inflammatory response and cytokine synthesis, declines in the presence of excess 20:5*n*-3. Also, PGE_2, which normally increases during infections and acute inflammation, declines, and the series-3 prostaglandins and series-5 leukotrienes, which have a less potent effect, increase. These effects are attributed to 20:5*n*-3, rather than 22:6*n*-3.

Because of anecdotal and epidemiological evidence suggesting that FO had a positive influence on decreasing the incidence of CHD, in 1993, the US Food and Drug Administration (FDA) conducted a study to determine whether to allow a health claim for *n*-3 fatty acids. At the time, the FDA concluded that findings were inconsistent in the general population, and there was insufficient evidence to support a health claim for *n*-3 FA and CHD. Some suggested an adverse effect. A part of the problem with the early epidemiological and intervention studies is that plasma total cholesterol or low-density lipoprotein cholesterol (LDL-C) was used as the biomarker for reduced risk of CHD. Almost all studies with fish oil showed no significant decline in LDL-C, and some showed an increase. More recently, the FDA again considered whether to allow the health claim, and in this review, different endpoints and clinical measures of the risk of CHD were evaluated. These included the endpoints of fatal or nonfatal myocardial infarction and clinical measures of reduction in fasting and postprandial serum triacylglycerol levels, reduction in platelet aggregation and adhesion, and changes in the composition of serum lipoproteins. In the mid- to late 1990s, all intervention trials of persons with diagnosed CHD supplemented with fish oil or *n*-3 derivatives showed no decrease in LDL-C but decreases in the risk of CHD using the mentioned endpoints. After reviewing the relevant data on beneficial effects on the risk of CHD, adverse effects of any type and the intakes associated with these effects, the FDA found that the use of 20:5*n*-3 and 22:6*n*-3 as dietary supplements is safe, provided the intake does not exceed 3 g per day from all food and supplement sources.

ESSENTIAL OILS

Contents

Properties and Uses

J Grassmann and E F Elstner, Technical University of Munich, Munich, Germany

Background

Essential oils have been used in folk medicine for a very long time, but their mode of action in healing was not clear. Recently, these oils have become increasingly important, such as in aromatherapy, which is controversial, but also in traditional medicine and nutrition. For this reason, an increasing number of researchers are becoming interested in the biochemical effects of these oils.

This article gives an overview of the definition, abundance, components, biosynthesis, and biological functions of essential oils in the plant kingdom, but the main aim is to describe the use and biochemical effects as well as the pharmacological properties of these oils. A short chapter deals with the stability and, in this context, with the problem of aging of essential oils.

Essential Oils: Definition and Abundancies

Essential oils (EOs) are complex mixtures of more or less lipophilic substances obtained by distillation or pressing of plants or parts of them. Most of the components are terpenoids (isoprenoids), mostly mono- and sesquiterpenes. Furthermore, this main group is followed by aromatic compounds (phenylpropanoids) derived from the shikimate–chorismate pathway, polyketide derivatives, paraffinic hydrocarbons, alcohols and ketones, fatty acids, and finally sulfur- and nitrogen-containing compounds. The compartments of highest concentration of EOs in the plant are special oil cells, which are eventually converted into oil containers. They are also found intercellularly, with the oil compartments being divided into schizogenic and lysigenic oil containers. Furthermore, milk tubes and plant-surface gland hairs may also contain EOs. The plant families containing EOs include the Apiaceae, Asteraceae, Cupressaceae, Lamiaceae, Myrtaceae, Pinaceae, Poaceae, and Rutaceae.

Isoprenes and monoterpenes play crucial roles in atmospheric chemistry (tropospheric ozone formation) where annual global fluxes between 250 and 450 million tonnes are estimated to arise from the vegetation, mainly from trees. This important function in the atmosphere is due to their fast reaction with reactive oxygen species (ROS) such as the OH radical (see also section on Antioxidative Effects). Terpenoids also seem to play an important ecological role in plant–herbivore interactions, since their biosynthesis is induced by insect feeding, eventually triggered by an elicitor from oral secretion of the feeding insect.

Technical Procedures: Extraction from Plants or Plant Organs

The technical procedures for obtaining EOs from plant material comprise steam distillation, extraction and, as mostly in the case of citrus oil, pressing of peels. These procedures are dealt with in a special chapter of this encyclopedia. (*See* **Essential Oils**: Isolation and Production.)

Physical Properties, Chemical Structures, and Reactivities

Fundamental work on EOs was started as early as 1884, by O. Wallach (1847–1941). EOs are in a liquid state at ambient temperatures, but they are volatile (with boiling temperatures between 50 and 320 °C), thus distinguishing them from mineral or fatty oils. Because of their volatility, EOs have a characteristic odor. They produce a transparent spot, on adsorbent paper, that disappears within 24 h. Most of the EOs are almost colorless, have a high refractive index, and are optically active (see below). They are soluble in most organic solvents, but have a very limited solubility in water. Their density is lower than that of water, with the exception of the oils of sassafras, clove, and cinnamon. An important feature is their property of being steam-distillable, thus

enabling physical separation from other lipophilic plant constituents such as 'fixed oils' or membraneous components. In the following the most important groups of compounds of essential oils will be listed.

Most Important Components

Today, several thousand different components are known, by far the most prominent being the terpenoids, followed by phenylpropanoids and other less important ingredients of plant oil compartments.

-Monoterpenes The monoterpenes (MTs) are widely distributed and sometimes contribute over 90% of the total oil content. They can be divided into regular and irregular monoterpenes and iridoids. Most components of essential oils have regular structures. Irregular members such as chrysanthemic acid and its derivatives are found in EOs of Asteraceae. Other examples of irregular MTs are the artemisanes, santolinanes, and lavandulanes or the artemisiaketon, which is present in *Achillea millefolium*.

Iridoids are another group of the MT family, in which the bicyclic ingredients of the Valerianaceae-like baldrinal, valeranone, or valtrate compounds from the olive tree (oleacin, oleuropein) or from yellow gentian (gentisin, sweroside, gentiopicrin) are the best known.

Since the 'regular' MTs are the most common components in essential oils, this chapter will deal only with this group. They can be subdivided into MT hydrocarbons, MT alcohols and their esters, MT aldehydes, MT ketones, and MT ethers such as cineol or dill ether. A special MT is the endoperoxide ascaridol.

MT hydrocarbons This group comprises several important compounds present in various essential oil compartments of different plant groups and include well-known compounds such as pinene, limonene, and terpinene. These compounds are frequently found as isomers, e.g., α- and γ-terpinene, as optical isomers, for example (+)- and (−)-limonene or both, for example (−)-α-phellandrene and (−)-β-phellandrene or (+)- and (−)-α-pinene together with (−)-β-pinene.

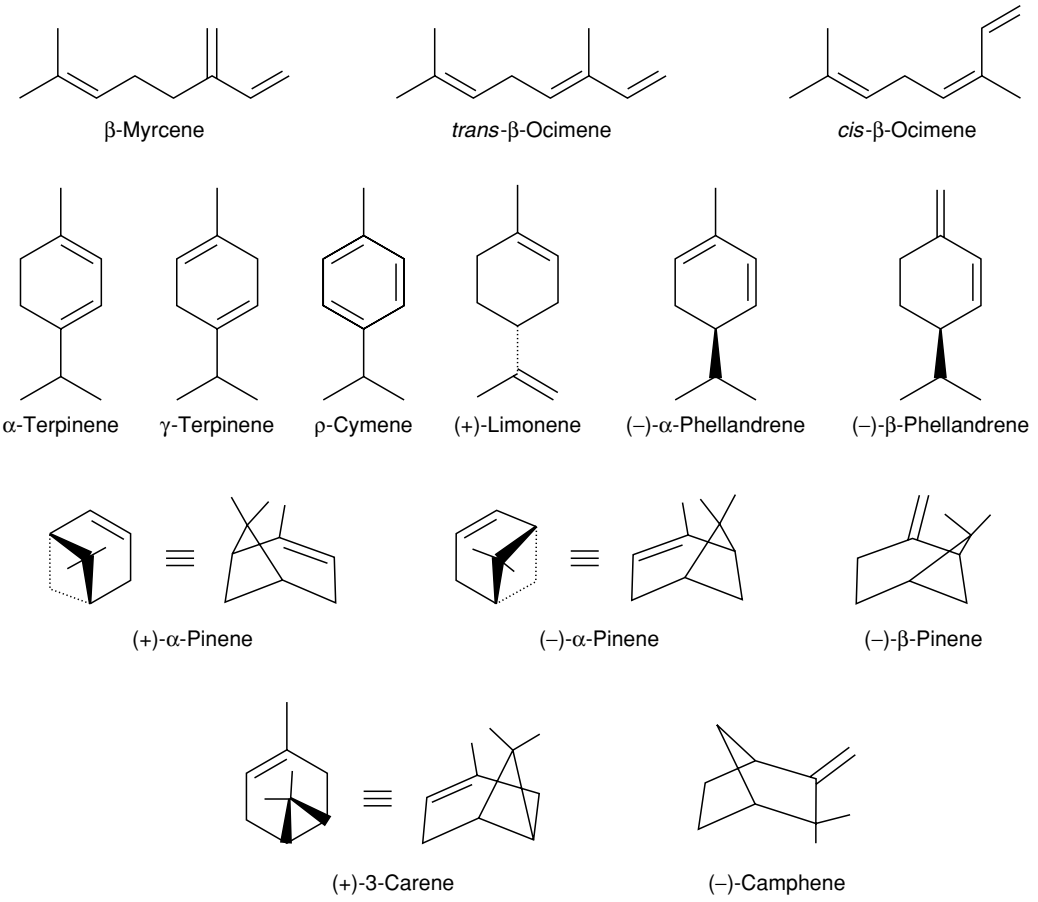

Figure 1 Examples of acyclic and cyclic structures of regular monoterpene hydrocarbons in essential oils.

A selection of important structures in this class is shown in Figure 1.

MT alcohols Important members of this class are the widely distributed compounds geraniol, nerol, linalool, citronellol, terpineol, and borneol. They also comprise both acyclic and cyclic forms. Several important structures are shown in Figure 2.

MT aldehydes and MT ketones Again, both acyclic compounds (geranial, neral, citronellal) and cyclic forms (carvone, menthon, pulegone) are found. A mixture of the isomers geranial and neral is called citral. Bicyclic MT ketones are the well-known (+)- and (−)- camphor, fenchone, and thujone (Figure 3).

MT ethers and endoperoxides Menthofuran, dill ether, cineol, and ascaridol are representatives of this class of compounds and are shown in Figure 4.

-Sesquiterpenes With more than 50 different structural types, sesquiterpenes constitute another important group of compounds within the EOs. They arise from farnesylpyrophosphate, which in turn is formed by head-to-tail condensation of geranylpyrophosphate and isopentenylpyrophosphate, forming a C15 carbon skeleton (see below). They are especially abundant in essential oils of the plant family of the Zingiberaceae and sesquiterpene lactones in the Asteraceae. β-Carophyllen-1, 2-epoxide is found in

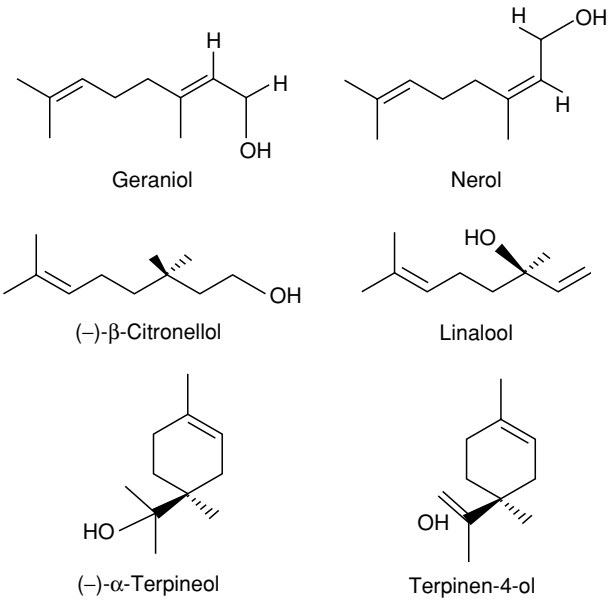

Figure 2 Examples of acyclic and cyclic structures of monoterpene alcohols in essential oils.

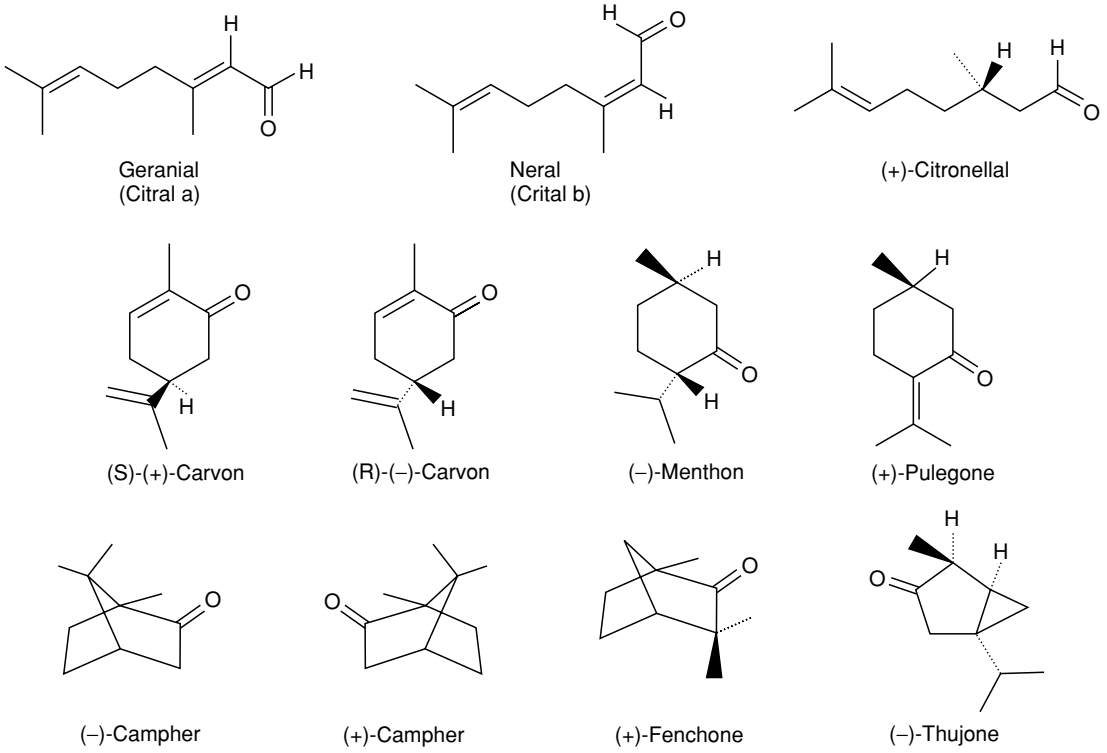

Figure 3 Examples of acyclic and cyclic structures of monoterpene aldehydes and ketones in essential oils.

clove and sage oil, in which it can be used for quality control (Figure 5).

-Aromatic compounds of the phenylpropane group Aromatic compounds (ACs) are minor components in EOs. They essentially comprise phenylpropanoids, propenyl- or allylphenols and coumarins. Typical members from this group, like anethol or estragol, are found in Apiacean oils (fennel, anise) but also in Rutacea. Eugenol and vanillin are two typical ACs of this type (Figure 6).

-Other compounds EOs also may contain degradation products of membraneous unsaturated fatty acids such as 'green odor' components (*cis*- or *trans*-hexenal, hexanal, and hexanol) and several lactones. Furthermore, compounds from terpene degradation, for example C_{13}-norisoprenoids, and sulfur- and nitrogen-containing compounds (e.g., pyridine derivatives in spearmint oils) are found. Several volatile terpenoids are present in plants as glycosides and contribute to the overall, typical fruit flavors.

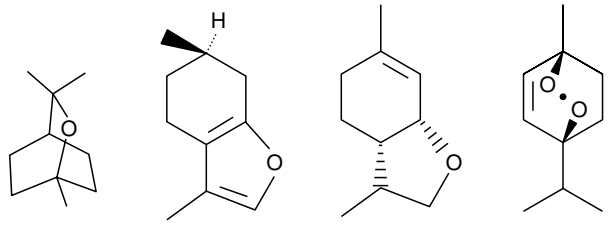

Figure 4 Examples of structures of monoterpene ethers and endoperoxides in essential oils.

Biosynthetic Pathways

The two cell compartments of plant isoprenoid biosynthesis, plastid and cytosol, have two different ways to synthesize terpenoids: the classic mevalonate pathway and the alternative 1-deoxy-D-xylulose-5-phosphate (DOXP) pathway, which occurs in the plastids and leads to, among others carotenoids,

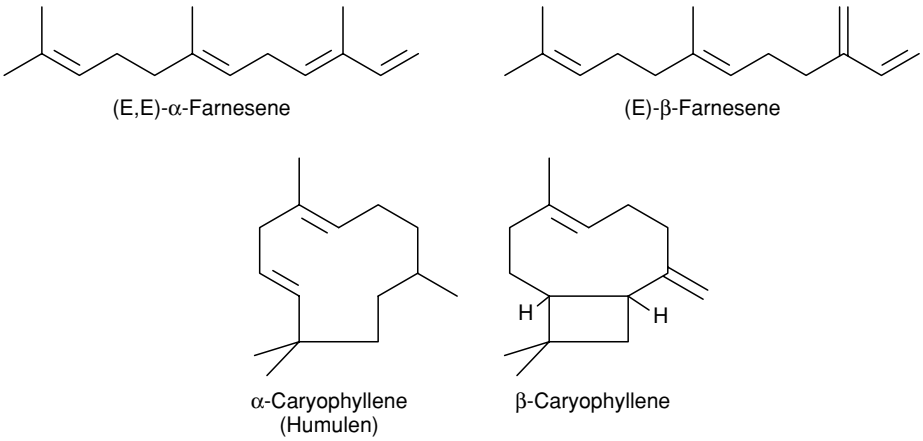

Figure 5 Examples of structures of sesquiterpenes in essential oils.

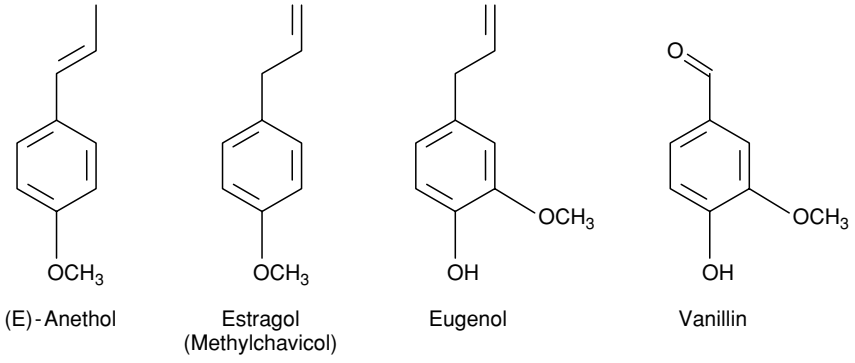

Figure 6 Examples of structures of aromatic compounds of the phenylpropane group.

monoterpenes, and isoprene. In the cytoplasm, the mevalonate pathway takes place and forms sesquiterpenes, for example.

The Mevalonate Pathway

The biosynthesis of monoterpenes in the cytoplasmatic space proceeds via the well-known mevalonic acid pathway, starting from acetyl CoA by various condensations including activation by ATP and reduction by NADH. A key step is the two-step reduction of hydroxymethyl-glutaryl-CoA (HMG CoA) into mevalonate under CoA release by the enzyme HMG CoA reductase. This step has become extremely important, since it represents the main possibility of interaction with several types of inhibitors with this pathway and is used for the treatment of hypercholesterolemia in humans. After the condensation of two C5 bodies (activated isoprenes: isopentyl pyrophosphate (IPP) and dimethylallyl pyrophosphate (DMAPP), with pyrophosphate as a thermodynamically preferred leaving group (splitting into two orthophosphates, E_0' approx. $-35\,\mathrm{kJ\,mol^{-1}}$), the product is geranylpyrophosphate (GPP), the first C10 backbone of the monoterpenes. The formation of acyclic monoterpenes from GPP is obvious, and the generation of monocyclic and bicyclic monoterpenes involves monoterpene cyclases. These enzymes catalyze an isomerization–cyclization mechanism generating the α-terpinyl cation. Loss of a proton leads to the formation of hydrocarbons and addition of water to alcohols. Generation of oxygenated terpenoids also can be carried out by classic oxidases that catalyze allylic hydroxylation, oxidation of the alcohol to an α, β-unsaturated ketone, and possibly reduction of the double bond. Thus, the α-terpinyl cation is the origin for a large number of different monoterpenes.

The precursor of sesquiterpenes, farnesyl pyrophosphate, is the product of the addition of one molecule IPP to GPP. Similar to monoterpene cyclizations, rearrangements, isomerizations, or oxidations lead to a wealth of different structures.

The DOXP Pathway of IPP Biosynthesis

Recently, another pathway, starting not from acetyl-CoA but from pyruvate and glyceraldehyde-3-phosphate (GAP), was established for plastidic-derived terpene derivatives in the middle of the 1990s, especially by the Lichtenthaler group in Germany. This pathway, in contrast to the above mevalonate pathway, is not inhibited by HMG CoA-reductase inhibitors. It includes, after a thiamin-dependent condensation of pyruvate and GAP (CO_2-release), DOXP. An intramolecular C-C-skeleton rearrangement catalyzed by DOXP reducto-isomerase generates 2-*C*-methyl-D-erythrose-phosphate (MEP). In 2000, it was shown that the following steps involve a cytidylyl transfer (catalyzed by MEP cytidylyl-transferase) generating 4-(cytidine 5′-diphospho)-2-*C*-methyl-D-erythritol (CDP-ME), which is phosphorylated by CDP-ME kinase, leading to 2-phospho-4-(cytidine 5′-diphospho)-2-*C*-methyl-D-erythritol. This compound finally undergoes cyclization to form 2-*C*-methyl-D-erythritol-2, 4-cyclodiphosphate (MECDP), a reaction catalyzed by MECDP synthase. MECDP is then converted into DMAPP, but the reactions leading to this product are still unknown.

Biological Functions in the Plant Kingdom

There are good reasons to assume ecological functions for most of EOs such as acting as allelopathic agents, repellants, or attractants in plant–plant or plant–pathogen/herbivore interactions. Observations in the Californian Chapparal and corresponding experimental approaches have made clear that certain evergreen shrubs such as *Salvia leucophylla* or *Artemisia leucophylla* retain a 1–2 m plant-free area in the grassland around them by inhibiting the growth of annual species such as *Avena fatua*, *Bromus rigidus*, *B. mollis*, *B. rubens*, *Festuca megalora*, or *Erodium circutarium*. As reason for this phenomenon volatile terpenes present in the epidermal glands of these shrubs such as cineol, camphor, α- and β-pinene, camphene, and thujone have been identified acting as germination inhibitors. The terpenoids are emitted during hot periods and condense in the soil surface around the shrubs.

Another function is seen in defense and wound sealing in pine tree species where a coordinated induction of the biosynthesis of MTs and resin acids is observed. MTs are thought to function as a solvent and vehicle for resin acids whereby the MTs evaporate from the wound region, and resin acids undergo oxidative polymerization and crystallization in this region, closing the wound and thus preventing access to pathogens.

Furthermore, volatile MTs released in response to herbivore activity or insect feeding are 'designed' as deterrents or antibiotics by plants, but they may act as a guide for predators or host-seeking parasites, as shown for parasitoid wasps, which find their egg host, a herbivorous caterpillar: they inject their eggs into the herbivore and thus propagate their life cycle at the expense of their egg hosts. Plants in extreme environments often have to tolerate extreme temperatures. The direct correlation between isoprene concentration and thermotolerance has led to the speculation that these compounds increase

thermotolerance by interacting with membranes of the plants. Such an interaction is also assumed for physiological and pharmacological functions in man (see below). In horticulture, MTs already may have or receive some practical function, acting as flowering promoters or as nematicides.

Uses and Effects

Use of EOs

The use of EOs is mainly restricted to the perfume and flavoring industries; above all, citrus oils are used in perfumery and to flavor soft drinks or sweets. Recently, aromatherapy has become increasingly important, with the treatment of functional disorders or even diseases by using a pleasant odor, which is often achieved by evaporating EOs. This kind of therapy, however, is controversial, mainly because most studies are questionable, but the use of a pleasant smell can help a person to relax and may help them to feel better. In pharmacy, oils are mostly applied as combined preparations like bath salts, embrocations, and inhalants; another application is external antiseptics. Examples of oils used for pharmaceutical use include eucalyptus oil (and its main component, cineol), peppermint oil, and menthol. Peppermint oil is also often used to alleviate headaches by rubbing the oil into the temples, and its effect may be due to its cooling effect on the skin. In folk medicine, there are various applications for essential oils and their components, as shown in Table 1 (see also section on Pharmacological Properties).

Some terpenoids like pinenes from turpentine, geraniol, (+)-citronellal, or eugenol are also used as a starting material for the synthesis of other substances. The applications described indicate that the most commonly used essential oils are citrus oils like sweet orange, lemon, or grapefruit oil, followed by peppermint and eucalyptus oil.

Biochemical Effects

EOs are mixtures of many compounds belonging to several biochemical classes (see above). Thus, a distinction has to be made between the properties of single isolated compounds and EOs generally, i.e., oil mixtures. To make things even more complicated, although an isolated compound may exhibit toxic properties if tested on its own, it may prove inactive in its 'natural environment' as an oil mixture.

Table 1 Pharmacological properties of some essential oils

Action	*Essential oil*
Expectorant	Anise, fennel, eucalyptus, pine needle
Spasmolytic	Anise, fennel, lavender, caraway, peppermint
Antiinflammatory	Sage, camomile

Uptake, Metabolism, and Elimination in Man

Essential oils and their components are readily absorbed via the respiration tract in the case of inhalation; resorption through skin and uptake in the stomach after oral application are less effective but still possible. After being absorbed, the terpenoids are readily distributed throughout the body.

The terpenoids are metabolized in the liver, e.g., by hydroxylation or glucuronidation, and then eliminated through the kidneys. Small quantities reach the bile or mother's milk unchanged, so, during breastfeeding, the baby may take up terpenoids. Some terpenoids, such as cineole and menthol, are also eliminated unchanged through the respiration tract or skin. Thus, even if they are taken orally, these terpenoids can exert their effects in the bronchial tract, which explains their preferential use in diseases of the respiratory tract, e.g., bronchitis.

There are very few studies on the pharmakokinetics of essential oils or their components, so it is not clear which concentrations they really can reach in blood or plasma. Some studies have examined plasma concentrations of α-pinene, limonene, and/or cineol, and have reported values of 5–20 μM, but mostly, such studies have been carried out with too few participants. Since, as already mentioned, the components of essential oils are very lipophilic, they can be enriched in adipose tissues or membranes and therefore reach much higher concentrations in those environments. If they are distributed in biological membranes, they can exhibit both stabilizing and destabilizing effects.

Pharmacological Properties

EOs exhibit antiseptic, sedative, spasmolytic, and irritating properties. Some oils have local anesthetic and antiinflammatory effects, and recently, anticarcinogenic and serum-cholesterol-lowering activities of terpenoids have been discussed. Some terpenoids are also capable of inhibiting HIV.

The antibiotic and antiseptic properties are against bacteria, fungi, and yeast. The most antiseptic oils are savory, cinnamon, thyme, clove, lavender, and eucalyptus. Thymol, a compound found in thyme oil, for example, is 20 times more antiseptic than phenol. It has been shown that the different enantiomers of limonene and α-pinene, respectively, exhibit different antibacterial and antifungal activities. This result draws attention to the fact that receptors may play a

role in the antiseptic properties of essential oils. Another possible mechanism of antimicrobial activities involves membrane disruption by lipophilic compounds, and it has been shown that reducing the lipophilicity by the introduction of a hydroxyl group reduces the antimicrobial activity of certain diterpenoids.

In vitro, many oils like camomile, clove, mint, and thyme exhibit spasmolytic activity. Some essential-oil drugs like mint or European vervain have a positive effect on gastrointestinal spasms; they are also capable of stimulating gastric secretion and are therefore known as digestives. The oils of fennel, dill, and caraway have positive effects on stomach upset and flatulence.

EOs coming into contact with the skin and mucous membranes may lead to irritations such as reddening and a sensation of hot or cold. These irritating properties are probably due to an increase in capillary blood flow or to an effect of terpenoids on the calcium channels, as shown by the cooling effect of peppermint oil. These effects are also the basis for the use of EOs in ointments, embrocations, and gels.

Eucalyptus oil is thought to increase the motility of the ciliated epithelia in the bronchia, thus explaining the expectorant effect of this oil.

Some terpenoids, such as limonene, geraniol, menthol, and carvone, have been shown to possess anticancer activity, increasing tumor latency and decreasing tumor growth. These effects may result from the ability of the terpenoids to inhibit the activity of HMG-CoA-reductase. This is probably also the reason for the serum-cholesterol-lowering capability of some terpenoids.

The anti-HIV activity can be attributed to different mechanisms; the terpenoid carnosolic acid, for example, has been shown to inhibit HIV-1 protease, whereas the terpenoid nigranoic acid inhibits the reverse transcriptase.

Toxicity

The first point to mention in this section is that one should not confuse essential oil plants and essential oils: even if the plant is harmless, the essential oil derived from it may be toxic. Fortunately, acute toxicity by oral intake is generally very low with an LD50 of 2–5 $g\,kg^{-1}$ or above.

There are more toxic oils such as boldo (LD50 = 0.13 $g\,kg^{-1}$), chenopodium (LD50 = 0.25 $g\,kg^{-1}$), thuja (LD50 = 0.8 $g\,kg^{-1}$), pennyroyal (LD50 = 0.4 $g\,kg^{-1}$), and mustard oil (LD50 = 0.34 $g\,kg^{-1}$) and their components, such as thujone (LD50 = 0.2 $g\,kg^{-1}$), carvone (LD50 = 0.16 $g\,kg^{-1}$), carvacrole (LD50 = 0.8 $g\,kg^{-1}$) and pulegone (LD50 = 0.47 $g\,kg^{-1}$). Thujone is a strong neurotoxin and is found in thuja and sage. Pulegone can be oxidized to menthofuran in the liver and can cause liver damage.

If taken up erroneously in high quantities, intoxication and even death may result. This is especially the case for camphor (LD50 = approx. 1.5 $mg\,kg^{-1}$), which causes epileptic convulsions, and also for EOs from plants such as clove, wintergreen, and parsley.

There is very little knowledge about chronic toxicity, but it seems that the use of essential oils as food flavorings is essentially safe. Especially in aromatherapy, the interactions of products – which may be harmless if used alone – may lead to unexpected side-effects.

There have been several observations concerning skin toxicity (irritations or sensitation after topical applications, e.g., cosmetics or purfumes), including phototoxicity (e.g., photodynamic compounds in the Apiaceae = Umbelliferae family; see below). Allergic reactions caused by EO application are mainly due to the formation of isomers, cyclic compounds, or peroxides during storage under inadequate conditions such as high temperature, light, and access to air and oxygen (see below).

Carcinogenic effects have been observed in rodent models, in which EOs from sweet flag have been found to cause intestinal tumors, and hepatic tumors induced by sassafras, sweet basil, or terragon. Carcinogenic activity is probably due to various allylphenols and alkenylbenzenes (arene structures), and because of the different metabolic pathways, the toxicity has been calculated to be 13 million times higher in rodents than in humans.

Antioxidant Effects

The pathogenesis and symptoms of inflammatory processes are accompanied and/or initiated by the production of ROS. These include, for example, the OH radical, superoxide, hydrogen peroxide, hypochlorite, and peroxynitrite, and are generated, amongst others, by several types of inflammatory cells, e.g., neutrophils and alveolar macrophages, to defend the organism against invading microorganisms. Continuous production of these ROS accompanied by a weak antioxidant defense in the organism may lead to tissue and finally organ damage. Recently, many researchers have regarded antioxidative properties as an important fact in the mode of action of several drugs, food ingredients, or food additives. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants; Synthetic Antioxidants, Characterization and Analysis; Role of Antioxidant Nutrients in Defense Systems.)

EOs have been shown to have significant antioxidant properties in different biochemical model reactions simulating different pathological situations. It has been shown that several essential oils show a high antioxidant capacity regarding lipid peroxidation, which simulates the situation in biological membranes during oxidative stress. Since lipid peroxidation can cause cell death, EOs may be able to protect these cells. EOs also have a positive effect on reactions of stimulated neutrophilic granulocytes, which appear in great numbers during inflammatory processes. Therefore, the antioxidative capacity of essential oils may be an explanation for their antiinflammatory properties, acting by several different mechanisms on different organizational platforms.

Another pathological situation related to oxidative stress is the oxidation of low-density lipoprotein (LDL), which is regarded as an important factor during atherogenesis. Recently, it has been shown that after incubation of human plasma with components of essential oils, these can be enriched in LDL and protect it from copper-induced oxidation.

EOs and Food

As mentioned previously, citrus oils are used in perfumery and to flavor soft drinks or sweets. The use of spices to flavor foods is an indirect use of essential oils, since often, the characteristic taste of herbs is based on their content of EOs oils. EOs are also antibacterial against some species involved in meat spoilage, so the use of spices in food may not only improve the taste but also prevent spoilage. Essential oils of sweet basil, bay, cinnamon, clove, and thyme, for example, show antimicrobial activity against a wide range of foodborne Gram-positive and -negative bacteria.

Lipids containing unsaturated fatty acids are important food components, but they are very susceptible to autooxidation, which leads to undesirable products. To retard this process, different antioxidants like butylated hydroxytoluene and butylated hydroxyanisole are used. Owing to safety considerations (some of these synthetic antioxidants may be carcinogenic), natural antioxidants are under investigation as to whether they can replace synthetic antioxidants. Since essential oils have been shown to have a high antioxidant capacity (see section on Antioxidant Effects), particularly regarding lipid peroxidation, these substances may be good alternatives to synthetic antioxidants.

Stability of EOs

During storage of EOs photoisomerization, photocyclization, generation of peroxides and free acids, thermoisomerization, transition-metal catalyzed decay, and other reactions may initiate the decomposition of essential oils, which leads to changes in color and consistency. Since this alters the properties of the oil – the generation of peroxides in tea tree oil, for example, is responsible for the irritating activities of this oil – it is important to store essential oils securely under a nitrogen atmosphere, away from light and heat, and perhaps to add antioxidants.

For the determination of peroxides and thus the 'age' of an essential oil, conventional methods such as iodine titration and peroxide determination via photometrical procedures have been described, but the best and most convenient method is based on chemiluminescence by following the light emission of the peroxides formed in the presence of sulfite. This method is much faster and produces much less toxic waste than the traditional iodine titration.

Isolation and Production

B Sankarikutty and C S Narayanan, Council of Scientific and Industrial Research, Trivandrum, India

Background

Essential oils can be given a simple definition as the predominantly volatile and odorous fraction isolated by some physical process from vegetable materials. The term 'essential oil' was coined by Paracelsus and other alchemists to represent the quintessence or the total odor and flavor of each plant species. In plants, essential oils impart their distinctive and often diagnostic odor. Essential oil from a selected single plant species is made up of organic compounds whose nature and relative proportions are dependent on a number of agricultural factors, viz. environment, climate, soil conditions, time of harvesting and postharvest handling prior to isolation. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Essential oils isolated and identified from the vast number of plant species amount to over 3000, and of these, several hundreds have been produced commercially. The price of any particular commercial essential oil is dependent on the percentage oil yield from the plant species, its availability (production rate), and finally, the most important factor, its demand (application).

Essential oils are isolated from various plant components such as leaves, fruit, bark, root, wood, heartwood, gum, balsam, berries, seeds, flowers, twigs, and buds. The plant components are suitably processed to yield essential oils, which are mostly devoid of cellulose, glycerides, starches, sugars, tannins, salts, and minerals. The yield of essential oils from plants varies widely, and the broad range is 0.05–18.0%. Information on isolation, production, and markets of some selected commercial essential oils are presented in Table 1. The essential oil is present in various plant components in oil sacs and is isolated by comminution and the action of heat, water, and solvents. Distillation, selective solvent extraction, and mechanical expression are the three general basic methods employed for essential oil isolation with improvements or modifications incorporated for each as available. Thus, essential oils include concretes (flower 'concretes' – hexane extractives), absolutes, resinoids, distillates, etc. (*See* **Herbs**: Herbs and Their Uses.)

Distillation Techniques

The most popular physical method for essential oil isolation is distillation. Prior to distillation, plant materials are in most cases dried and are then suitably ground so that the oil sacs are broken and a maximum of surface area is exposed for efficient oil release. Various distillation techniques widely adopted for essential oil isolation are briefly discussed below.

Direct-heating Distillation (Hydrodistillation)

Suitably ground plant materials are placed in a boiler with water completely covering them. As heat is slowly applied, steam alone will be initially formed, and the distillate will be clear. With continued heating, the essential oil starts to distil over with the steam, and the distillate becomes milky white. Distillation is continued until the distillate becomes clear, with no more oil distilling over from the material. Even though the essential oils have relatively high boiling points, codistillation like this brings about a satisfactory recovery of the oil because, in accordance with Dalton's law, a mixture boils when the sum of the vapor pressures of the individual components equals the atmospheric pressure. However, this method is somewhat slow and requires close manual attention and separation of the oil and aqueous phases of the condensate.

Steam Distillation

This method is widely used and is faster than direct distillation. Steam under pressure is passed through the prepared plant material, and the volatile oils are condensed along with the water. Steam can also be bled directly into the boiler. To avoid thermal decomposition of lower-boiling-point constituents, steam pressure is increased only gradually. The distillation temperature with water or steam at atmospheric pressure is usually slightly under 100 °C and can be reduced further by drawing a partial vacuum on the still.

-Hydrodiffusion In this method, the steam enters the still at the top and passes down through the charge. Oil and water vapor condense on coils fixed below the bottom grid within the still. The oil and water are separated in the usual way. The plant design results in considerable energy savings and minimum degradation of the volatile oil. This method is found to be very advantageous in the distillation of seed oils.

Vacuum Distillation

This method is faster than steam distillation. Vacuum distillation is generally adopted to rectify an oil and very rarely to distil an oil directly from the plant material.

Table 1 Isolation, production, and markets of a selection of commercial essential oils

Essential	*Botanical source*	*Plant part used; method of oil isolation*	*Principal producing countries/areas*	*Approximate volume of production (tonnes per year)*	*Major consuming markets*
Amyris	*Amyris balsamifera* L. First	Wood; steam distillation	Haiti	70	France, Germany, USA
Anise	*Pimpinella anisum* L.	Dried fruit; steam distillation	Spain, Russia, Poland	40–50	France
Anise, Star	*Illicium verum* Hook f.	Dried star-shaped fruit; steam distillation	China, Vietnam	60–70	France
Basil (Réunion)	*Ocimum basilicum* L.	Herbaceous tops; steam distillation	Réunion, Comoros, Madagascar, South Africa	10–12	
Basil (sweet)	*Ocimum basilicum* L.	Herbaceous tops; steam distillation	Egypt	~2	USA, Europe, Switzerland, Japan
Bay, Turkish (Laurel)	*Laurus nobilis* L.	Leaves; steam distillation	Turkey	1–2	Germany, Netherlands, USA, UK
Bay, West Indies	*Pimenta racemosa* Mill	Leaves; steam distillation	Dominica	40–45	USA, UK, Switzerland
Bergamot	*Citrus aurantium* L. ssp. *bergamia*	Fruit peel (rind); expression	Italy, Ivory Coast	175–225	USA, France, Netherlands
Caraway	*Carum carvi* L.	Ripe seeds; steam distillation	Western Europe	10–30	North America
Cardamom	*Elettaria cardamomum* Maton	Seeds; steam distillation	India, Sri Lanka, Guatemala	10–20	Western Europe, Scandinavia, USA
Cassia	*Cinnamomum cassia* Blume	Leaves, twigs and inner bark; steam distillation	China	140–150	USA, Japan, Western Europe
Cedarwood, Southern Red, East African	*Juniperus virginiana*	Wood; steam distillation	USA, China, Kenya	700–1 400	USA, Western Europe, Japan
	Juniperus procera	Wood; steam distillation			
Cedarwood, Texas	*Juniperus mexicana* Schiede	Wood; steam distillation			
Cinnamon	*Cinnamomum zeylanicum* Nees	Dried inner bark; steam distillation	Sri Lanka	100	Western Europe, USA, India
Citronella, Ceylon	*Cymbopogon nardus* Rendle	Herb; steam distillation	Sri Lanka	~2 000	USA, Europe, Japan, Mexico
Citronella, Jawa	*Cymbopogon winterianus* Jowitt	Herb; steam distillation	Indonesia, China, Guatemala, India	~2 000	USA, Europe, Japan, Mexico
Clove	*Eugenia caryophyllata* Thunb	Unopened bud; steam distillation	Madagascar, Indonesia, Tanzania, Sri Lanka	2 000	USA, Western Europe, Japan
Coriander	*Coriandrum sativum*	Seeds; steam distillation	Russia	20–40	USA
Davana	*Artemisia pallens* Wall.	Flowers; steam distillation	India	~2	Western Europe, USA
Eucalyptus	*Eucalyptus globulus, E. citriodora, E. dives* 'A' & 'C'	Leaves; steam distillation	China, Portugal, Spain, South Africa, Brazil, Australia	~1 800	Western Europe, USA, Japan
Fennel, bitter	*Foeniculum vulgare* var. *vulgare*	Seed; steam distillation	Germany, Spain, India, China	10–20	USA, Japan
Fennel, sweet	*Foeniculum vulgare* var. *duler*	Seed; steam distillation	Spain	10–20	France
Garlic	*Allium sativum* L.	Bulbs; steam distillation	Egypt	2–3	France, Spain

Quality of Distilled Essential Oils

Conditions of distillation must be carefully established and controlled according to the nature of the raw material to ensure *optimum*, not necessarily maximum, yields of quality essential oil. Extended periods of distillation adversely affect the oil quality and also the cost of distillation. The distillation conditions must be established by trial in order to maintain the quality of the oils and also to avoid only batch-to-batch variation.

The yield of oil depends on the efficient separation of the essential oil from the steam/oil vapor condensate. The distillation water also may contain a variable proportion of the essential oil in colloidal suspension or in solution. Its recovery is achieved either by redistillation or by continuously recycling the aqueous distillate through the still, and this system is termed 'cohobation.' When the recovery is incomplete or unsatisfactory by cohobation, the distillate is passed through a packed column of solvent or codistilled with an immiscible solvent such as hexane or pentane, and the solvent is carefully removed by controlled high-vacuum distillation. Some losses of low-boiling components will occur, and these oils must be used with discretion.

A modified frontal liquid chromatographic technique has also recently been employed for recovery of oil from the distillate. Here, the distillate water flows through a column packed with porous poly(tetrafluorethylene), which holds on its surface 20% by volume of a low-boiling water-immiscible solvent. The solvent is renewed as necessary during the process of distillation, and the amount of solvent required is about 1–3% of the water volume. Essential oil is recovered from water distillates by this technique at $500\,l\,h^{-1}$ in a $30\,cm \times 60\,cm$ column.

Rectification

Essential oils are redistilled to improve a particular property, to effect a higher degree of separation and purity, or to concentrate or enrich a particular fraction of the oil. Such redistilled oils are called rectified oils. Traces of water, resinous materials, undesirable flavor notes, etc. may be removed by rectification. The processing methods for concentration or enrichment include, in addition to fractional distillation, solvent extraction, countercurrent extraction, thin-film evaporation and molecular distillation. In some cases, distillation followed by any of the other methods is also employed for the desired fractionation or enrichment of the oil.

Solvent Extraction

Heat-sensitive essential oils can be isolated by extraction using an organic solvent. Solvents used should be of a low boiling point, free of odor and impurities, and inert towards the oil constituents. Pentane or hexane is preferred for flower oils. For spices, in most cases, solvent extracts (volatile and nonvolatile fractions) are more representative of the total flavor than is the steam-distilled oil, which contributes only towards the aroma. To obtain spice essence (oleoresin) extracts, solvents such as ethanol, chlorinated

hydrocarbons, and acetone are employed, solvent selection depending on the nature of the spice and its flavor constituents.

Expression (Pressing)

This method is generally employed for fruit peels rich in oils. In this technique, the selected whole fruits are washed and then crushed between rollers, and oil is then separated from the juice. Also, they are automatically handled in specially designed extractors that recover both juice and oil concurrently. The oil collected is washed with a spray of water and then separated by means of a centrifuge. The method is limited generally to citrus fruits (orange, lemon, and lime). Steam-distilled citrus oils are usually byproducts of the frozen juice concentrate industry. The oil may be recovered by distillation from the juice-and-oil emulsion. The expressed oils and distilled oils differ widely in their flavor characteristics.

Enfluerage

Essential oils of delicate flower petals are prepared by this technique. The method involves the absorption of oil on purified fat on special pressing equipment. The process is repeated until the fat is saturated, and it is then removed and extracted with alcohol and recycled. To reduce the time and cost of the process, hot fat at 40–60 °C is also used for absorption of the oil.

Carbon Dioxide Extraction

High-pressure extraction with supercritical or liquefied gas, e.g., CO_2, is a relatively new technique for obtaining essential oils without thermal or hydrolytic deterioration. Thus, the product obtained by this technique is without artefacts or solvent residues. The use of liquefield CO_2 at 0–10 °C and 8–80 bar results in a product devoid of fixed oils, protein, waxes, chlorophyl and pigments. In the supercritical state, the pressures generally used for extraction of essential oils at 40–80 °C range from 75 to 200 bar.

Considerations of Quality

The composition, and thereby the quality, of the essential oil of a selected plant species depends mainly on the nature of raw material used, the method of isolation employed, and the oil's storage conditions. In distilled oils, differences in oil quality are more likely to arise from variations in distillation time, rate of distillation, efficiency of vapor condensation, method of separation, and postdistillation handling. Irrespective of the method of isolation adopted, to produce a standard quality of essential oil, it is always necessary to ensure that the raw material used is of the correct botanical source and geographical origin and that it is clean and free from contamination and has been correctly prepared for oil isolation. Also, the conditions or the relevant parameters involved in the chosen method must be clearly defined.

ETHNIC FOODS

J Dwyer and O I Bermudez, Jean Mayer US Department of Agriculture, Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA

Introduction

Ethnic foods are foods that are regarded as unique to a particular cultural group, race, religion, nation, or heritage. Consumers of ethnic diets often have cultural but also socioeconomic, religious, or regional characteristics that are distinctive. From the cultural standpoint, ethnic foods serve as a familiar link with the past and help those who are accustomed to them maintain ethnic identity. Ethnic foods provide eaters from other culinary traditions with opportunities to experience new cuisines and cultures. They are also important in designing or tailoring culturally relevant nutrition interventions to reach nutritionally vulnerable, hard-to-reach ethnic groups within the community. In addition to being familiar, many ethnic foods have actual or perceived health importance that may heighten their appeal. Finally, ethnic foods provide a platform for developing attractive new foods that appeal to broader segments of the population.

Foods that are regarded as ethnic foods in a culture vary over time and with the degree of acculturation of the group consuming them. Even within major race and ethnic subgroups, many variations in ethnic foods exist. Some foods only bear a passing resemblance to the original cuisine from which they were derived. For example, in the USA, pizza, tacos, chile con carne, and chicken chow mien are very different from the Italian, Mexican, and Chinese dishes that inspired them. Hispanic-Americans with a Mexican-American heritage differ in their food preferences from Puerto Rican Americans, whose eating patterns involve a blend of Spanish, African, Taino Indian, and continental American influences. Similarly, Asian-Americans of Filipino, Japanese, or Chinese origins have very different food choices and traditions. Among the 300 different Native American groups, the staples and other foods that they regard as unique and distinctive to their cultures also vary. In the UK, foods from China, Japan, and the Indian subcontinent are referred to as Asian food whereas in the USA, they refer to Chinese and Japanese cuisines.

Most ethnic cuisines have been influenced by centuries of food exchanges between indigenous groups and immigrants from all over the world. For example, the American cuisine is a multiethnic blend. No single eating pattern has prevailed over all the others, and no ethnic or cultural group has emerged with an unchanged food pattern.

The traditional Mediterranean diet includes liberal amounts of fruits, vegetables, legumes, and grains, high amounts of monounsaturated compared to saturated fats, moderate consumption of alcohol, liberal amounts of fish, and low amounts of meat and milk products. It has been associated with decreased risks of coronary artery disease. Although there is debate about the extent to which such a regimen is exportable, some Mediterranean ethnic foods have become very popular.

Ethnic food preferences and choices are important aspects of the cultural heritage they represent. Some of the many sources available on food-related aspects of culture are summarized in Table 1; these include both the cultural anthropology literature on foodways, cookbooks, and nutrition information materials that describe the foods and their uses.

Origins of Ethnic Foods

Table 2 describes the factors that are thought to be involved in the development of ethnically distinctive cuisines and ethnic foods. Nutritional anthropologists subscribe to various theories on how ethnic food patterns have developed (Table 3). No one theory appears to predominate at present.

Individuals in different ethnic groups have different ways of categorizing foods, which are sometimes at variance with medical views of foods as sources of nutrients that are based on physiological and biochemical characteristics. They may also differ in their attitudes toward medical care and their health behaviors, in their beliefs about the therapeutic and preventive properties of foods, and the appropriate balance between different foods. For example, there are systems in various cultures that categorize foods into hot and cold, or yin or yang – both classification schemes that are based on properties other than nutrient content (Table 3).

Ethnic Differences in Food Classification Systems

Cultures differ not only in the foods that are eaten but also in how foods are viewed and classified by eaters. Some of the relevant factors are listed in Table 4.

Ethnic groups vary in their foodways, social and physical contexts in which food preparation, serving, and eating occur. Food classification systems may

Table 2 Factors involved in the development of ethnically distinctive cuisines

- Food availability constraints (geography, climate, range of native plant and unusual species in area)
- Social factors: migrant (both voluntary and involuntary) social structures, social relationships, social status
- Economics
- Philosophical, religious, and moral attitudes
- Individual factors

affect nutritional status because they cause the exclusion of healthful foods or food groups from the diet, encourage consumption of harmful items, or produce a false sense of security among eaters that all of their nutritional needs are met when in fact they are not.

Dietary Assessment

Familiarity with ethnic foods is important for dietary assessment. The foods themselves, their names, composition, portion sizes, and frequency of consumption vary. Accurate assessment of nutrient intakes depends on a knowledge of these factors. Some ethnic foods may be especially rich sources of nutrients or other food constituents, such as phytochemicals. Presently, there is much interest in the possible health effects of the traditional soy foods contained in many Asian diets, which contain relatively high amounts of soy isoflavonoids. These compounds have weak estrogenic effects and have been associated with decreased risks of coronary heart disease in some studies. Other ethnic foods such as some home-brewed alcoholic beverages contain contaminants such as heavy metals that have adverse health effects.

Table 3 Theories on how ethnic food patterns develop

Theory	*Comments*
Environmentalism	Ethnic food traditions are determined primarily by environmental and external influences
Cultural determinism	Humans mold their environments and diets quite independently of their physical surroundings
Cultural ecology	Both culture and environment are important influences
Cultural history	Historical influences affect how foods evolve and develop over time
Functionalism	Foods are used to identify or place people within society

Table 5 provides some examples of the importance of using ethnically appropriate dietary assessment tools. One challenge in evaluating diets that include many ethnic foods is the appropriate choice of methods for dietary assessment. Methods such as semiquantitative food frequency questionnaires are often designed to capture intakes of important nutrients for those who conform to the predominant food culture. These are often inappropriate for subgroups with very different dietary patterns. Subgroup members may call the foods by different names, consume items not included on the food lists, or vary in amount and frequency of consumption. The use of such instruments to assess intakes of individuals with unconventional dietary preferences can lead to highly erroneous conclusions. Subgroup-specific food frequency questionnaires that take account of these factors are sometimes available, and when they are these should be used. For example, well-validated ethnic-specific food frequency questionnaires have been developed for Japanese and Chinese-Americans living in Hawaii, and for elderly Puerto Ricans. However, for many groups, it is not possible to obtain accurate information on intakes without further data collection and validation of new food frequency questionnaires. Some information can be obtained by adding important ethnic foods to existing food lists, but nutrient analyses are still likely to be inaccurate, since consumption of foods within each food group on the otherwise unadjusted questionnaire is apt to be very different among those with ethnic eating patterns than it is among those who consume mainstream diets. Another alternative is to use food

Table 4 How food is classified in different cultures

Food habits	Foods categorized as core, secondary core, or peripheral, depending on their frequency of consumption
Gastronomic	Foods versus nonfood, edible versus nonedible
Religious/philosophical	Sacred versus profane, allowed versus forbidden
Opposing categories or properties	Hot versus cold, yin versus yang, or other schemes for balancing food intakes to prevent or cure disease. The important properties cannot be determined from their chemical composition
Medicinal	Foods used as treatment for certain diseases or psychological problems
Social system	Foods are viewed as symbolic of a culture or belief
Emotional significance	Foods for the sick, foods for celebrations or special needs
Nutritional nutrients	Chemical composition – by macro and micro
Hygienic	Wholesomeness, cleanliness, freedom from environmental contaminants, microorganisms or other toxins

records, recalls, or direct observation of food intake. This permits exact descriptions of the amount, type, and use of all foods, including unusual items. Food records also provide information on how ethnic foods are used in everyday diets. They identify differences in food use that may exist between the subgroup and the mainstream culture. Food records also provide the information from which ethnicity-specific dietary probes and semiquantitative food frequency questionnaires can be developed. For those who eat many different foods in small amounts rather than discrete portions of foods, or for those who eat from a common pot, these assessment techniques are more appropriate than food frequency questionnaires.

A second problem in the dietary assessment of ethnic cuisines is that nutrient databases for converting dietary intakes into nutrients for ethnic foods may not be available. In research studies on individuals who use many ethnic foods, nutrient databases that include entries for ethnic favorites are needed to obtain complete information about intakes. Whenever possible, food tables that are specific to the country or ethnic group should be used. Country-specific tables of food composition and nutrient databases are increasingly becoming available and these are the best option. For individuals who eat largely ethnic cuisines in countries where the parent food culture is different, often special food composition tables for the ethnic foods that are most popular in mainstream diets are available. However, the recipes described may differ somewhat from those that members of the ethnic group prepare for themselves. Even for ethnic foods that are included in nutrient databases, food composition information may be incomplete, inappropriate, or lacking. Moreover, nutrient values for foods that are rarely consumed outside of the ethnic group may be absent, especially if the ethnic group is small. This is a problem with many local foods consumed by Alaskan natives, for example.

The dietary assessment task is more difficult when no country or ethnic specific food table is available. Recipes made from locally available ingredients or imported foods may differ in their food composition from recipe values in food tables used in western countries. For example, a typical curry dinner as served in India, Ghana, and the UK varies greatly in its nutrient composition. For this reason, country-specific food consumption tables are needed. The option of adding ethnic foods to the food composition database for the foods in question from country-specific food tables prepared elsewhere is not recommended unless there is good reason to suspect that the foods are similar. Imported ethnic foods and those eaten in the country of origin may differ considerably both in their nutritive value and in other food constituents.

The degree of error that incomplete entries for ethnic foods introduce in nutrient calculations may be large, so it is important to consider these factors in interpreting the resulting information. Food composition tables should separate true null values (analyzed and found to be devoid of the nutrient in question) from simple lack of information (no analytic information available). Before drawing conclusions about the nutrient contributions of such foods, it is important to ascertain how much information is missing.

Some computerized nutrient databases now include food composition values for imported ethnic foods. When such values are not included, the best option is to obtain representative chemical analyses of the major food items that are likely contributors of the nutrients or other substances of interest. This procedure is time-consuming and expensive but it may be necessary if the task is to describe the intakes of individuals who consume large amounts of specific items of unknown chemical composition that are expected to make valuable nutritional contributions.

A third option is to use botanical and zoological classification schemes and expert knowledge of food-processing techniques to develop provisional values for the likely food composition of unknown foods. However, such estimates are usually very crude.

In the past few years, some culture-specific interactive computer programs have become available for some ethnic groups (e.g., Mexican-American, Chinese-American) that greatly simplify dietary assessment tasks. These programs include photographs of various ethnic favorites as well as mainstream foods, and common food names in both English and the native language, and permit queries by typical meal patterns. Expanded nutrient database entries that include foods eaten in both cultures permit accurate calculation of nutrient intakes.

Dietary Planning and Interventions

Table 6 provides some examples from the recent literature of ethnically appropriate nutrition interventions.

The consumption of ethnic foods is at root a cultural phenomenon but it has physiological implications. Sometimes alterations in eating habits are necessary to achieve nutritional ends, but this is a difficult goal to achieve. Food habits are among the oldest and most deeply entrenched aspects of many cultures, and they cannot be easily changed. When they are changed, they often produce unexpected and unwelcome reactions.

There is no simple formula for success, but ethnic-specificity and cultural sensitivity are important ingredients in crafting successful nutrition planning and interventions. The expertise of nutritional anthropologists who specialize in cultural anthropology as it relates to food and foodways is helpful. Some general principles that must be kept in mind are discussed below.

Some foods are more important than others to eaters. Foods in diets constitute a continuum or gradient that consists of the core diet which includes universal, regular staple foods; the secondary core of foods that are used widely but not universally; and peripheral foods, that are used infrequently. Such groupings are useful in planning nutritional interventions since they often suggest opportunities for making acceptable changes as well as possible pitfalls that need to be avoided. Food habits are always difficult to change. The most resistant habits of all involve foods in the core diet, especially those that are also viewed by the eaters as ethnically appropriate and vital to group cohesion.

The language used about foods, and the names of favorite foods themselves must be used in recruitment. Ethnic-specific nutrition information, recommendations, dietary guidance, and education are also vital if interventions are to be appropriate to the dietary patterns and culture of intended recipients. In many countries, ethnicity, socioeconomic status, educational level, geographical location, religious, and ethical views are often confounded. As these other factors vary, so will the appropriateness of the intervention.

The importance of including ethnic foods in determining the ultimate acceptance of nutrition interventions varies within as well as between ethnic groups. In general, those who are the least accultured to the larger mainstream society, those with language barriers, the ill, the geographically isolated, the economically disadvantaged, traditionalists, and the religiously conservative may regard ethnic foods as particularly important. Those who are innovators and desire acceptance in the larger culture may regard ethnic foods as less important. The degree to which new foods are incorporated into eating styles varies depending on contact between cultures, food availability, trade, and social status of the group introducing the food, as well as philosophical, religious, and individual factors. Immigrants differ in the extent to which they wish to remain unassimilated in their foodways and true to their native cuisines. Ethnic borrowing and mingling rather than rigid preservation of unique eating traditions often occur.

Ethnic-specific food-based dietary guidelines and graphics to guide food choices are now available that present nutritionally appropriate food patterns in a culturally acceptable manner for many ethnic groups. Many guidelines are currently available.

They have the advantage of including ethnic foods as a part of overall diets. These guidelines are helpful as starting points for developing population-based nutrition education materials for healthy persons. Graphics that depict appropriate food choices have the additional advantage of being understandable even to those who may be illiterate.

Special attention must be paid to the ethnic appropriateness of nutritional counseling for those who are ill or in especially vulnerable groups from the physiological standpoint. Therapeutic diet manuals are sometimes available or obtainable that can be helpful in designing diets that provide medical nutrition therapy that is culturally appropriate.

Additional useful techniques for crafting nutrition information, education, and counseling interventions include the use of ethnic and regional terms for foods and recipes. Interventions should be adopted to be culturally appropriate. Food preparation and cooking demonstrations can be used to show how to incorporate recommendations into existing food patterns. Nutrition education and counseling should include attention to ethnic issues. Community social structures in the ethnic group are helpful to make contacts with the target ethnic groups.

Those who develop nutritional interventions that involve food enrichment, fortification, or special supplements must also pay attention to the role of ethnic foods and food patterns in the diet. In many cultures the very target groups for such efforts, who are nutritionally vulnerable because of their age, sex, economic status, or physiological state, are likely to have eating practices that are deeply embedded in their culture. Persons in certain age, sex, or physiological categories are often expected to avoid some foods and to eat others. Nutrition counselors must remember that care of the sick is heavily intertwined with food and health beliefs, social relationships, and acculturation. In summary, nutrition workers must avoid cultural biases and ethnocentricity in dealing with their clients in both dietary assessment and planning.

EUROPEAN UNION

European Food Law Harmonization

P Berry Ottaway, Berry Ottaway & Associates Ltd, Hereford, UK

Introduction

With the signing of the Treaty of Rome on 25 March 1957, the European Economic Community (EEC) came into existence with the founder members being the six signatories to the Treaty: Belgium, France, Germany, Italy, Luxembourg, and The Netherlands. With entries at different intervals over the following 25 years, the Community increased in size to 15 members with the addition of the UK, Spain, Greece, Portugal, Denmark, Sweden, Ireland, Finland, and Austria. The enlargement of the Community (now known as the European Union) is expected to continue with an anticipated 25 member states by 2005.

In the Treaty of Rome, emphasis was placed on consumer protection across the Community. Article 39 states *inter alia* that the objective of the Common

Agricultural Policy is to insure 'that supplies reach consumers at reasonable prices' and Article 86 prohibits undertakings from 'limiting production, markets or technical developments to the prejudice of consumers.'

Right from the inception of the Community it was realized that to insure the freedom of trade in foodstuffs there had to be common rules on labeling, food additives, food composition, and food safety. Initially, the emphasis was on food additives, with the first directive being that on coloring matter authorized for use in foodstuffs for human consumption, which was adopted in 1962. This was followed 2 years later by a directive on preservatives, which was adopted in July 1964. Both these directives gave lists of the permitted additives and controls on the use of the additives for certain applications. During this time, work started on directives to control other groups of food additives such as antioxidants, emulsifiers, and stabilizers.

In 1965 the European Commission published its Recommendation 65/428/EEC of 20 September 1965 to the member states, which required prior communication to the Commission, in draft form, of certain laws, regulations, and administrative instructions. This included the notification of intended new legislation or amendments to existing legislation on foodstuffs.

Harmonization Programs 1969–85

The next major step was the harmonization program which was drawn up in 1969 following the Council Resolution 617/69/EEC of 28 May 1969. This included the drawing-up of a program for the elimination of technical barriers to trade in foodstuffs that resulted from disparities between provisions laid down by law, regulation, or administrative action in the member states. The Resolution also introduced the requirement for mutual recognition of inspections.

The program that emerged from this resolution was, in retrospect, too ambitious. It was divided into priority groups with a time schedule of five stages, 70 subjects were to be covered, and the work was to be completed by 1971. Needless to say, the schedule was by no means complete by this deadline and there was another Council Resolution of 17 December 1973 that included a revized calendar for the elimination of technical barriers to trade in foodstuffs. This required completion of the program by 1978. Again, progress was far slower than anticipated and a further revision was adopted in 1977.

One of the main objectives of the harmonization program during the 1970s was the development of compositional or 'recipe' legislation, covering specific groups of foodstuffs. This 'vertical' legislation, as it came to be known, was considered essential for free movement of foods and a large number of directives were envisaged, each concerned with the composition and control of a product category. By the mid-1970s, over 30 categories of foodstuffs had been identified as requiring recipe or vertical legislation.

The first of these directives was that on cocoa and chocolate products, which is still in force, having been amended numerous times. Although work commenced on over 25 vertical directives during the first half of the 1970s, very little of this proposed legislation had been adopted by 1977. Most of the delays were caused by lack of agreement between the member states as to what was important for the control of the product category. The degree of detail envisaged by the European Commission was found to be incompatible with the current practice in each of the member states.

In 1977, one of the main objectives of the revised program was to review the requirements for many of the vertical directives and to stop work on those that were not considered essential to the facilitation of trade. The program required that the European Commission concentrated on legislation that covered all classes of food such as labeling, prescribed quantities, packing by weight or volume, and purity criteria for the additives already covered by directives. A number of vertical directives that were at an advanced stage were also to be finalized. These included the directive on fruit jams, jellies, marmalades, and chestnut purÕe which was finally adopted in 1979, the directive on coffee extracts and chicory products (1977), and the directive on natural mineral waters (1980).

Of the other proposals for vertical directives, one controlling the levels of erucic acid in fats and oils was adopted in 1976. The directive on the methods of analysis for determining the erucic acid content was eventually adopted in 1980. Whilst these two directives were introduced for reasons of food safety, they have traditionally been regarded as belonging to the vertical legislation.

A directive defining edible caseins and caseinates and specifying the chemical standards and labeling requirements for these ingredients was adopted in 1983 after protracted discussions on the proposals. It took another 2 years before the directive on the methods of analysis was agreed and this was followed a year later in 1986 by a second directive laying down the sampling methods for the chemical analysis.

Except for directives on the methods of analysis of coffee and chicory extracts, the sampling and analysis of preserved milk products, and the manufacture of fruit nectars, the only other vertical directive that was

retained was that on the quality of water intended for human consumption.

By 1980, the original 1969 and 1973 programs had been virtually abandoned and only a handful of the proposed vertical directives survived. These directly related to nine commodities or products, discussed above.

Following the 1977 initiative, work was concentrated on the directive on the labeling, presentation, and advertising of foodstuffs which was adopted in 1979 and on the specific directives required by the directive on materials and articles in contact with food which had been adopted in 1976.

During the early 1980s a number of proposed directives were under discussion but very few were adopted. By 1985 only two-fifths of the original 1969 and 1973 harmonization programs had been implemented. The food industry was finding the cost of compliance extremely high, particularly in the implementation of the requirements of the vertical directives that had been adopted.

A major turning point in the progress towards harmonization and an important influence on the revised programs for the 1980s was the European Court of Justice judgment on the 'Cassis de Dijon' case. This concerned a German prohibition on the import of the blackcurrant liqueur Cassis de Dijon from France as the alcohol content was lower than that permitted by German law. The court ruled that the barrier created by the German regulation was incompatible with the Treaty of Rome, and that quantitative restrictions on imports should be prohibited. This judgment provided a general principle for the trade in foods between member states which was that, provided a foodstuff complies with the regulations in force in the member state in which it is manufactured, it should be permitted on the market of any other member state.

The Cassis de Dijon case is now regarded as being pivotal in the major change of approach by the European Council and Commission to the harmonization program. There was a shift away from the vertical directives and it was determined that future Community legislation on foodstuffs should be limited to provisions that are justified by the need to protect public health, provide consumers with necessary information about foods, provide for necessary public controls, and insure fair trade.

The 1985 Initiative

By the early 1980s it was becoming very clear that, despite revised timetables and changes to strategy, the harmonization program was not working and a completely new approach to food legislation was required. The need for a new approach to harmonization was given an additional impetus in 1985 with the publication of a White Paper from the Commission to the Council entitled *Completing the Internal Market*. The White Paper addressed the fact that there had been a significant imbalance between the 'horizontal' food legislation (e.g., labeling and additives), where considerable progress had been made, and the vertical legislation covering composition, in which there had been relatively little progress.

To overcome these problems it was proposed that a concept of food legislation was required which only contained provisions that could be justified as being essential in the general interest. The main principles to be followed were the protection of public health and the assurance of fair trading. The legislation should also insure that consumers were provided with information and protection in matters other than health and that provisions were made for necessary public controls.

The new approach, initiated by the 1985 White Paper, redefined the method of harmonization and replaced the vertical system with a horizontal one. It also attempted to simplify the procedures to reduce the amount of work involved and to speed up the harmonization process. This new approach was to be based on three general principles. In summary these were:

- that there was the need to distinguish between what was essential and required harmonization and what may be left to the mutual recognition of national legislation and standards;
- that Council Directives based on Article 100 of the Treaty of Rome would be restricted to specifying essential requirements for health and safety which would be obligatory in all member states and compliance with these would allow free movement of products within the Community;
- that, whilst the harmonization of standards would be encouraged, the absence of a European standard could not be used as a barrier to trade. In the absence of a European standard the recognition of national standards would be the guiding principle.

The White Paper, and a Commission communication which followed it, defined a new approach in which the vertical system was to be replaced by a horizontal one. The procedures were also simplified to reduce the work involved and to speed up the harmonization process. The new program was to be centered on five framework directives that were considered crucial to the single market in foodstuffs. These were:

- additives
- food labeling and presentation

- official control of foodstuffs
- foods for particular nutritional uses
- materials and articles in contact with food

The new proposals required the European Council to adopt the framework directives that laid down the general principles and essential requirements for health and safety. The European Commission had the responsibility to introduce measures giving the details and technical specifications that would enable the requirements to be achieved. For example, the framework directive on food additives (89/107/EEC) outlines the general principles for the evaluation and control of food additives based on the criteria of safety and need. From this are derived a number of technical directives giving the lists of permitted additives, their conditions of use, and their purity criteria.

A further, and significant, influence on the need for a change of harmonization policy was the publication of a report in 1988 entitled *The European Challenge 1992 – The Benefits of a Single Market*. The research was funded by the European Commission and the chairman of the steering committee of the research group was Paolo Cecchini, hence the popular description of the paper as the Cecchini Report. This substantial report evaluated all the industry sectors, including those involved with food production and manufacture. It pointed out that the foodstuffs sector was the biggest contributor to jobs and most value-added of all the industries in the European Community, and that it appeared to be well placed to confront international competition in the 1990s. However, it then qualified these statements by saying that appearances may be misleading as the trend towards global consolidation is dominated by companies from the USA. With the exception of Unilever and Nestlé, US companies fill the other eight places of the world's top 10 food companies.

The second, and very crucial, proviso was that the Community market for foodstuffs was segmented by a range of trade barriers that appeared to be on the increase. The harmonization program, which by then had been in operation for almost a quarter of a century, had failed in its primary objectives.

The estimation of the financial cost to the food industry which resulted directly from nontariff barriers was in the range of Ecu500–1000 million annually, not counting the inevitable restrictions in consumer choice. The report also estimated that the savings, which would follow the elimination of these trade obstacles, would represent between 2 and 3% of the value-added component of the food sector, which alone accounted for just over 4% of the Community's gross domestic product. The savings were also estimated to equal up to a 2-year gain in the industry's productivity.

The 1990s

Even with the more simplified and streamlined system introduced with the 1985 initiative, progress was slow and much of the proposed legislation was not adopted at the introduction of the Single Market in January 1993, 35 years after the signing of the Treaty of Rome.

Between the end of 1991 and early 1993, five hygiene directives were adopted. Directive 93/43/EEC covered general food hygiene whilst the other four were for specific groups of foods such as milk and milk products; poultry meat; farmed game bird; and rabbit meats and wild game meats. This plethora of hygiene requirements was soon found to be overlapping and a few years later moves had already started to effect a consolidation into a single piece of legislation.

Other legislation in the early 1990s covered organic food production and control, genetically modified organisms, and the protection of designations of origin and geographical indications.

A communication from the Commission to the Council and Parliament on the *Management of the Mutual Recognition of National Rules after 1992* was issued in December 1993. This document listed 20 barriers to trade in foodstuffs which had been identified by member states during the period 1990–92 and for which many of the Community measures planned in the 1985 White Paper were yet to be adopted or to enter into force.

By the end of 1994 the greater part of the proposed harmonization legislation was in place. Two of the important additives directives, those on colors and sweeteners, were adopted in June 1994, and although the directive on additives other than colors and sweeteners reached common position in December 1994, it was only finally adopted in early 1995.

Legislation still outstanding by the middle of 1995 included the proposed regulation on novel foods and the directive on quantity indication (QUID), both of which achieved common position in June 1995. However, further delays meant that both the novel foods regulation and the QUID directive were only finally adopted in January 1997. By this time draft directives to amend the directive on sweeteners and the directive on additives other than colors and sweeteners had also been circulated.

A number of directives required under the framework directive on foods for particular nutritional uses were still outstanding by mid-1995, as were proposals for the fortification of foods and food supplements. A proposal for a directive on food claims was

withdrawn and a new proposal on unit pricing introduced.

During 1994 the Commission received a total of 35 complaints about obstacles to trade in foodstuffs in contravention of Article 30 *et seq* of the Treaty of Rome. An analysis of these complaints showed that the principal obstacle was the national requirements of prior authorization procedures, whether or not they involved the issuing of certificates, designed to control the composition of the foodstuffs, in particular those containing nutrients such as vitamins and trace minerals and/or additives.

Other examples of complaints listed in the Commission's report for 1994 were the requirement that an accompanying note be produced when sugar is imported into Italy (this was in order to control its use in wine), the ban on the use of sorbic acid in milk-chocolate fillings in France, and the requirement imposed by the Spanish authorities that an official health certificate of the country of origin be produced as evidence that products have been manufactured in accordance with the rules in force in the country of origin and that their consumption presents no health risks.

Post-2000

At the end of 1999 it was apparent that the program was still incomplete. Although some directives and regulations had been under discussion for a number of years, they had still not been adopted. These included a directive on sports nutrition products, one on fortified foods, and a controversial directive on food supplements. There were also a number of outstanding technical directives and regulations, such as those on the control of additives used in flavorings, and further controls on the labeling of foods containing genetically modified organisms.

In December 1999 the European Commission published its White Paper on food safety. This reiterated previous statements that the European Union's (EU's) food policy must be built around high standards of food safety that serve to protect, and promote, the health of the consumer. It also stated that the central role of the Internal Market was to insure that consumers were offered a wide range of safe and high-quality products coming from all member states. This principle should also apply to food imported from countries outside the EU.

The White Paper stated that both EU and member-state food safety systems had been under unprecedented pressure during the food and animal feed emergencies in the second half of the 1990s. These emergencies had exposed weaknesses in the systems both at EU and member-state level and the White Paper assessed the requirement for action by the responsible authorities (the Commission, member states, and European Parliament) to reinforce, improve, and further develop existing food safety systems.

The paper outlined the requirement for a farm-to-table policy that included traceability of animal feed, human foods, and their ingredients.

It was also determined that risk analysis must form the foundation on which the future food safety policy should be based. This was developed into the three components of risk analysis, which are risk assessment, risk management, and risk communication. The paper also stated that, where scientific evidence is insufficient, inconclusive, or uncertain, measures based on the 'precautionary principle' should apply.

A new legal framework of the control of human food and animal feed was laid out in the paper. The inclusion of animal feed was on the premise that the safety of food from animal origin begins with safe animal feed.

The Commission proposed that there should be a comprehensive piece of legislation to recast the different food control requirements already in existence. This would take into account the general principle that all parts of the food production chain should be subject to official controls. An annex to the paper gave an action plan on food safety, which included a number of initiatives relating to food and animal feed safety. This plan covered 84 proposals for regulations, directives, and supporting procedures. The timetable given in the plan required that the majority of the legislation would be adopted by the Commission by the end of 2000, with final adoption by the Council and European Parliament by the first half of 2002. By the end of 2001 many had already fallen behind the timetable.

The rationale for the establishment of a European Food Authority was given in detail. The Food Authority was envisaged as having particular responsibilities for both risk assessment and communication on food safety issues.

From early 2000 onwards two subtle changes were taking place in the European food law. One was the development of legislation not directly related to the original harmonization program but dealing with emerging issues. This included detailed legislation on contaminants in foods such as mycotoxins and dioxins.

The other change that has been taking place is the move from directives to regulations for a wider spectrum of food law. This is an interesting move as it effectively speeds up the legislative process. Directives require member states to modify their internal legislation to incorporate the requirements of the directive

within a given period, which can be quite long. Regulations, however, require the member state to introduce the legislation as the unaltered text of the regulation and the time allowed is relatively short, often a matter of months. As a consequence, regulations allow for a more rapid implementation of the law.

General Food Law

One of the most glaring omissions, which had still not been resolved by the end of the 1990s, was the legal definition of a food and a single document giving the principles and philosophy of European food law. Although the precepts of the legal aspects of European control had been introduced into individual directives and regulations, there was no single official document to cover these aspects. For many years the concept of a directive on general food law had been under discussion, with the objective of producing a piece of legislation to clarify the parameters for the structure and operation of European food law.

It was not until 1997 that the European Commission published its Green Paper on food law, which laid down the common principles underlying the food legislation and established food safety as the primary objective of food law. The Green Paper was followed at the end of 1999 by the Commission's White Paper on Food Safety. Chapter 6 of the White Paper advocated a new legal framework for food safety embodied in legislation covering general food law.

Just a year later, at the end of 2000, the Commission published a proposal for 'a Regulation laying down the general principles and requirements of food law, establishing the European Food Authority, and laying down procedures in matters of food safety.' Article 2 of the proposal gave a definition of food for the first time. In essence, this covered any substance or product, whether processed, partially processed, or unprocessed, intended to be, or reasonably expected to be, ingested by humans. It included drink, chewing gum and any substance, including water, intentionally incorporated into the food during its manufacture, preparation, or treatment. Exclusions from the definition included medicinal products, cosmetics, tobacco and tobacco products, and narcotic or psychotropic substances.

As stated in its title, the proposed regulation also contained the requirement for the establishment of a European Food Authority, which would have the objective of providing scientific advice and scientific and technical support for EU legislation in all fields that have a direct or indirect impact on the safety of human food and animal feed.

The mission for the Authority as given in the proposal was the contribution to a high level of protection of human life and health and in this respect to take account of animal health and welfare, plant health, and the environment. This was to be carried out in the context of the operation of the internal market.

The Authority was to comprise a management board, an executive director and staff, an advisory forum, a scientific committee, and permanent scientific panels. The proposal specified eight scientific panels, which would be required to cover the various aspects covered by the Authority's remit. The panels were to be composed of independent scientific experts.

A further part of the proposed regulation specifically related to food safety and covered the requirement for a rapid alert system, emergencies, and crisis management. This initiative was mainly as a consequence of a number of European food scares during the late 1990s such as bovine spongiform encephalopathy (BSE) in cattle and the Belgian and Dutch dioxin crises.

The proposals also included the requirement for full traceability of food, animal feed, and food-producing animals. The responsibilities of food and animal feed operators are given and the concept of the precautionary principle is laid down in law.

These proposals were finally adopted in January 2002 as Regulation (EC) N° 178/2002.

Evaporated Milk *See* **Condensed Milk**

EVAPORATION

Contents

Basic Principles

P H Ferguson, Cornwell Products, Edenbridge, UK

Background

Evaporation is the removal of water, or another solvent, from a solution by the application of heat – primarily the latent heat of vaporization – to the solution. Thus, it can be seen that evaporation involves a heat-transfer process that heats a liquid in order to generate a vapor, which in turn has to be separated and, in nearly all cases, subsequently condensed. The theory of evaporation therefore is based upon the principles of heat transfer and, in particular, their application to the boiling (evaporation) of fluids, and the condensation of vapours. (*See* **Heat Transfer Methods**.)

Considering the process economics aspect, the heat-transfer step is important as its efficiency is the factor having the greatest influence on both the capital and the operating costs. The vapor–liquid separation is also critical as the effectiveness with which it is carried out influences the product losses (by way of vapor entrainment), pollution of the condensate steam byproduct, and potential corrosion problems of the condenser surfaces. The subsequent condensation of the evaporated vapor also requires careful consideration, because not only does it have a bearing on the operation of the evaporator system, but perhaps more importantly, it significantly affects the system's operating economy.

Conventionally, the heat required is provided by low-pressure steam (generated from a range of primary fuels), although in practice, this requirement can be minimized by the reuse of vapors from the evaporation process itself. Less common than these indirect heating techniques are direct heating methods (e.g., solar heating of salt brines).

General Principles of Heat Transfer

Heat can be transferred by conduction, convection, or radiation. The last means of heat transfer is not usually significant in industrial evaporation systems.

Heat Transfer by Conduction

The quantity of heat transferred between two points (see Figure 1) is defined as

$$Q = -KA\frac{T}{X}, \tag{1}$$

where Q is the quantity of heat, K is the thermal conductivity, A is the surface area through which heat is passing, T is the temperature difference between the two points, and X is the distance between two points (the negative sign shows that the heat flow is in the opposite direction to the temperature gradient).

Thermal conductivity is a property of the material through which the heat is passing, and can vary from, for example, 15.93 for stainless steel, 0.62 for water, to 0.024 for air, a difference factor of nearly 700. (Units are $J\,s^{-1}\,m^{-1}\,K^{-1}$.) Interestingly, stainless steel (the most common material of construction for food industry evaporators) has one of the lowest thermal conductivities for metals, whilst water has one of the highest thermal conductivities for liquids.

Another useful parameter to consider is thermal resistance:

$$R = \frac{X}{K}. \tag{2}$$

Where we are considering heat transfer through a composite wall (i.e., several layers of different materials), thermal resistances are cumulative in their effect on heat transfer. Hence, if one layer is a material with a high thermal resistance (e.g., an insulating material or fouling scale), the overall heat transfer will be low, even if other layers have a low resistance (e.g., metals).

In the instance of conduction through the wall of a tube (Figure 2), the surface area across which the heat transfer takes place is the tube wall itself. The equation for determining the heat load transferred is:

$$Q = -K2\pi rl\frac{T}{W}, \tag{3}$$

where r is the tube radius, l is the length of the tube, and W is the wall thickness.

Heat Transfer by Convection

Heat transfer by convection occurs as a result of the movement of fluid on a macroscopic scale, in the form of eddy and circulation currents. This convective movement can take two forms:

1. Natural convection: these currents arise from the heating process itself, because of the differences in density between the heated fluid and the surrounding colder fluid, which causes the former to rise, and the latter to sink to take the place of the former.
2. Forced convection: in this type of convection, the currents are created by an external device, e.g., a circulation pump causing turbulent flow in a pipe.

When heat transfer occurs from a surface into the body of a fluid, natural convection currents are weakest at the surface, which is covered by what is effectively a static film. Consequently, heat transfer across this film can only occur by conduction, and, as mentioned above, thermal conductivity in fluids is low. Hence, the main resistance to heat transfer into fluid in a pipe is this film adjacent to the pipe wall. An increase in the velocity of the fluid moving through the pipe will reduce the thickness of this static film and give rise to an overall increase in the heat transfer into the fluid.

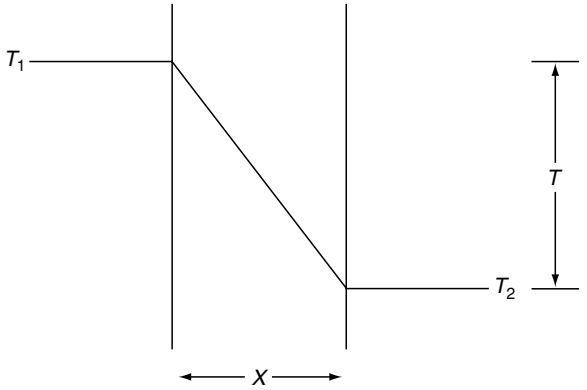

Figure 1 Heat transfer by conduction between two points. Reproduced from Evaporation: Basic Principles, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

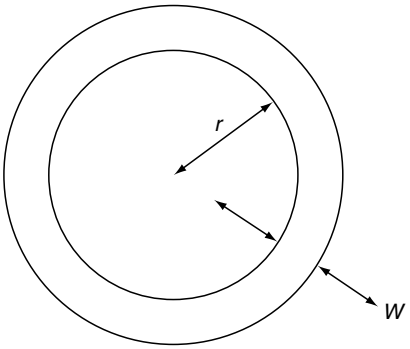

Figure 2 Heat transfer through the wall of a tube. Reproduced from Evaporation: Basic Principles, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

In theory, the heat load transferred across this film is defined as in eqn (1). However, in practice, it is difficult to calculate the film thickness, X, and so the following relationship is used:

$$Q = -hAT, \tag{4}$$

where h is the heat-transfer coefficient.

Thermal resistance is therefore the reciprocal of the heat-transfer coefficient, i.e., $1/h$.

Forced convection is of more importance than natural convection in industrial food processes and equipment, where the fluids are under turbulent flow conditions. It should be noted, however, that evaporators can be classified as either 'natural circulation' or 'forced circulation' systems. In the former case, the eddy and circulation currents described above are greatly enhanced by the currents caused by the rising bubbles generated in the boiling processes.

Whenever possible, streamline flow conditions should be avoided or at least minimized, as the heat transfer coefficients of fluids (in convective heat transfer) are much greater than thermal conductivity factors (in conductive heat transfer). With very viscous fluids (e.g., food pastes and slurries), turbulent flow can only be produced by a high-pressure drop across the heat-transfer device (e.g., by the input of a large quantity of pump energy).

In a tubular heat exchanger (e.g., an evaporator), where perhaps one fluid is flowing inside a pipe and being heated (or cooled) by another outside, the consideration must be of heat transfer both inside and outside the tube. In the latter case, flow can be either lengthwise along the tube (in either direction) or at right angles to the single tube or tube bundle.

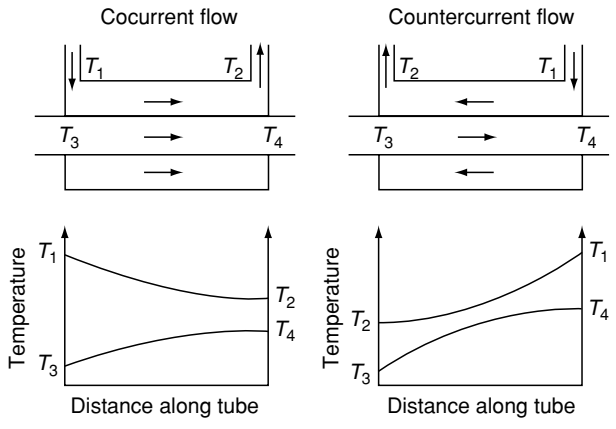

Figure 3 Logarithmic mean temperature difference. Reproduced from Evaporation: Basic Principles *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Also, those fluids passing along the length of the heat exchange tube (either inside or outside) will experience either an increase or decrease in temperature, obviously because of heat transfer. This means that in order to correctly quantify this heat transfer, it is first necessary to define the difference in temperature between the fluids, given that it will not only vary at different points along the length of the tube, but will also vary depending on whether cocurrent or countercurrent flow is being employed. It is necessary to calculate an 'average' value for the temperature difference, and the factor normally employed is the logarithmic mean temperature difference (LMTD):

$$\text{LMTD} = \begin{cases} \dfrac{(T_1 - T_3) - (T_2 - T_4)}{\log_e (T_1 - T_3)/(T_2 - T_4)} & \text{(cocurrent flow)} \quad (4a) \\ \dfrac{(T_2 - T_3) - (T_1 - T_4)}{\log_e (T_2 - T_3)/(T_1 - T_4)} & \text{(countercurrent flow),} \quad (4b) \end{cases}$$

where T is the temperature (see Figure 3 for a definition of subscript numbers).

Heat-transfer Aspects of Evaporation and Boiling

As already stated, evaporation is the removal of water (or other solvent) from a solution by boiling the liquor in a suitable heat exchanger (i.e., the evaporator) and removing the resultant vapor.

In boiling liquids (e.g., inside an evaporator tube), the heat-transfer coefficient (h) depends very much on the temperature difference (T) between the heating surface and the boiling liquid.

Boiling can be classified into three types: interface evaporation, nucleate boiling and film boiling (Figure 4).

Interface Evaporation

Here, relatively few bubbles are formed on the heating surface, and they move to the vapor–liquid interface by natural convection, causing negligible agitation in the liquid. Full boiling is often suppressed owing to the hydrostatic head of the liquid above the heating surface. This phenomenon is particularly likely at the bottom of a vertical evaporator tube.

The heat-transfer coefficient increases slightly with increasing temperature difference.

Nucleate Boiling

Here, a large number of bubbles form on the heating surface, and their escape to the vapor–liquid interface

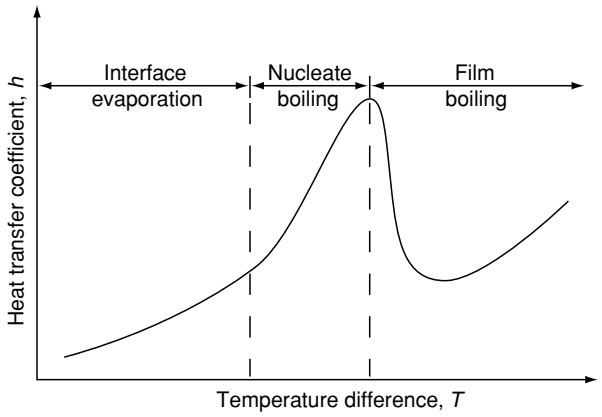

Figure 4 Types of boiling. Reproduced from Evaporation: Basic Principles, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

brings about significant turbulence in the liquid. This in turn means that the heat-transfer coefficients are greater, and rise more rapidly with increasing temperature difference, than in the instance of interface evaporation. The maximum heat-transfer coefficient is reached at the top end of this boiling category.

Film Boiling

Film boiling occurs at higher temperature differences, when the quality of vapor being generated at the heating surface is so great that the bubbles start to coalesce to form a vapor film over the heating surface. This in turn means a large drop in heat-transfer coefficient as the latter is obviously much lower for vapors than for liquids, and therefore the quantity of heat transferred falls in proportion.

The critical temperature difference at which the heat transfer coefficient is at its maximum depends on the physical properties of the boiling fluid and also on the geometry of the heating surface.

With even further increases in temperature difference, the heat-transfer coefficient eventually starts to rise again, as heat transfer by radiation (across the vapor film) starts to become a significant part of the total heat transferred. These very high temperature differences are rarely found in practice, however, and most evaporation systems are designed to operate at, or just below, the temperature difference at which the heat transfer coefficient becomes a maximum.

Boiling-point Rise

In addition to the nature of the boiling regime present, another characteristic of evaporation systems is the boiling-point rise (BPR). The boiling point of a solution (e.g., a liquid foodstuff) is always higher than that of pure water, and the magnitude of this temperature elevation is proportional to the concentration of solids in the solution – hence, as the solids increase during the process of evaporation, the boiling point will increase. By way of example, the BPR of milk is only 0.5 °C at 16% total solids, rising to 2 °C at 50% and 5 °C at 80% total solids.

The consequence of this phenomenon is that the temperature difference between the heating medium (e.g., steam at 110 °C) and the boiling liquid (e.g., milk at 50% total solids; BPR = 2 °C; boiling point = 102 °C at atmospheric pressure) is less (110 °C − 102 °C = 8 °C) than in the case of pure water (110 °C − 100 °C = 10 °C). The 20% drop in the temperature difference, from 10 °C to 8 °C, means a pro rata drop in heat transfer, as it is directly proportional to the temperature difference. The resultant vapor will be at the temperature of the boiling liquid and hence will be superheated by the amount of the BPR (i.e., 102 °C − 100 °C = 2 °C).

In practice, the sensible heat associated with this superheating is often harder to recover than the latent heat itself and effectively is partly or totally lost, causing a loss in energy economy.

Heat-transfer Aspects of Condensation

When a saturated vapor is brought into contact with a cooler surface, and falls below its dew point, vapor will condense on that surface, giving out its latent heat of vaporization.

This condensation can occur in two ways:

1. Dropwise condensation: here, the condensing vapor forms a large number of small individual drops on the surface, which do not wet the surface but, after growing slightly, fall away and hence expose fresh surface for further similar condensation to take place on. This type of condensation can result in very high heat-transfer rates, as heat does not have to flow through a film of liquid by conduction. However, dropwise condensation is rarely found in practice and in fact has only been definitely demonstrated with pure steam, under specialized conditions.
2. Film condensation: in this form of condensation, the condensing vapor forms a continuous film on the cooler surface, and subsequent condensation actually takes place on this film of liquid. If the surface is vertical, the condensate film flows downwards, the flow being predominantly streamline, and hence heat-transfer will be by conduction. It can be assumed that the temperature of the film at the cool surface is equal to that of the surface itself, and the film temperature at the vapor surface is at the same temperature as the vapor.

Another aspect of vaporization to consider is that, in most evaporation systems encountered, the vapors will contain a small quantity of noncondensable gas (e.g., air that has either entered the product or via leaks into the main body of the evaporator, most of which will often be operated under varying levels of vacuum). This mixture of gas and vapor, when cooled in the condenser, will give rise to a layer of condensed vapors only, on the heat exchange surfaces of the condenser. Heat transfer to this surface will, therefore, be not only by the vapor condensing, and hence releasing its latent heat, but also by the transfer of sensible heat from the noncondensing gas. The design of the condenser will need to take this factor into account.

below its boiling point (**Figure 1**). As the outside of the tube is heated by steam, the liquid rises in temperature, and its density falls, causing it to rise. As it passes up the tube, its temperature reaches boiling point, and small vapor bubbles appear in the liquid. This causes a greater drop in the overall density, causing the liquid–vapor mixture to rise further, and as the liquid continues to pick up further heat, additional vapor is produced, and more bubbles form, until the volume of vapor is greater than that of the liquid. Eventually, at the top, only vapor and liquid mist occurs.

It is possible to classify this overall flow regime into five stages:

1. Single-phase flow: at the base of the tube, where the liquid enters – no bubbles present.
2. Two-phase flow: liquid predominates, but contains a swarm of small vapor bubbles.
3. Plug flow: liquid plus large vapor bubbles (formed by coalescence of small bubbles).
4. Annular flow: large vapor bubbles coalesce to occupy central core of tube, and the liquid forms a film on the inner wall of the tube.
5. Mist flow: at the top end of the evaporator – the liquid film breaks up, and the remaining liquid appears as droplets in the flow of vapor out of the top of the tube.

This type of evaporator is also known as a natural-circulation evaporator.

Uses in the Food Industry

P H Ferguson, Cornwell Products, Edenbridge, UK

Background

This article deals with the main types of evaporator used in industry and how to select the correct configuration, and finally, a range of applications in the food, dairy, and related industries are considered.

Types of Evaporator

Primarily, evaporators are characterized according to the manner in which the liquid phase circulates.

Climbing-film Evaporator

This is the traditional form of vertical tube evaporator where liquid to be evaporated enters the evaporator tube at the bottom, at a temperature

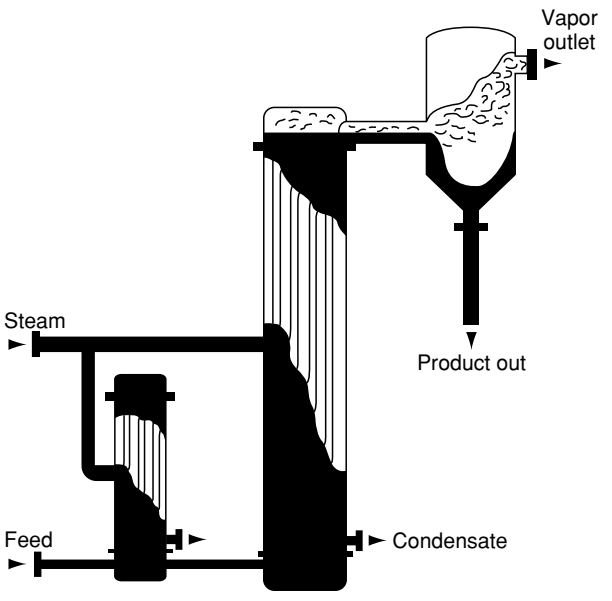

Figure 1 Climbing film evaporator. Reproduced from Evaporation: Uses in the Food Industry, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Forced-circulation Evaporator

This form of evaporation plant (Figure 2) is employed with liquids which, for technical or economic reasons, cannot be concentrated with natural circulation evaporators. These are very viscous fluids, liquors that cause scaling and fouling problems (exhibiting inverse solubility/temperature characteristics), or corrosive liquids. The disadvantages are higher capital and operating (i.e., pumping) costs than for film evaporators.

In this liquid flow configuration, product is pumped at high velocity through a heat exchange section where boiling is prevented by the application of a hydrostatic pressure: this absence of boiling greatly reduces the scaling on heat-exchange surfaces. Boiling subsequently takes place in the separator.

Flash evaporators are effectively special cases of forced-circulation evaporators, where boiling is suppressed artificially by means of an orifice or valve, and the product is flashed through into a separator. Higher temperature rises are therefore possible through the heat exchanger, giving reduced circulation rates and pumping costs. However, this also reduces the suitability of the plant for products containing substances with inverse temperature/solubility characteristics. Plate heat exchangers are often used for flash-evaporation duties.

Forced-circulation evaporator configurations are often used as crystallizers – the alternative being the cooling evaporator. In the evaporative crystallizer, the conditions are approximately isothermal, and supersaturation is achieved as a result of the removal of solvent. Evaporative crystallization must of course be used where the solubility shows little variation with temperature.

Falling-film Evaporator

Compared to the falling-film evaporator (Figure 3), the energy economy of the climbing-film system remains relatively poor. The residence time of the liquid is greater, as are the associated temperatures (and temperature differences), in the climbing-film units, and hence they are rarely found in the food and related industries (e.g., for use with heat-sensitive products). Other advantages often found in the much more common falling-film arrangement are easier control, simpler construction, and greater ease of cleaning.

In a falling-film evaporator, the liquid – as the name implies – enters the top of the tube, and passes down to the bottom, as a film. This latter characteristic is effected primarily by insuring that the liquid, as it enters the top of the evaporator, is superheated so that, as it passes into the top section of the tube, vapor is flashed off, filling the central core of the tube and thereby holding the liquid as a film against the tube wall. Another positive difference, in terms of energy economy, between the falling- and climbing-film evaporators, is that the former type – because its liquid feed is superheated – does not have part of the tube surface employed for preheating purposes (i.e., to bring it to the boiling point). It is more

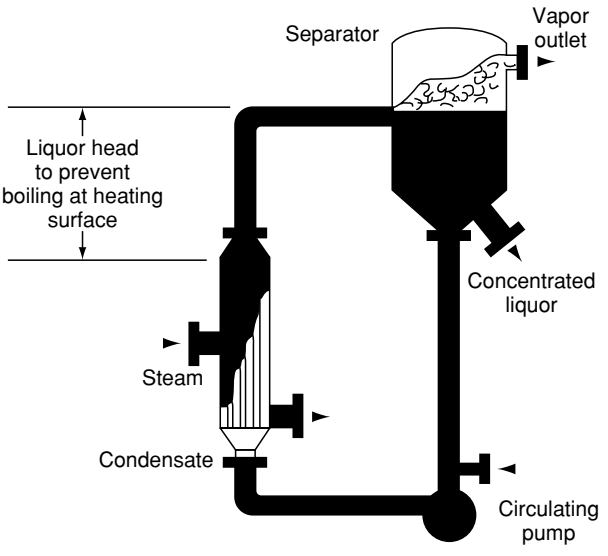

Figure 2 Forced-circulation evaporator. Reproduced from Evaporation: Uses in the Food Industry, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

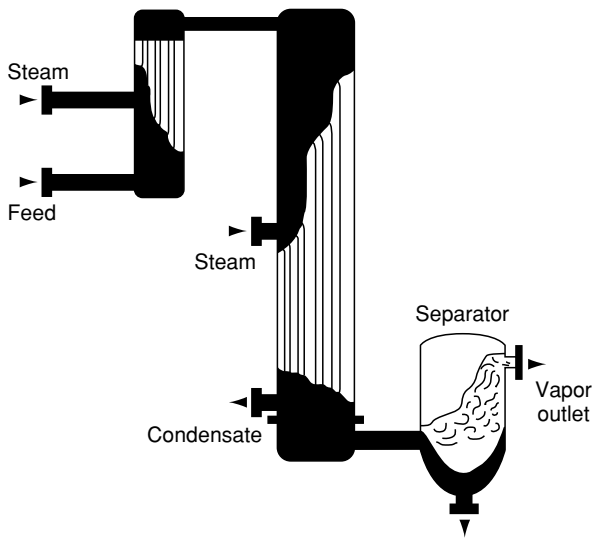

Figure 3 Falling film evaporator. Reproduced from Evaporation: Uses in the Food Industry, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

cost-effective to preheat the liquid in a separate heat exchanger. This can be either a stand-alone system or, more likely, one that is integrated into the overall evaporator plant – for example as a preheating coil located in the steam jacket around the main tube.

Falling-film evaporators in the food industry normally operate under vacuum, thus reducing the product boiling point and minimizing heat damage.

Other Types of Evaporator

The thin-film (or wiped-film) evaporator can be used for very viscous, scaling, or crystallizing materials. The tubular body of this evaporator is fitted with a central rotor, which has blades along its length. These blades almost touch the tube wall (with a clearance of typically about 1 mm) so that, when they rotate during the normal operation of the evaporator, a very thin and well-agitated film of liquid is formed on the surface of the tube wall. In some equipment models, the outer edge of the blade is hinged, so that this edge is forced by centrifugal action on to the wall, and consequently, the thickness of the film so produced is determined by the balance between this centrifugal force and the hydrodynamic forces produced in the liquid film on which the blade rides. This version of the thin-film evaporator is usually known as a swept-surface evaporator. Another configuration of this evaporator group is the scraped-surface evaporator. Here, as the name suggests, the blades (made from a synthetic material or perhaps rubber) actually scrape against the wall. Owing to the relatively high capital cost of this evaporator type, it has relatively limited applications.

Strictly speaking, most driers are forms of evaporators, where the evaporation process is taken to the extreme where effectively all the solvent is removed, leaving the dissolved solids in dry form.

As mentioned at the beginning of this article, evaporator classification is usually based on the way in which the liquor circulates. However, it is also possible to classify evaporation plants according to the mechanical configuration, the most common types being tubular or plate. Although tubular systems are most widespread, plate systems have certain attractions. As the plant height is relatively low, they can operate in process areas where there is limited headroom. Hence, building and installation costs can be modest. It is also often possible to increase their heat-transfer surface at relatively little additional expense. (*See* **Drying**: Theory of Air-drying.)

Evaporator Selection

Once the need for an evaporator for a particular product application has been established, it is necessary for a specification to be prepared, which will be obviously helpful to both purchaser and supplier to identify plant configuration and component selection. In carrying out this exercise, the following points should be borne in mind:

1. Throughput:
   - hourly rate and/or daily rate;
   - length of production run (hours/days).
2. Feed specification:
   - total solids (or equivalent, e.g., degrees Brix);
   - other relevant parameters (e.g., suspended solids, pH, volatile components).
3. Product specification:
   - temperature;
   - total solids;
   - other requirements or characteristics (e.g., vis cosity).
4. Utility requirements:
   - steam, electricity, air, cooling/chilled water (in cluding temperature);
   - existing on-site availability, and proximity to proposed evaporator location.
5. Plant dimensions, building requirements (or outdoor location), foundation loadings, installation aspects (e.g., access for cranage, etc.).
6. Plant access for operation and cleaning (e.g., ladders, platforms, inspection ports) and maintenance (e.g., extra headroom and/or additional space for unhindered removal of individual plant components). Manways should be easy to use (power operated, if necessary).
7. All cleaning requirements ('cleaning in place' (CIP) and also manual cleaning operations – both routine and emergency) must be specified. Additional site facilities identified and procured as necessary.
8. Effluent loadings and associated treatment facilities quantified.
9. Specify individual components (e.g., choice of pumps, electronic controls, etc.). Materials of construction and surface finishes confirmed.
10. Manufacturing and equipment standards to be laid down. Plant testing (e.g., pressure and vacuum). The need for acoustic and thermal insulation should be examined.
11. Control and automation to be specified, including links to adjacent plant, e.g., drying equipment.
12. Obtain recommended spares list, and order as required.
13. Determine pretreatment process which might affect evaporation process. Identify storage/buffer tanks needed, for both feedstock and end product.
14. Identify training requirements, including operator manuals, maintenance schedules, plant

drawings, etc. Plant inspection, delivery, installation and commissioning activities, and arrangements for plant handover.

Applications

A list of established evaporation duties in the food and related biological industries would include the materials listed in Table 1. A few of the applications in Table 1 are considered in more detail in the remainder of this article.

Dairy Products

-Milk From the first recorded use of evaporation, as a means of enhancing the shelf-life of milk, batch vacuum pans were almost universally employed up until the 1920s. However, after stainless steel came to replace copper and aluminum as the material of construction, more sophisticated evaporator configurations (requiring CIP techniques, in turn employing stronger chemicals – now feasible with the new material of construction) became possible. The natural circulation (i.e., rising film) evaporators that replaced the earlier pans were mainly tubular systems and were used up until the early 1950s, when falling film evaporators became more common, and eventually ousted the older styles of evaporator. All three types of plant employed a vacuum, so as to lower the boiling point of the milk, and hence minimize thermal damage (and burn on). Single-stage plants had given way to multieffect units before 1940. All modern-day milk evaporators are multieffect plants, and they almost always employ either thermal (TVR) or mechanical (MVR) vapor recompression. (See below for further details of vapor recompression systems.)

For an example of a typical installation, consider a multiple-effect TVR unit. Prior to the milk entering the first effect, it is usual practice for the milk to be pasteurized. This is generally effected by ensuring that the milk-feed line, which passes through each of the jackets so as to preheat the milk (final effect jacket first, first effect last), goes through a special section in the first effect jacket. Here, the temperature is boosted by extra steam. After regenerative cooling, the milk then enters the first effect or is diverted for additional heat treatment (for example, holding at elevated temperatures, as required for milk to be used for high-heat powder production). The milk then passes through each of the calandria in turn, its concentration obviously increasing (and boiling

Table 1 Materials in the food and related biological industries that require evaporation in their manufacture

Dairy products	*Food products*	*Other biological liquids*
Baby foods	Agar	Amino acids
Buttermilk	Beef stock	Calcium formate
Fat-enriched milk	Beer	Corn steep liquor
Icecream mix	Brewers' yeast	Distillery pot ale
Reconstituted milk	Chestnut extract	Distillery spent wash
Skim milk	Chicken stock	Fish stick liquor
Sweetened condensed milk	Clam broth	Formic acid
Whey	Coffee extract	Gelatine
Whole milk	Dextrose	Gluconic acid
Yogurt milk	Glucose	Glycerine

temperature decreasing) in each subsequent effect. The last effect is often termed the 'finisher' and operates at a higher temperature (and temperature difference) than the penultimate effect, due to an additional steam supply. One or two thermal vapor recompression units are used. The internal design of the finisher is usually configured to handle the higher viscosity associated with the end product.

Alternatively, an MVR system could be employed. Depending on the overall plant capacity, and final product solids, the system would typically comprise a main calandria, where most of the water would be removed, followed by a finisher (possibly TVR), to remove the remainder of the water. (*See* **Milk**: Processing of Liquid Milk.)

-Whey Whey is often characterized by its level of acidity, and hence can be either low-acid 'sweet' whey (from hard or semihard cheese) or high-acid 'acid' whey (from soft cheese, e.g., cottage cheese).

The whey (typical 6% total solids) is normally evaporated after pretreatment to remove fat (and/or cheese fines) up to between 40 and 60% total solids, the choice of the final product solids depending on subsequent processing needs. If the whey concentrate has to be transported, 40% is preferred, to avoid crystallization taking place *en route* and causing unloading difficulties. Alternatively, when the whey is to be spray-dried (on-site), 60% is better. Both TVR and MVR falling-film equipment can be used, the latter configuration usually giving – in this application as well as others – better energy economy. (*See* **Whey and Whey Powders**: Production and Uses.)

Fruit Juices

-Citrus juices High-quality orange juice has been concentrated to between 65 and 75% total solids. Some types of comminuted orange can only be evaporated to about 45%.

Grapefruit juice is typically concentrated to 65% total solids, whilst lemon and lime juices are processed to 45 and 40% total solids, respectively. At these final evaporator concentrations, color quality is maintained intact.

In order to maximize flavor retention, an aroma recovery system should be incorporated into the plant design.

-Apple juice Most apple juice plants concentrate to 72–75% total solids. Aroma recovery should be used to ensure maximum retention of the original fruit flavor characteristics.

-Tomato juice It is possible to use film-type evaporators to preconcentrate tomato juice up to approximately 20% total solids. To obtain higher solids, a swept-surface unit can be considered.

-Other juices Typical concentrations that are possible from commercial evaporation systems are blackcurrant 65–70%, grape 70–75%, pineapple 65%, raspberry and strawberry 70–75%.

Food and Related Products

-Starch industry The main evaporator duties in the corn starch industry are associated with the concentration of corn steep liquor (e.g., for animal feed and antibiotic production medium purposes). Because corn steep liquor is primarily a byproduct, it contains many ingredients, including mainly sugars and proteins, and their derivatives. It shows, therefore, relatively high fouling characteristics, particularly at higher concentrations. Its evaporation requires the use of a plate or tubular falling-film evaporator for the lower concentration stages, and a forced-circulation arrangement for the final effect. Similar byproduct recovery systems, using evaporation technology, are employed in the wheat starch industry. (*See* **Starch**: Sources and Processing.)

-Sugar industry The beet and cane sugar industries use evaporation to concentrate the dilute sugar steam, as extracted from the beet or cane, up to the final concentration prior to crystallization, itself a form of evaporation. Such systems are typically multieffect tubular systems, incorporating vapor recompression. (*See* **Sugar**: Refining of Sugarbeet and Sugarcane.)

The production of sugar syrups (glucose, maltose, fructose) also requires evaporation: the raw syrup (often a product of the acid, alkali, or enzymatic hydrolysis of starch) is typically generated at 20–30% total solids and will need concentration up to 70–80% final solids. The evaporator is almost always a falling-film unit, incorporating either thermal or mechanical vapor recompression. Unlike the byproducts of starch processing (see above), sugar syrups show very low fouling factors on evaporation.

-Gelatin industry The current method is to employ a multiple-effect TVR or single-stage MVR (with or without finisher). The feed material will usually be a dilute gelatin material at around 5% total solids. It will be concentrated to typically 20% total solids, at which point, there is an option of sterilizing the product by live steam injection (at 135–145 °C) and holding the product for up to 8 s. Flashing into a vacuum chamber cools the product down to 100–105 °C, and then the gelatin is further concentrated to a final level of 30% total solids or thereabouts, usually by flash evaporation.

-Lactic acid Food-grade material is usually generated by fermentation, and the resultant acid – after primary removal of impurities – will be at around 10% total solids. This can be concentrated by evaporation to 80–82% total solids. A typical installation, operating at a feed rate of 5 tonnes per hour, consists of three effects (including thermal vapor recompression) and a finisher unit. The boiling temperatures in these three effects are, respectively, 87, 75, and 50 °C, and 50 °C in the finisher. Grade 316 stainless steel is required due to the acidity of the product.

-Beverage industry Most fermented beverage industries that employ distillation to produce a concentrated alcoholic product (e.g., whisky, gin, cognac) generate large volumes of low-alcohol 'waste' streams, i.e., the remaining fraction after the alcohol has been removed by distillation.

The Scotch whisky industry produces two effluent streams: 'pot ale' from malt distilleries and 'spent wash' from grain distilleries. Although these materials closely resemble each other, spent wash is normally more difficult to evaporate to high solids due to a higher level of suspended solids and a greater degree of fouling.

An example of an evaporator to handle, say, 60 tonnes of feed stock (pot ale) per hour at 4% total solids, and concentrate to a final value of 50% total solids, would be configured as follows: a double-effect falling-film MVR system (with turbine fans to recompress the vapor, and optionally a double calandria for the first effect to handle the volume of feed material), supplemented by a forced-circulation finisher. The feed temperature depends on prior handling and storage. The boiling temperature in the two MVR effects would be, respectively, 96 and 91 °C. The finisher would operate at 91 °C also. The main fans would draw around 500–550 kWh, which, together with other motors on the evaporator, would give an overall power consumption of some 12 kWh per tonne of feed stock. TVR systems are still used; however, most new installations incorporate MVR.

Other whisky distilleries (in Ireland and the USA) yield similar byproducts, which can be evaporated in a similar manner.

The neutral spirits industry (gin, vodka, etc.) generates byproducts of a related composition, albeit higher in inorganic salts (e.g., calcium sulfate), which have inverse solubility curves, leading to increased levels of fouling at higher concentrations. Again a forced-circulation layout will be the preferred design for the finisher.

Effluent from the production of cognac requires pretreatment to remove tartaric acid and tartrates before evaporation can be carried out.

Energy Economy

The vapor removed in a single evaporator stage (effect) basically equals the amount of steam fed to that effect. The temperature of the evaporated vapor is, however, lower than the temperature of the heating steam and cannot therefore be used as such to reheat the same stage; instead, the vapor in such a system is led to the condenser, where the remaining heat content is lost. The specific steam consumption (i.e., steam used/vapor removed) of a single-effect evaporator is thus unity.

The specific steam consumption can be halved by the addition of a second effect, which is heated by the vapor from the first effect but is operated at a lower temperature because the heating medium is at a lower temperature.

Addition of further effects thereby reduces (i.e., improves) pro rata the specific steam consumption. Although it would be possible in theory to keep adding effects *ad infinitum* so as to reduce the specific consumption to an almost negligible level, in practice, this possibility is limited for two reasons. First, the increase in capital cost associated with adding extra effects has to be balanced against the reduction in operating cost (i.e., steam); for example, in the dairy industry, it was found that additional effects over and above seven did not pay for themselves in terms of savings in operating costs. Second, between each effect, there is a drop in temperature of perhaps 5 °C (because of the above-mentioned difference in temperature between heating medium and vapor driven off), and coupling this with the fact that, for most food and related products, there is a maximum and minimum evaporation temperature (for reasons of thermal and bacteriological stability, respectively), there is thus another limit to the maximum number of effects permissible in industrial practice.

An alternative method of improving the energy consumption is by the use of vapor recompression. This technique involves taking the product vapor from the effect, compressing it to increase its temperature, and then returning it for reuse in that same effect as the heating medium; the vapor condenses as a result and is subsequently led away for disposal. However, in the process, the specific steam consumption for that effect has been nominally halved. It must be remembered, of course, that additional energy is required to recompress the vapor, but this is small when compared to the energy content of the compressed vapor generated.

The vapor can be compressed either thermally or mechanically: in practice, this means, respectively, either by fresh, high-pressure steam or by a form of mechanical compressor. Where steam is employed, the

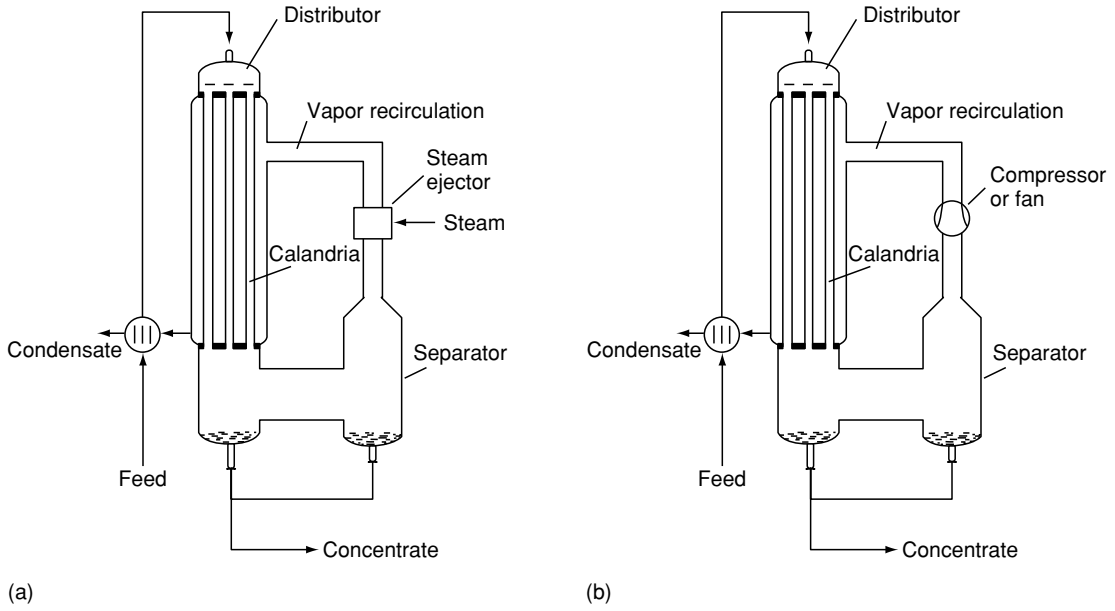

Figure 4 Main components of vapor recompression evaporators: (a) TVR and (b) MVR. Reproduced from Evaporation: Uses in the Food Industry, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

system is known as TVR, whilst mechanical systems are known as MVR. This latter system will usually involve a fan-based compressor rather than a conventional centrifugal-type unit, but individual applications and circumstances will dictate the final choice.

The relatively small additional energy costs required for this vapor recompression are hence in the form of either extra steam or extra electricity costs. The main components of a vapor-recompression evaporator are shown in Figure 4.

As can be seen, once the evaporation process has been brought up to a steady-state operating condition (that is, from start-up), no further addition of primary heating steam is needed (i.e., excluding steam to the steam ejector, for thermal vapor compression). Evaporation is brought about solely by recompressing and 'recycling' vapor separated from the product. In practice, however, heat losses – and often the requirements of (steady-state) control systems – mean that a small but finite quantity of additional steam is required.

Energy Consumption

The power demand of the compressor depends on the vapor quantity and the pressure difference (equating to the temperature difference, T). This means that the power demand is inversely proportional to the heat-transfer surface of the evaporator. When the heat-transfer surface of the evaporator is increased, the T required and the power demand decrease.

With evaporating temperatures between 50 and 70 °C, the power demand of the compressor can be generally calculated using the following equation:

$$P = CMT, \qquad (1)$$

where P is the power demand (kWh^{-1}), M is the vapor mass flow (tonne h^{-1}), C is a constant, which depends mainly on the size of the compressor and is usually between 2.5 and 3.0 (kW $tonne^{-1}$ $°C^{-1}$), and T is the temperature difference across the compressor.

Usually, the T is between 3 and 8 °C, which corresponds to a specific power consumption of between 8 and 20 kW per 1000 kg of water evaporated.

Muscle

S C Dennis and T D Noakes, University of Cape Town Medical School, Observatory, South Africa

Introduction

Muscles in the human body can be broadly classified into three main types: smooth, cardiac, and skeletal. Smooth muscles surround many of the body's internal organs and control such functions as the motility of the gastrointestinal tract and the flow of blood through a vascular bed. Cardiac (heart) muscle regulates the rate at which blood is pumped around the body. Skeletal muscles account for around 40% of body weight and are responsible for posture and movement. In this article, attention is focused on the physiology of skeletal muscle.

Skeletal Muscle Organization

Unlike smooth and cardiac muscles, which contract spontaneously and are regulated by hormones and electrical messages from the subconscious regions of the brain, skeletal muscle fiber cells are under voluntary control. With the exception of certain reflexes, skeletal muscle fibers contract only when an electrical signal is sent from the motor cortex of the brain to the muscle via the spinal and motor nerves.

Motor Units

The response of a skeletal muscle to electrical impulses from the brain depends on the motor nerves used to send the signal to contract. When signals to contract are sent via motor nerves that supply as few as 5–15 muscle fibers, tension is adjusted in small increments, and movements are precise. However, when signals to contract are delivered to the muscle by motor nerves that supply several hundred muscle fibers, large increases in tension lead to strong, but less precise, contractions.

Information on the contraction of the skeletal muscle motor units is relayed back to the central nervous system from stretch receptors in the muscle spindles and tension receptors in the Golgi tendon organs. This feedback allows the initial movement to be refined by either reducing motor unit activation or recruiting additional motor units.

Muscle Fiber Types

The small to intermediate motor units in skeletal muscle are generally recruited first during exercise. They are comprised of either red slow-twitch (type I) or red fast-twitch (type IIa) muscle fibers, which are relatively resistant to fatigue. Type I and IIa muscle fibers contain high concentrations of a red oxygen transport protein called myoglobin and obtain most of their energy for contraction from oxidative processes in structures called mitochondria.

In contrast, large motor units are used only when either a very heavy weight has to be lifted or an explosive movement is required. These units are comprised of white fast-twitch (type IIb) muscle fibers, which contain few mitochondria and little myoglobin, and fatigue rapidly. White muscle fibers are designed to power escape reactions and, as will be described later, they generate energy for contraction via an oxygen-independent pathway which maintains maximum force development for around 20 s.

Skeletal Muscle Ultrastructure

When cross-sections of skeletal muscle are viewed under a microscope, type I, IIa, and IIb fibers are found to be arranged in parallel and to be mixed randomly. Ratios of types I:IIa:IIb range from 51:41:8% in untrained persons, to 78:19:3% in elite endurance athletes. (*See* **Cells**.)

Myofibril Arrangement

Within the different muscle fibers, there are several hundred to several thousand smaller parallel fibers known as myofibrils. Surrounding each myofibril is a lattice-like network of tubules, which is part of the sarcoplasmic reticulum. As will be described, the sarcoplasmic reticulum is involved in the initiation and termination of contraction.

Interspersed amongst the myofibrils are columns of small semicircular mitochondria which provide

energy in the form of adenosine triphosphate (ATP). Between the mitochondria are scattered glycogen granules and triglyceride droplets. The muscle triglyceride and glycogen stores are important intracellular sources of fuel during prolonged, low-intensity exercise. (*See* **Glycogen**.)

When viewed laterally at high magnifications, myofibrils are seen to be comprised of a series of units known as sarcomeres. Sarcomeres are separated by structures called Z disks, which pass from myofibril to myofibril. Adjacent to the Z disks are light I bands and in the center of each sarcomere is a dark A band.

Myofilament Arrangement

The I and A bands of the sarcomere are caused by a partial interdigitation of yet smaller parallel fibers, called thin and thick myofilaments. Thin myofilaments emerge from the Z disks to form the I bands, and centrally positioned thick myofilaments create the A band.

Within the A band, around 1500 thick myofilaments are surrounded by hexagonal arrays of twice that number of thin myofilaments. Thick myofilaments are anchored by a lattice network of proteins at the center of the sarcomere. Thin myofilaments are kept in register by their interdigitation with the thick myofilaments and their attachment to the Z disks.

Skeletal Muscle Contractile Proteins

When sarcomeres contract, the thin myofilaments slide between the stationary thick myofilaments and pull the Z disks closer together. Sarcomeres shorten whenever the proteins of the thick and thin myofilaments are allowed to interact.

Myosin

Thick myofilaments are comprised of around 300 spirally arranged protein molecules called myosin. Each myosin molecule is composed of two heavy chains and four light chains. The heavy chains form fibrous, rigid 'coiled coils' in what are known as the tail and neck regions and then split into globular heads, on to which the light chains are attached. Hinges at either end of the neck allow the myosin heads to protrude from the thick myofilaments and rotate freely during the cross-bridge cycling (described later) with the thin myofilaments.

Actin

In thin myofilaments, chains of globular G actin protein molecules are assembled into double helical filaments. On each G actin molecule are sites to which myosin heads will bind and, in resting muscle, these myosin binding sites are blocked by tropomyosin protein molecules, which are similar in structure to the myosin tail.

Tropomyosin–Troponin Complex

At 40-nm intervals along the thin myofilaments, tropomyosin molecules are attached to troponin complexes. In the troponin complexes, there are three proteins: troponin I, troponin T, and troponin C. Troponin I anchors the complex to the thin myofilament; troponin T attaches to the tropomyosin molecules, and troponin C binds calcium. As will be described, an elevated intracellular calcium ion (Ca^{2+}) concentration is the mechanism by which electrical signals lead to muscle contraction.

Skeletal Muscle Electromechanical Coupling

Electrical signals to contract are delivered to the midpoints of muscle cells by branches of the motor nerve. As the motor nerve enters the muscle, it divides into a number of nerve endings that come to lie in troughs in the outer membranes of each of the muscle cells of the motor unit.

Neuromuscular Transmission

Within the nerve endings are about 300 000 small vesicles, which contain the chemical neurotransmitter, acetylcholine. When a wave of electrical excitation arrives at the nerve ending, some Ca^{2+} ions flow into the nerve and cause around 300 vesicles to fuse with the nerve cell membrane. Acetylcholine molecules released from the vesicles then diffuse across a 20–30-nm cleft and bind to receptors on the underlying muscle cell membrane. At the membrane, the binding of acetylcholine opens receptor-operated channels which allow positively charged sodium ions (Na^+) to flow into the electronegative interior of the muscle cell. In the millisecond or so before the acetylcholine is broken down, the entry of Na^+ ions decreases the electrical potential across the muscle cell membrane and triggers a subsequent wave of electrical excitation along the muscle cell.

Electrical Conduction Along Muscle Cells

Electrical excitation arises when the electrical potential across the muscle cell membrane decreases to a threshold at which voltage-gated Na^+ and potassium (K^+) channels open. First, Na^+ channels open and a rapid influx of Na^+ ions causes the inside of the cell to become positive for 1–2 ms. Then, as Na^+ channels close, K^+ channels open and a rapid efflux of K^+ ions

returns the interior of the muscle cell to its resting electronegative state.

With the transient depolarization of the muscle cell membrane at the neuromuscular junction, ions are pulled away from adjacent muscle regions which decreases their membrane electrical potential. This sets off further voltage-activated Na^+ influx. In this manner, waves of depolarization propagate outwards from the center of the motor unit towards the ends of the muscle fibers.

Voltage-dependent Sarcoplasmic Reticulum Ca^{2+} Release

Waves of depolarization on the muscle cell surface descend to the myobrils via transverse T tubules, which are continuous with the surface cell membrane and pass into the muscle cell at the junctions between the thick and thin myofilaments. On either side of the T tubules, the cisternae or 'chests' of the sarcoplasmic reticulum are attached to the T tubules by structures known as foot processes.

These foot processes are comprised of four proteins which open Ca^{2+} channels in sarcoplasmic reticulum cisternae by altering their shape during waves of T tubule membrane depolarization. Under these circumstances, the rapid release of Ca^{2+} from the cisternae of the sarcoplasmic reticulum exceeds the rate at which Ca^{2+} is pumped back into the sarcoplasmic reticulum via the previously described network of longitudinal tubules. As a result, the concentration of Ca^{2+} ions around the myofilaments rises. (*See* **Calcium**: Physiology.)

Ca^{2+} Activation of Thin Myofilaments

As the free Ca^{2+} concentration inside the muscle cell increases from its resting value of around $4\,\mu g\,l^{-1}$ to $40–400\,\mu g\,l^{-1}$, the troponin–tropomyosin protein complexes on the thin actin myofilaments rotate to expose the binding sites for the myosin heads. The mechanism by which this occurs is not precisely known, but one possibility is that the binding of Ca^{2+} to troponin C tugs the tropomyosin into the grooves between the double helical actin myofilaments.

Cross-bridge Cycling

Once thin actin myofilaments are 'activated' by Ca^{2+} ions, they are pulled towards the center of each sarcomere by a process known as cross-bridge cycling. Cross-bridge cycles are formed by repeated attachments and detachments of the myosin heads of the thick myofilaments to the actin of the thin myofilaments.

Energy for cross-bridge cycling comes from the binding of ATP to the myosin head, which causes the myosin head to be cocked like the trigger of a gun at a 'strained' 90° angle to the thick myofilament. At this angle, the bound ATP is cleaved to adenosine diphosphate (ADP) and inorganic phosphate (P_i) and that cleavage creates an actin-binding site on the myosin head. Attachment of the myosin head to actin then leads to a release of P_i which causes the 'strained' 90° myosin head to move to an 'unstrained' 45° angle to the thick myofilament. This movement pulls the actin thin myofilament and the attached Z disk some 12 nm towards the center of the sarcomere. At full excursion, the ADP is then replaced by ATP which causes a rapid detachment from the actin and a return of the myosin head to the 'strained' 90° angle.

Myosin head detachments do not occur in unison. While some myosin heads are hydrolyzing ATP to reestablish actin-binding sites for further cross-bridge cycling, other myosin heads are attached. Thus, while free intracellular Ca^{2+} concentrations remain high, a sarcomere shortens continuously and that continuous shortening, repeated in millions of sarcomeres in series, is what we see as muscle contraction.

Muscle Movement

The slowest step in a muscle contraction depends on the load opposing the movement of the myosin heads to their 45° state. When a muscle shortens against a near-zero load, contraction velocity is limited by the rate at which the myosin heads can hydrolyze ATP to recreate an actin-binding site. However, as the load opposing shortening is increased, control of contraction velocity shifts away from the rate of ATP hydrolysis towards the speed at which the myosin heads can detach from the actin filament.

A useful analogy is a man pulling on a rope tied to an increasingly heavy weight. As the weight becomes heavier, less of his time is spent in changing hands and more is spent in hauling on the rope.

Maximum Shortening Velocity

In unloaded contractions at high velocity, where less than 5% of the myosin heads are attached at any one time, maximum rates of shortening depend almost exclusively on the speed at which the myosin heads can hydrolyze ATP to form actin-binding sites. Since fast-twitch muscle fibers hydrolyze ATP at more than twice the rate of slow-twitch muscle fibers, muscles with a high proportion of fast-twitch motor units are able to contract more rapidly against a minimal load than are muscles with mainly slow-twitch motor units.

Maximum Power Output

A high proportion of fast-twitch muscle fibers is also of advantage for maximum power output. Optimum

power output is achieved by adjusting the number of motor units recruited so that each shortens against one-third of its maximum load. Against such loads, muscles contract at around one-third of their maximum velocity, and about 20% of the myosin heads are attached. Maximum power output is therefore also largely determined by the rate at which myosin heads can hydrolyze ATP to recreate binding sites for actin.

Maximum Load

As the load opposing shortening is further increased, however, rates of ATP hydrolysis become less important. Once a muscle can only restrain a load, all of the myosin heads are attached and the maximum load is more a function of the size of the muscle than of its fiber-type composition.

Energy Supply for Muscle Movement

Irrespective of the mode of muscle contraction, the ATP hydrolyzed by the myosin heads has to be immediately resynthesized to allow the cross-bridges to detach. In working muscles, the half-life of an ATP molecule can decrease to a few seconds.

Phosphocreatine Hydrolysis

With a sudden increase in muscle work, ATP for relaxation and contraction is regenerated from ADP and P_i via a number of mechanisms. The most immediate source of ATP is from a reservoir of chemical energy stored in the form of creatine phosphate. From measurements of muscle creatinine phosphate breakdown to creatine and P_i during severe exercise, it has been calculated that net creatine phosphate hydrolysis can sustain maximal contractile activity for about 4 s.

Oxygen-independent Glycogen Utilization

Following the initial hydrolysis of creatine phosphate, the next major source of energy for ATP resynthesis is from the breakdown of the glucose molecules in muscle glycogen to lactate ions via a metabolic pathway known as oxygen-independent glycolysis. Because it takes time for muscle blood flow to increase at the start of exercise, the oxygen-independent glycolytic pathway is particularly important in the white fast-twitch (type IIb) muscle fibers that power escape reactions. Type IIb muscle fibers generate almost all of their ATP for contraction by an acceleration of glycogen to lactate conversion.

During sprinting, glycogen breakdown is increased by activation of an enzyme called glycogen phosphorylase. Glycogen phosphorylase activity is increased by two rather complex mechanisms. Both occur simultaneously but, for the sake of simplicity, they are described separately.

One mechanism of glycogen phosphorylase activation is via a hormonally controlled conversion of the enzyme from a 'b' form to a more active 'a' form. If a need to escape is anticipated, circulating epinephrine (adrenaline) concentrations rise and stimulate the intramuscular production of cyclic adenosine monophosphate (cAMP). Increases in cAMP concentration cause a rapid conversion of glycogen phosphorylase b to a when free Ca^{2+} concentrations increase for contraction. (*See* **Hormones**: Adrenal Hormones.)

Another mechanism of glycogen phosphorylase activation arises from the sudden increase in ATP hydrolysis at the myosin heads. This ATP is initially resynthesized by a breakdown of creatine phosphate to creatine and P_i and by a condensation of two ADP molecules to form one of ATP and one of adenosine monophosphate (AMP). A reduction in creatine phosphate concentration and a rise in P_i, and AMP concentrations act in concert to stimulate glycogen phosphorylase activity.

At the same time, changes in creatine phosphate, P_i, and AMP concentrations also accelerate the rate of glycolysis by increasing the forward reaction and decreasing the backward reaction of a substrate cycle involving two enzymes known as phosphofructokinase and fructose diphosphatase. Fructose diphosphatase is unique to type IIb fibers and inhibition of its backward reaction allows the forward rate of glycolysis in these fibers to be increased more than 1000-fold.

In response to intense muscle activity, glycogen utilization in type IIb fibers rises from around 0.01 to 11 g min^{-1} kg^{-1} fresh weight. Since the glycogen content of human muscle is roughly 15 g kg^{-1} fresh weight, oxygen-independent glycolysis could in theory provide enough energy for 80 s of maximum activity. In practice, however, the mobilization of glycogen is limited to around 5 g kg^{-1} fresh weight and maximum power output cannot be maintained for much longer than 20 s.

When ATP is resynthesized by glycolysis, rather than by mitochondrial oxidative phosphorylation or creatine phosphate breakdown, the hydrogen ions (H^+) produced by its hydrolysis are not reconsumed and H^+ accumulation may be an important factor in the rapid development of fatigue under these circumstances (Figure 1). When carbohydrates are metabolized at high rates to fuel intense muscle activity, hydrogen ions accumulate from the turnover of glycolytic ATP. Hydrogen ions buffered by P_i^{2-} ions form P_i^- ions, which inhibit P_i^- release from the myosin heads and slow cross-bridge cycling.

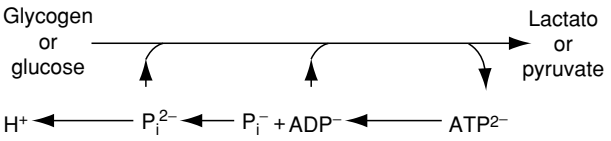

Figure 1 Hydrogen ion production from glycolytic adenosine triphosphate (ATP) turnover. P_i, inorganic phosphate; ADP, adenosine diphosphate. Reproduced from Exercise: Muscle. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

This feedback inhibition of cross-bridge cycling by P_i^- accumulation insures that the muscles' demand for energy cannot exceed the energy supply. If that were to occur, falling ATP concentrations would lead to an irreversible muscle rigor and cell death.

Oxygen-dependent Metabolism

Oxygen-independent metabolism is therefore of little use to the endurance runner. For sustained exercise, the H^+ ions arising from ATP hydrolysis have to be used in its resynthesis and this means that most of the ATP must be derived from mitochondrial oxidative phosphorylation.

The major fuels for mitochondrial oxidative phosphorylation are muscle glycogen, blood glucose, and circulating fatty acids. Muscle glycogen and blood glucose are particularly important fuels during high-intensity exercise. As work rate is increased beyond 70% of an individual's maximum oxygen (O_2) uptake ($V\text{O}_{2\text{max}}$) to 95% of $V\text{O}_{2\text{max}}$, the contribution to energy production from carbohydrate oxidation rises to 100%.

For some reason, fatty acid oxidation can only provide enough ATP for around 50% of maximum power output. Fats are therefore mainly used, together with carbohydrate, in prolonged low-intensity (30–65% of $V\text{O}_{2\text{max}}$) exercise. During such exercise, the contribution to energy production from fat oxidation climbs from 37–39% to 62–67% as rises in blood glucose utilization increasingly fail to compensate for muscle glycogen depletion. (*See* **Fatty Acids:** Metabolism.)

The advantage of muscle fatty acid oxidation in prolonged exercise is that it spares some liver glycogen breakdown for tissues such as the brain which are totally dependent on glucose. Without fat oxidation, it can be calculated that the carbohydrate reserves of the liver would be exhausted within an hour or so of exercise, while the remaining fat cell triglyceride stores would be sufficient for another 2–3 days.

Consequently, muscle fuel utilization is ultimately regulated by the delivery of glucose from the liver into the blood stream. Release of liver glucose is promoted by decreases in circulating glucose concentration and rises in circulating glucagon and epinephrine concentrations. Glucagon and epinephrine binding to the liver cell membrane increase liver glycogen phosphorylase b to a conversion via a mechanism similar to that in muscle fibers. The only differences in the liver are that glucagon binding accelerates intracellular cAMP formation, and epinephrine binding raises free intracellular Ca^{2+} concentrations. (*See* **Glucose:** Function and Metabolism; Maintenance of Blood Glucose Level.)

Glucagon and epinephrine binding also increase the provision of fatty acids to the muscles by activating the cleavage of triglyceride stores to fatty acids and glycerol. In fat cells, both hormones act via a stimulation of cAMP production to convert a less active triglyceride lipase b enzyme to a more active triglyceride lipase a enzyme. Release of fatty acids extends endurance by decreasing blood glucose utilization.

Use of blood glucose and fatty acids by contracting muscles is regulated by the rate of mitochondrial ATP resynthesis. Mitochondrial ATP resynthesis is coupled to a metabolic pathway known as the electron transport chain. In the electron transport chain, H^+ ions and electrons from carbohydrate and fat breakdown are oxidized to water and this oxidation only proceeds when ADP is available for phosphorylation. Thus, until the carbohydrate stores become depleted, muscle metabolism is controlled by the demand for energy rather than the supply of fuel.

Metabolic Requirements

S C Dennis and T D Noakes, University of Cape Town Medical School, Observatory, South Africa

Anaerobic and Aerobic Metabolism

It has become traditional to group energy metabolism during exercise into that which is independent of oxygen (O_2) supply, so-called anaerobic metabolism, and that which requires the utilization of O_2, so-called aerobic metabolism. Anaerobic metabolism includes net muscle creatine phosphate hydrolysis and conversion of muscle glycogen or blood glucose to lactate. Aerobic metabolism includes the mitochondrial oxidation of the endproducts of the breakdown of muscle glycogen, blood glucose and circulating fatty acid.

Anaerobic (Oxygen-Independent) Metabolism

Anaerobic metabolism is particularly important in short-duration, high-intensity exercise. With extreme exertion, most of the adenosine triphosphate (ATP) for contraction is generated from a net breakdown of creatine phosphate and an acceleration of the conversion of glycogen or glucose to lactate. (*See* **Glycogen**.)

The metabolic pathway leading to lactate formation is called anaerobic glycolysis but, strictly speaking, it should be termed O_2-independent glycolysis. Contrary to popular opinion, blood lactate accumulation during intense exercise is not a 'threshold' response to inadequate O_2 delivery. Rather, muscle lactate production increases as a continuous function of work rate. Blood lactate accumulates only when the rate of lactate efflux from the working muscles into the blood stream exceeds the rate of lactate clearance from the blood by oxidation to carbon dioxide (CO_2) in skeletal and heart muscle, and by conversion to glucose in the liver.

During exercise in which the work rate is increased progressively, there are a number of factors that promote muscle lactate production. One is the hormonal acceleration of muscle glycogen breakdown by the rising concentrations of epinephrine (adrenaline) in the blood stream. Another is the greater recruitment of fast glycolytic (type IIb) muscle fibers at high exercise intensities. A third is the metabolic acidosis arising from the increasing reliance on carbohydrate oxidation at high work rates.

In contrast to the general belief, hydrogen ions (H^+) do not come from lactic acid production (eqn 1).

$$\text{Glucose or glycogen} \longrightarrow 2\,\text{Lactate}^- + 2H^+ \qquad (1)$$

When ATP formation is taken into consideration and the likely electrical charges at intracellular pH are summed, the reactions of the O_2-independent glycolytic pathway do not produce a net gain of H^+ ions (eqn 2).

$$\text{Glucose} + 2\text{MgADP}^- + 2P_i^{2-} \longrightarrow 2\text{Lactate}^- + 2\text{MgATP}^{2-} \qquad (2)$$

where ADP = adenosine diphosphate; P_i = inorganic phosphate; and Mg = magnesium.

Instead, metabolic acidosis during progressive exercise is more a consequence of the increased rate of glycolytic ATP turnover. When ATP is resynthesized by oxidative phosphorylation or by phosphate transfer between creatine phosphate and ADP, the H^+ ions produced by ATP breakdown are utilized in its resynthesis (**Figure 1a, b**).

However, when ATP is resynthesized by glycolysis, the H^+ ions arising from its hydrolysis are not reconsumed (**Figure 1c**). Net proton production therefore occurs irrespective of whether lactate is formed or pyruvate is delivered to the mitochondria for oxidation.

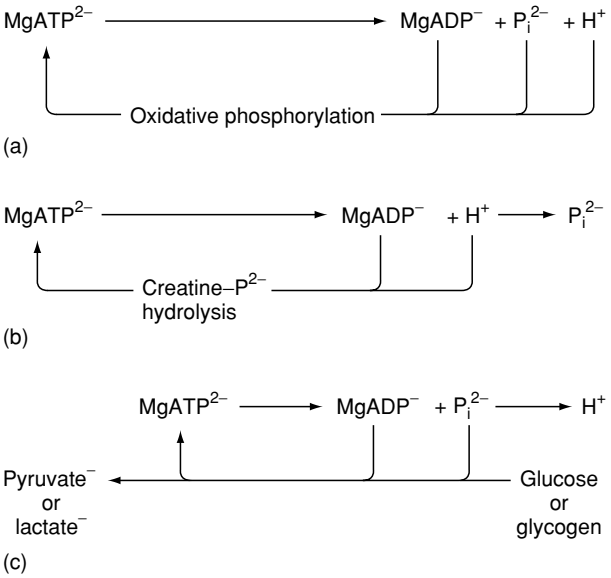

Figure 1 H^+ ion production from glycolytic adenosine triphosphate (ATP) turnover. Unlike when ATP is resynthesized by oxidative phosphorylation or creatine phosphate breakdown, the H^+ ions arising from ATP hydrolysis are not reconsumed when ATP is resynthesized by the conversion of glycogen or glucose to lactate or pyruvate. H^+ ions are therefore produced whenever carbohydrate is metabolized. ADP, adenosine diphosphate. Reproduced from Exercise: Metabolic Requirements, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK, Sadler MJ (eds), 1993, Academic Press.

Since any acceleration of carbohydrate utilization will increase H^+ ion production, lactate formation is more a consequence of, than a cause of, metabolic acidosis. Increases in intracellular H^+ concentration shift the lactate dehydrogenase and lactate permease equilibria towards lactate production and H^+ plus $lactate^-$ coefflux (Figure 2). Thus muscles 'dump' fuel (lactate) to remove H^+ ions into the blood stream whenever carbohydrate utilization is increased to provide energy for exercise of very high intensity.

Once H^+ ions accumulate, however, further acidification by glycolytic ATP turnover is prevented by a slowing of muscle contraction. The H^+ ions combine with the P_i^{2-} ions from creatine phosphate breakdown to form P_i^- ions, which inhibit P_i^- release from myosin heads (Figure 3). In terms of muscle cell survival, this metabolite-induced 'mechanical arrest' during intense, 'anaerobic' muscle activity is an important protective mechanism. If muscles were to become truly 'anaerobic,' energy demand would exceed energy supply and ATP depletion would lead to irreversible muscle rigor and cell death.

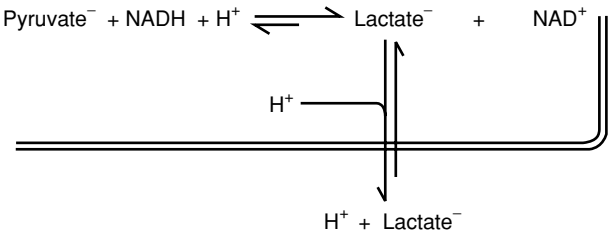

Figure 2 Muscle lactate formation and efflux. Increases in intracellular H^+ ion concentration, arising from rapid carbohydrate oxidation, promote lactate production and efflux from muscle cells. Lactate formation is therefore more a consequence of, rather than a cause of, metabolic acidosis. NADH, reduced nicotinamide adenine dinucleotide; NAD^+, oxidized nicotinamide adenine dinucleotide. Reproduced from Exercise: Metabolic Requirements, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

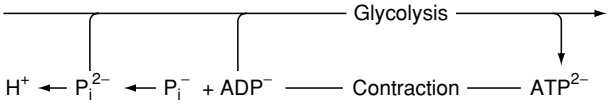

Figure 3 Inhibition of contraction by H^+ ion accumulation. H^+ ion accumulation from glycolytic adenosine triphosphate (ATP) turnover is self-limiting in that H^+ ions $+P_i^{2-}$ ions form P_i^- ions, which slow contraction by inhibiting P_i^- release from the myosin heads. This 'mechanical arrest' is an important protective mechanism to prevent ATP depletion during intense muscle activity. ADP, adenosine diphosphate. Reproduced from Exercise: Metabolic Requirements, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Aerobic Metabolism

Because metabolite-induced mechanical arrest develops during high-intensity exercise in which there are high rates of muscle glycogen and/or blood glucose metabolism, such exercise cannot be sustained indefinitely. For continued physical activity over several hours, the contribution to energy production from carbohydrate utilization must be reduced from nearly 100% to around 60% or 2–3 g min^{-1}. At these rates of carbohydrate oxidation, most of the H^+ ions arising from glycolytic ATP turnover leave the muscle cells in exchange for extracellular sodium ions (Na^+). (*See* **Carbohydrates:** Digestion, Absorption, and Metabolism.)

Since the rate of ATP production from fatty acid utilization is approximately 50% slower than from carbohydrate metabolism, exercise requiring 40% of the energy to come from fat oxidation has to be performed at intensities corresponding to 70–85% of maximum O_2 uptake ($\dot{V}O_{2max}$). Typically, an athlete runs a 42-km marathon (126–240 min) at 85% of $\dot{V}O_{2max}$ and a 100-km ultramarathon (360–540 min) at 70–75% of $\dot{V}O_{2max}$.

During exercise at 70–75% of $\dot{V}O_{2max}$, the average rate of muscle glycogen utilization is around 1·5 g min^{-1}. At this rate of depletion, an athlete's prerace working muscle glycogen content of around (30 g kg^{-1}) × 15 kg or 450 g would be sufficient for approximately 5 h of exercise.

In practice, however, depletion of the carbohydrate stores in the liver may cause premature fatigue. About 135 g of glycogen is stored in the liver after a meal and these stores are sufficient only to sustain exercise at ultramarathon pace (70–75% of $\dot{V}O_{2max}$) for around 3 h. As the initially rapid breakdown of muscle glycogen gradually slows from around 2.1 to 1.0 g min^{-1}, conversion of liver glycogen to blood glucose progressively rises to a maximum rate of approximately 1.1 g min^{-1}. At this point, further increases in blood glucose oxidation can no longer compensate for the decline in muscle glycogen utilization, and work rates must be decreased to allow more energy to come from fat metabolism. Unlike carbohydrate stores, fat reserves could provide energy for many days of exercise.

If an athlete fails to slow down when the demand for blood glucose exceeds liver glucose output, circulating glucose concentrations fall, producing a condition known as hypoglycemia or, in common sporting parlance, the 'bonks.' Because the brain depends on an adequate glucose supply, hypoglycemia leads to a lack of coordination, an inability to concentrate

and, ultimately, collapse. This collapse prevents an individual from dangerously depleting the body's carbohydrate stores. (*See* **Glucose**: Maintenance of Blood Glucose Level.)

For prolonged 70–75% of $V\text{O}_{2\text{max}}$ exercise, an athlete must therefore ingest carbohydrates and spare liver glycogen. Provided that enough carbohydrate is ingested to satisfy the eventual 2 g min^{-1} demand for blood glucose by the muscles, an athlete can continue exercising for some time after muscle glycogen has been completely exhausted.

Despite the maintenance of high rates of carbohydrate oxidation and normal blood glucose concentrations, however, a point is eventually reached where an athlete can no longer sustain an exercise intensity of 70–75% $V\text{O}_{2\text{max}}$. Under these circumstances, there is an increased perception of fatigue. Some believe that this fatigue is due to the slow utilization of plasma branched-chain amino acids by skeletal muscle during prolonged activity. Since the contribution to energy production from branched-chain amino acid metabolism is trivial, it has been suggested that branched-chain amino acid oxidation might provide a communication link between working muscles and the brain.

Over the course of a marathon, plasma branched-chain amino acid concentrations have been shown to decline from 650 to 500 mg l^{-1}. At the same time, the increases in circulating free fatty acid concentrations during exercise were found to raise the free plasma tryptophan amino acid concentration from 1.4 to 2.9 mg l^{-1}, by competing with tryptophan for binding to blood albumin.

Decreases in the circulating branched-chain amino acid concentration and rises in plasma free tryptophan concentration with sustained physical activity promote tryptophan entry into the brain. Passage of tryptophan across the blood–brain barrier is normally limited by its low free concentration and by a competition from branched-chain amino acids for access to the neutral amino acid transporters.

Once in the brain, tryptophan is converted to the neurotransmitter 5-hydroxytryptamine (serotonin) in the serotonergic nerve terminals of the hypothalamus. Serotonin biosynthesis is unusual in that it is exclusively regulated by the rate of entry of tryptophan into the brain.

Since serotonin is involved in the control of sleep, food intake, pain sensitivity, pituitary hormone release and mood, it is tempting to speculate that the elevated serotonin levels in the brain might contribute to the perception of fatigue in prolonged exercise, when muscle fuel supply appears to be adequate. Certainly, excessive serotonin release would account for the improvement in mood and increased drowsiness after long-duration, low-intensity exercise.

The Athlete's Diet and Supplementation

Additional Protein

Whether increased amino acid utilization during and following exercise significantly increases an athlete's daily dietary protein requirement is not known. Despite considerable research on this subject, there are still two schools of thought. Some argue that the 78% safety margin in the 0.8 g per kg of body weight per day recommended dietary allowance (RDA) for protein is sufficient to cover the increased amino acid requirements of both endurance- and strength-trained athletes. Others feel that frequent exercise elevates the daily need for dietary protein. The balance of evidence suggests that an athlete should probably ingest around 1.2 g of protein per kg of body weight per day. (*See* **Protein**: Requirements.)

Daily protein intakes of 1.2 g per kg of body weight, however, do not necessitate protein supplementation. An athlete's larger than normal daily kilojoule ingestion more than adequately covers any increase in his or her protein requirements. Furthermore, there is no evidence that protein intakes in excess of 1.2 g per kg of body weight per day improve sporting performance. Provided that an athlete eats enough to meet his or her daily energy expenditure, protein is not a major fuel for exercise. A significant use of protein for energy occurs only in starvation, when body protein is converted to carbohydrate to maintain an adequate supply of glucose to the brain.

Higher than recommended (1.2 g per kg of body weight per day) protein intakes are also unlikely to help increase muscle size. Muscle hypertrophy is under much more subtle control than the supply of amino acids for protein synthesis.

Additional Vitamins and Minerals

Another question frequently asked by athletes is whether or not they should increase their intake of vitamins and essential minerals. Unless an athlete is malnourished or follows an extreme vegetarian diet, the answer is probably no. Vitamin and mineral deficiencies are extremely uncommon among athletes and there is no evidence to show that extra vitamins and minerals improve performance. Vitamin and mineral supplements are not being promoted to meet the unique nutritional requirements of athletes, but rather to satisfy commercial interests.

However, there is growing interest in the possibility that very heavy training and competition may suppress the immune response and thereby increase an athlete's risk of infection. Since vitamin A and perhaps also vitamins C and E are thought to improve

resistance to infection, an athlete might consider an increased intake of these vitamins during periods of intense training and competition. (*See* **Ascorbic Acid**: Physiology; **Retinol**: Physiology; **Tocopherols**: Physiology.)

Additional Carbohydrate

With heavy training, it is essential that an athlete eats sufficient carbohydrate. Studies of the effects of daily, 2-h, 70% of $V\text{O}_{2\text{max}}$ training runs on leg muscle glycogen contents have shown that a standard 40–45% carbohydrate diet is not sufficient to maintain body carbohydrate stores. For the last 4 or 5 days' intensive training, the subjects' preexercise muscle glycogen contents progressively declined from around 22 to 5–6 g kg^{-1}.

Even a high-carbohydrate (70%) diet failed to replenish completely the subjects' muscle glycogen stores between exercise bouts. With the ingestion of 560 g of carbohydrate per day, muscle glycogen levels still fell from approximately 22 to 17 g kg^{-1}.

Three days before an endurance race, therefore, an athlete should stop training and follow what is known as a 'carbohydrate-loading' regime. During carbohydrate loading, the optimum strategy is to eat 500–600 g of simple carbohydrates for the first 24 h and then consume the same quantity of mainly complex carbohydrates on the following 2 days. By ingesting large amounts of carbohydrate and not exercising, athletes can increase their muscle glycogen content from 22 to 36 g kg^{-1} and their liver glycogen stores from 70 to 90 g kg^{-1}.

As mentioned above, it is also important for an athlete to drink carbohydrate solutions during prolonged exercise to prevent hypoglycemia. Provided that the volumes described below are ingested, it does not matter whether the carbohydrate is glucose, sucrose, maltose or a commercial 7–22-chain-length glucose polymer. In each case, peak rates of exogenous carbohydrate oxidation occur 75–90 min after ingestion and are 0.7–0.9 g min^{-1}. (*See* **Carbohydrates**: Metabolism of Sugars.)

The exception to this pattern is fructose. Because ingested fructose is (1) slowly absorbed from the intestine and (2) converted to glucose in the liver before being oxidized, its maximum rate of use is only 0.4–5 g min^{-1}.

Maintaining Water and Electrolyte Balance

Interestingly, the first evidence that carbohydrate ingestion can enhance performance during prolonged exercise was published in the 1930s but was ignored by athletes, coaches, and scientists until the mid-1980s. Even the idea that fluids should be ingested by athletes during prolonged exercise is of recent origin. Prior to the early 1970s, the prevailing opinion was that any fluid ingested during exercise, including marathon running, adversely affected performance. This fact is frequently overlooked by today's athletes and their advisors who have emphasized the perceived value of fluid replacement during exercise, sometimes to excess.

Factors Influencing Fluid Loss

The important principles underlying fluid and electrolyte balance during exercise are that the rate at which sweat is lost is determined principally by the athlete's rate of energy expenditure (metabolic rate) which is largely determined by his or her mass and speed of movement. Thus sweat rate is highest in activities of short duration and high intensity, such as competitive running over distances of 3–10 km, and is slower in prolonged, lower-intensity exercise, such as marathon and ultramarathon running or ultratriathlon events. Sweat rate also tends to be greater in heavier than in lighter athletes. At the same speed, the heavier cyclist or runner has to expend more energy in moving a larger mass.

When cyclists and runners exercise at the same metabolic rate, the sweat rate of cyclists is lower than that of runners. Cyclists travel faster than runners and therefore lose more heat by convection to the passing air than by sweat evaporation.

Sweat rate is also influenced by the ambient temperature but, in practice, environmental conditions may affect sweat rates less than expected. When forced to exercise in severe heat, athletes usually choose to exercise at a lower exercise intensity. Athletes are well aware that they will fatigue rapidly when exercising in the heat, and a lower metabolic rate reduces their sweat rates.

Contrary to popular opinion, however, 'heat exhaustion' is not caused by excessive body heat accumulation. In very severe environmental conditions, the rate of energy expenditure appears to be regulated specifically to prevent the development of high sweat rates, severe dehydration, and heat injury.

There is also some uncertainty as to whether or not all the fluid lost during exercise must be replaced if serious dehydration is to be prevented. Up to 1.8 l of fluid can be stored in association with the glycogen contained in a carbohydrate-loaded athlete's working muscle and liver. Thus, in activities that largely deplete liver and muscle glycogen contents, a mass loss of up to 1.8 kg can be incurred without the athlete's fluid status being seriously compromised.

Fluid Replacement

In athletes losing more than 1.8 kg of mass, the principal aims of fluid ingestion during exercise are to replace the fluid and electrolytes lost during exercise and to provide carbohydrate in solution to supplement the body's limited carbohydrate stores. Usually, adequate fluid replacement has been considered of greater importance than carbohydrate supplementation, but more modern studies indicate that an adequate carbohydrate supply is at least as important as optimum fluid and electrolyte replacement.

Failure to replace adequately the sweat losses incurred during exercise leads to progressive dehydration. Symptoms of dehydration are: (1) an increase in heart rate with a fall in cardiac stroke volume; (2) a reduction in sweat rate; (3) a decrease in blood flow to the skin; and (4) a progressive rise in body core temperature.

It is not yet clear to what extent the symptoms of dehydration adversely influence athletic performance. A small weight loss resulting from unreplaced sweat losses during exercise might enhance performance by reducing the mass which the athlete must carry. Eventually, however, there must be a crossover point at which the negative cardiovascular and other effects of more severe dehydration outweigh the beneficial effects of weight loss.

Electrolyte Replacement

In considering fluid replacement, it is important to realize that, in health, it is not the fluid content of the body that is regulated but the electrolyte concentration in the extracellular and intracellular compartments. In the 15-l extracellular compartment of a 70-kg man, the major electrolyte is sodium (Na^+) and, in the 30-l intracellular compartment, the main electrolyte is potassium (K^+).

As Na^+ is the principal electrolyte in sweat, the initial site of fluid loss is from the extracellular compartment, which includes the circulating plasma volume. The extent to which dehydration of the extracellular compartment occurs is determined by the amount of Na^+ lost in sweat.

An important consequence of exercise training, especially in the heat, is a reduced sweat Na^+ content. The result is that fluid losses from the extracellular compartment and circulation are decreased in trained, heat-acclimatized athletes. This might explain why highly trained athletes are better able to cope with dehydration during exercise, because more of their fluid loss will come from the intracellular compartment than from the plasma.

Because the concentration of electrolytes regulates the volumes of the extra- and intracellular compartments, it follows that rehydration of these compartments can only occur when their electrolyte losses are corrected. Consequently, there is the need to ingest Na^+ and, perhaps, some K^+ during and after exercise.

Solutions containing sodium chloride (NaCl) are best ingested together with carbohydrate. Carbohydrate digestion leads to Na^+–glucose cotransport across the intestinal brush border and that accelerates the absorption of NaCl and H_2O into the blood stream.

Practical Implications

The present opinion is that an athlete should ingest between 300 and 800 ml of fluid per hour. The high (800 ml) value is for heavy athletes exercising at fast speeds; the low (300 ml) value is for light athletes exercising slowly. Ideally, the fluid should contain NaCl at concentrations of 5–6 g l^{-1} but salt concentrations closer to 2 g l^{-1} are more palatable.

To provide carbohydrate at rates equal to that at which glucose is absorbed into the blood stream and oxidized by the working muscles (approximately 1 g min^{-1}), a mono-, di-, or oligosaccharide should also be added to the solution. For an athlete drinking 600 ml h^{-1} or 10 ml min^{-1}, it can be calculated that the optimum concentration of carbohydrate after 1–2 h of exercise is around 0.1 g ml^{-1}.

EXTRUSION COOKING

Contents

Principles and Practice

R C E Guy, Campden & Chorleywood Food Research Association, Chipping Campden, UK

Extrusion Cooking

Extrusion cooking technology was invented in the 1940s by the Adams Company to manufacture snack foods from maize grits. It is derived from the earlier extrusion technologies used to form pasta at temperatures of 70–80 °C. These processes involved the conveying, mixing, and compressing of moist wheat semolina to form dough and to extrude it as well-defined shapes.

In extrusion cooking, a feedstock of moist powders is also conveyed, mixed, and compressed before shaping at a die (**Figure 1**). However, the dough temperature is raised to much higher levels in the range from 110 to 200 °C on the screws within a barrel. This means that any water present is superheated within the dough but remains in the liquid state. The high temperature also causes changes in the structures and form of natural biopolymers such as starch and soya globulins. Physical bonds can be broken at high temperatures, and the new forms of the polymer can be used to create novel structures for foodstuffs. A particular feature of extrusion cooking is the ability of the process to manipulate these polymers at low moistures and to form doughs or fluid systems from them with the minimum of moisture.

The basis of the technology is a screw system within a tube or barrel, which conveys the dough towards small openings called dies. In the confined space of the barrel, the dough is compressed and heated to high temperatures at high pressures before being extruded through the dies into the atmosphere. An extrusion cooking process has a number of key features, the feeding devices supplying the raw material feedstocks, the design of the screw system and its barrel, the dimensions and number of the dies, and the devices that handle the extrudates.

Extrusion cooking is a continuous process in which the raw material feedstock is metered in at a constant rate, and the machinery maintains a steady-state equilibrium. This is achieved by balancing the forward flow produced by the screws against the pressure at the die. It is a multivariate process depending on all the independent variables of the machinery and the raw materials to produce a range of dependent variables in the machinery and a further range of dependent variables in the extrudates and products. The consequence of varying one independent variable may be to change several of the product characteristics. Therefore, a good systems approach must be used to control such a process.

The range of products manufactured by extrusion cooking can be divided into two groups: animal products and human foods. The animal products themselves include basic feeds for stock animals, marine feeds for freshwater and saltwater fish, shrimps or prawns. They also include large markets for both dry and canned dog and cat foods and treats, and a number of products for other pets and for wild and tame birds. Human foods include the original maize snacks and many new forms including modern versions of prawn crackers and other traditional snacks.

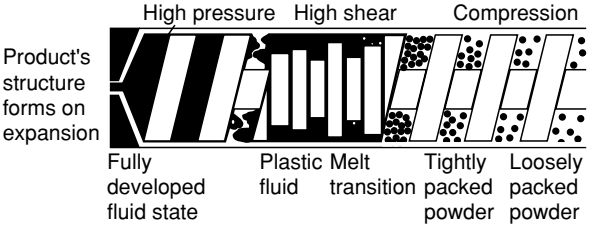

Figure 1 Diagram of the development of raw materials in a twin screw extrusion cooker.

There are many breakfast cereal products formed into balls, hoops, and flakes that have large traditional markets in the USA and UK and growing markets in many areas. Similar expanded pieces of rice and maize are used in chocolate confectionery bars. These bullets of cereal are also used in other products where a crisp, expanded-foam particle is required, such as in granola bars, biscuits, and even icecream.

The range of extruded foods has been extended to coatings, such as breadings. These are used on fried foods, particularly frozen fish and chicken portions. Extruded products have replaced some of the traditional baked crumbs. They are made by expanding cereal extrudates and slicing them into crumbs. This process may be taken a step further in the manufacture of baby foods from extruded feedstocks of cereals and milk powders. For these products, the extrudates are ground to a fine powder, sieved and used to replace the powders manufactured by the more expensive roller drying process.

Principles of Extrusion Cooking: Overall Balance

The extrusion cooking process is used to transform a feedstock of raw materials into a fluid dough and to continue to change the physical nature of this dough until it is forced out of the die (Figure 2). At that stage, the dough must have attained the ideal form to create a structure in the extruded product. The transformation of the native raw materials has an optimum range for most product types. For some products, only small changes are required, whereas for others, a very high degree of change must be induced. For each individual product type, the process must be maintained in a balance between the independent input variables to obtain the ideal conditions within the barrel to achieve this level of transformation.

A good view of an extrusion cooking process is given by the publications of Meuser and van Lengerich. They showed that the relationships between the independent process inputs from the machinery and raw materials created a series of dependent variables within the barrel of the extruder. Most notable of these are residence time, temperature, pressure, moisture level, applied mechanical energy, and mass flow rate. Biopolymers in raw materials, such as starch, were affected by these variables and changed in physical form to dominate the physical features of the fluid dough. As the dough was extruded, the new forms of biopolymers controlled the expansion process influencing the shape, extent of expansion, and the foam texture of the extrudates. The important principle in this section is that the continuous process is in a metastable steady state. Guy and Robert showed that all extrusion cooking processes fluctuate as the balance is maintained between the independent inputs of the process. A fluctuation in an independent input could upset the balance and cause a larger fluctuation in the outputs and therefore in the product quality. It is important, therefore, to minimize any fluctuations in the input variable such as the powder and liquid feed rate, feedstock raw material mix, and quality.

Principles of Extrusion Cooking: the Screw Design

The screws of an extrusion cooker are designed to convey a powder or viscous fluid from the feed port to the die and to force the material through the die (Figure 3). Single screws were used in the early machines leading on from the pasta equipment. More recently, pairs of corotating intermeshing screws have been adapted from their use in the plastics industry to become important machines for the food and feed industries. For conveying materials, the screws are designed with a pitch of 0.5–1 times the screw diameter and a small clearance between the leading edge and the wall. This provides a screw with excellent conveying power for viscous fluid and powders. The effect of a simple conveying screw on the raw materials is minimal, and even with a very small die, the physical transformation of biopolymers is small.

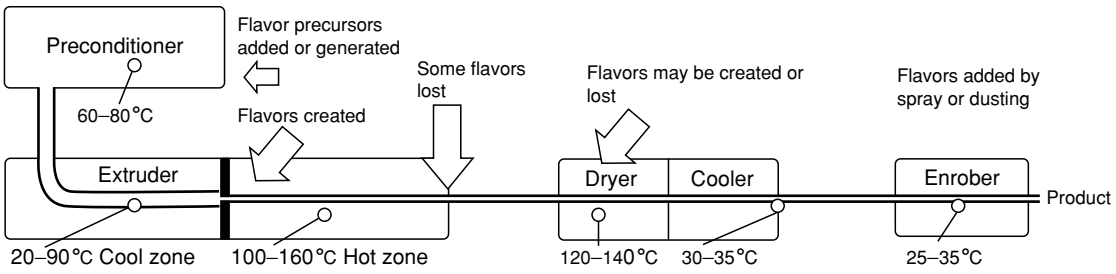

Figure 2 Extrusion cooking equipment in a processing line, with a powder feeder, preconditioner, extruder, dryer and enrober.

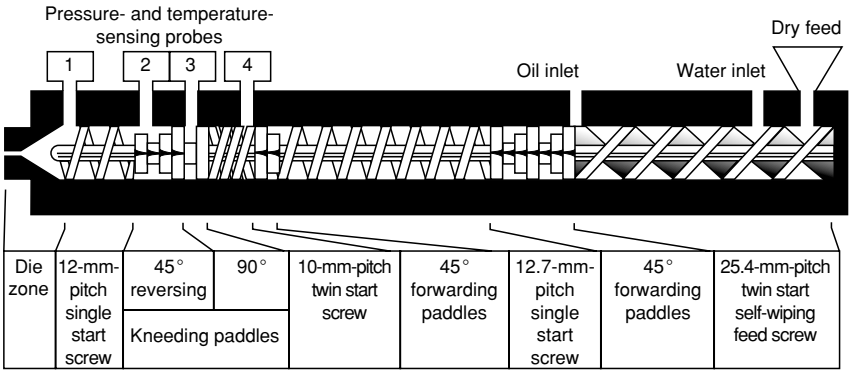

Figure 3 Side view of screw system for a twin screw extruder used at CCFRA showing the functions of the elements.

The second feature of design for a screw system is to apply high levels of mechanical shear to the feedstock being conveyed along its length. In the single screw, this is achieved by reducing the depth of the flights as the material approaches the die and by introducing cuts in the flights to increase back-leakage, thus extending the residence time in the high temperature/high shear zone for the fluid. In the twin screw machines, special sections are added in which the flights are reversed to give a back-pressure pump acting against the main flow. These sections are made weaker by cutting gaps in the flights so that the main pumping screws overcome them. This achieves a steady flow of the fluids though the reversing section under shear.

A special form of reverse section can be constructed from elliptical paddles placed on each shaft in a series. If successive pairs are placed at an angle to the upstream pair, a screw-like structure can be formed. This type of section acts on the fluid as it passes through, kneading the fluid against walls and the other elliptical paddle. An important feature of such a section is that it is set up as a reversing screw to ensure that all the paddles are full of fluid. If they are not full, they have little or no shearing effect on the fluid.

The final role of the screws is to push the fluid melt through the dies in a controlled manner. Normally, the extruder is run with the final sections completely full so that pressure is transmitted from the main conveying screws to the dies. In those cases where reverse sections are used, there may be a pressure drop after the reverse section, and a final section of conveying screw can be used to pump the fluid through the die. In most processes where the extrusion melt fluid has a temperature above 100 °C, the pressure in the die will need to be higher than the water vapor pressure. This insures that the fluid emerges from the die and expands in the air rather than in the die cavity. Normally, the pressure at the die for good control of hot melt extrusions is above 40 bar.

Principles of Extrusion Cooking: the Transformation of Biopolymers

The main feature of extrusion cooking is the transformation of the biopolymers in a raw material feedstock. In 90% of the extruded products manufactured, the active biopolymer is starch, and for the remainder is a protein from oilseeds, such as soya or wheat gluten. Physical transformation is necessary to obtain a more suitable form of the biopolymer for structure creation in the postextrusion expansion processes (Figure 1).

Starch is found in the world's major crops, cereals, such as wheat, rice and maize, and in important tubers such as potato and manioc. In all cases, it is found as partial crystalline granules, 5–80 μm in maximum dimension. The polymers can be released from the granules (Figure 4) by melting their crystalline regions and applying large shearing forces, or by dispersing in an excess of water (>30–35%). For extrusion cooking, low moisture is used, 15–20% in many cases, and the melted starch must be dispersed purely by mechanical shear to obtain a melt fluid of partially or fully dispersed aggregates. The melting temperature for a low moisture feedstock may be in the range of 120–160 °C. Therefore, it is necessary to heat the feedstock to this temperature by the action of the screw and by barrel heating. In low moisture systems with up to 25% moisture, the action of the screws on the powders under compression to a density of $1.4\,g\,ml^{-1}$ will normally achieve the required temperature by frictional heating and the dissipation of mechanical energy from the drive motor.

The second part of the transformation of the starch is more subtle. It has been shown that the major polymer in starch, amylopectin, has a molecular weight range of 10^8–10^9 Da. This size range is too

large for good flow properties in fluids at the concentrations found in the melt fluids. It interferes with the expansion process and reduces the extensibility of the starch films in cell walls. However, the application of high shear inputs to the fluid using reversing screws and high compression ratios can degrade the starch to a much smaller range of $1–5 \times 10^6$ Da. This material is much more extensible and gives a more expanded range of products.

The principle of extrusion is to transform the biopolymers, by heat and shearing forces, to a new form. This may be a completely dispersed form in which the native structures have all been destroyed, and the polymers now form a continuous fluid in water. Such a processed starch would be suitable for forming films that can retain gases during expansion to form fine foams. In examples with proteins, the fluid may be made to texturize during laminar flow through long dies.

The processing of starch may be set up to produce any type of starch structure from the native to the fully dispersed and degraded forms. If the range is divided into a number of stages, as in Figure 4, the type formed at each stage may be associated with a different product in the list discussed earlier.

Principles of Extrusion Cooking: Miscellaneous Reactions and Physical Effects

The extrusion cooker is a chemical reactor that can cause interactions between some of the ingredients such as amino acids and reducing sugars to take part in Maillard reactions and similar degradative and condensation reactions. These reactions produce color and flavor compounds and may also reduce amino acid and vitamin contents. More details of these reactions are given in the chapter on Extrusion Nutrition.

Extrusion cooking also has a unique action that serves to sterilize the materials being processed when their processing temperatures are above 100 °C. The time spent in the extrusion processing zone is short, only 45–120 s in most processes, but the high shear fields and temperatures of 140–160 °C in the shear zone help to reduce the viable cell counts to low levels. Finally, the explosive release of superheated water from within cells ruptures their structure and kills off the residual level of viable cells.

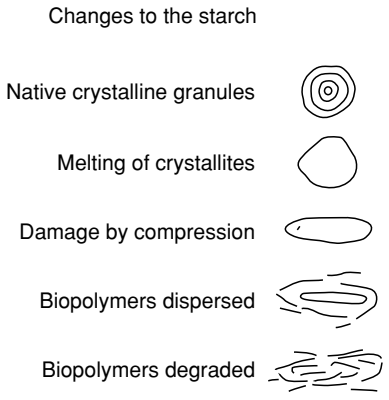

Figure 4 Stages in the transformation of starch in an extruder.

Practice of Extrusion Cooking: Animal Feedstuffs

The basic stock feeds are made using cookers and pelleting presses. This does not gelatinize the starch and merely pasteurizes and compacts the material as loose pellets. The second level of processing is obtained with expanders that add steam to an open screw system feeding pelleting presses. This process also fails to gelatinize more than a small amount of starch, until a die is used, and the equipment becomes a full extrusion cooker.

Feedstuffs with gelatinized and dispersed starch are made for special weaning foods and for all the marine feeds for fish and shrimps. In these products, the pellets are held together by the melted dispersed starch so that a strong structure is formed.

Extruders are also used to improve the nutritional value of oilseed and other protein stocks by denaturing proteins that inhibit digestion such as lectins and trypsin inhibitor in soya beans and dough ball forming elastic glutenins in wheat flours.

Practice of Extrusion Cooking: Pet Foods

Dry pet foods are made from an extruded feedstock of cereals, fortified with protein-rich materials such as dried meat meal, chicken digest, and similar materials. They tend to be fairly dense products with a specific density of 0.35–0.45 g ml^{-1}. The structural material is normally starch, which is supplied by a cereal such as wheat or maize for standard products, and rice for special dietary feeds. There may also be higher levels of oils and fats and minerals to provide a balanced diet for the animals.

Many processes incorporate a preconditioning unit (Figure 2) in which the bulk of the feedstock is conveyed and mixed with oil and steam to produce a hot feedstock at 80 °C for the extruder. This enables a higher throughput of materials to be processed by the extruder.

Processes containing high oil contents must be balanced with materials that absorb oil and prevent

slippage in the machinery. Alternatively, the oil can be sprayed on to the extrudates postextrusion.

Practice of Extrusion Cooking: Snack Foods

The snack foods are made in several forms by either direct expansion or expansion of dense cooked pellets. In direct expansion, the feedstock may be formed from a cereal or potato base mix containing 75–85% starch. The extrusion process is high shear at a low moisture to give highly degraded starch with no granular structure and a large amount of molecular degradation. This allows an expansion to a very low specific density of 0.14–0.20 g ml^{-1}. Directly extruded snacks may be formed as tubes at the die and injected with a cream or jam through the center to manufacture a coextrusion or coextruded snack. The simple products are coated with oil and flavorings to complete the products.

For the pellet process, a similar feedstock is processed at low shear to melt the starch crystalline regions but to retain its granular structure. The cooked melted fluid is cooled to 95–100 °C after cooking, before extruding to the final shape. This soft dense extrudate is cut into a pellet and dried to < 12% moisture. As it cools to ambient temperatures, it assumes a glassy structure and is known as an intermediate pellet or half-product.

A snack is formed by heating the half-product for a few seconds in hot oil or hot air at 190 °C. Recent developments have seen the production of such products in two layers with a half-product. On frying, this forms a large central cavity and is sometimes called a '3-D snack'.

Practice of Extrusion Cooking: Breakfast Cereals

A simple form of breakfast cereal is made for a cereal feedstock with wheat, maize, or rice flours and some small additions of sugar, salt, and proteins. The feedstock is processed at 20–25% moisture to a medium expansion at 150 °C, to give a specific density of 0.22–0.28 g ml^{-1}. The desired products are formed with a coarse cellular texture and thick cell walls, so that they remain crisp in milk for a few minutes. This is achieved by melting the starch granules and degrading about 50% of the granular structures.

The recipes for directly expanded breakfast cereals may be varied to form single cereal varieties such as crisp rice or corn pops, or to form multigrain cereals from blends of wheat, rice, maize, barley, and oats.

A unique form of the expanded breakfast cereal is the high bran product in which wheat bran may be used at levels of 70–75%. In this product, a small amount of starch (15–20%) is used to bind the bran fibers together in a cellular structure. The starch must be melted and completely dispersed to achieve this effect.

The second major form of extruded breakfast cereal is the flaked product, such as the cornflake or multigrain flake. This product is similar in processing requirements to the half-product snack in that it is made from a cereal feedstock at 120–130 °C at low shear. The starch granules are melted, but not dispersed to any significant level. In the process, the cooked cereal feedstock is extruded as a dense fluid at 90 °C and cut into small beads. Each bead forms the basis for a flake when rolled out to a thickness of 0.5–0.7 mm. This process occurs under temperature control at 40–60 °C and is followed by a toasting process at high temperature 240 °C for a few seconds to blister and dry out the flakes. The degree of processing of the starch is very important for the quality of the flakes when they are consumed in milk as a breakfast cereal. If the starch is sheared too much, the flakes take up water too quickly and become limp and flabby in the bowl.

Practice of Extrusion Cooking: Breadings and Coatings

Traditional breadcrumbs are manufactured by making loaves of bread, and shredding and drying their crumb to produce a small range of products. Several extrusion cooking processes have been set up to make similar products from the same materials and a wider range from other ingredients, which cannot be used in traditional bread. The extrusion of a wheat-flour feedstock at 28–35% moisture at temperatures of 110–120 °C at low shear produces expanded extrudates with cellular textures similar to that of breadcrumbs. Starch granules within the structure should be melted to lose their crystalline structure, but only dispersed to a small degree so as to provide material for expansion. The extrudates may be cut while still warm and moist to form crumbs, and then dried to <10% to form the glassy structure required for coating crumbs. The recipe for coating crumbs may be based on wheat flour and modified with some chalk to increase the number of cells. Other cereals such as maize and rice may be used with, or instead, of wheat flour to give a variety of products. Maize adds an attractive yellow color to products, whereas rice give whiter crumbs.

Practice of Extrusion Cooking: Baby Foods

Extrusion cooking has been used to produce expanded baby foods from rice and vegetable flours

such as peas and carrots. These products are similar to snack foods in that the starch must be well dispersed to give good expansion and a light texture. The process must be controlled in terms of temperature to keep the mass temperature as low as possible <130 °C during processing.

The second form of baby foods is more important because it represents a larger amount of production. It was developed to match the roller-dried instant baby food, which is consumed as a porridge, prepared by mixing water or milk with a dry instant powder. The extruded product is made by processing a feedstock of cereals with milk solids under conditions of medium shear input and controlled temperature. The aims are to melt the starch granules, but to retain their structures to a large extent. This gives a high paste viscosity when added to water or milk and produces a more attractive porridge. It is also important to control the temperature of the fluid to reduce any browning reactions that would discolor the products and reduce the nutritional quality of the proteins.

Chemical and Nutritional Changes

I T Johnson, Institute of Food Research, Norwich, UK

Background

The extraordinary versatility of the extrusion cooking process and its variants has led to the use of this technology in a very wide range of applications by the food-processing industry. In developed countries it is widely employed to fabricate snack foods with novel characteristics of flavor and texture, but which usually have little nutritional significance in the diet as a whole. However, the technique can also be applied to the production of more substantial products such as breakfast cereals and crispbreads and even weaning foods, which may contribute a very large proportion of the total nutrient intake of infants. Even in the developing world, where a suitable technical environment exists, extrusion cooking may be applied to the production of staple foods from indigenous crops. This remarkable variety of applications is a direct result of the extreme physical conditions which the process imposes upon raw materials, and the complex transformations which are achieved in the final product. The chemical and physical reactions which underlie these changes can have both positive and negative implications for nutrition and food safety. This issue has attracted increasing attention in recent years.

Changes in Carbohydrates

Cereals and potatoes were the first commodities to be widely processed by extrusion cooking, and they are still the most common. This fact has helped to focus particular attention on the behavior of complex carbohydrates during high-temperature extrusion. Cereal grains and vegetable tubers are storage organs which contain starch, and some free sugars, embedded within a complex cellular matrix. Starch consists of glucose molecules, linked in the case of amylose exclusively by α-1,4 bonds, or, in the case of amylopectin, by a combination of α-1,4 and α-1,6 bonds, which give a branching structure to the molecule. All such links are susceptible to hydrolysis by the digestive enzymes of the human alimentary tract. Cell walls are much more complex structures containing a variety of different polysaccharides, all of which are resistant to digestion. These materials, together with lignin, comprise dietary fiber. (*See* **Carbohydrates**: Interactions with Other Food Components; **Dietary Fiber**: Properties and Sources; **Lignin**; **Starch**: Structure, Properties, and Determination.)

Native, uncooked starch also resists digestion because it is localized within plant cells in the form of semicrystalline granules containing varying proportions of amylose and amylopectin. The polysaccharides are tightly bound together by hydrogen bonding, but the density and orderliness of the bonding vary within the granule matrix. In the presence of moisture, hydrogen bonding in the less ordered regions of the granule is susceptible to

disruption by heat. This allows the entry of water into the granule, which then swells and becomes increasingly susceptible to mobilization and dispersion of its constituent polysaccharides. Where substantial quantities of excess water are present, the granular structure of starch is completely converted into a viscous fluid dispersion. This process is called gelatinization and it is one of the most important functions of processing and cooking because it renders starch readily available for digestion in the small intestine.

During the extrusion cooking process a dough is driven continuously through a die by one or more screws rotating within a high-pressure barrel. As the dough is pressurized its temperature rises. An external source of heat may also be employed, and working temperatures ranging from 100 to 180 °C are commonly achieved. When the dough emerges from the die, the sudden fall in pressure causes rapid expansion and instantaneous generation of steam. Thus, the extrusion cooking process is characteristically one in which high temperature, pressure, and shear forces are imposed upon a starch-rich matrix, which has a relatively low water content, for a short time. All of these conditions are varied at will by the processor, in striving to optimize the texture and other properties of the final product.

There have been numerous empirical investigations of starch behavior during extrusion under different conditions, but no completely adequate theoretical account has been developed. Nevertheless, some useful generalizations are possible. Under low-moisture conditions, starch granules degrade or melt at a temperature higher than that of conventional gelatinization. This process can take place within the high-temperature environment of the extruder barrel. The high pressures and shear stresses of extrusion cooking increase the efficiency of gelatinization so that finished products often possess a completely amorphous and hence readily digestible starch matrix, which nevertheless has a very low water content. Moreover, it is not only starch granules which are degraded under extreme extrusion conditions. Scanning electron micrographs of cereal grains such as maize demonstrate a loss of structural organization within the extruded tissue, and an apparent absence of intact cell walls.

One of the most important attributes of dietary fiber is the structural organization which it confers upon lightly processed plant foods. There is strong evidence that intact cell walls tend to encapsulate gelatinized starch granules in conventionally cooked foods, and thereby slow the access of pancreatic enzymes so that starch digestion is delayed. This leads to a relatively slow rate of glucose absorption and an attenuation of the peaks and troughs of blood glucose which occur after meals. In studies with human volunteers, test meals consisting of breads processed by extrusion cooking have been shown to be more rapidly digested than conventionally cooked breads. The principal aim in the dietary management of diabetes mellitus is the maintenance of blood glucose at levels as close as possible to the normal range, and it has been suggested that diabetics should avoid extruded cereal products and snack foods. However, this principle has not been fully confirmed in patients consuming mixed diets over a long period of time, and there is little or no evidence that such relatively minor differences in carbohydrate availability are of any nutritional significance in healthy subjects.

Apart from the disruption of cell walls, dietary fiber also undergoes chemical changes during extrusion cooking. Under relatively mild conditions the total fiber content of extruded wheat flour remains more or less constant, but there is some increase in the soluble fiber content at the expense of insoluble fiber. Under more severe conditions a moderate increase in total fiber content has been reported. Clearly, this material is not true dietary fiber in the sense of cell wall polysaccharides. It probably represents a combination of Maillard reaction products and amylose-resistant starch complexes. The physiological significance of these substances is unknown, and they may be best regarded as artifacts.

Interaction of Protein and Carbohydrates

Under extreme extrusion conditions the disruption of complex carbohydrates extends to the molecular level. A proportion of the starch may be hydrolyzed to release glucose which then becomes available for further chemical reactions within the extruder. The most important of these is the Maillard reaction which occurs between reducing sugars and the free amino group of lysine, and gives rise to a very complex family of 'browning products.' Such compounds alter the flavor and color of the finished product and are responsible for many of the organoleptic consequences of cooking. However, Maillard reaction products are usually indigestible and, since lysine is an essential amino acid, any such loss of bioavailability has an adverse effect on the nutritional quality of protein. (*See* **Protein**: Interactions and Reactions Involved in Food Processing.)

The extent of lysine loss in extruded products depends upon the extrusion parameters and the composition of the dough. In general the biological availability of lysine is markedly reduced at temperatures in excess of 180 °C, but it is improved by increasing

the moisture content to more than 15% and by minimizing the presence of reducing sugars.

Losses of Micronutrients

There are relatively few foods which can be consumed without some form of processing or cooking. Indeed, as in the case of starch, mechanical and thermal processing is often essential in order to render nutrients available for absorption and utilization by the body. On the other hand a high water content, high temperature, and vigorous mechanical disruption tend to cause losses of vitamins and minerals by leaching or chemical reaction. Thus, a balance is needed to achieve the optimal nutritional value in a manufactured food, and this applies to the use of extrusion technology, as much as to any other form of industrial processing. (*See* **Vitamins**: Overview.)

Water-Soluble Vitamins

The water-soluble vitamins are a diverse group of reactive compounds. In general, a high moisture content and temperature will favor the destruction of such compounds during processing, but of course these effects can be minimized by a short duration. With its relatively low moisture content and short residence times, extrusion cooking has some advantages over other forms of processing, but these tend to be offset if the particular application requires a very high temperature and shear stress. This complex situation is reflected by the diversity of results reported for water-soluble vitamin losses after extrusion.

In general, thiamin is the B-group vitamin which appears to be most vulnerable to destruction during extrusion. On the other hand, riboflavin is retained well and is least susceptible to processing variables. In one set of experiments with extruded maize grits, for example, the recovery of added thiamin was only 46% under the most mild conditions used, and fell still further when temperature and screw speed were increased. In contrast, riboflavin recovery was 92% under the mild conditions and was relatively unresponsive to increases in temperature. However, increases in screw speed and water content did lead to a significant reduction in riboflavin content. In studies with an extruded crispbread formulation it has been shown that losses of thiamin and other B-group vitamins are linearly related to energy input. Similar considerations apply to folic acid, pyridoxin, and niacin, although these vitamins appear to be more stable. (*See* **Niacin**: Properties and Determination; **Vitamin B_6**: Properties and Determination; **Riboflavin**: Properties and Determination; **Thiamin**: Properties and Determination.)

Vitamin C is susceptible to oxidation during processing, cooking, or prolonged storage. Extrusion cooking, like other methods of processing, leads to losses of vitamin C from raw materials such as potato. Supplementation can be used to overcome this problem, but retention is maximized by supplementing after extrusion. At high operating temperatures the stability of vitamin C during extrusion cooking is favored by a low water content. (*See* **Ascorbic Acid**: Properties and Determination.)

Fat-Soluble Vitamins

Vitamin A activity may be destroyed during extrusion cooking, but the losses depend both upon extrusion conditions and the nature of the carotenoids in the commodity. Higher screw speeds have been reported to favor increased retention of β-carotene in maize meal. Vitamin E appears to be particularly susceptible to severe extrusion conditions, and losses as high as 66% have been reported for an extruded product containing wheat germ. There is little information available on the fate of vitamins D and K. (*See* **Retinol**: Properties and Determination; **Tocopherols**: Properties and Determination.)

Minerals

Unlike many other nutrients, suboptimal mineral status occurs relatively frequently in industrialized societies. This is particularly true for iron and calcium, which are essential constituents of red blood cells and bone matrix, respectively. Mineral nutrients are susceptible to aqueous leaching and to reduced bioavailability due to the formation of unabsorbable organic complexes. Extrusion cooking offers potential advantages over other forms of processing because of the generally low moisture content of extruded doughs. However, it has been reported that retention of the phytate in wheat bran, which forms indigestible complexes with zinc, iron, and calcium in the human small intestine, is higher in extruded products. This is probably because the phytase of cereals is destroyed more readily at the high temperatures of extrusion cooking. There is conflicting evidence as to whether this is of any nutritional significance in humans. (*See* **Bioavailability of Nutrients**; **Calcium**: Physiology; **Iron**: Physiology; **Phytic Acid**: Nutritional Impact; **Zinc**: Physiology.)

Investigations using techniques which model the release of bioavailable iron *in vitro* suggest that extrusion may help to solubilize iron in maize. Furthermore, flavoring substances and preservatives added

to extruded snack products in the final stages of production may act as enhancers of iron absorption.

Extrusion of abrasive commodities inevitably leads to destructive wear within the die and other vulnerable surfaces of the extruder. A measurable rise in available iron levels from this source has been observed in some samples of food extruded under experimental conditions. In theory, other metallic contaminants might enter extruded foods, but there is no evidence that the phenomenon constitutes either a benefit or a hazard in any commercially manufactured products.

Destruction of Antinutrients and Toxins

Although the most familiar role of extrusion cooking is in the manufacture of commercial food products in industrial societies, it also lends itself to the production of nutritious and palatable flours from such staple commodities of developing countries as amaranth and sorghum. In these applications the process has been shown to improve protein digestibility, probably by a combination of partial protein denaturation and the destruction of protease inhibitors. Furthermore, the safety of the product may be improved by the destruction of mycotoxins. This is particularly important in the case of peanut meal, where extrusion cooking in the presence of ammonia has been shown to reduce aflatoxin concentrations significantly. (*See* **Amaranth; Sorghum**.)

Microbial cells and spores are also rapidly destroyed at the temperatures achieved during extrusion cooking. The efficiency of sterilization depends upon a combination of temperature and residence time within the extruder. For example, in studies with the spores of the heat-resistant microorganism *Bacillus stearothermophilus* FS 1518 it has been shown that, at 165 °C, destruction of spores was complete after a residence time of 75 s, whereas at 182 °C a residence time of only 45 s was sufficient. One possible application of the technique is in the sterilization of spices, as an alternative to irradiation or treatment with ethylene dioxide. Black pepper has been successfully sterilized by this method. The extruded product is then reground and has been shown to be indistinguishable from conventionally processed pepper. (*See* ***Bacillus***: Occurrence.)

The Sensory Properties of Extruded Foods

From the point of view of the food manufacturer, one of the principal advantages of extrusion cooking lies in its ability to compress a series of manufacturing steps into a single continuous process. The extreme conditions of temperature, pressure, and shear which this requires also allow the texture and shape of the final product to be varied in ways which have been used to create a variety of foods with novel organoleptic properties. However, the physical conditions which favor the creation of expanded products with an attractive texture also encourage the loss of volatile compounds which make an important contribution to flavor and aroma. This is also a major concern in other applications of extrusion cooking, such as the sterilization of spices or cocoa, but in both these examples it has been shown that the extrusion conditions can be manipulated so as to achieve a practical balance of microbiological decontamination and preserved sensory properties. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.)

Formation and Loss of Volatile Flavorings

The extreme physical conditions associated with extrusion cooking encourage a variety of chemical reactions which can modify the sensory properties of the final product. This creates both problems and opportunities for the food scientist. The high temperature generated within the extruder barrel, coupled with the 'flashing' of superheated water as the extrudate emerges from the die, inevitably leads to the loss of volatile compounds which would otherwise contribute to the flavor and aroma. For this reason many products are subsequently flavored by enrobement with mixtures of oil and synthetic flavorings during the final stages of production. To overcome the cost and other limitations of this approach, various attempts have been made to stabilize flavorings added to the feedstock before extrusion. Techniques employed include careful selection of carrier materials, complexation with compounds such as cyclodextrin, or the use of multiwall microcapsules to protect flavorings from thermal damage and volatilization. These approaches have been successful under experimental conditions, but their wide application has been limited by the need to tailor sophisticated thermostable flavorants to suit each particular product and processing strategy. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Nonvolatile Flavoring Compounds

Despite its adverse effects on protein quality, the Maillard reaction is of considerable importance as a source of aroma, flavor, and colored compounds which contribute to the palatability of cooked and processed foods. Through its secondary and tertiary stages, the Maillard reaction gives rise to a large number of products. The volatility of these compounds varies, but many are known to be retained

within the extrudate during extrusion cooking and can contribute to the sensory quality of the final product. The pattern of Maillard compounds which is obtained is sensitive to the primary amino acid and sugar substrates available, and to temperature, water activity, pH, and residence time within the extruder. Since all of these factors can, in theory, be varied during the design of a product, there would appear to be considerable scope for 'designing' the flavor of the product, along with the texture and shape.

Conclusions

There is no evidence that extrusion cooking poses unique problems for the food manufacturer. All forms of food processing alter the nutritional quality of foods. These changes are frequently beneficial, but deleterious effects such as changes in protein quality or vitamin content will often occur. The balance of positive and negative changes has to be judged in relation to the role which the final product will play in the diet of the consumer. For example, a reduction in protein quality, perhaps in a cereal product which has been subjected to extreme extrusion conditions, will need to be taken much more seriously in an infant food intended for use in developing countries than it would in a snack food intended for occasional consumption in the industrialized west.

FACTORY CONSTRUCTION

Contents

Environmental Considerations

M O Brolchain, National Standards Authority of Ireland, Dublin, Ireland

General Requirements

The suitability of a site and premises for the manufacture of safe food at an economic cost is the main consideration when deciding on the location and construction of a food factory. It is frequently quite difficult to meet these requirements. A number of factors can put the safety of food at risk. These factors include the external environment of the factory, the internal design and layout, the materials and finishes used in construction, and the security of the site. Also included is the visual impact, both externally and internally, as this can affect the attitudes of the workforce. To manufacture food economically, it is necessary, in addition to choosing the right process and equipment, to have the correct layout and construction. The layout of the process must be such as to minimize labor costs, and the premises must be constructed so that cleaning can be carried out efficiently and effectively. When designing a factory layout, allowance should be made for possible future expansion.

External Environment

Food can be contaminated by airborne material, birds, insects, and rodents. Hence, food factories should be sited in areas free from these possible sources of contamination.

Airborne material includes dust, microorganisms, gases, and particulate matter. Dust in factory air usually results from unpaved roads and yards, and handling of products containing dust in close proximity to the factory. The most common sources of airborne microorganisms are effluent plants, other food processing plants, and decaying vegetation. Discharges of gases and particulate matter into the atmosphere are usually associated with heavy industry but can result from the domestic or industrial use of coal. Discharges of gases can also be associated with industries that use solvents.

Birds, insects, and rodents must be excluded from food factories. They must therefore also be excluded, in as far as is practicable, from the immediate environment around the factory. To achieve this, the environment around the factory should not be attractive to birds, nor should there be favorable locations for the harboring and breeding of insects and rodents. Birds are attracted by trees and a supply of food. Stagnant or slow-moving water and overgrown vegetation provide favorable locations for insects and rodents. (*See* **Insect Pests**: Insects and Related Pests; Problems Caused by Insects and Mites.)

It can be seen from the above that there are a number of environmental factors that can affect the suitability of a particular location as a site for a food factory. These requirements are in addition to the normal requirements when choosing any factory site. A sufficient supply of suitable water and facilities for the disposal of effluent must also be available. (*See* **Effluents from Food Processing**: On-Site Processing of Waste; Disposal of Waste Water.)

Internal Environment

There are many factors that must be taken into account when designing the internal environment of a food factory, if the safety of food is to be assured and

the cost of maintaining a hygienic environment is to be minimized. The main factors are plant layout, plant construction, surface finishes, services, and personnel facilities. These are dealt with, in detail, in the following sections of this article. Badly designed or incorrectly installed processing equipment can have serious implications for food safety. Hence, care must be exercised in choosing and installing equipment. To obtain the ideal internal environment, the factory should be designed around the process and the equipment. (*See* **Plant Design**: Basic Principles; Designing for Hygienic Operation; Process Control and Automation.)

Plant Layout

Figure 1 shows the layout of a food processing factory. The principles used in this layout apply to all food factories. It can be seen from the figure that there is a logical flow of raw material from intake to final dispatch. The raw material preparation, the processing, and the packaging are carried out in separate areas, and there is separate storage for raw materials and for both finished product and packaging. It should be noted that access to the packaging area is via a changing room. This is necessary for access to areas where high-risk food is exposed.

High-risk foods are foods that may be eaten cold or eaten after warming only, and which have the potential to support the growth of food poisoning microorganisms.

It should also be noted that the windows are on the north side of the building. The purpose of north-facing windows is to prevent them from being a source of heat. The choice for the location of service equipment is important, if the installation and operational costs are to be optimized.

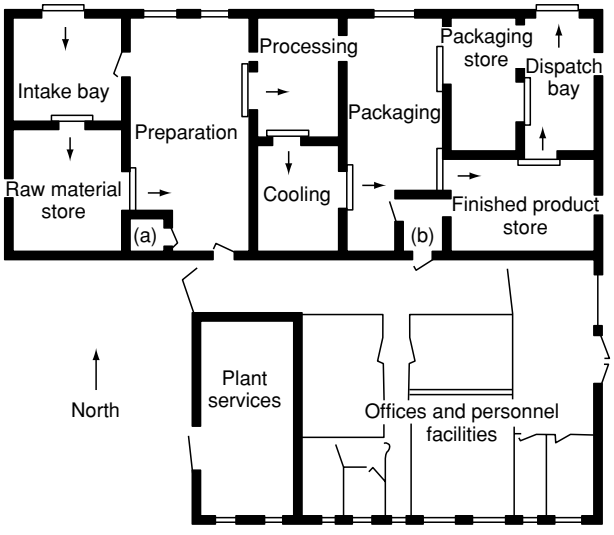

Figure 1 Plan of a food factory. Reproduced from Factory Construction: Environmental Considerations, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Constructional Requirements

As food must be processed in a hygienic environment, the cost of maintaining this environment should be taken into account, when designing and constructing a food factory. The additional capital cost associated with a well-designed factory is more than offset by the savings on cleaning costs.

When designing roof structures, external valleys should be avoided. Even partial blocking of such valleys will lead to the presence of stagnant water, which can be a source of food contamination. For similar reasons, gutters must be designed so that they can be easily cleaned. Drainpipes should be water-trapped at the entrance to storm or other drains. Access to roofs should be external rather than internal, so as to avoid contaminants from roof surfaces being brought into the premises.

Internal open-girder work should be avoided, and ceilings should be smooth and impervious. Ceilings should be accessible for cleaning, and ideally, the surface should be coved where ceilings and walls meet. In many food-production areas, the ceiling must have thermal insulation. This may be necessary either to prevent surface condensation or to reduce the energy costs of maintaining low environmental temperatures.

Walls should also be insulated, to prevent surface condensation. They should be free from rising damp and be protected, where appropriate, from damage by forklift trucks, by use of a guard rail. In modern factories, there is always a coved surface where walls meet the floor. It is also usual for there to be a coved surface where walls join at right angles. The purpose of these coved surfaces is to avoid corners and thus aid cleaning. Panels are frequently used to construct walls, and, if used, they must be adequately sealed. There should be no internal horizontal ledges, such as window sills. Such ledges lead to the accumulation of dust and foreign material. Where ledges are unavoidable, they should be sloped, at a minimum angle of 45 °.

Windows must be accessible for cleaning. In food handling areas, they should be double glazed to avoid condensation. In such areas, transparent polyvinyl chloride should be used instead of glass. Broken glass is a frequent cause of food contamination. Windows should only be used as a source of natural light and should be north-facing. Windows should never be used, in a production area, as a secondary source of ventilation.

External doors must be rodent-proof, which means that the gaps between the door and the frame, and the door and the floor, or riser, must not exceed 6 mm. External personnel doors, with the exception of emergency doors, should not lead directly into a production area. All personnel doors should be fitted with a self-closing device. Other doors, both external and internal, which are in frequent use, should be protected by a plastic strip curtain or an efficient electric air curtain, if they are not self-closing.

When designing floors, allowance must be made for the effect of the use of a forklift truck or the installation of vibrating equipment. In production areas, floors should be constructed so that they have natural slopes to drains. The use of heavy metal grids to cover open drainage channels should be avoided, as they are difficult to keep clean. In high-risk production areas, it is now being recommended that facilities should exist to enable the floor to be flooded with a sterilant solution.

Surface Finishes

When choosing surface finishes in a food factory, due cognisance must be taken of the type of food being handled and of the type of operations to be carried out in each area of the factory. These operations usually include environmental cleaning, and hence the use of detergents and, possibly, steam. There are no materials, therefore, that can be recommended for use as factory finishes, in all areas of a food factory. (*See* **Cleaning Procedures in the Factory**: Overall Approach.)

For floors, there are three broad categories of materials that may be used: concrete, tiles, and polymers. Floors must be impervious, easy to clean, and not slippery, even when wet. The suitability of a given flooring material may, also depend on its resistance to impact, wear and abrasion, and its inertness to chemical or biochemical attack. Ordinary concrete can be used in some areas, but it is subject to attack by strong acids and alkalis. Additives, or special aggregates such as granite chips, can be used to increase surface strength and nonslip characteristics. Ceramic or quarry tiles can be used for factory floors. However, floor tiles are usually only as good as the bedding, jointing, and grouting materials that are used. When laying tiles on floors, rubber latex cements, epoxy resins, and furane cements are often recommended. Polymers can be used on their own, as a surface finish or as additives to cement. Most polymers used in food factories are derivatives of epoxy, polyester and acrylic resins, and rubber latex. Care must be exercised in selecting a suitable polymer and in preparing the surface prior to laying the polymer.

Walls must be impervious, smooth, and easy to clean. To achieve this requirement, cement rendering, paints, and polymers are used. The choice is dependent on the operating environment. Failures in paints are usually attributable to inadequate preparation of the surface, to environmental conditions, or to unsuitability of the paint. Such failures can lead to contamination of food, as a result of flaking. Suitable finishes on walls can also be obtained by using cladding or paneling, provided that they are properly sealed.

Services

In modern food factories, it is usual to have all the service lines, with the exception of drainage, located between the ceiling and the roof. Services are then fed vertically to the various pieces of equipment. This design has many advantages. In particular, it makes the maintenance of hygiene in food handling areas more economical. In some factories, this type of design is impractical. In such cases, the service lines must be designed and installed so that they do not interrupt the smooth finish on walls and ceilings. They must also be designed so that they are accessible for cleaning. The problem with exposed service lines is that dust and food particles form deposits on the top surfaces of the lines. It is usually expensive to maintain such lines in a clean condition. When services are being installed, it is critical that service entry and exit points are adequately sealed, to prevent access by rodents.

As mentioned earlier, windows should not be used for ventilation in food factories. Ventilation must be sufficient to prevent condensation on walls, ceilings, and overhead structures. Airflows within the factory must be designed so as to avoid product contamination. Where there are single air entry and air exit points, airflows must be in the opposite direction to product flows. Air-intake points must be at least 1 m above both internal and external surfaces. They must be fitted, at least, with a fly screen and ideally with dust filters. It is now generally accepted that high-risk processing areas should be kept under positive pressure and that the air supply should be filtered to the required class. Where refrigerated air is required, for food-safety reasons, in production areas, low air velocities are required to reduce the chill factor. To achieve low air velocities, various refrigeration systems may be used.

In most areas of food factories, floor drainage is essential. All floor drains must be fitted with an effective water trap and a suitable grill. The sewerage lines must be adequate in size for effective drainage during washing. When designing factory drainage, allowance must be made for equipment, which requires a drainage outlet. Manholes should

not be present internally within the factory, and, if present, they must be doubly sealed. As food factory sewers have to be cleaned on occasion, manholes must be provided outside the factory to enable this cleaning to take place.

Facilities for Personnel

Adequate facilities must be provided for personnel. Such facilities include a canteen, locker room, toilets, and hand-washing facilities in production areas. The provision of suitable showers is also recommended. It is important that these facilities are well designed and can be maintained in a hygienic condition. This is necessary to maintain the correct hygiene ethos in the workforce. Toilets and canteens must be ventilated separately and must not lead directly into a production area. The doors leading into the lobby and into the toilets should be fitted with a push plate on the outside and a handle on the inside. Ideally, the lobby outside toilets, used by production personnel, should be of sufficient size to enable personnel using the toilets to hang up their protective clothing, prior to entering the toilet. Hand-washing facilities in production areas and in toilets used by production workers must be fitted with taps that are either knee-, foot-, or electronically operated, to prevent recontamination of hands after washing. Hand-drying facilities must be provided, and air driers are not recommended in production areas, as they could lead to the spread of aerosolized bacteria. Paper towel or cabinet roller towels may be used in such areas. Access to high-risk production areas should be restricted. Entry and exit should be via a changing room with hand-washing facilities.

Security

It is now becoming the norm to control access to food factory premises. This is usually achieved by fencing the factory site and having a single combined entry and exit point manned by security personnel. In some cases, this is supplemented by the use of television cameras and monitors for surveillance of the premises and the perimeter fences. Frequently, car parking is only permitted in a parking area external to the fenced site. Car parks can be located within the site, if under the supervision of the security personnel.

The purpose of this level of security in food factories is to reduce the level of pilferage and to prevent entry to the site by unauthorized personnel. The latter is of increasing importance, as a means of preventing either inadvertent or deliberate contamination of the company's products. Various systems can be used for the authorization of entry to the site of visitors, and their identification while on site.

Esthetic Design

In designing food factories, the emphasis has tended to be on functional design. The appearance of the buildings and site from an esthetic point of view has often been ignored. All food factories should be attractive and pleasing to the eye. The importance of a visually pleasing factory and factory site cannot be overemphasized. Such a site helps to create a better ethos in the workforce and better hygiene practices. It also helps to improve the image of the company projected to customers and prospective customers.

In summary, there are many factors that must be taken into account when designing a food factory if the external and internal environments of the factory are to be suitable for the production of safe food at an economical cost. Ignoring any one of these factors can result in the environment being unacceptable for food production.

Materials for Internal Surfaces

A C Jolly, Frodsham, Cheshire, UK

Introduction

As a result of the fact that the synthetic resin-based material has been used over the last 20 years in a rather ill-informed way, the rate of exploitation of the technology and properties offered has been slow, held back by the inevitable on-site failures. The resin-makers possessed no experience of on-site conditions (metereological, physical, and quality of labor); the architects, specifiers, and civil engineers usually received no professional education in polymers *per se* (in the UK, for example, 'resins' has nearly always been taken to mean 'epoxies'), and, finally, the contractor's labor force had no real understanding of the specific handling requirements, whilst the formulators of the products and systems were simply commercially keen to sell their wares. The tense of the above verbs is chosen deliberately in view of the fact that, at last, there appears to be a realization by all concerned that successful use of synthetic resin-based products requires a basic understanding of the polymers concerned and the preparational work and handling they require.

Background

Synthetic resins have been with us in a substantial way since the end of World War II. Before this time they had been seen to be having a great influence in the coatings field, as was indeed borne out later with the volume sales of alkyd-based paints, giving quicker tack-free times and a wide range of possible colors. Furthermore, the beginnings of molding materials other than Bakelite were appearing.

World War II itself had, of course, a gigantic catalytic effect upon the rate of development of resins for practical purposes. In the subsequent years they have gradually, and almost surreptitiously, made enormous inroads into the building industry. They have been used not only in paints and varnishes, but also in sealants, roofing, as foamed insulation, in cladding for the exterior and interior of buildings, adhesives, seamless wall and floor finishes (coatings and screeds) and, of course, in the upgrading of concrete (in terms of resistance to wear and carbonation), to name just some of the main examples.

There is absolutely no doubt that synthetic resins possess the properties and characteristics to improve the design, technology, and efficiency of building construction and refurbishment. What has been the greatest drawback is that too many disasters have been associated with their use. This has by no means been attributable to their deficiencies, but usually to other very significant factors.

Amongst these, the major factor is a complete lack of understanding of what synthetic resins actually are, how they should be used, and where they should be used. They have been wrongly specified and installed, and operatives have mishandled their installation.

The Resins and their Uses

Synthetic resins are organic (carbon-based) materials with molecules that can be made to link up with one another into larger units. These basic building blocks are called monomers and the larger groups they form are called polymers. There are many kinds of linking arrangements and many different ways of stimulating the link-up (or polymerization).

Emulsions are usually water-based and consist of resins most frequently based upon styrene, butadiene, or acrylic polymers (thermoplastic materials) which harden when the water or other solvent evaporates, allowing the polymer groups to coalesce.

Alternatives to thermoplastic emulsions are thermosetting polymers (sometimes dissolved in organic solvent) that undergo a permanent chemical change when they cure. The reaction that transforms the resin liquid or paste into a solid tends to continue long after the initial cure is complete. The result is a harder and more chemically impervious material than is the case with the emulsion types referred to above.

In general, and taking the above into consideration, synthetic resins are suitable where seamless surfaces are required to minimize the occurrence of trapped dirt or contamination, and to provide easily cleaned hygienic surfaces (i.e., good British Standard (BS) 4247 rating). Coupled with this facility are the factors of excellent serviceability, safety and, if applied correctly, esthetics. Furthermore, they can act as binders in screeds and provide, as in the case of polyurethanes (PUs), insulating and also roof stabilization foams, to mention just a few applications.

No one resin type will provide satisfaction in all situations encountered. What follows is not a complete statement of the advantages and disadvantages of the various types, but it will give a general idea as to how careful specifiers have to be.

Resin Species

Resins are as varied in their nature as food. Similarly, epoxy is a subdivision of the former, as cheese is of the latter, both being collective terms for a number of connected variants.

Specification of the correct resins requires as much understanding as that required by a diner choosing a menu for a successful meal: no one would order Blue Stilton to quench a thirst. Examples of the variations in the nature of some synthetic resins are as follows:

1. PUs give all-round properties resulting from their hardness, coupled with flexibility; the surface preparation required to avoid their delamination has to be more scrupulous than with, for example, acrylics; PUs possess excellent acid resistance.
2. In general, acrylics are used for hardness and, principally, color retention.
3. Polyesters carried in styrene offer quick cure and good chemical resistance to some chemicals, but produce a strong smell during application and need a temperature of at least 10 °C to cure satisfactorily.
4. Epoxy types (i.e., epoxy–hardener two-pack systems) are versatile in that the resultant properties can be varied by selection of the appropriate hardener; they undoubtedly have excellent resistance to alkalis and can be used in a solvent-free form, but their resistance to marring and certain chemicals is poor. (Marring is the phenomenon of marks being left on a surface through the moving contact of another over it. Epoxy-derived surfaces are prone to this marring effect.)
5. Methacrylates cure quickly and at low temperatures, and exhibit rapid hardening, but during application they give off a pungent smell which dissipates quickly. (They are used, with special care, extensively in Europe in food factories and breweries.) Again, chemical resistance properties vary with relation to specific chemicals.

The methods of curing of the above resins differ widely, from using the moisture in the atmosphere to requiring a peroxide catalyst (when it is known as a free radical mechanism).

Floors

There has long been a search for a floor finish that is as near perfection as possible, and the arguments concerning seamless surfaces and tiles have continued for some years.

In the years since 1945, seamless resin-based floor finishes have developed considerably from small beginnings. Initially they were mainly to be found in the form of clear varnishes or paints based on synthetic resins such as alkyds and phenolics, which gave harder coatings than the traditional types then available.

Using resins as binders for fillers and/or aggregates to produce polymer concretes or screeds (self-leveling or troweled) began to be feasible with the exploitation of the emerging technology associated with epoxy resin chemistry. Since then, other polymers have come to the fore in this applicational area; PUs, unsaturated polyesters, and methacrylates are perhaps the most prominent. The substitution of part of the water component of a cementitious formulation with a thermoplastic emulsion resin, in order to offer a moderately upgraded performance over the unmodified original, yielded an economical product (so-called polymer concrete but, more correctly, polymer-modified concrete).

When there is a new development in any area, there are usually two positive reactions amongst those who are to specify their use. One is to resist the trend, to adhere to the traditional methods or products and look for examples of failures that argue for this attitude. Caution is to be applauded and encouraged, but not if it means totally resisting cost-effective improvements. The opposite situation is perhaps more frightening in that a specifier welcomes a new development with open arms and wishes to use it at the slightest provocation. The disastrous consequences can be heightened by the fact that the first few installations may be successful and the next, failures.

It must be firmly established that no single synthetic resin will offer all of the properties that will cope with the varying in-service requirements presented to the specifier, whether it be in connection with a new floor area or a refurbished one. For example, the solvent resistances are quite different, as are the resistances to specific chemicals. Physical properties associated with impact, abrasion, elongation, and hardness also differ widely. Consideration during application of health and safety, and particularly odor, are also of considerable relevance.

The retardation of the rate of acceptance of all seamless resin-based floors has been caused by highlighting the failures rather than the greater majority of successes. These failures have, in the main, been attributable to the following, and stating them will not only be of historical interest but act as a cautionary and educational exercise:

1. Lack of basic understanding by specifiers of the substance, nature, and properties of synthetic resins and the formulated derivatives.
2. Lack of experience of many self-styled 'specialist' contractors in installing the systems on the one hand, and a lack of basic understanding of this particular medium to cope with the unexpected on site, on the other.
3. Lack of site knowledge by certain of the formulators of the systems, resulting in the systems not being 'workman-proof,' but only 'technologist-friendly'!

Indeed, in many cases the decision as to whether a coating (measured in μm) or a screed (measured in mm) should be laid is made without real understanding and often decided purely on cost – a sure recipe for disaster! A specific procedure for preparing the surface to take the finish is essential.

Coatings

In order simply to keep the level of dusting of concrete down, impregnation or coating with a clear resin is satisfactory. Acrylics, methacrylates, PUs or epoxy types, in unmodified or clear form, give good results. As far as impregnation or priming is concerned, the variable porosity of a concrete surface must first be taken into consideration; in this respect just one application of the resin may not seal the surface as, in areas of high porosity, there will be no resin present on or at the surface. In such cases additional applications have to be made until a satisfactory state is arrived at; if much extra solvent-carried medium has had to be added, the surface must be allowed to vent before proceeding further.

Clear or pigmented (paint) multicoat systems are suitable where the substrate is smooth or of very low profile. Antislip characteristics can be built in by casting fine sand in an intermediate film.

Perusal of trade and academic literature will provide information concerning the respective chemical resistance of the various resin species. Various key facts must be elicited and thence a specification drawn up in an informed way.

Screeds

If a substrate is pitted, potholed, or simply uneven, or has special requirements, a screed is needed. By substituting part of the water in a cementitious formulation with a thermoplastic emulsion, the so-called polymer screeds are constituted. These provide nondusting flat surfaces of varying hardness and certainly upgrade the 'straight' cementitious finish. However, they do not have the degree of chemical and abrasion resistance often required in industry. This is where other synthetic resins come in – epoxies, PUs, acrylics, and methacrylates. These are now well-known, and success is achieved by combining the most advantageous combinations of resin and aggregate (the selection of the latter plays a major part as far as wear and antislip properties are concerned). The main two methods of application are by trowel or, where a formulation where self-level is used, by pouring.

One of the requirements of the food industry, as mentioned before, is a sterile floor; in order to achieve this, the topping must give an excellent BS 4247 rating. One method, of course, is to steam-clean or to use virtually boiling water. Many systems, such as epoxies, do not possess a high enough heat distortion temperature to resist such daily treatment and, as a result, develop hairline cracks (thermal degradation). To some extent this can be overcome by introducing some elasticity, but the solution is to use a medium that does possess a high distortion point.

Another approach is to utilize a PU-modified concrete; this has been done and improvements are still being made (Figure 1).

Table 1 details the characteristics of a typical epoxy-based screed. Choosing from a wide variety of hardeners which, with the epoxy resin itself, form the two-pack system, a wide variation of properties can be achieved.

Table 2 details the characteristics of a typical PU-modified concrete used where high heat distortion temperatures are required, together with excellent physicals.

Table 3 proposes a scheme for the project manager to follow when installing a resin floor.

Finally, one very important matter, often overlooked, is cleaning or aftercare. The chemicals used previously may well not be at all appropriate for the resin-based surface, and it is the duty of the formulator, through the contractor, to identify the best means and detail it in the relevant technical data sheets. (*See* **Cleaning Procedures in the Factory**: Types of Detergent; Types of Disinfectant; Overall Approach; Modern Systems.)

Figure 1 Polyurethane-modified concrete laid by Swansback. Photographic Unit of the Boots Company plc.

Table 1 Typical characteristics of an epoxy concrete (filler and/or aggregate and resin)

Characteristic	*Value*	*Units*
Compressive strength	55–110	N mm^{-2}
Compressive modulus	0.5–20	kN mm^{-2}
Flexural strength	25–50	N mm^{-2}
Tensile strength	9–20	N mm^{-2}
Elongation at break	0–15	%
Linear coefficient	25–30 × 10^{6}	per °C
Water absorption (7 days at 25 °C)	0.1	%
Maximum service (temperature under load)	40–80	°C
Rate of development of strength	6–48	h at 20 °C

Table 2 Typical characteristics of a polyurethane-modified concrete

Characteristic	*Ucrete HF*	*Concrete (124)*[c]

Walls

Much of the reasoning and statements contained in the Floors section of this article apply to walls. For example, a seamless surface is usually easier to keep sterile than a grout-containing tiled surface, although in many situations tiles are preferable. A good example of the latter is in the corridors of the London Underground system where gouging and graffiti are made very difficult by using specific and glossy tiles; but here sterility is not a significant factor.

In the food industry, as in industry as a whole, the wall finish must resist the chemical and physical attack of the inherent service conditions. For example, it is quite common to steam-clean and, in such cases, the basic resin in the finish is required to (but does not always!) possess a sufficiently high heat distortion temperature to resist the frequent expansions and contractions.

It has been firmly established by psychologists that the color and texture of surroundings have a great effect on the mental attitude of those in the vicinity. This is not surprising when one considers the effect the sun has on all of us when it comes out. Until 20 years ago, there was no pressure to arrange for the decor in the fitting shop to be the same as that in the chairman's office. Although this attitude has changed in essence, the desire could not be sensibly realized owing to the technical shortcomings of available prestigious wall finishes. In other words, the formulation of multicolored and textured systems of classical or upmarket appearance has never been a problem, but the technical inadequacies of the systems did not make them suitable for the more demanding service conditions found in food industry situations.

Multicolored, durable, and resistant coatings have been around for some time, but they have been paint-like and thus of flat profile (Figure 2); in addition, the application of more than one coat was required, thus involving considerable labor costs. They have also been associated during application with the unpleasant smell and fire risk characteristic of solvents. This has meant either causing aggravation amongst those working in the vicinity, or carrying out the particular project only when the building was totally vacated; the suitable time for application was therefore somewhat restricted. Textured systems have often had an upmarket appearance suitable for the chairman's office, but lacked the physical and chemical resistance properties needed for more aggressive service conditions, or they have had the necessary degree of resistance but not the necessary classical and upmarket appearance needed for the more prestigious sites.

Figure 2 A polyurethane-based wall finish by Sempol Surfaces Ltd in association with an epoxy seamless floor in a food factory.

Thus the way has been open for some time for systems of virtually universal suitability, with minimum hazards on application, and the ability to provide textured or smooth finishes. These are now gradually becoming available, especially utilizing the properties of PU-based systems which are no longer handicapped by yellowing on exposure to light.

Within reason, what applies to floors applies to ceilings. Thus, by using resin-based systems, a complete hygienic envelope can be achieved for floor, walls, and ceiling.

Roof Stabilization

Many factories in the food industry were built before World War II and consequently have tile roofs. These can become unstable with the passing years. Puresin-sprayed systems have been developed to secure and stabilize these structures internally without complete rebuilding.

Stability and insulation are achieved through technically advanced closed-cell, rigid polyisocyanurate (or related) foams which are tailor-made for the purpose with British Board of Agrément (BBA) approval. Application is by spray at right angles to the prepared underside of tiles or slates of a roof requiring refurbishment. The latter procedure, coupled with a very fast-curing or setting time, insures that foam does not run out from between the tiles or slates and down the outer surface of the pitched structure. Such foam has fire-retardant qualities, passing class 1 (BS 476 part 7, 1971). Typical characteristics of the system are shown in Table 4.

Table 4 Typical stabilizing foam properties

Property	*Value*
Closed-cell content	90% minimum
Thermal conductivity[a]	Initial 0.017 WMC Aged 0.020 WMC
Water vapor transmission[b]	10.6 μg per Nh[c]
Service temperatures	−50 °C to 70 °C
Density (overall)	42 kg cm^{-3} (approximate)

[b]25 mm thick at 30 °C, 88% relative humidity.
[c]Nh are Newton hours.
All tests results according to BS 4370.
WMC, watts per square metre per Kelvin.

Figure 3 Stabilizing polyurethane Spraybond foam being applied. Courtesy of Liquid Polymers plc.

As with all resin-based systems, the installation must be carried out by trained and experienced contractors who can appraise the site as being suitable, recognize and carry out the vital preparation work, and spray the system correctly. In addition, they should insure that the roof space is adequately ventilated to avoid structural deterioration through condensation (Figure 3).

The foam is sprayed between (not over) the rafters and the purlins and over the battens (i.e., on their

inside face), leaving the outer face uncoated and thus allowing moisture evaporation. A foamed thickness of 25 mm is preferred. Before expanding (foaming), the liquid penetrates cracks and joints and, on curing as a foam, bonds the slates or tiles, thus increasing the stability of the structure chiefly against the force of winds.

In the industrial context, the duration of application will depend on the surface area of the structure which may, of course, be of considerable size. A single day is all a house-sized roof will take.

As already mentioned, a roof thus treated will be sealed against wind, driven rain, and snow, i.e., storm conditions. However, it must be noted that this will not prevent leaks owing to cracked or displaced tiles, slates or faulty flashings, valleys, and gutters. These are avoided by correct, appropriate preparation of the roof before refurbishing with the system.

Being one of the best insulants commercially available, the foam, when of the order of 25 mm thick, achieves a degree of improved insulation that should be approximately 0.8 $W\,m^{-2}$ per °C. Because of this, coupled with good ventilation, the chances of condensation are reduced.

There are other attractions associated with this method of refurbishment. It is carried out at a lower cost than reroofing. The application is easy, being from inside the roof, so that no scaffolding is required. Furthermore, there is minimum disturbance of below-roof activity during the initial installation.

Final Comments

Most problems stem from lack of knowledge of the nature of the synthetic resin involved. Such knowledge must be acquired through the medium of either an informed contractor, fair-minded suppliers who are prepared to say 'you need a system based upon a type *x* resin which we do not make', or an independent resin consultant. The academic institutions can help considerably by including far greater input on the basic subject of synthetic resins in their syllabuses for graduate courses in architecture, civil engineering, and surveying.

An informed, experienced, specialist contractor is essential and can often be identified by the fact that the company has existed for a considerable number of years and can offer visits to past installations or, at least, produce a substantial list of case histories and offer good postinstallation technical service. The basic technical knowledge referred to above is likely to be present if the contractor formulates his or her own systems, and is not purely a 'menu-reader' of material suppliers' literature which cannot hope to cover all of the potentially threatening situations arising on site.

For success, not only should a system based upon the correct resin be selected, but also a good major percentage of the effort put into the project should be in preinstallation activity by way of full appraisal of the site, coupled with the resultant, specifically appropriate substrate preparation. Sadly, all too frequently this is carried out after, for example, a floor finish has failed, and only then do protimeters and the like appear on the scene! A protimeter is an instrument which measures the degree of moisture in a surface (concrete) by means of a probe and the reading on a dial of a small current of electricity which indicates the percentage moisture. Increasing the depth of the hole into which the probe is placed allows moisture levels at different depths to be determined – so quantifying 'rising damp.'

FAMINE, STARVATION, AND FASTING

E M Widdowson[†] **and A Ashworth**, London School of Hygiene and Tropical Medicine, London, UK

Background

Despite man's ingenuity and technological advances, it is a sad reflection that at the start of the twenty-first century, famine and starvation still abound, often with such catastrophic loss of life that it can be measured in millions. Indeed, 'food security' has become an industry, and 'humanitarian assistance' the vocation of a burgeoning number of organizations who do nothing else. It is a damning indictment of our times that when the medical relief organization Médecins Sans Frontières was awarded the Nobel Peace Prize, they were working in over 80 countries.

We shall examine the causes of famine and starvation, both past and present, and some of the physiological changes that have important consequences for those looking after the afflicted. We shall also look at fasting and starvation in the midst of plenty, in particular anorexia nervosa and bulimia.

Causes and Effects of Famine

Famine can be defined as a prolonged scarcity of food causing many in a district or country to die from starvation and/or disease. In communities dependent on subsistence farming, 'hungry seasons' are not uncommon, but coping strategies exist to mitigate the adverse effects and insure survival. For example, nonessential items may be sold and debts called in, and there may be greater use of wild foods. What distinguishes 'famine' from 'hunger' is that in famine, the usual coping strategies are insufficient. Thus famines are characteristically accompanied by extreme measures that may disrupt future livelihoods, for example, the selling of animals, land, and other essential items. In a famine, families are often driven to eat unconventional items, such as rodents, beetles, worms, roots, leaves, bark, grass, candles, and leather.

Famines have occurred from time to time throughout history, and there are many records of them in early writings, such as the Bible. In general, they were caused by crop failure due to droughts, floods or pestilence (e.g., locusts, blight). In Europe in the Middle Ages, they were often accompanied by outbreaks of typhus, cholera, typhoid, dysentery, smallpox, measles, and scarlet fever, and famine led to their spread and severity. In more recent times, misguided political gambits have caused disastrous food shortages, as witnessed by the famines in the former Soviet Union and China, where privately owned small farms were merged into collectives and crops procured by the State to provide the wealth to support industrialization. Some 30 million people are estimated to have starved to death in China during Chairman Mao's Great Leap Forward.

Starvation may be used as a political tactic and knowingly engineered (as in the internment camps of Belsen). Incongruously, countries gripped by famine often continue to export staple food crops, as was the case in the Irish famine of the 1840s and more recently in the famines in Ethiopia and Sudan. Mass movements of populations in search of food or fleeing from conflict situations have become commonplace on our television screens. Tented camps and humanitarian aid may be a refuge from starvation, but thousands of people with weakened immune systems living in close proximity are vulnerable to epidemic diseases, and many die as a result. Table 1 shows some of the twentieth century famines and the estimated number of deaths.

Increasingly, famines are linked with ineffective political structures, armed conflicts, environmental degradation, and ethnic or religious unrest emanating from disregard of civil and human rights. The effects are wide-ranging. The use of land mines, for example, limits access to local markets and hampers food relief efforts in the short term, but also continues to kill, maim, and disrupt agricultural production in the long term, as seen in Mozambique, Angola, and Somalia. Forced conscription of young men for combat adversely affects food production and food security in rural areas, and arms purchases divert foreign exchange from already under-resourced health and development budgets and deter inward economic investment. Evidence of the effects of climate change can be seen in unusually prolonged periods of low rainfall at one extreme and increased

[†]Deceased.

Table 1 Selected twentieth century famines.

Year	*Location*	*Number of deaths*	*Notes*
1899–1900	India	1 million	Drought
1915–1918	Germany	200 000	War
1918–19	Uganda	4 400	
1920–21	North China	500 000	Drought
1921–22	Russia, Ukraine and Volga region	1.3–5 million	Drought
1928–29	China, Shensi, Honan, and Kansu	3 million	
1932–33	Russia	3–10 million	Collectivization
1941–43	Greece	450 000	War
1941–44	Leningrad	1 million	War
1941–42	Poland, Warsaw	43 000	War
1943	Ruanda-Urundi	35 000–50 000	
1943–47	India, Bengal	3 million	Drought and war
1958–62	China	30 million	Collectivization and natural disasters
1967	India, Bihar	Relief operations mitigated the effects of the disaster	Drought
1971–73	Ethiopia	1.5 million	Drought
1988	Sudan	250 000 in Bahr El Ghazal	War
1998	Sudan	60 000	War

frequency of hurricanes and floods at the other. These wreak havoc to crops and livelihoods, decrease soil fertility, increase erosion, desertification and salination, and disrupt transport routes. These factors, however, are associated with famine only where populations are chronically poor. Hence, combating poverty is a major concern in famine prevention and mitigation.

Structural and Physiological Consequences of Undernutrition and Starvation

Starvation implies that little or no food is eaten. Undernutrition arises when some food is eaten, but the amount is insufficient to meet physiological and metabolic requirements. In many ways, the effects of starvation and undernutrition are the same, and the differences are those of degree. It goes without saying that a starving or undernourished person loses weight, but the organs and tissues lose weight at different rates. The least essential tissues suffer first; hence, adipose tissue is mobilized and the fat oxidized to provide the energy necessary for the metabolic processes that must go on if life is to be preserved.

Some loss of nitrogen is inevitable despite the increased production of free fatty acids, and this comes, to a large extent, from the proteins of skeletal muscle, leading to shrinkage of the muscle fibers. The breakdown of muscle proteins provides the amino acids alanine and glutamine, whose carbon skeleton can be used to make glucose. The skin also loses protein, both structural and cellular, and becomes thin and easily infected. The loss of its protein, together with the loss of subcutaneous fat, makes the skin hang loosely on the bones.

The internal organs lose weight, the liver sometimes a great deal. In edematous malnutrition, however, the liver may increase in weight by as much as 50% owing to the accumulation of fat, which is caused, at least in part, by a reduced synthesis of lipoproteins that transport triglycerides out of the liver and into plasma. The alimentary tract loses weight and becomes thin, and there are marked changes in the gut mucosa, especially the villi, which become flattened and broader, and have reduced levels of digestive enzymes. The heart and kidneys tend to lose weight in parallel with the body, and their function is impaired. The brain is preferentially protected, although there is a reduced density of neuronal synapses and dendrites.

Healthy, well-nourished individuals operate with considerable 'spare capacity.' Thus, our bodies are able to respond when we run very fast or eat a very large meal. This excess capacity, however, is expensive to maintain, and when food intakes are insufficient, it is reduced to conserve energy. This 'down-sizing' of the body's functional capacity affects every system, organ, and cell, and is termed 'reductive adaptation' (see **Figure 1**). One example of reductive adaptation is the slowing down of the sodium pump in cell membranes. The purpose of this pumping activity is to maintain the correct concentration gradient, and it normally accounts for about one-third

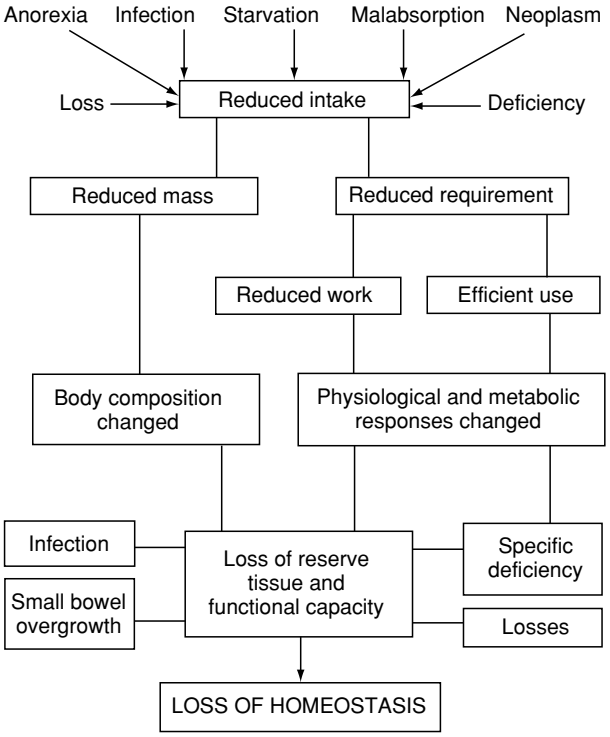

Figure 1 Schema showing the changes that occur in severe malnutrition. When malnutrition is prolonged, the adaptive changes are insufficient to maintain homeostasis. Reproduced with permission of Oxford University Press from Golden MNH (1996) Severe Malnutrition. In: Weatherall DJ, Ledingham JGG and Warrell DA (eds) Oxford Textbook of Medicine, Vol. 1.

of the basal energy expenditure. Although energy-sparing, this slower pump rate is not entirely beneficial, as it allows sodium to accumulate inside cells and potassium to be lost, thus contributing to potassium deficiency. There are several serious consequences of potassium deficiency, including fluid retention and edema, and impaired cardiac function. Other functional changes in starvation include a slower heart rate, reduced ability of the kidneys to excrete excess sodium and excess fluid, which increases the risk of heart failure, and reduced ability to make glucose, increasing the risk of hypoglycemia and hypothermia. Thus, there are both positive and negative consequences of 'reductive adaptation'.

The resting metabolic rate per kilogram bodyweight is not greatly reduced in moderate undernutrition, but in a starving person, it ultimately falls, as does body temperature. In moderate undernutrition, the digestive tract functions normally, provided there is no infection, but in a starving person, diarrhea may become severe. This has been attributed, at least in part, to the colonization of the normally sterile upper intestine with bacteria, which then produce toxins, damaging the gut mucosa and increasing fluid secretion into the gut. The dehydration resulting from this may prove fatal. In addition, some of these bacteria deconjugate bile salts, reducing the body's ability to absorb fat.

The survival time of an adult who takes no food depends upon the availability of clean water. If plenty of water is available, a previously well-nourished adult can survive without any food for about 60 days – the exact time depending partly on the amount of fat in the body. Starving or near-starving infants and young children are in a far worse plight, particularly if they are also short of water, because their requirements for energy and water per kilogram bodyweight are greater than those of adults.

Extreme wasting occurs among hospitalized patients, the causes varying with the nature of the disease or type of trauma. Some conditions, including cancer, markedly depress the appetite leading to semi-starvation as a result of low food intake. Some conditions lead to actual loss of nutrients, for example gastrointestinal diseases and postoperative drainage. Injury and infections trigger an increased demand for nutrients to fuel the immune response, including amino acids for the synthesis of acute phase proteins. These are derived from muscle protein breakdown, causing wasting. Malnutrition in hospital, however, is also often the result of prolonged underfeeding due to inadequate or inappropriate nutritional support. Even in affluent countries, as many as 50% of hospitalized patients are malnourished.

Refeeding after Undernutrition and Starvation

When World War II ended in Europe in May 1945, several groups of doctors and nutritionists went to the liberated camps to supervise the feeding of the starving inmates. It was generally believed that the digestive tract would not be able to tolerate food for some time, and that intravenous feeding would be necessary in the early stages. This proved not to be true. The previously starving men had good appetites and took very large amounts of food (25–42 MJ, 6000–10 000 kcal per day). They gained about 10 kg in 6 weeks, and the response was similar in young and old men. The same is true for severely malnourished children. After a few days of treatment, they become very hungry and will double their food intake and gain weight very rapidly. After a few weeks, when their weight deficit has been corrected and they approach a normal weight for their height, their appetites and food intakes revert back to levels appropriate for well-nourished children of a similar size.

The physiological and metabolic changes that occur in starvation have to be taken into consideration

during refeeding, otherwise death from cardiac failure, infection, hypoglycemia, and hypothermia are likely. Treatment is considered in two main phases: a short stabilization period to treat infections and correct the main metabolic disturbances (e.g., fluid and electrolyte imbalance, and micronutrient deficiencies) and a longer rehabilitation period to replace lost tissues. Many humanitarian aid agencies looking after starving populations have a very organized system of identifying those who are severely malnourished so they can prioritize them for supervised refeeding. Aid agencies often use food preparations that have been specifically formulated for severe malnutrition to provide the correct amounts of energy, protein, potassium, magnesium, and micronutrients. In hospitals and nutrition rehabilitation centers, suitable preparations can be made from milk, sugar, oil, and an electrolyte/mineral mix, and/or modified local foods.

The essential characteristics of successful dietary treatment in the stabilization phase are small, frequent feeds day and night that provide just enough energy and protein to meet maintenance needs. This will halt any further loss of tissue and, together with provision of potassium, magnesium, and micronutrients, will restore normal functioning of the deranged metabolic machinery. In the rehabilitation phase, the aim is to restore the lost tissues. This involves providing large amounts of the nutrients that provide the building blocks for tissue synthesis, and high energy intakes to cover the energy cost. Thus, the aim in this phase of rapid catch-up growth is to encourage children to eat as much as possible and to provide them with diets that are high in energy and protein, whilst continuing to give extra potassium, magnesium, and micronutrients.

Fetal Undernutrition

The question sometimes arises as to whether an infant born small for its gestational age because of undernutrition before birth will remain small. This is difficult to answer because the genetic make-up of human individuals is so diverse, and genes, as well as nutrition, influence the rate of growth. Animal studies with pure-bred strains provide some information. The 'runt' pig, born much smaller than its littermates, is unlikely to catch up to its larger siblings, and rats that are born very immature, when undernourished during the suckling period, take less food after weaning and remain small for the rest of their lives. There is some evidence that this is also true for small newborns in developing countries, especially if their smallness is because they are short in length, rather than thin. It is difficult, however, to separate the effect of fetal undernutrition from the growth-limiting effects of being raised in the same environment that detrimentally affected fetal growth. Interestingly, no long-term effects on adult size were found in those individuals whose mothers suffered 6 months of starvation in the Dutch famine of 1944–45 but then were raised with a good standard of living. There seems little doubt, however, that the earlier undernutrition is imposed, the more likely it is that the effect will be permanent. Barker and colleagues have suggested that retarded growth of the developing fetus is associated with a number of chronic conditions in adulthood, including diabetes, hypertension, and ischemic heart disease.

Role of Fasting in Health and Disease

Some people fast even when they are healthy and there is plenty of food available. The reason may be political: thus, 'hunger strikes' are used by political prisoners and others from time to time to draw attention to their cause. Some fast for religious reasons. Religious fasting is usually of a short duration. Ramadan, for example, held in the ninth month of the Muslim year, involves going without food or drink between sunrise and sunset for the month. This short period of abstinence is likely to do little harm, and in any case, those who might be injured by it (e.g., pregnant women) are exempt from the fast.

A more serious problem is anorexia nervosa. This is a psychiatric eating disorder that tends to run in families and appears to be increasing in prevalence. The sufferers, usually adolescent girls and young women, are obsessed with the idea that they are too fat, and that they must lose weight and remain very thin. They may have been overweight in the past, but not necessarily so. They often come from better-off homes, where there is no shortage of food. Long-standing cases may repress the sensation of hunger, but for others, the sensation persists, and so the term 'anorexia' is misleading. Sometimes, the desire for food overcomes them; they eat a great deal and then deliberately induce vomiting; this condition is called bulimia. Or they may resort to laxatives and diuretics. The effects of insufficient food are the same as those already described, and death from starvation is not unknown. One of the symptoms is often amenorrhea. This is also characteristic of ballet dancers and gymnasts who deliberately eat too little food in order to maintain an acceptable size and shape. (*See* **Anorexia Nervosa**; **Bulimia Nervosa**.)

If the patient with anorexia nervosa can be persuaded to take more food, which is not easy, then physical recovery and restoration of weight take place just as in others who have starved and then been refed.

FAT SUBSTITUTES

Use of Fat-replaced Foods in Reducing Fat and Energy Intake

D L Miller, Central Soya Company Inc., Fort Wayne, IN, USA
L J Cheskin, Johns Hopkins University, Baltimore, MD, USA

Introduction

The availability of 'fat-free,' 'low-fat,' and 'reduced-fat' foods has skyrocketed in recent years. This rise in the number of fat-modified products is due in large part to the development of 'fat replacers' which are substances that replace one or more of the functional qualities of fat in a food without supplying all of calories associated with fat.

The safety of using fat replacers has received much attention, but comparatively few studies have investigated how these products will influence food intake and energy regulation in humans. Until recently, few studies examined the effects of varying the level of fat in foods on energy intake and body composition. Indeed, until the mid-1980s, there was relatively little emphasis on the role of dietary fat in obesity, and the technology for formulating palatable reduced-fat foods was limited. Thus, only recently have studies assessing the effectiveness of such substances in reducing both dietary fat and energy intake been undertaken.

Despite this paucity of published data, some nutrition professionals and the general public alike assume that using fat-replaced products will bring about automatic reductions in fat intake. We know very little, though, about how consumers will use fat-replaced foods. For example, fat-replaced foods may be substituted for higher-fat versions of foods (using low-fat mayonnaise instead of regular mayonnaise), and/or substituted for 'forbidden foods' (eating fat-free potato chips when regular potato chips had been omitted from the diet), or, finally, used as a license to increase intake of other types of foods ('If I use the fat-free salad dressing I can have a piece of cheesecake for dessert'). If fat-replaced foods are used ineffectively, this could potentially result in increases in

energy or fat consumption instead of the intended decreases. Also, it is debated whether the overconsumption of dietary fat in and of itself leads to negative health outcomes, or if it is the resulting increase in overall energy intake due to the overconsumption of dietary fat that contributes to adverse health outcomes. Unfortunately, the message that much of the general public has received is: 'I can eat as much food as I want as long as it is low in fat or fat-free.'

This article summarizes the existing scientific literature regarding the effects of adding low-fat/fat-replaced foods to the diet on fat and energy consumption, and discusses the efficacy of using fat replacers as a means of reducing dietary fat and total energy intake.

Background and Significance

In the developed world and, recently in the developing world, high consumption of dietary fat has been epidemiologically linked to a variety of medical conditions, including obesity, coronary artery disease, and certain types of cancer. Many regard it as the top dietary problem in the USA. Currently, dietary fat comprises nearly 34% of the energy content of the American diet. Most health guidelines recommend that no more than 30% of daily energy be derived from dietary fat in order to reduce the incidence of related morbidity and mortality.

Perhaps the most obvious method of decreasing the percentage of energy from fat is to substitute low-fat foods for high-fat foods. However, it is difficult for many people to restrict their food choices to achieve this end. Laboratory-based experiments suggest that, for most people, high-fat foods are overeaten because they are highly palatable. When a substantial amount of fat is removed from the diet, the resulting menu is often bland and monotonous. Even those whose health is directly threatened (postmyocardial infarction patients, those with type 2 diabetes or hypertension) find it difficult to maintain long-term compliance with a reduced-fat diet. The development of fat-replaced foods has the potential to reduce fat and energy consumption by satisfying the preference for the taste of a high-fat diet while consuming low-fat foods. The recent availability of highly palatable reduced-fat or fat-free foods offers consumers new choices, but because there have been few controlled studies of how these products will be used, questions remain about their efficacy in reducing dietary fat intake.

Several issues to consider when assessing products made with fat replacers are:

1. Why do many people eat more dietary fat than the recommended 30% of total energy, and will fat-replaced foods satisfy people's desire to consume high-fat foods?
2. Will consuming foods made with fat replacers aid in lowering the intake of fat and energy, or will the fat and/or energy reduction be compensated for in subsequent episodes of eating?
3. Will these products be used in place of regularly eaten foods, as a license to eat previously 'forbidden foods,' or to allow for increased consumption of other foods?

Why is Fat Overconsumed?

Palatability

Fats contribute much of the texture, flavor, and odor of a variety of foods. Although not usually consumed in pure form, fat is readily consumed as part of complex foods containing the other macronutrients (protein and carbohydrate) in varying amounts. Thus, it is difficult to isolate a fat-specific preference in foods. Fats contribute a number of sensory properties of food. First is the olfactory perception of volatile fat-soluble molecules that impart the characteristic aroma to many foods. Second, fats endow foods with certain textures (such as softness, oiliness, elasticity, flakiness, viscosity, or smoothness) and mouth feel, (the food's distribution in the oral cavity during chewing and swallowing). These textural and mouth-feel characteristics enhance the richness of food flavor, and positively influence the palatability of the diet.

A number of experiments have studied the nature of diet palatability. Preferences for sweet/fat mixtures such as milkshakes, cake frostings, and ice cream have been identified by sensory panel testing. In one sensory study, the palatability of sweetened, fat-free milk and unsweetened heavy cream were both rated relatively low, but the combination of sugar and fat in sweetened heavy cream was highly appealing. Anecdotally, people who 'crave' sweet desserts often describe themselves as 'carbohydrate cravers;' however, it is fat, not sugar, that provides the majority of the energy in sweet, rich desserts. In addition, not just sweetened, high-fat foods are considered highly palatable. A survey of US military personnel found that the most preferred foods were 'savory' high-fat foods such as steak, French fries, and whole milk. Some of the least preferred foods in this survey were vegetables, skim milk, and diet soda, which are very low in fat. Other surveys of attitudes toward dietary fat also indicate that highly preferred foods often have a high-fat content. In these studies, taste is the primary reason given for the selection of a particular food. Because fat imparts the textural and mouth-feel

characteristics associated with high palatability, high-fat foods are often chosen.

Can Fat Preference be Changed?

The question of whether our preference for high-fat foods is innate or learned is of great importance. If it is learned, it can presumably be more easily altered than if it is innate. It is believed that the preference for sweet taste, for example, is innate. A preference for sweetness was useful in identifying foods that were safe to eat, and may have aided survival for our nomadic ancestors. It follows that an innate preference for fat may have also been adaptive for survival: consumption of a dense, easily stored energy source would provide an energy reserve for periods of scarcity. Unfortunately, if humans did acquire adaptations that favored high fat consumption, these adaptations have become maladaptive in today's society, which is characterized by an abundance of fatty food and opportunities to consume energy above our metabolic needs.

There is some evidence in favor of an innate fat preference. Children generally display preferences for high-fat foods. In experiments with high- and low-fat yogurt shakes, however, it was found that preferences for new foods high in fat content can be learned, and that conditioning of these preferences is the result of the postingestive consequences of consumption. It has been contended that Pavlovian or associative conditioning is central to the acquisition of food preferences. Because high-fat foods are palatable and satisfying, which are positive consequences of consumption, children may learn to like these foods. Such foods are also often used as treats or rewards for children, which may magnify this preference.

Animal studies suggest that, at least in rats, fat may be preferred at an early age. Appetite for fat was measured in 12–15-day-old infant rats. Intake of an oil emulsion solution was nearly as high as intake of a dilute sucrose solution ($0.03\,\mathrm{mol\,l^{-1}}$) or a milk formulation similar to rats' milk. It was concluded that the taste for fat is acquired at an early age and fat is as pleasant to the pups as sweet solutions and mother's milk.

In humans, however, there is no evidence to support the hypothesis that there is an innate, unlearned preference for fat. Indeed, the possibility of an innate fat preference seems unlikely because the form and function of fat are not unitary across food systems. Furthermore, it has been found that there is no relationship between taste preferences for high-fat foods and childhood (< 10 years)-onset obesity, drawing the conclusion that environmental as opposed to genetic factors may be more salient determinants of taste preferences and food choice.

Variability of Fat Preference

Gender differences While it is mere anecdote that 'Jack Sprat would eat no fat and his wife would eat no lean,' surveys have provided epidemiologic evidence that there are, indeed, sex differences in regard to fat preferences. Although both men and women seem to find high-fat foods highly palatable, men often derive the bulk of their dietary fat from meat, especially red meat, while women derive the bulk of their fat intake from margarine, whole milk, shortening, and mayonnaise, and are more likely than men to express preferences for sweet/fat desserts like cake and icecream. Such sex differences exist among obese individuals as well. The favorite foods of obese men and women were surveyed and it was found that obese men cited predominantly fat-protein foods (meat dishes) among their favorites, whereas obese women listed more carbohydrate/fat sources and more sweet-fat foods (doughnuts, cake, cookies, and chocolate).

Obese/lean differences A possible mechanism for obesity is that obese persons may have an enhanced preference for high-fat foods, leading to overconsumption of energy-dense foods. In sensory tests, obese individuals do, indeed, show a preference for higher levels of fat in foods than lean individuals. Several investigators have found that body weight is related to preferences for fat. It was found that obese and formerly obese individuals preferred higher levels of fat in mixtures of dairy products and sugar than did lean individuals. However, in a later study, Drewnowski found that only the subset of obese individuals with a history of large weight fluctuations showed an enhanced fat preference. Even among normal-weight individuals, there is a positive relationship between sensory preferences for fat in a variety of foods and percent body fat. As body fat increases, the percent of energy derived from fat increases. In one 3-year longitudinal study, high weight gain was associated with high fat intake in both men and women. In all, this work suggests that enhanced preferences for fat could be important in the development and maintenance of obesity; however, no controlled, laboratory-based experiment has studied this issue directly. Further research is needed to understand how individual differences in preference for dietary fat influence human food intake and body composition.

Fat Replacers and Fat Preference

There is a theoretical concern about the use of fat replacers, especially products like sucrose polyester (SPE), that mimic the properties of fat so closely, that they may reinforce and maintain the preference for fatty foods. It can be argued that the most

effective strategy for fat reduction is to decrease the preference for high levels of dietary fat. The effects of two different reduced-fat diets have been studied: one allow the use of fat replacers and one which did not, and the effects on the preference for a limited range of high-fat foods were noted. This study found that the group which was given low-fat foods without fat replacers (no fatty sensory qualities) showed a decrease in the preferred level of fat in foods, whereas the group using fat replacers showed no such shift. It was concluded that the preference for fat in foods is governed more by exposure to fatty flavors than by the actual level of fat in foods. It was further suggested that the preference for fat can be lowered, and that the best strategy for lowering fat preference is, therefore, to avoid foods with fat replacers. Because of methodological limitations, however, firm conclusions cannot be drawn from this research. First, hedonic measures were obtained on only four foods. Since fat imparts so many different sensory properties to foods, it appears unlikely that changes in preferences for fat in one type of food will generalize to other types of foods. Second, because subjects consumed products at home, there was little control over the experimental setting. Finally, data were obtained from self-reported diet records, with scant checks for compliance.

A recent study measured participants' sensory ratings to foods with various levels of fat while they were consuming diets that varied in overall fat content: 37, 30, and 26% energy from fat. Participants rated their sensitivity to and liking for fat in several foods at baseline, after each 8-week diet period, and at the end of the entire study. They found no differences in liking of foods as a function of fat level of the overall diet. Thus, exposure to a low-fat diet for an extended period did not diminish fat preference, and exposure to a higher-fat diet did not increase fat preference. In this study, however, the low-fat diets did not use fat-replaced foods exclusively. Thus, although the hypothesis that exposure to fat-replaced foods may maintain a fat preference may have merit, further research is needed to investigate this issue fully.

Energy density Metabolism of dietary fat yields approximately 9 kcal g, more than twice the yield of 4 kcal g for carbohydrate or protein. There is evidence that people tend to eat a consistent weight of food. Given this, the relatively high energy density of fat would be an important factor in its overconsumption. For example, 50 g of potato chips (which typically derive 60% of their energy from fat) provides 269 kcal of energy, while an equal weight of pretzels (which typically derive about 8% of their energy from fat or less) provides only 187 kcal. This effect was tested experimentally in a serving of a milk-based preload that had varying amounts of water added to change the volume (300, 450, and 600 ml), while macronutrient and energy content and palatability were held constant. The resulting drinks differed solely in the density of the provided nutrients and energy. The results showed that the energy density of these milk-drink preloads affected energy intake at lunch 30 min later, such that intake was significantly lower (by 18%) after the high-volume, low-energy-density drink than after the low-volume, high-energy-density drink. Further, this energy deficit was not compensated for at the dinner meal. Thus, consuming more energy-dense, higher-fat foods may easily lead to higher daily energy intakes than eating foods that are low in fat and less energy-dense.

Fat and satiety It has been proposed that fat may be overeaten because it does not satisfy hunger as well as other macronutrients. Ingested fat may differ from ingested carbohydrate and protein in how it affects such factors as stomach distention, stomach emptying, nutrient absorption, hormonal release, and/or oxidation of nutrients. Indeed, fat and carbohydrate have very different postingestive dispositions. In experiments that measured postabsorptive metabolism, dietary fat was shown to be metabolized much more slowly than carbohydrate or protein. Carbohydrate ingestion produces rapid rises in blood glucose, while fat ingestion often depresses blood glucose. The 'glucostatic theory,' which suggests that the sensation of hunger is maintained until blood glucose levels reach adequate levels, would posit that carbohydrates produce more rapid satiety than fats. Opponents of the glucostatic theory argue that there are other, more important factors influencing satiety, including the release of 'satiety hormones.'

One such putative satiety hormone is cholecystokinin (CCK). CCK is particularly released when amino acids and/or some types of fat enter the small intestine. Thus, the ingestion of fat could lead to early satiety despite having less of an effect on blood glucose than carbohydrates. Because of these differing physiological effects, it is difficult to make any definitive statements regarding the satiety value of fat versus carbohydrate. However, data from controlled-laboratory feeding studies suggest that, for some people, carbohydrate may be more satiating. One group reviewed various studies that utilized a preloading model (giving fixed amounts of macronutrients and assessing the effects on subsequent satiety/hunger and food intake) to detect any differences in the satiety value of fat versus carbohydrate. They concluded that carbohydrate seems to have greater

satiety value than fat in individuals with certain subject characteristics (e.g., obese and those concerned with their body weight). Overall, however, there is little evidence that carbohydrate is more satiating than fat, and additional research is needed to determine if overconsumption of fat is related to a physiological insensitivity to the amount of fat in food or other factors.

Types of Fat Replacers

The National Heart, Lung, and Blood Institute of the National Institutes of Health recommends that the food industry accelerate its efforts to develop and market foods reduced in total fat, saturated fat, and cholesterol content. The food industry response has been vigorous. Recent advances in food science and technology have led to the development of reduced-energy and energy-free, fat-like substances. The use of these substances in foodstuffs provides consumers with new options for highly palatable, lower-energy, low-fat products. The American Dietetic Association (ADA) favors the use of these products for consumers seeking to reduce dietary fat intake and perhaps body weight. The ADA's 1991 position paper on fat replacements states: 'the ADA recognizes the innovative development and use of traditional food ingredients and processing methods to reduce or replace fat in foods'.

Fat replacers comprise a diverse range of chemical and processing sources; they possess varied sensory, functional, and physiologic properties. Some of the currently used and newly developed fat replacers are described below. Table 1 provides a summary of the replacers and their characteristics.

Carbohydrate- and Protein-Based Fat Replacers

Several carbohydrate- and protein-based materials are presently in use. These substances generally add bulk, viscosity, or structure to a food by stabilizing water into a gel-like structure. In contrast, microparticulated protein mainly provides a textural continuity (often associated with fat). Because it consists of particles so small that the units are undetectable by oral sensory systems, microparticulated protein gives the illusion of a creamy, smooth texture. Protein-based fat replacers can also provide bulk and viscosity characteristics similar to carbohydrate fat replacers and can supply added functionality to food systems, including opacity and emulsification. These products are partially or fully digestible and provide between 1 and 4 kcal g.

Unfortunately, protein- and carbohydrate-based materials are very limited in their functional usage in general fat replacement. Both types of fat replacers can only be used in a few categories of food (e.g., dairy products, dressings, spreads, cold applications, and some meat products); further, some are not well-suited for baking application, cannot be used to fry foods, and have a limited shelf-life due to high water content. Most of the carbohydrate- and protein-based fat replacers cannot be used for the development of lipid-associated flavors or flavor modification in foods; microparticulated protein-based fat replacers, in contrast, do have a clean flavor base and good flavor-release qualities. Studies indicate that protein- and carbohydrate-based replacers pose little or no toxicological risk when used in the moderate quantities proposed.

Lipid-Based Fat Replacers

One lipid-based fat replacer is currently being marketed (olestra or Olean) and others are under development. Lipid-based fat substitutes have the advantage of having similar functional and sensory properties to the fats they replace. Thus, the potential applications, in contrast to carbohydrate- or protein-based substances, include most or all areas where fat and oils are presently used.

SPE or olestra, its generic name, is a fat-like material compound of hexa-, hepta-, and octa-esters of sucrose and long-chain fatty acids. Its physical properties are nearly identical to those of conventional dietary fats. Because of the molecular bonds in SPE, it cannot be hydrolyzed by pancreatic lipases, and the large molecule, consequently, cannot be absorbed through the intestinal mucosa. Because SPE is not digested or absorbed, it passes through the gastrointestinal tract intact and is excreted in the feces, adding no energy to the diet.

Caprenin, another lipid-based fat substitute, consisting of a glycerol molecule esterified with caprilyc, capric, and behenic acids, was developed for use in chocolate. Unlike SPE, the glycerol-based molecule is hydrolyzable by pancreatic enzymes, but provides only 5 kcal g (instead of the 9 kcal g of triglyceride) due to the poor absorption of behenic acid. Other low-calorie fat replacers include Salatrim (5 kcal g) and Aldo MCT, Captex, and Neobee (8.3 kcal g). Other lipid-based fat replacers include partially and poorly digested organic compounds. A list of such fat replacers can be found in Table 1.

Other Fat Replacers

Polyglycerol esters form an intermediate category between lipid-based and nonlipid-based fat replacers. The functional metabolic properties of polyglycerol esters range between carbohydrate- and lipid-based fat replacers, depending on their level of esterification. Polyglycerols may be partially or wholly

Table 1 Types of fat replacers

	Composition	*Chemical name/process (if any)*	*Trade name/company*	*Applications*
Carbohydrate-based				
Starch-based	Modified starch		Amalean Leanbind N-Lite PureGel Sta-Slim	Cheesecake, pourable salad dressings, sauces, cream fillings, dips, spreads, bakery, dairy products, meat and poultry products, icecream, yogurt
	Maltodextrin		C*Pure CrystaLean Lycadex Maltrin Novelose	Extruded products, bakery products, dressings, sauces, spreads, frozen desserts, toppings, cakes, buttercream and fillings, snacks
	Hydrolyzed flours	Enzymatically and acid-hydrolyzed flour	Quaker Oatrim Rice-gel Rice-trin	Processed meats, bakery, prepared foods, baby foods, sauces, cheese spreads, cream cheese
Fiber-based	Celluloses and hemicelluloses		Avicel Ac-815 Cellulon Ex-cel Fibrex Just Fibre	Mayonnaise, salad dressings, butter substitutes, cheeses, sour cream substitutes, spreads, bakery products
	Fructose polymers	Inulin	Raftiline Fibruline	Icecream, cheese spreads, chocolate, dressings, meat
	Gums	Gellan gum Xanthan gum Acacia gum Guar gum	Kelcogel range Ketrol range Gelamix Rhodigel Spraygum Procol range Supercol F	Margarines, spreads, cakes, cookies, dips, frozen desserts, salad dressings, sauces, gravies, instant products, soups, toppings, canned foods, frozen foods
	Gels	Carrageenan	Aquagel BenGel Liangels	Bakery products, beverages, sauces, confectinery, dairy products, salad dressings, meat products

Protein-based				
	Whey protein		Dairy-Lo Dairylight Nutrilac Simplesse Trailblazer	Frozen desserts, dairy products, baked goods, salad dressings, spreads, sauces, toppings, frosting
	Soy protein		Soy protein Concentrate Supro range	Meat and dairy products, patties, hamburgers, frankfurters, cream cheese
	Milk protein		Complete Milk Protein Lactalbumin Lactomil Miprodan	Yogurt and cultured products, dressings, mayonnaise, sauces, dips
	Microparticulated zein protein (from corn gluten)		Lita	Frozen desserts, mayonnaise, sour cream, salad dressing, whipped topping, milk, yogurt, confectionery and chocolate
Lipid-based				
	Low-calorie fats	Medium-and long-chain triglyceride molecules	Aldo MCT Caprenin Captex Neobee M-5 MCT Oil Salatrim	Chocolate, chocolate coatings, confectionery products, replacement for liquid vegetable oils in products
	Synthetic fats	Sucrose polyester	Olestra	Cooking and frying utilities.
			Colestra	Currently only approved for use in savory snack foods
		Other esters	Alkyl glycoside fatty acid polyesters Carboxy/carboxylate esters Dialkyl dihexadedecyma lonate (fatty acid ester) Polyhydroxyl esters	Baked goods, chocolate flavored products, frozen deserts, margarine, meats, salad dressings, snack foods

digestible, but are generally used in low concentrations relative to the quantity of fat they replace as part of an aqueous emulsion.

Low-Fat Diet Research

Fat replacers are a relatively recent development in the field of studying dietary fat intake. Thus, much of the research regarding dietary fat intake predates the development of many fat replacers. This section reviews research involving manipulations of dietary fat intake with and without fat replacers. Some studies have reduced the fat content of the diet by using foods naturally or intrinsically low in fat (fruits, vegetables, and grains). Others have used specific fat-replaced foods available at the time of study or a combination of naturally low-fat foods and fat-replaced foods. The following studies will serve to illustrate the effects of reducing the fat content of the diet on both energy and fat intake.

Short-Term Dietary Fat Manipulation

A number of studies have investigated the effects of manipulating the fat content in certain meals on energy intake on a short-term basis (≤ 5 days). One such study manipulated the energy and fat content of a midday meal for 5 days by using intrinsically low-fat foods, as well as some commercially available reduced-fat foods. They found that both men and women compensated for energy dilutions in the diet. Interestingly, compensation for excess of energy intake was weaker, especially when the additional energy was derived from dietary fat. Unfortunately, the data for fat intake were obtained via diet records, and such data must be interpreted cautiously due to the potential errors and biases inherent in self-reported measures. However, similar results were obtained in a well-controlled residential laboratory study that manipulated the carbohydrate and fat content of certain meals. Participants (lean males) compensated well and quickly for the caloric dilution in this study, but when the energy level was again raised to baseline levels, participants did not compensate and consequently overate. In a subsequent residential study that studied the affect of altering fat and carbohydrate content of a lunch meal using four conditions (high-fat, high-carbohydrate, low-fat, low-carbohydrate; with 3 days per condition), energy compensation was observed regardless of macronutrient composition (mean daily energy intakes: 2824, 2988, 2700, and 2890 kcal respectively). However, energy intake from dietary fat was fairly constant in all conditions except the high-fat condition, which resulted in significantly greater energy intake than the other three conditions. These studies suggest that decreasing the fat (and thus the energy) content of the diet will result in compensation for energy in subsequent meals or snacks, but not for fat. Furthermore, there is some evidence that when additional fat is included in the diet, it is unlikely that a spontaneous reduction in energy and fat intake will occur to compensate for this surfeit. It is important to note that these findings are dependent on both the magnitude of the manipulation (amount of fat/energy reduction) and the characteristics of the study participants (e.g., lean/obese, restrained (concerned about body weight)/unrestrained (not concerned about body weight)).

Longer-Term Manipulations

The studies discussed above manipulated fat intake within specific meals or over the course of a day. This type of intervention provides useful information about short-term regulation of fat and energy intake when dilutions and surfeits are encountered in specific meals or snacks, but they provide no information about long-term regulation of fat and energy intake or the ability to maintain compliance with a low-fat diet. In contrast, a few naturalistic studies have examined the effects of reducing intake of dietary fat in certain groups over a longer timeframe. These studies utilized various strategies, including nutritional counseling, behavioral therapy, and financial incentives, to aid subjects in reducing their dietary fat consumption. These studies generally found that the intervention groups did consume less dietary fat than control groups. Intervention periods in these studies ranged from 12 to 20 weeks. These studies suggest that compliance with a low-fat diet can be maintained over at least this moderate amount of time. There are few data, however, regarding longer-term compliance with a low-fat diet. One group of researchers followed 303 women participating in the Women's Health Trial for 1 and 2 years. These women either received no specific intervention or intensive instruction in maintaining a low-fat diet by such means as reducing cooking fats, substituting low- or no-fat variants of high-fat foods and increasing traditional low-fat foods in the diet. After 1 year, the intervention group had reduced their dietary fat intake by 45% of their baseline intake and energy intake by 59%. Most of the reduction occurred within the first 6 months of the intervention and was maintained at 1- and 2-year follow-up. Results of naturalistic studies such as these are often used as a basis for advocating low-fat diets and that compliance to low-fat diets can be maintained over time. However, although these studies may have validity, they relied heavily on self-report (diet records or food-frequency questionnaires) as a source of data on fat intake, and should be interpreted cautiously.

Laboratory-based experiments provide more accurate intake measurements and stringent controls over the experimental setting. Three controlled laboratory studies have investigated the effects of high- and low-fat diets on energy intake and body weight over varying periods of time. The first study allowed lean and obese participants to consume a low-energy-density diet comprised of intrinsically low-fat foods (fruits, vegetables, and whole grains) or a high-energy density diet ad libitum for 5 days (0.7 vs 1.5 kcal g). Both obese and nonobese groups significantly reduced their energy consumption on the low-energy diet. Nearly twice as many calories were consumed during the high-energy-density diet compared to the low-energy-density diet (3000 vs 1570 kcal day). Weight change data were not reported.

Two other studies, both conducted at Cornell, are often cited in both scientific and popular literature as proof that ad libitum consumption of low-fat foods can reduce fat intake and produce weight loss. The low-fat diets in these two studies included fat-replaced foods (a limited selection of margarines, salad dressings, and mayonnaises available at the time the studies were conducted) as well as intrinsically low-fat foods. In the first of these studies, all food (meals and snacks) was provided for 24 women divided into two groups: < 101% ideal body weight (IBW) and > 101% IBW. Each participant was fed three diets (in a counterbalanced order): low-fat 15–20%, medium-fat 30–35%, and high-fat 45–50% of energy. Participants could eat the foods ad libitum. Each diet was fed for 14 days with a 7-day washout between test periods. Energy consumption was found to be positively correlated with the level of dietary fat: total daily energy consumed on the low-fat diet averaged 2087, the medium-fat diet 2352, and the high-fat diet 2614 kcal. Over the 2-week intervention periods, the diets did not produce any statistically significant weight changes.

The second Cornell study was similar, but extended the intervention period to 11 weeks. It is unclear whether normal-weight or obese women were studied: although a mean subject height is reported, no mean weight is reported, though it is noted that individuals < 101% of IBW (according to Metropolitan Life standards) were excluded. This study examined two diets: one was comprised of 20–25% energy from fat (low-fat) and the other, 35–40% energy from fat (control). Again, the women were allowed free access to foods. It was found that participants consumed an average of 286 fewer kcal day on the low-fat diet. In contrast to other Cornell study, these participants did lose weight on both diets (low-fat: − 2.54 kg and control: −1.26 kg). There were no reasons given by the authors for the weight loss on the control diet.

A longer-term animal study examined the impact of replacing fat using a carbohydrate-derived fat replacer on three groups of 20 female Sprague-Dawley rats. The rats were chronically fed either a high-fat diet (45% energy from fat) or a low-fat diet (25% energy from fat) containing either no added fat replacer (control diet) or the maltodextrin, Paselli. The three diets differed in texture. Rats were fed the control diet for 10 days, and were then divided into three groups, receiving one of the three diets for 42 days. Preference tests for the three diets were assessed before and after the 42-day period. It was found that all but two of the rats preferred the diet with the fat replacer over the high-fat and control diets, and that food intake was the greatest in the group fed the fat-replacer diet (741 g per 58 days = control, 736 g per 58 days = high-fat, 900 g per 58 days = fat replacer). However, energy intake was greatest in the group fed the high-fat diet (3250 kcal per 58 days = control, 3871 kcal per 58 days = high-fat, 3585 kcal per 58 days = fat mimetic). The higher energy intakes of the high-fat and fat replacer-fed animals resulted in greater weight gain during the experimental period compared with control rats, largely due to an increase in fat mass. These data suggest that the inclusion of highly preferred, fat-replaced foods in the diet may result in a reduction in fat intake, but consumption of such foods is not associated with reductions in energy intake.

Overall, the evidence from the human studies presented here indicates that low-fat diets are potentially useful for reducing both total energy intake and the amount of fat consumed. While these early results have some validity, their interpretation is often oversimplified. It is important to recognize that the methods available to assess the effects of low-fat diets have limitations that may influence outcome. Participants in the three laboratory-based studies reviewed above allowed subjects to consume food ad libitum during the dietary interventions; however, this access was limited to the particular fat-level that was under study. Thus, during a low-fat condition, the subjects could only choose from low-fat foods, while in the high-fat condition, only high-fat choices were available. Although the subjects rated the high- and low-fat diets equally palatable, this does not mean that, given a choice, they would voluntarily eat the low-fat foods, making it difficult to determine if the findings are applicable to free-living individuals. As demonstrated in the animal study described above, even when restricted to a highly palatable low-fat diet, overall energy intake may not be reduced.

Labeling Effects of 'Low fat'

A further limitation of these initial studies is that they did not provide participants with any information (nutritional or otherwise) about the foods that they were eating. Food products labeled with claims such as 'lite,' 'reduced-fat,' and 'fat-free' send powerful messages to the consumer. The results of the low-fat diet studies cited above might be different for individuals who are aware of whether their diet is low or high in fat or who knowingly choose to substitute a low-fat food for a high-fat food outside an experiment. A few studies have examined the impact of such information on subsequent food intake. It was found that intake at a self-selection meal was higher following a yogurt preload labeled 'low-fat' than following equicaloric yogurt preloads labeled 'high-fat.' Another study fed 96 men and women a snack of potato chips made with olestra or triglyceride every afternoon for 2 weeks in a counterbalanced order. Half of the participants were given full nutrition labels about the potato chips and the other half were given bags that simply said 'potato chips.' Interestingly, in the group that received no nutrition information about the chips, all participants ate the olestra and the triglyceride potato chips in similar quantities. In the group that received information, a subset of the participants, those who are very concerned about their body weight and tried to control their food intake (as measured by the Three Factor Eating Questionnaire), consumed significantly more olestra potato chips (60 ± 7 g) than regular potato chips (50 ± 17 g). Other subgroups (obese/normal weight; male/female) did not eat the chips in different quantities. Results from these studies indicate that information about fat (and energy) content can influence intake of the low-fat food itself or of food eaten subsequently. It is apparent that cognitive processes can override or interact with physiological processes in regard to food intake and, therefore, play an important role in energy balance. It may be those who are the most restrictive in their dietary choices who may be at most risk for overconsuming fat-free and reduced-fat foods.

Cognitive processes may also be involved in the phenomenon of food intake being controlled by weight or volume rather than by its energy content. In other words, individuals may control how much they eat by setting a 'standard portion size' of food consumed rather than a 'standard energy amount.' As discussed previously, it is likely that it is the low-energy density of the diets provided in these low-fat diet studies and not a physiological satiety mechanism that accounts, at least in part, for the differences in the amount of energy consumed. In each of these studies, subjects ate similar gram weights of food on both low-fat and high-fat diets. It is likely that subjects are eating a 'standard' weight or volume rather than specifically responding to the covert energy manipulation. Thus, a diet of low energy density consumed in equal amounts to a higher-density diet would provide less energy. Fat-replaced foods may have their greatest impact on fat and energy intake by simply reducing the energy density of the foods we consume.

There is evidence that energy intake may be more a function of the energy density of the diet than the actual fat content. Three studies have found that energy intake is constant despite variations in fat content when the energy density of the diet is held constant. Given this robust effect, a group of researchers investigated the effects of varying the energy density of the diet while holding fat content constant. This manipulation was achieved primarily by altering the water content of foods. The researchers then fed normal-weight women all of their meals in a laboratory setting over three 2-day periods using three levels of energy density in provided entrées (low $= 1.03\,\mathrm{kcal\,g^{-1}}$; medium $= 1.17\,\mathrm{kcal\,g^{-1}}$; and high $= 1.34\,\mathrm{kcal\,g^{-1}}$). The women, like participants in the earlier studies, ate a constant weight of food across the dietary conditions, resulting in a 30% decrease in energy intake in the low-energy-density condition compared to the high-energy density condition; however, there were no corresponding changes in ratings of hunger and fullness. These results provide clear evidence that alteration in energy density of food can affect energy intake. Similar studies need to be done to investigate the effect of using foods made with fat replacers to reduce energy density instead of water.

If fat-replaced foods are consumed in much greater quantities than their high-fat counterparts, however, this net energy reduction will be nullified. The belief that one can consume an unrestricted amount of low- or no-fat food and still expect to bring about desirable dietary change and/or weight loss or maintenance is not supported by the animal or human literature. For example, Sprague-Dawley rats were fed high-fat (41% energy from fat) or fat-free (0% energy from fat) pound cakes in addition to chow for 30 days. The fat-free pound cake was prepared with nonfat milk and egg whites, and used modified cornstarch, xanthan gum, and guar gum to simulate the orosensory properties of fat. Rats fed the high-fat cake and chow consumed more energy ($P < 0.05$) and gained more weight ($P < 0.05$) than did rats fed fat-free cake and chow. The rats fed the fat-free cake, however, overate and gained more weight than did the chow-only controls. The authors concluded that removing

the fat from the cake reduced, but did not eliminate, its obesity-promoting effects, and that low-fat diets have to be consumed in moderation if used for weight control purposes.

To examine the question of whether isolated reduction of fat with no other dietary restriction leads to weight loss in humans, the effects of a low-fat diet consumed ad libitum were compared with a low-fat diet with caloric restriction. It was found that participants on the calorically restricted, low-fat diet lost significantly more weight and reduced fat intake to a greater extent than those on the low-fat diet consumed ad libitum. Hence, advocating that an individual can eat as much as he/she desires and lose weight as long as the food is low in fat content is unwarranted based on these data. For maximum weight control, total energy intake must also be restricted below energy needs.

Another important question is whether varying the fat content, while keeping energy equal, of an energy-restricted diet enhances weight loss. This question was addressed by an animal study. It was found that when rats previously maintained on a high-fat diet (40% of energy) were switched to equicaloric diets (75% of their previous ad libitum intake) that varied in fat content (12, 28, or 45% fat), rats fed the 12% fat diet lost significantly more body fat than the rats fed the 45% fat diet. These results indicate that, at least in rats, an energy-restricted diet produces greater weight loss when it is also low in fat. Although similar data are not available for humans, if weight loss is the goal, it is reasonable to recommend restriction of both dietary fat and overall energy intake to achieve the maximum benefit. Thus, reduced-fat foods will enhance weight loss if an individual who is consuming greater than 30% of energy from fat restricts food choices to those low in fat but not high in energy, while keeping the volume of food consumed constant.

Fat-Replaced Foods and Disease Risk

Although the usefulness of fat-replaced foods for energy reduction and weight loss requires further investigation, it is reasonable that reductions in dietary fat may be helpful in reducing the risk of diseases associated with high fat intake, such as cardiovascular disease and type 2 diabetes. In a recent study, 30 men and women (15 of whom had diabetes) were supplied with five low-fat or fat-free products or their regular fat counterparts and asked to consume them as part of their regular diet in a free-living, free-choice setting for 3 days. No difference was found in usage of the fat-modified foods between people with or without diabetes. Participants consumed the fat-replaced foods in similar quantities to the full-fat counterparts, which resulted in a significant reduction in overall fat (g) intake, but total energy intake was not different between the fat-modified and the full-fat conditions. Cholesterol and saturated fat intake were also significantly lower in the low-fat condition than in the full-fat condition. It has been shown that foods made with fat replacers were less acceptable than foods made with sugar replacers among participants diagnosed with diabetes. Foods made with olestra were less acceptable still than foods made with fat replacers in general. In a recent survey, it was found that knowledge about fat replacers, fat-replaced foods, and general nutrition was poor among individuals with type 2 diabetes. Respondents were much more familiar with sugar replacers than fat replacers. Thus, despite evidence that inclusion of fat-replaced foods may be helpful for people with diagnoses such as type 2 diabetes, knowledge about and acceptance of such foods are low.

Noncaloric, Lipid-Based Fat Substitute Research

Because noncaloric, lipid-based fat substitutes have the greatest potential range of applications as fat replacers, it is important to review the current research on the effects of consuming these materials on food intake and body composition. At this time, only olestra (Olean) is approved for use by the Food and Drug Administration in the USA. Olestra's approval is limited to applications in savory snacks.

Animal studies comparing varying levels of fat and SPE have demonstrated that the higher the percentage of energy from fat in the diet, the greater the fat intake and, in some cases, the body weight. For example, in one study mature female Sprague-Dawley rats were fed five diets that varied in fat content: control diet (21%), low-fat diet (2%), high-fat diet (63%), and two medium-fat diets (30% and 51%) fat. The rats compensated for the low-fat diet compared to the control diet by increasing food intake, resulting in no difference in overall energy intake. However, when the control diet was replaced with the high-fat diet, the rats became obese and hyperinsulinemic. When rats fed the high-fat diet were switched to the medium-fat diets, they also increased food intake to compensate for the energy reduction. These rats were more obese than control rats, but less obese than the rats fed the high-fat diet, suggesting that a modest reduction in dietary fat content can attenuate fat's obesity-promoting effects. In another animal study, the effect of SPE replacement was examined on the body weights of lean and obese Zucker rats by

feeding 8-week-old lean and obese animals either a control diet (15% corn oil) or an SPE diet (5% corn oil and 10% SPE). The obese, control-fed animals gained more weight than the animals fed the SPE diet, while the lean rats given the fat substitute did not have significantly different body weights compared to the lean controls. It was concluded that the obese rats could not defend their higher weights when the fat content of their diet was diluted using SPE.

The first controlled study using sucrose polyester in humans was conducted in 1982. The effect of using SPE in hypocaloric diets for obese persons seeking weight loss was investigated. The effects of SPE and a hypocaloric diet were studied in a counterbalanced, crossover design over two 20-day periods. Participants also had access to non-SPE-modified snacks in the evening, which provided an opportunity for subjects to compensate for the calorie/fat dilution. Participants showed weak compensation for the missing calories, resulting in a significant overall reduction in energy intake ($P < 0.05$) and fat intake ($P < 0.05$). However, a potential confounding factor exists because subjects were actively trying to lose weight in this study, which may have reduced their likelihood of consuming snacks. Thus, this study does not provide an adequate design to assess energy/fat compensation.

In another study the fat content of the diet of five obese men confined to a metabolic ward for 36 days was diluted by replacing the fat in margarine and mayonnaise with SPE. Energy intake was measured during three periods: preintervention baseline (days 1–9), intervention (days 10–28), and postintervention baseline (days 29–36). During the intervention period, the manipulation created a 10% reduction of overall energy of the diet. Participants increased the amount of food consumed during the SPE period relative to the pre- and postintervention baselines so that there was no significant effect of diet on energy intake (baseline = 3924 kcal day^{-1} and SPE=3812 kcal day^{-1}). Participants did not selectively ingest more fat, but rather increased their intake of all three macronutrients to compensate for the energy dilution created subsequent to the addition of the SPE.

Parallel studies in the USA and the UK were the first to study the effect of olestra in lean individuals. Twenty-four healthy, lean males participated in each trial that investigated a SPE manipulation in a breakfast meal (biscuits/scones and margarine). Subjects were fed the three breakfasts (control = 765 kcal, 20 g SPE = 582 kcal, and 36 g SPE = 445 kcal) in a counterbalanced, crossover design followed by self-selected lunch and dinner meals. Subjects also recorded any evening snacks to account for 24-hr energy intake. Despite geographical differences, similar results were obtained in both studies. The lean men compensated well when the breakfast was reduced in energy and fat due to SPE replacement, but there was very little fat-specific compensation. The end result was a significant ($P < 0.0034$ and $P < 0.0066$) reduction in fat consumption in the 20 g and 36 g SPE substitution, respectively, compared to placebo.

Children also appear to compensate well for energy deficits, but not for fat specifically. In one study (Birch *et al*., 1993), the intakes of 29 normally developing 2–5-year olds were measured during 2 days per week over 5 weeks. Approximately 14 g of SPE was substituted for fat (− 125 kcal) in the children's diet over the course of the morning and afternoon. By the end of the first day, the children had compensated for some of the energy dilution and by the end of the second day they had compensated for all but 24 of 125 kcal. Like the adult men, children did not show macronutrient-specific compensation. Instead, the manipulation produced a reduction in the percentage of fat consumed without a reduction in total energy of the diet because the children increased their intake from carbohydrate sources.

In other studies, neither fat nor energy compensation was detected when SPE was incorporated into foods. In one study 47 g of SPE was incorporated into meals and snacks across a day (creating a diet which derived 20% of energy from fat). This manipulation represents a more severe reduction in the amount of fat replaced by SPE than in previous studies. The results were that this level of fat/energy reduction was not compensated for during the day that SPE-replaced foods were provided, and only partial (74%) energy compensation occurred the following day. Incomplete fat/energy compensation was also seen in two studies from the Netherlands. The first incorporated SPE into croissants and found incomplete short-term energy compensation so that daily energy intake was reduced. This group also found that energy was not fully compensated for in a study which used SPE to replace fat in warm meals over a longer term (12 days). However, these studies used control meals that were actually higher in fat content and energy content than the typical Dutch meal, as either triglyceride oil or SPE oil was simply added to dishes. This resulted in a 'surfeit' of fat and energy in the control condition, while the SPE condition matched more closely the fat and energy content of the typical Dutch meal. Given this and other methodological issues, firm conclusions on energy compensation cannot be based on these data.

Overall, therefore, the efficacy of using foods prepared with SPE to reduce fat and/or energy intake is

equivocal. The existing evidence from the relatively few studies that have been published suggests that SPE incorporation into foods may aid in reducing the amount of fat consumed. The evidence is, however, less clear regarding SPE's efficacy in reducing total energy intake. Again, it is important to note that all of these studies used covert manipulations: participants were unaware of the fat manipulation. This may or may not be representative of how such products will be consumed in a free-choice, full-knowledge setting. More studies are, therefore, needed to clarify the effects of fat replacers on energy intake.

There has also been considerable focus on possible negative health effects associated with SPE, especially olestra, most notably gastrointestinal (GI) complaints and decreased absorption of fat-soluble vitamins. Since olestra is nonabsorbable and passes through the gut unchanged, it has been anecdotally linked with GI complaints such as diarrhea, bloating, and cramps. However, one study found no difference in prevalence of GI complaints following a single episode of snacking on chips made with triglyceride or chips made with olestra. Unpublished data from the Olestra Post-Marketing Surveillance Study (OPMSS) found only a limited association with one symptom (bloating) among the highest consumers of olestra. In addition, OPMSS data indicate that GI complaints are rarely attributed to fat replacers such as olestra, while most food-related GI problems are attributed to beans, and spicy and diary foods. Further, another study, also using OPMSS data, found that olestra consumption was not associated with changes in serum carotenoids or serum concentrations of other fat-soluble vitamins; however, serum vitamin K was higher in the highest consumers of olestra. This may be due to olestra being fortified with vitamins A, D, E, and K. Thus, according to current measures, olestra does not present a significant risk of GI upset or reduced absorption of fat-soluble vitamins.

Conclusions

In this article, we have examined the available data regarding whether or not reduced-fat foods, especially those made using fat-replacer technology, are useful in reducing the current trend to overconsume dietary fat and energy in western societies. This question is difficult to answer because it is only since the 1980s that dietary fat consumption has been a focus of nutritional research, and many of the advances in fat-replacer technology are of even more recent vintage. What is clear is that foods that taste good are consumed more readily than those that do not. Thus, it is axiomatic that the availability of low- or no-fat foods that are also highly palatable may aid in compliance with low-fat diets that were previously bland and unsatisfying. However, while fat-replaced foods offer consumers new food choices, considering the conflicting data, it should not be assumed that the use of fat-replaced foods will, indeed, result in significant reductions in fat and energy intake.

The research cited in this article supports the notion that fat-replaced foods may aid in reducing dietary fat intake, but perhaps not overall energy intake. Most studies using traditional low-fat foods and currently available fat-replaced foods have resulted in at least partial compensation for energy reductions, but have not resulted in macronutrient-specific (or fat-specific) compensation. Results from SPE studies are equivocal in respect to energy compensation, with some finding energy compensation, while others do not. Better controlled, laboratory-based human studies are needed to estimate just how useful SPE replacement will prove to be in reducing overall fat and energy intake.

Also still unclear is how consumers will use new and existing fat-replaced foods. Will they be used as a one-to-one substitution for foods previously high in dietary fat, or as a license to overeat other rich foods? It may be that the most important predictors of the successful use of fat-replaced products will be the motivation of the consumer to bring about a reduction in his/her intake of dietary fat. More naturalistic studies exploring the potential usage patterns of fat-replaced products are needed to determine their usefulness in bringing about these desired dietary changes, and additional nutrition education regarding fat-replaced foods is necessary among those with diet-modifiable diseases, such as type 2 diabetes, cardiovascular disease, and hypertension.

Because overall energy intake has been shown to be a critical factor in weight loss and weight maintenance, the use of fat-replaced foods alone should not be expected to produce spontaneous improvements in weight management or obesity. Lasting changes in body weight will still be dependent upon long-term behavioral change that includes not only modification of fat intake, but also reductions of overall energy intake, along with an increase in energy expenditure. Because fat is the most energy-dense macronutrient, substituting low-fat foods can substantially reduce the energy density of the diet, provided these foods are also low in energy. If the energy density of the diet is reduced and the volume of intake remains constant, reductions in total energy intake are likely.

These caveats aside, fat-replaced foods, like other modified foods (e.g., with aspartame or saccharin) could aid motivated individuals to reduce their intake of dietary fat and energy. Thus, fat replacers may

prove a useful tool in reducing fat intake, but, as with most novel approaches, more detailed investigations need to be conducted to examine the efficacy of such products in reducing fat intake. Future studies are needed to resolve issues of fat and energy balance using fat-replaced foods, especially those replaced by SPE, and how such foods can be used to alter the energy density of the diet. Results of such studies will have important implications for how fat-replaced foods should be used in the prevention and treatment of obesity and related conditions such as cardiovascular disease and diabetes. Longitudinal studies, both laboratory-based and naturalistic, need to be conducted to determine the best strategies for long-term compliance with a low-fat, low-energy-density diet.

Production of Animal Fats

T J Wertelecki and R K Bodarski, Wroclaw Agricultural University, Wroclaw, Poland

Introduction

All metabolic processes carried out in animal cells depend on exogenous energy sources. The level of anabolic and catabolic processes in plant cells is lower compared with animal cells, especially with organisms of stable temperature. The chemical composition of food for humans and animals are exogenous sources of energy synthesis, which is in contrast to the plant world, where one of the energy sources is solar radiation – the warranty of photosynthesis.

The main energy sources are carbohydrates and fats and occasionally proteins. The highest values of energy content derive from lipids (energy donors); lipids are also an important form of energy store in animals (acceptor energy). Fat (animal fat) has another more important function in organisms: storing metabolic water (endogenous water); as building timber; creating the structure of muscle; and as protection for other organs – kidneys, liver, intestine, and pancreas. The main function of lipids in organisms is thermostability. Lipids are often connected with lipophil vitamins: A, D, E, and K. Lipids are an important source of essential and important fatty acids. As animal fat is vital it is suggested that is impossible to eliminate fat (animal fat) from the human diet and especially from that of animal.

Evolution of Human and Animal Production

The evolution of the species *Homo sapiens* was connected with the animal world. In the earliest times human beings were hunters, who trapped animals for food – meat (protein and fat) and skin were of the greatest value. From the beginning of hunting, humans began a new era of human nutrition (with animal products on the menu). Later on humans bred animals and so could use animal produce without hunting: animals were domesticated in Asia nearly 10 000 years ago and in Europe 5000 years ago. From this time humans started to carry out breeding programs with animals. Initially breeding animals was uncharted territory but as civilization evolved, it was based on developing sciences. The underlying aim was to increase production value of domestic animals, but at first civilization developed faster than animal production. The principles and aims of breeding focused on one thing only: more animal products – meat, milk, eggs. At that point the quality of the product was not an issue, because there was always a lack of energy and protein.

The revolution in the ideas behind animal breeding started with the development of human food sciences. A wider knowledge of human nutrition created new expectations for animal products, especially as far as quality was concerned. The top priority was animal protein as a source of amino acids (exogenous) for the human diet. The production of animal protein in meat, milk, and eggs increased over time and correlated with this an increase in production of animal fat. This fat was concentrated in tissue, which is impossible to eliminate in an organism. At the same time, opinions on the harmful effect of animal fat on human health were proposed by respected academics, and the lipid theory of coronary heart disease was expounded. This opinion changed the culture of human nutrition towards a decreased use of animal fat and increased use of plant oils. For example, in the USA consumption of animal fat was reduced by about 21%, over a 30-year period, and in developing countries over a similar period (correlated with a marked lack of protein-energy balance in the diet) the consumption of animal fat increased by about 80%! This situation created a negative balance between production and consumption of animal fat. In developing

countries now there is substantial overproduction of animal fat (with regard to the high breeding value of domestic animals) (Table 1).

The development of food sciences and chemical analysis has shown that consumption of animal fat is beneficial for human health: oily fish, modified concentrate and ratio of fatty acids in meat, and eggs. This opinion has suggested the possibility of the changed value of animal fat preferred by human food direction.

The Process of Lipid Synthesis in Animal Organisms

The main function of fat in animal organisms is as an energy-building store. The animal organism accumulates energy in glycogen stored in muscles and liver, but it is only 1% of energy used. The main sources of endogenous energy are accumulated in fatty acids which create fat tissue. The synthesis of endogenous animal fat could be conducted metabolically from carbohydrates, feed fat, and proteins. Part of this endogenous fat is synthesized in a simple way by absorbing and building in organs fat form without transforming it from feed fat. The main precursor of the fat synthesis process is coenzyme A (Co-A), which is created by the chemical conversion of carbohydrates and exogenous lipids.

Fat synthesis is an important chemical process which guarantees the stabilization of the organism. The main organ of lipid synthesis or degradation is the liver. The liver is a many-sided organ which is useful for energy and the process of metabolism. There are between 800 and 2000 mitochondria in a cell of the liver. Lipid synthesis in animal cells is an effect of positive energy balance. Intake delivers a high energy level compared with requirements. This energy is supplied by carbohydrates (starch for monogastric animals, as it can be easily digested, and for ruminants structural carbohydrates such as cellulose or easily digested starch) and secondly by exogenous lipids in the form of fat. Occasionally proteins supply energy for the chemical process in the organism.

Starch is the most important carbohydrate in animal production: it is used for energy and lipid synthesis. For example, 1 g of starch provides 4.15 kcal GE g^{-1} while 1 g of fat provides 9.4 kcal GE g^{-1} (GE, gross energy (calorimetric value)). Excess intake of energy concentrated in carbohydrates can be metabolized to fat in the cells of the liver and stored.

The basic biochemical structure of animal endogenous lipids is the chylomicron, which can be transported with blood and deposited in fatty tissue. Accumulated exogenous fats can be transported from the digestive tract to the blood and fat tissue without transformation in a similar way.

Fat synthesis is conducted in the organism in two ways: (1) liponeogenesis – biosynthesis of different specific fatty acids in liver cells; and (2) lipogenesis – synthesis of triacylglycerols. Lipogenesis influences the quality and time ratio of fat synthesis and deposition in tissue. The synthesis of fatty acids depends on different factors, such as: ACP (acyl carrier protein, a 9 kDa protein), another protein within the SH cysteine group, called the HS enzyme, NADP (nicotinamide adenine dinucleotide phosphate), FMN (flavin mononucleotide) and CoA (coenzyme A) (Figure 1). This process is calling β-reduction.

Synthesis of fatty acids in animal products (fat tissue) may be conducted in an intermediary path from exogenous fatty acids. These fatty acids are transported to reserve tissue or organs either with or without transformation and as phospholipids of membrane cells, or to yolk egg lipids. A simple schema showing transformation and deposition of fat and fatty acids in chicken is given in Figure 2.

In the animal world, for example, in mammalian species, the synthesis of fatty acid could access acids with 18 carbon atoms. In energy balance in an organism easily digested carbohydrates also have an important function. Some energy is gained from undigested carbohydrates by endogenous enzymes fermented by microorganisms from the cecum and colon intestine. In this way animals may gain short-chain fatty acids, which are precursors of energy and fatty acids, especially for monogastric animals.

Milk plays an important role in human diets. Synthesis of milk fat is a specific process. The main components of milk are triacylglycerols. The synthesis of triacylglycerols is conducted in epithelial cells of the mammary gland in two ways: first, from blood lipids (rebuilding blood triacylglycerols to milk form) and second, in *de novo* synthesis. Sixty percent of milk (especially long-chain) fatty acids can be gained from blood fat very-low-density lipoproteins (VLDL) or from chylomicrons containing ingested fatty acids directly from the intestine. The main sources of VLDL and chylomicrons are fat from feed and endogenous tissue fat. Medium- or short-chain fatty acids of milk are synthesized in the epithelial cells of the mammary gland or from blood precursors. The differences in fat synthesis between mono- and polygastric animals are shown in sources of carbon atoms for fatty acids. In monogastric animals the source is glucose while in ruminants it is actetate or beta-hydroxybutyrate (BHBA). In the next conversion fatty acids are esterified at the cytoplasmic surface of the smooth endoplasmic reticulum (SER) of the mammary epithelial cells to hydroxyl groups of

the glycerol molecules. In this way triacylglycerols are synthesized; they are agglomerated and create micro-lipid droplets. They are secreted from the SER surface into the cytoplasm, and transported directly to small milk fat globules (<0.5 mm) and unite to form larger droplets. The cytoplasmic lipid droplets may fuse with each other and be secreted as larger milk lipid droplets. The size of fat globules in milk ranges from less than 0.5 to greater than 15 mm. The micro and cytoplasmic lipid droplets are apparently surrounded by a nonbilayer coating of protein and gangliosides (polar lipids); the large lipid droplets are typical membrane-surrounded milk fat globules.

Types of Animal Product, Nutritive Value, Quality and Quantity of Animal Fat

Fat and Fatty Acid Content in Animal Product

Muscles and carcass Different species of animals have different contents of fat in the organism and in their products Table 2.

The average highest content of fat is in pork and mutton. In the organism fat accumulates under skin tissue, around some organs and intestines or between muscles. Compared with other animal products, the content of meat fat ranges from 3 to 55% (depending on animal species).

The characteristic value of the poultry carcass is because of the greatest concentration of fat under skin

Table 2 Nutrient content in animal species and products, including fat

Turkey meat	5.7			
Lard	99.5			

tissue and the skin compared with other animals, such as pigs. Poultry meat, and especially chicken, is a valuable product, which contains about 20% of fat (in total with skin). Poultry meat without the skin has about 5% fat content. This meat has a lower level of saturated fatty acids (about 33% of all fat content) and a high level of unsaturated fatty acids – especially polyunsaturated fatty acids (PUFA) – 14%. Duck meat has a higher level of fat than chicken or turkey. In summary, fat content is about 35–45% with skin and under skin tissue, and 25–27% is saturated fatty acids (SFA). Meat from game birds like: grouse, partridge, pheasant, and pigeon has a fat content about 5, 7, 9 and 13% respectively, and one fourth of this is SFA. The composition of fatty acids is in an interesting new product in the human diet – ostrich meat – is given in Table 3.

An important characteristic of fat quality parameters is not only the relation between fat and the weight of the carcass but also the content of fatty acids SFA, monounsaturated fatty acids (MUFA), and PUFA.

Table 4 gives a comparison of the fatty acid content of different animal species. The highest content of PUFA is observed in poultry meat and the worse balance in ratios of fatty acids is in mutton or beef. Probably the genetic and nutrition sciences works could modify in future the profile relations of fatty acids, especially in beef meat.

A higher level of SFA is observed in ruminants than in monogastric animals (for example, SFA in ruminants may be about 50% of total fat content). This profile depends on specific rumen degradation.

In cattle there is more MUFA and PUFA in fat between the muscles compared with under the skin or around the organs. The quantity and quality of this intermuscular fat is a decisive factor in the cooking and taste of this meat (marbling of beef meat). In pig production the highest level of fat is accumulated in fat under skin tissue and in particular areas. In the carcass the deposition of fat is different: there is a low level in ham and high level in the shoulder.

Fish and especially oily fish is an important source of fat in the human diet in some countries. Fish may be classified according to the fat content in the carcass. In the human diet fish are classified as lean (low fat content) such as flatfish, cod, where the concentration of body fat is not greater than 5%, and oily fish, like salmon, trout, and tunny (total fat content is 9–20%). Ocean fish have a genetic tendency to accumulate the highest level of unsaturated fatty acids, in particular PUFA, which makes up about 20% of total fat (Table 5).

PUFA have an important function in human health. PUFA are classified in groups omega-3 and omega-6. A high ratio of omega-6 to omega-3 fatty acids in the human diet has been linked with an increased risk of cancer, cardiovascular disease, allergies, depression, obesity, and autoimmune disorders. Animal fat does not have a beneficial ratio of fatty acids from omega-6 to omega-3 groups. Animal products used in dietary health protection include fish oil, which contains the highest level of fatty acids in the omega-3 group.

One form of fatty acids is conjugated linoleic acid (CLA), which is found in ruminant meat. This fatty acid is healthy for humans. Studies have shown that CLA can change fat to muscle, reduce heart disease, and fight diabetes.

Trout	7.7	0.1	0.5

Milk The highest concentration of fat is observed in sheep milk, in contrast with mares' milk, which has less fat. Cows' milk has a fat level of 3.2–4% (Table 6).

The chemical composition of milk lipids is made up of glycerophospholipids and sphingolipids (Table 7). The physical form of milk fat is a sphere (size 2–10 μm). In one molecule of fatty acid of milk there are 4–20 carbon atoms. In domestic animals the milk fats that predominate are fatty acids: palmitic (C16:0), oleic (C18:1), myristic (C14:0), and to a lesser extent, capric acid (in small ruminants). In unsaturated fatty acids linoleic acid (C18:2) and linolenic acids, have an important position in milk fat, but the ratio between these acids depends on the form and level of animal nutrition.

In human nutrition when raw milk is not consumed, the main function in diets is fulfilled by butter, which is a source of energy and vitamin sources. Butter has a high concentration of short-chain (saturated), fatty acids as well as vitamins A and D.

Eggs In laying hens there are two types of production: (1) eggs for reproduction: fatty acids are particularly important for the hatchability of eggs during incubation, and the quality and health of the chick; and (2) eggs for consumption: fatty acids have an influence on human health.

Eggs for consumption are a good source of lipids and vitamins. Fat in eggs is centered in the yolk, and is $32\,g\ 100\,g^{-1}$ of yolk weight. Important components of Hens' egg yolk are oleic acid ($11\,g\ 100\,g^{-1}$), linoleic acid ($2.61\,g\ \ 100\,g^{-1}$), and arachidonic acid ($0.50\,g\ \ 100\,g^{-1}$) (Table 8). Yolk triacylglycerols are about 60%, and they are the main source of fat energy. Monodiacylglycerols are 1.5–6.7%; the highest level is deposited in high-density lipoprotein

Modification of Quality and Quantity of Animal Fat

The scientific promoter of lipid metabolism, and in particular the influence of organic feed compounds on lipid synthesis in animals, was the German Oskar Kellner. Kellner ascertained that 1 kg of digested feed components such as starch, fat, or protein produced in cattle a particular level of fat, e.g., 1 kg starch produced 248 g fat, 1 kg protein produced 235 g fat. The results of trials in practice showed that in reality the levels of synthesis in organisms depended on nutrition value, the feed taken, the physiological conditions of the organism, age, digestibility, and the development of the digestive tract. One important point in lipid synthesis is the ratio between quality and quantity of feed consumption. The interaction between different feed components such as starch and cellulose also influences energy metabolism and energy balance.

Lipid synthesis in an organism is conducted differently in monogastric and polygastric animals. The level and system of digestibility and kinds of energy and lipid precursors (exogenous) are important.

Monogastric Animals (Domestic Animals, e.g., Poultry and Pigs)

The highest growth rate, highest protein synthesis and changing fat relation between protein content and fat in tissue are characteristic parameters of slaughtered monogastric animals. When breeding this group there are only two possibilities for changing body composition. One is genetic research and hybridization – there are new genetic lines of animals which have unusually high muscle content. The second way is a nutrition combination, using special balanced diets and special components in feed, which may modify fatty acid content (Figure 3).

Within the feeding system of young slaughtered poultry (chickens) there is a specific procedure relating to quality of feed. The important point is a ratio between energy content in feed and protein during the growth phase. The nutrition system must be correlated with body development in the short life span, which is only 6 weeks. This system allows increased protein synthesis in muscles compared with fat synthesis in the organism and is dependent on energy balance.

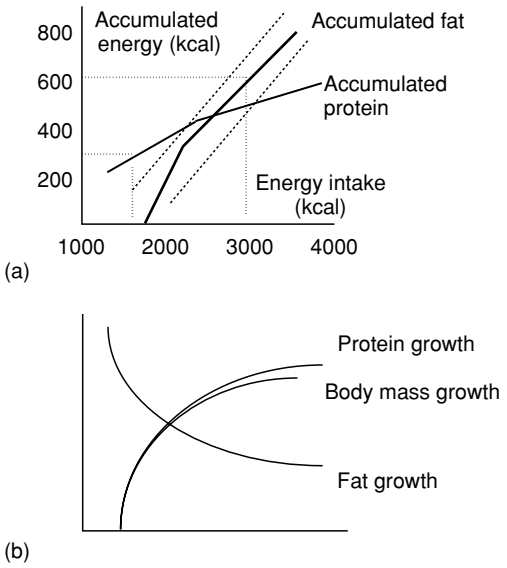

Figure 3 Influence of (a) feed energy intake and (b) proteinon body composition in poultry (chickens).

In chicken or turkey endogenous fat is synthesized from glucose, and the final product of carbohydrate degradation and digestibility – starch. In poultry diets 95% of starch is given by corn, wheat, and barley. The level of energy in poultry feed is balanced by exogenous fat supplementation by oil and tallow. The maximum level of this supplement is about 10% in feed, but is often 3–6%. The balance of energy in poultry is important, because when the balance increases by about 10–25%, fat synthesis is also increased. At this point feed intake is decreased and amino acids and minerals intake are also decreased (only in negative composition mixture).

The influence of systems, contents, and level of nutrition on development and quality poultry products has been determined in scientific research. Change in carcass composition is highest in poultry, especially in relation to fat and protein content. This suggests the possibility of modifying carcass composition by nutritional changes in a short time. One important factor is increased feed protein level and decreased growth rate of endogenous body fat.

A mean increase in protein concentration in the diet ($1\% = 10\,g\,kg^{-1}$) reduces fat content in the carcass of chicken 0.7–1.4% ($7–14\,g\,kg^{-1}$). A similar effect is observed using low-energy components in feed. Research trials have demonstrated that a high level

of rye plus enzyme in the diets decreased endogenous level of fat in the body composition of chickens compared with a corn diet. The specific combination of different energy sources in feed (tallow, soyabean oil, rapeseed oil, fish oil) may influence the quality and composition of endogenous fat in poultry. This correlation between composition of feed fat and carcass fat has been demonstrated in other studies. There was a strong correlation between dietary fatty acid composition and tissue fatty acid composition for all fatty acids except C14:0, C20:0, C20:2*n*-6, and C20:4*n*-6.

Not only energy sources in feed but also protein levels and sources have an effect on abdominal fat. In one study, protein concentrates were used in different combinations, compared with mixtures of a DKA-grower diet containing 11% fishmeal and 35% of a 1:1 mixture of faba bean and full-fat rapeseed and a DKA-grower diet containing 18% soyabean meal, 7% fishmeal, and 4% rapeseed oil. These nutrition combinations influenced differentials in abdominal fat composition: abdominal fat content was 12, 21, and 40 g. Of total fatty acids in abdominal fat, 37.55, 33.96 and 30.43% was saturated, and 62.43, 65.74 and 69.39% was unsaturated. When used in the feeding system in chickens, high-fat yeast (HFY; *Cryptococcus curvatus*) reduced the proportion of oleic acid in breast and thigh muscle in compare to chicks fed mixtures with tallow or without fat supplementation.

The main fat content in poultry is accumulated under skin tissue. The content of fatty acids in this tissue can be modified by different feed additives (Table 9).

The influence of nutritional factors on laying hens, performance and production is important. In reproduction eggs of laying hens, the lower content of linoleic acid or linoleneic acid gives rise to decreased hatchability, lower weight of embryos and chicks, and slower rate of development during incubation. Cholesterol has an important function in this process, too. Modification of consumption eggs is very popular, especially as regards changes of fatty acids and vitamin content. Changing eggs using the nutrition system is called nutritionally enriched eggs (NEE) (Table 10).

During feed modification of egg content, it is important that the cholesterol level is 90% of that required genetically.

In pork production the fatty composition of feed grains has an important function. In pigs fed mixtures with high levels of barley, the lard was white and strong, compared with pigs fed mixtures principally made up of corn, in which case the lard was yellow and clammy.

There are three important principles in pig production:

1. Pigs fed a diet with a lower protein level cannot produce a high level of protein in muscles (in relation to genetics);
2. The highest level of protein in a low-energy diet may increase fat synthesis;
3. All organic components in a low-energy diet may increase fat synthesis.

Table 9 Fatty acid composition in skin influenced fat supplements

	Specification of fatty supplements to mixture			
	Corn oil 6%	*Tallow 6%*	*Corn oil 5% and cod-liver oil 1%*	*Tallow 5% and cod-liver oil 1%*

		Omega-6: omega-3 ratio	9.90	1.75
		Unsaturated-to-saturated acids ratio	1.94	2.46
		Cholesterol (mg)	400	350

NEE, nutritionally enriched eggs; BHT, butylated hydroxytoluene; BHA, butylated hydroxyanisole; MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids.

Ruminants

The possibility of modifying fat quality and content in the body and milk of ruminants can be conducted genetically and nutritionally. In genetic terms cross-breeding special species of cattle with famous domestic lines is a popular route. For example, the Japanese meat-cattle Wagyu has a high intramuscular fat content (shown by marbling of the meat) and a high ratio of MUFA to SFA. A second example of genetic modulation in fatty acid composition in beef is cross-breeding between domestic cattle and bison in the USA, creating a new species which was called beefalo. Beefalo meat has less total fat, less saturated fat, less cholesterol and fewer calories in comparison with domestic breeds of cattle. In milk fat there are large differences between species of cattle, for example, Holstein cattle produce low fat milk (3.2–3.5%), Ayrshire and Brown Swiss give 3.9–4.0% fat and the highest content of fat is in milk produced by Guernsey and Jersey cows (4.6%). Milk fat and meat content can be modified by nutrition. Fattening young cattle on grass fields (extensive model) has decreased fat content in carcass in comparison with the intensive model of feeding mixtures with grass and high level of grains. Feeding milk-cattle a mixed ration with lower effective fiber reduces the fat content in milk. Similarly, supplementing the diet with *trans* fatty acids to inhibit milk fat synthesis decreased milk fat level.

In ruminants improving the profile of fatty acids in the feed does not directly improve the profile of fatty acids in products, whether milk or meat. In normal conditions cows only ingest 2.5–3% of fatty acids in dry matter in their daily feed ration. Fatty acids are delivered by triacylglycerides, galactolipids, and phospholipids by ruminal microbial lipase activity, and are modified to stearic acid. This form is available in the intestine. Unsaturated fatty acids from feed are biohydrogenated in the rumen to the saturated acid form and fat in the ruminant's body (tallow) are highly saturated. The fat of ruminant milk content compared to other fats has a high degree of short-chain fatty acids. The precursors of fatty acids in the rumen are carbohydrates which produce volatile fatty acids: acetate, propionate, and butyrate. Using a fresh grass feed in cows' nutrition could modify the content of healthy fatty acids in meat, giving a decrease in SFA, increased intake of omega-3 fatty acids and CLA. Studies have shown that the ratio between omega-6 and omega-3 fatty acids is decreased from 4:1 to 2.3:1 in the meat of cattle fed grass. A similar effect is observed in milk cows fed grass; the content of CLA was three or five times higher then in ruminants fed grain diets. The final way of modifying fatty acids in milk is to use protected fatty acids before rumen degradation.

Uses in the Food Industry

L Boothby, Natland, Kendal, UK

Background

The first oil and fat products to be used by humans, apart from direct ingestion of vegetable oils from plants, were from animal sources. As the world's meat industry developed, animal fats became useful byproducts for baked goods. In the early 1900s, the introduction of hydrogenation, or hardening, revolutionized the usefulness of vegetable oils and enabled the production of fats and blends, with a wide range of physical properties overcoming some of the limitations associated with animal fats. Today's fat technologists also modify fats by fractionation and interesterification or a combination of two or more of the above methods to give a wide selection of tailor-made fats and blends. In more recent years, nutritional considerations have increased the usage of vegetable oils and fats. Similarly, the implication that *trans* acids in the diet increase the risk of coronary heart disease by raising low-density lipoprotein (LDL) cholesterol and reducing high-density lipoprotein (HDL) cholesterol levels has led some manufactures, particularly in yellow fats, to use blends with no hydrogenated oils. *Trans* acids also occur in animal and milk fats, albeit at lower levels than hydrogenated vegetable oils. (*See* **Vegetable Oils**: Dietary Importance.)

Functionality

In addition to being an energy source and fulfilling nutritional requirements, fats are necessary to carry out one or more of the following functions in various applications: (1) incorporate air; (2) provide lubrication; (3) soften texture; (4) aid moisture retention; (5) as a heat exchange medium and flavor enhancer in fried goods.

Bakery Fats

Properties

General-purpose fats or shortenings must have the following properties to perform satisfactorily in cake-making:

1. The shortening must be stable in the β-prime polymorph.
2. There must be a proportion of high melting triglycerols present: 5% is normally sufficient.
3. The ratio of solid to liquid triacylglycerols should be such as to give a plastic solid over the normal range of ambient temperatures.
4. The oxidative stability must be sufficient to meet product shelf-life requirements. (*See* **Oxidation of Food Components**; **Triglycerides**: Structures and Properties.)

Properties (1) and (2) are necessary to give a stable, aerated batter and good texture in the baked product. Property (3) is achieved by using a suitable blend of component oils. The shortening must blend readily with other ingredients during mixing. Plasticity also depends on the temperature history of the fat. During processing, rapid chilling is necessary to form a network of inter-locking small crystals which enmesh the liquid triacylglycerol phase. Slow chilling produces large, irregular crystals, and in products such as ghee a continuous liquid phase results. Storage temperature and ambient temperature in the bakery also affect plasticity. Property (4) is satisfied in most cases by using unmodified liquid oils for the liquid phase. If long-shelf-life products are required, oxidative stability is increased by using lightly hydrogenated oils for the liquid phase, e.g., soyabean oil with iodine value reduced from 130 to 105, or rapeseed oil reduced to iodine value 95 from 115. (*See* **Ghee**.)

General-purpose fats are suitable for pastry manufacture. β-Phase fats, notably lard, also produce excellent pastry products. Lard has a long plastic range but produces cake batters of poor stability and resultant poor cake texture. Its use in shortenings is thus limited to about 20% maximum. However, if costs permit, changing the polymorph to β-prime by interesterification significantly increases the inclusion level to 60–70%.

Component Oils

The physical characteristics of some typical shortening components are given in **Table 1**. Most fat

Table 1 Physical characteristics of some shortening components

Fat	Melting point[a] (°C)	Percentage of solid triacylglycerols at different temperatures (°C)					Stable polymorph
		10	20	30	35	40	
Butterfat	30	47	16	5	1	0	β-prime

Table 2 Typical general-purpose shortening blends and pulsed nuclear magnetic resonance (pNMR) profiles

Component	Not all vegetable fat (%)		All vegetable fat (%)	
	1	2	1	2
Tallow	65			
Hydrogenated fish oil (30 °C)		80		
Hydrogenated fish oil (49 °C)		20		
Palm oil			25	20
Hydrogenated palm oil (49 °C)			5	10
Hydrogenated rapeseed oil (33 °C)			40	25
Rapeseed oil	35		30	
Hydrogenated rapeseed oil (20 °C)				45
Percentage of solid triacylglycerols (pNMR)				
10 °C	35	45	47	45
20 °C	22	27	20	22
30 °C	12	10	12	10
40 °C	3	2	1	1.5

manufacturers have their own stock of standard hydrogenated or fractionated oils. There is no justification, for example, in a refiner carrying a range of hydrogenated soyabean oils with melting points ranging from 20 °C to 50 °C in steps of 5 °C since most user requirements can be met by blending a limited number of hardstocks. All the figures quoted for solid glyceride levels were determined by pulsed nuclear magnetic resonance (pNMR) using International Union of Pure and Applied Chemistry (IUPAC) method 2.150. Tallow, hydrogenated marine oils, hydrogenated cottonseed oil, hydrogenated palm oil, and palm stearin are all β-prime fats used extensively as hardstocks for shortening blends. (*See* **Fish Oils**: Composition and Properties.)

Shortening Blends

Typical shortening blends are given in Table 2, together with their pNMR profiles. Fat suppliers aim to have a library of formulations which can be used to give identical end products, so that least-cost options are always available. Shortening blends without middle melting triacylglycerols give satisfactory baked goods but there can be some loss of eating quality due to the increased level of high-melting triacylglycerols. Advantages of this type of formulation are an extended plastic range. Most manufacturers increase solid triacylglycerol levels by 2–4% during summer months. Hydrogenated marine oil-based shortenings possess excellent cake-making properties but the increasing all-vegetable trend has seen a decline in this type of shortening.

High-ratio shortenings have similar blends to the general-purpose fats, except for the addition of 2.8–3.2% α-monoacylglycerol, and in some cases a similar level of diacylglycerols. High ratio refers to the higher levels of liquor and sugar to flour that can be used. Resultant cakes are moister, sweeter, and resist staling longer than conventional cakes. Shortenings with 1–2% monoacylglycerol are used to give intermediate ratios of liquor and sugar.

Pourable or fluid shortenings are suspensions of emulsifiers, sometimes with the addition of a small level of high-melting β-phase fat, either in liquid vegetable oil, or in a lightly hydrogenated vegetable oil to give improved shelf-life.

Pumpable shortenings for large bakeries have similar blends to conventional shortenings. They are stored and delivered in jacketed tanks with temperatures maintained between 24 and 28 °C depending on the blend. At the bakery the shortening is delivered from controlled temperature storage by positive displacement pumps and metered into the mixer. (*See* **Bread**: Dough Mixing and Testing Operations.)

Puff Pastry Fats

Puff pastry fats need to be tough and elastic to achieve the multiple alternate layers of fat and dough required to produce good lift. Puff pastry margarines seem to be preferred to fats. To achieve the necessary consistency, relatively high-solid glyceride contents are used together with correct processing. An excellent puff pastry fat can be produced from lard containing 12–15% fully hydrogenated lard. Tallow-based fats are also produced. Vegetable-based fats utilize palm stearin and, hydrogenated palm oil together with other hydrogenated vegetable oils.

Biscuit Fats

Dough Fats

Biscuit dough fats must be β-prime-stable to avoid bloom development during the life of the biscuit. However, certain different criteria are required compared to shortenings:

1. The melting profile must be sharper for good eating quality. There must be generally less than 5% solid triacylglycerols at 35 °C and 0.5% maximum at 40 °C.
2. The oxidative stability needs to be high for a long-shelf-life product, typically 40 h minimum at 100 °C (measured by Rancimat instrument). Thus, liquid oils are normally excluded from blends, except for some specialized 'health' biscuits.

Typical dough fat blends and pNMR profiles are given in Table 3. Historically, the biscuit industry used large quantities of hydrogenated marine oils. Palm or hydrogenated palm oils are normally used to achieve the β-prime polymorph in vegetable blends.

Biscuit fats can be supplied ready for use in boxes. The major producers receive blends in road tankers at temperatures several degrees above the complete melting point, store in suitable tanks, and subsequently chill and texturize as required.

Cream Fats

Biscuit cream fats require medium to high solid triacylglycerol levels at ambient temperatures, together with a rapid melting profile, and, ideally, zero solid triacylglycerols at body temperature. On high-speed production lines the fat must set quickly and give good coherence to the biscuit. Biscuit creams are basically mixtures of icing sugar and fat with or without added colors and flavors. Typical cream fats and their melting profiles are given in Table 4.

The lauric oils – coconut and palm kernel – are ideal starting materials. In addition to rapid melting they are very bland and can be refined to very low color levels. Hydrogenated rapeseed and soyabean oils with high *trans* acid levels can be used singly or in combination with lauric fats. In these blends low-melting saturated acids are partially replaced by *trans* acids – mainly elaidic acid, which has a similar melting point to lauric acid (42 °C).

Low *Trans* Acids Blends

Suitable low *trans* acids blends can be formulated using fractionated or interesterified oils. Examples are given in Table 5 for different applications. To achieve zero to trace levels of *trans* acids it is necessary to use deodorization temperature below 235 °C, particularly if liquid oils are included in the blend; this precludes the use of physically refined oils.

Frying Oils

Frying oils need to be as stable as possible under the harsh conditions used. This is achieved by using oils with the lowest possible level of unsaturation concomitant with good eating quality and very low trace-metal levels. Thus, hydrogenated oils should be posttreated to remove traces of catalyst completely. Stability is also important to achieve a reasonable shelf-life, particularly in potato crisps and snack foods, with their large surface area to weight ratios, and oil contents up to 40%.

Oils are delivered in bulk to the snack-food industry. Suitable oils are lightly hydrogenated soya bean or rapeseed, with linolenic acid levels reduced below 3%, palm olein, and blends of palm oil with vegetable oils. Sunflower is used successfully to produce health-branded products. Frozen chip producers require harder oils to avoid problems during blast-freezing. Suitable oils are palm or hydrogenated palm oil.

These products contain 2–5% oil, which is diluted by the end users' frying media.

The catering industry uses palm oil, beef-tallow liquid vegetable oils, and long-life frying oils based on lightly hydrogenated vegetable oils. The latter normally contain a low level of a β-phase fat such as fully hydrogenated rapeseed oil. Chilling and texturizing produce a stable pourable frying oil. An antifoaming agent (methyl polysiloxane) is generally added to long-life frying oils. Antioxidants are not normally added; they give protection prior to use but there is little carry-through to the finished product. Residual tocopherols in vegetable oils give some benefit. (*See* **Antioxidants**: Synthetic Antioxidants; **Tocopherols**: Properties and Determination.)

Processing

Shortenings

Fats and blends are stored above their complete melting points immediately prior to processing. The first stage is normally a water precooler to reduce variations in feed temperature to the main chilling unit. The main chilling unit is a continuously scraped surface heat exchanger, comprising a cylinder with refrigerant on the outside, and inside a rotating shaft with floating scraper blades. The molten fat is pumped under high pressure through the annular space whilst the scraper blades remove chilled fat from the cylinder wall. This step initiates the crystallization before passing to the second unit, sometimes referred to as a 'B' unit or 'puddler' or 'worker.' In the 'B' unit the fat completes most of its crystallization whilst being agitated by a combination of paddles and baffles; most of the heat of crystallization is dissipated.

Absence of a 'B' unit results in nonplastic shortening. Processing plants normally consist of several chilling and 'B' units linked in series. The final stage involves further mechanical working by passing the shortening through an extrusion or texturizing valve immediately prior to filling the container – normally polythene-lined boxes. The whole system generally operates at pressures between 2 and 3 MPa. Depending on the blend, chilling temperatures can vary between 16 °C and 22 °C and filling temperatures between 19 °C and 25 °C.

The final stage after filling is 'tempering' or 'annealing'. Containers are stored in a temperature-controlled environment between 24 °C and 28 °C for at least 48 h. This step allows the shortening to stabilize in the β-prime polymorph and extends the plastic range, so enabling the shortening to be used over a wider temperature range without loss of performance.

Most shortenings have air or, preferably, nitrogen introduced prior to chilling to give a white appearance; the normal level varies between 8% and 15% by volume. The level of gas does not influence final performance and is introduced for cosmetic reasons. Shortenings without gas perform equally well but have a pale yellow, petroleum jelly-like appearance. Colors, such as β-carotene and vitamins, can be added if required. Colored shortenings do not normally include nitrogen.

Pumpable shortenings are processed similarly but after texturizing are stored in special temperature-controlled tanks at tempering temperatures. Further work softening occurs when the shortening is pumped into and out of the delivery vehicle, and again just prior to mixing by the end user. Omission of nitrogen from pumpable shortenings gives more accurate metering into the mixer.

Puff Pastry Fats

Puff pastry fats can be chilled in a similar manner to shortenings or on open chilling drums with a scraper

blade running the length of drum and refrigerant on the inside. Moisture condensation can give problems in the latter process. After chilling, the fat is allowed to crystallize slowly in long resting tubes or in skips. The fat is then plasticized before extruding into blocks. The drum method gives fats of excellent plasticity. No tempering is necessary but low storage temperatures should be avoided.

Other Fats

Confectionery, toffee, icecream, cream, and frying fats are chilled, texturized, and packed as shortenings, but without tempering. (*See* **Ice cream**: Methods of Manufacture.)

Digestion, Absorption, and Transport

T H M Da Costa, Universidade de Brasília, Brasília, DF, Brazil

Background

Fats or lipids are the concentrated form of energy in the diet, providing $9\,\text{kcal}\,\text{g}^{-1}$ ($37\,\text{kJ}\,\text{g}^{-1}$), and have evolved as the most advantageous form of energy storage, owing to their hydrophobic characteristics. Triacylglycerols are the most common of the lipids either in the diet or as lipid tissue stores. They are formed by the esterification of glycerol and fatty acids (1:3 molar ratio). Triacylglycerols vary depending on the three fatty acid residues they contain; simple triacylglycerols contain a single type of fatty acid residue. For example, trioleoylglycerol or triolein (a simple triacylglycerol) has three oleic acid residues, and mixed triacylglycerols contain two or three different types of fatty acid residues. The fatty acid moiety varies greatly in nature, and the ingestion of triacylglycerols containing saturated or unsaturated, long- and/or short-chain fatty acids depends on the source of lipids in the diet.

Fat is an important food energy source in the Western world, ranging from 30 to 40% of daily energy intake, equivalent to the daily consumption of 50–120 g in an adult. Other lipids play less important roles as energy sources under normal physiological circumstances, but serve as structural components of cell membranes, metabolic cofactors and as hormones (phospholipids, sphingolipids, cholesterol, diacylglycerol, and steroids). The diet constitutes the major source of lipids for the body and supplies essential fatty acids and lipid-soluble vitamins that cannot be synthesized endogenously. Lipogenesis, *de novo* synthesis of triacylglycerols from carbohydrate, occurs when there is a high ingestion of the latter.

The first part of this chapter reviews present knowledge on the mechanisms of digestion and absorption of dietary lipids, mainly triacylglycerols, and the second part deals with the complex transport system of lipids in the circulation.

Lipid Digestion and Absorption

Owing to their hydrophobic characteristics, lipids are digested by a dynamic and complex mechanism that facilitates their solubilization and hence availability for enzymatic action. The process can be divided into four main phases: emulsification, hydrolysis of fatty acid ester bonds by lipases, aqueous dispersion of lipolytic products in bile acid micelles, and uptake by the enterocytes (**Figure 1**).

In the process of fat digestion, there is a minor contribution of lingual lipase, which hydrolyzes some long-chain fatty acid triacylglycerols, and gastric lipase, which contributes to the hydrolysis of short- or medium-chain fatty acid triacylglycerols. The main process of lipid digestion takes place in the small intestine. In the duodenum, triacylglycerols aggregate in droplets and are emulsified by the action of the bile salts, monoacylglycerols (originating from intragastric lipolysis), and lysolecithin. The fat

droplets are attacked by the colipase and pancreatic lipase complex. Colipase, a pancreatic protein that protects the lipase from denaturation and anchors it to the lipid–water interphase of the droplet, permits access of the lipase to the inner core of triacylglycerols. In fact, when the lipase binds to the interphase of the lipid droplet, the catalytic rate of the enzyme is increased (surface activation). Pancreatic lipase hydrolyzes ester links in the 1–3 positions of the triacylglycerols releasing fatty acids and 2-monoacylglycerol (Figure 2).

Phospholipids from the diet or secreted in the bile (lecithin) are attacked by pancreatic phospholipase A_2, which cleaves the fatty acid at the 2 position, forming lysophospholipids and lysolecithin, respectively. Lysolecithin aids in the emulsification process. Cholesteryl esters, the main form of cholesterol in the diet, are hydrolyzed to free cholesterol by a pancreatic enzyme cholesterol esterase and aggregate into micelles. Cholesterol esterase also hydrolases retinyl esters. Its action increases the polarity of cholesteryl and retinyl esters, which are highly hydrophobic molecules, allowing their micellar solubilization. Free cholesterol derived from biliary secretion and cell decay is also incorporated into micelles. When the proportion of bile acids and phospholipids reaches a critical micellar concentration, micelles are formed and take up free fatty acids and monoacylglycerols, and the expanded micelle is water-soluble.

In the aqueous interface between the micelles and the epithelial cell surface, known as unstirred water layer, the micelles dissociate, and the concentration of fatty acids, monoacylglycerols, and lysophosphoglycerols increases, and these diffuse freely through the apical enterocyte membrane. Saturated fatty acids with a carbon length of 18 are poorly absorbed in the free state but well absorbed as 2-monoacylglycerols. Very-long-chain fatty acids with high melting points are less efficiently absorbed. Triacylglycerols and diacylglycerols, which are not acted upon by the lipase, do not dissolve well in bile salts and remain in lipid droplets. Unabsorbed fat in feces is usually below 5%. Bile salts that are separated from the micelles remain in the intestinal lumen and are absorbed in the distal ileum by an active transport system or are lost in the feces.

Short-chain (C:2–C:4) and medium-chain-length (C:6–C:14) fatty acids are more hydrophilic and are rapidly absorbed independent of micellar solubilization or re-esterification within the intestinal cells. They are transported via the portal circulation directly to the liver. In the newborn, about half of the

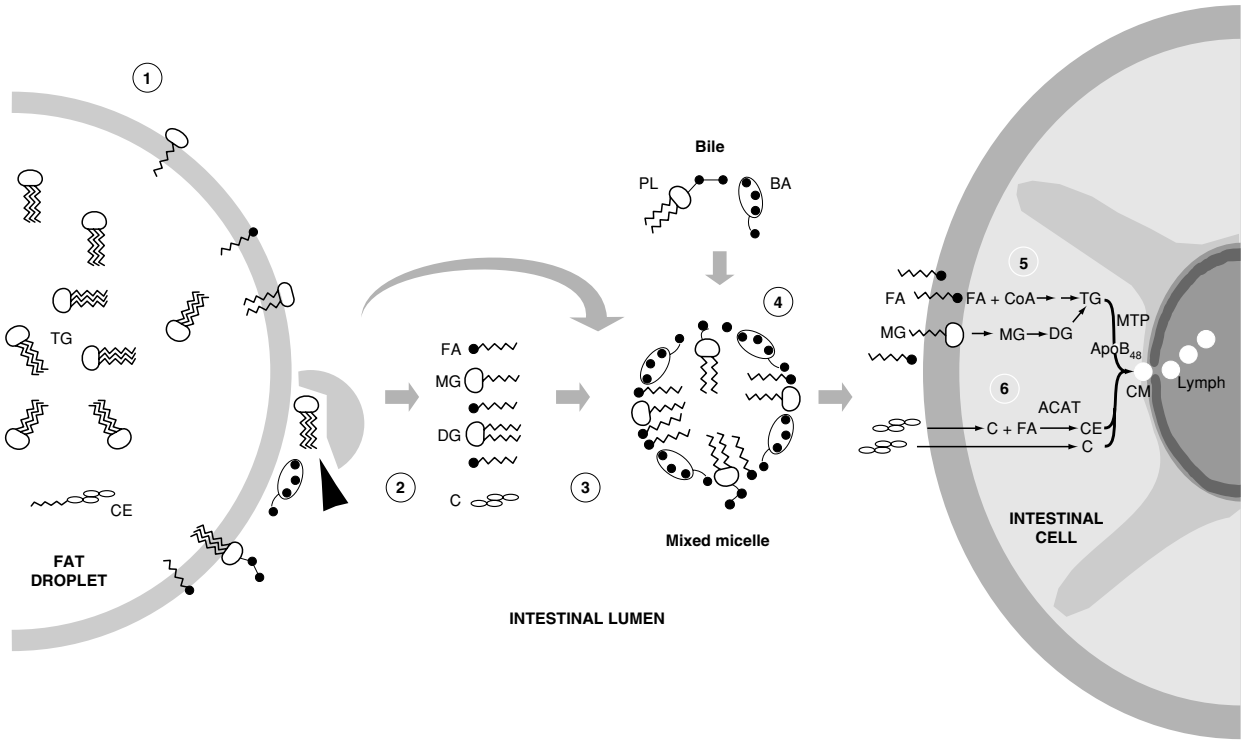

Figure 2 Diagrammatic representation of triacylglycerol and cholesterol digestion and absorption in the gastrointestinal tract. A fat droplet is shown (1) with insoluble triacylglycerols (TG) and cholesteryl ester (CE) in the core. The products of early lipolysis by lingual and gastric lipases: fatty acids (FA), diacylglycerol (DG) and monoacylglycerol (MG) and also dietary phospholipids with their polar heads face the outside of the droplet. Pancreatic lipase (2) acts at the water–oil interphase hydrolyzing TG molecules, with the participation of bile acids (BA) and colipase, which anchors the lipase to its catalytic site. Cholesterol esterase acts on cholesteryl ester forming free cholesterol (C). Lipolytic products (3) interact with bile acids (BA) and phospholipids (PL), facilitating their solubilization into micelles (4). In the unstirred water layer, micelles dissociate, and their content diffuses to the enterocyte. Inside the intestinal cell, fatty acids (FA) are activated and are re-esterified to TG (5). Cholesterol is absorbed and re-esterified with a fatty acid by the action of the enzyme acylCoA:cholesterol acyltransferase (ACAT) originating cholesteryl ester (CE) (6). Chylomicron (CM) synthesis requires the enzyme microsomal triacylglycerol transfer protein (MTP) to assemble the structural protein apo-B_{48} to triacylglycerols. Mature chylomicrons also incorporate cholesteryl esters to the core, and phospholipids, free cholesterol and apoplipoproteins to the surface. Chylomicrons exit the enterocytes by exocytosis to the lymph. Adapted with permission from Ros E (2000) Intestinal absorption of triglyceride and cholestrol. Dietary and pharmacological inhibition to reduce cardiovascular risk. *Atherosclerosis* 151: 357–379.

medium-chain fatty acids from milk can be absorbed in the stomach. In the enterocyte membrane, a fatty acid-binding protein (FABP) facilitates the transport of long-chain fatty acids (carbon chain length > 12) into the cytosol and reduces the potential cytotoxic effect of fatty acid soaps. Cholesterol binds to a sterol carrier protein as it enters the cell. In the enterocyte, cholesterol is re-esterified with a fatty acid by the action of the enzyme acyl-CoA:cholesterol acyltransferase (ACAT). The fatty acids and monoacylglycerols are re-esterified to triacylglycerols within the endoplasmatic reticulum of the enterocyte, and then are combined with phospholipids, cholesterol, cholesteryl esters, and apolipoproteins, forming chylomicrons. Apo-B_{48} is the structural protein of chylomicrons. The process of chylomicron assembly takes place in the Golgi apparatus, and the movement of triacylglycerides from the endoplasmatic reticulum to the Golgi appears to be a rate-limiting step in the process. The union of triacylglycerol to apo-B_{48} requires a microsomal triacylglyceride transfer protein (MTP). Finally, chylomicrons are released by exocytosis to the lymphatic system and enter the blood circulation by the left subclavian vein (Figure 2).

Lipid Transport in the Plasma

Lipids are transported in the hydrophilic blood plasma environment as lipoproteins. Lipoprotein particles consist of a core of triacylglycerol and cholesteryl esters, in varying proportions, surrounded by a more hydrophilic layer of phospholipids, unesterified cholesterol, and protein. In the circulation or as a constitutive component, each lipoprotein particle

contains specific proteins, termed apolipoproteins (Figure 3).

There are at least 12 apolipoproteins described and present in different proportions among the lipoproteins (apo-AI, II and IV, Apo-B_{48} and B_{100}, apo-CI, II and III, apo-D and apo-EII, III and IV). The apolipoproteins, apart from giving stability to the lipoprotein particle, also direct the lipoprotein to its site of metabolism by interactions with specific enzymes and transport proteins on cell membranes. The ratio of lipid to protein, which determines the density of lipoproteins, is important in the classification of the five major lipoproteins: chylomicrons; VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; and HDL, high-density lipoprotein. As the lipoproteins are delipidated, the diameter reduces, and the density increases. The lipoproteins exist in a dynamic state, and their separation into one of the above classes, according to their flotation characteristics, refers to average values. Chylomicrons, the least dense of all lipoproteins, have the highest proportion of triacylglycerols (85–90%) and transport mainly lipids from exogenous (dietary) origin. As already mentioned, during their assembly in the enterocytes, they acquire apo-B_{48}. Nascent chylomycrons also contain apo A-I, apo A-IV, and, to a lesser extent, apo A-II. Apo A-I and apo A-II enter the circulation in chylomicrons but are rapidly transferred to nascent HDL (Figure 3). Apo A-IV secreted by the enterocytes is likely to mediate the anorectic effect of a lipid meal. It is proposed that apo A-IV acts as endogenous antioxidant and is involved in fat absorption.

VLDL, IDL, and LDL are related particles that transport endogenous (synthesized in the liver) triacylglycerols and cholesterols to peripheral tissues.

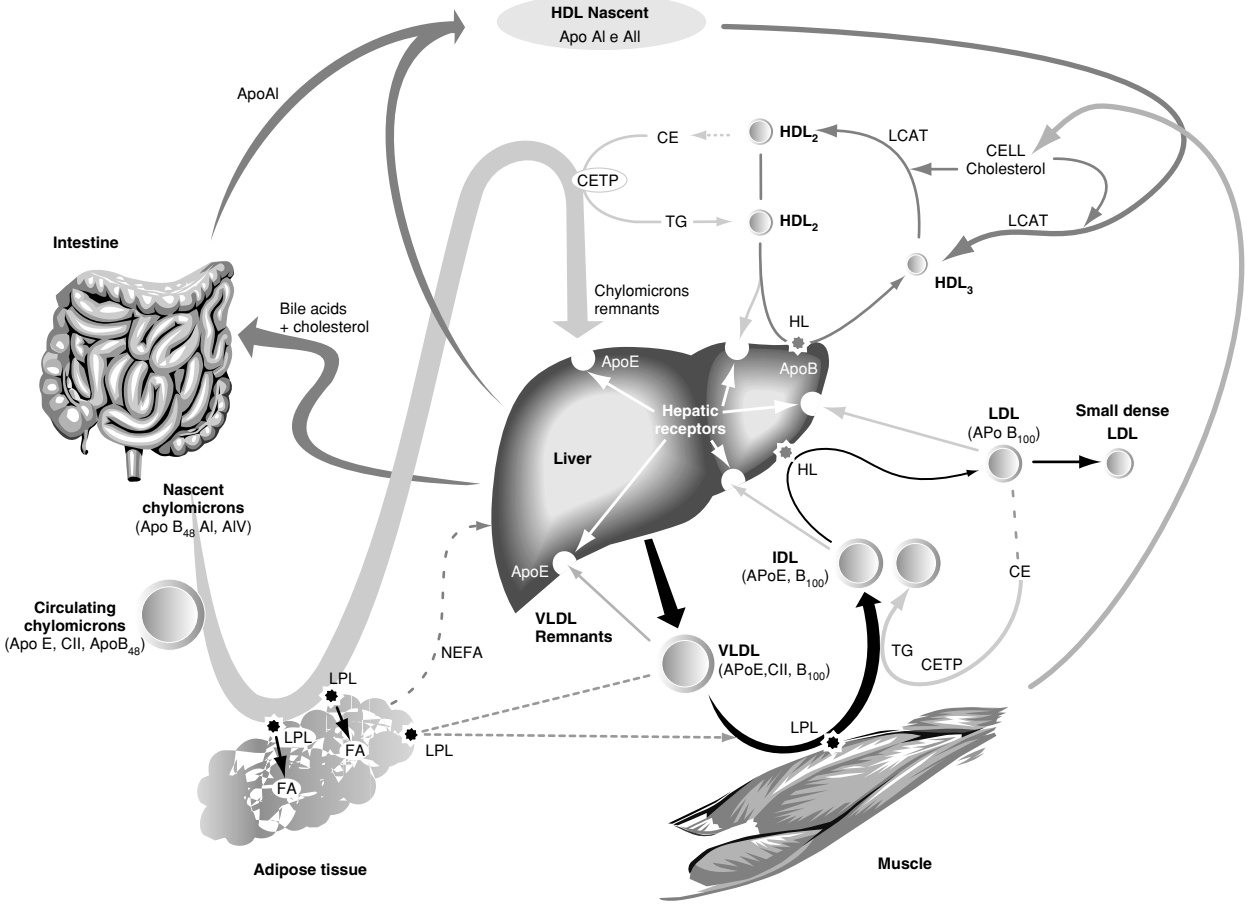

Figure 3 Scheme for the transport of triacylglycerol and cholesterol in plasma. The classes of lipoproteins are shown: chylomicrons and chylomicrons remnants; VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein, with its subclasses: nascent-HDL, HDL_2, and HDL_3. The major apolipoproteins associated with each lipoprotein are presented in parenthesis. Enzymes involved in the process of lipoprotein metabolism: LPL, lipoprotein lipase; HL, hepatic lipase. Enzymes related to lipoprotein lipid exchange: LCAT, lecithin:cholesterol acyltransferase; CETP, cholesterol:ester transfer protein. Hepatic receptors are indicated with their ligand for binding to cell-surface Apo-E or Apo-B. For more details, refer to the text. Adapted with permission from Packard and Shepherd (1996).

HDL, which is assembled in the plasma through the action of LCAT (lecithin:cholesterol acyltransferase) from hepatic or enteric nascent HDL, transports cholesterol from peripheral tissues to the liver and functions as an acceptor/donor of apolipoproteins to other lipoproteins (Figure 3). Among the lipoproteins that transport endogenously synthesized lipids, VLDLs are the principal source of triacylglycerols for the tissues (50–55%).

In the postprandial state, circulating chylomicrons interact with HDL and acquire apolipoproteins E and CII. Apolipoprotein CII activates the enzyme lipoprotein lipase in the capillary endothelium of adipose tissue and skeletal muscle. The interaction between the particle and the enzyme causes hydrolysis of the triacylglycerols in the core of the chylomicron. Repeated action of the lipases as the blood circulates removes most of the triacylglycerols, and the resulting particle (chylomicron remnant) is enriched in cholesteryl esters, apo-B_{48}, and apo-E. Apo-CII returns to HDL. In the liver, specific remnant receptors are activated by apo-E, and the remnants are taken into the cell by endocytosis. Lysosomal hydrolysis in the hepatocytes liberates fatty acids, cholesterol, and amino acids. The overall result of the chylomicron transport process is completed as dietary triacylglycerols are delivered to peripheral tissues and cholesterol to the liver.

Lipids within the liver, formed by *de novo* synthesis from carbohydrates (lipogenesis), chylomicron remnants, and nonesterified fatty acids (NEFA) mobilized from the adipose tissue, are incorporated into VLDL particles and secreted into the blood stream during the postabsorptive or fast period. The assembly and secretion of hepatic VLDL is a complex process, and the final particle is composed of a relatively rich core of triacylglycerols with smaller amounts of cholesteryl ester, surrounded by a monolayer of phospholipids and cholesterol enclosed by apo-B_{100} that differs from the apo-B_{48} secreted by the enterocytes. In the hepatocytes, MTP plays a comparable role, as in the enterocytes, in the assembly of triacylglycerides with apo-B_{100}. Secreted VLDL receives apo-CII and apo-E from HDL and is acted upon by the lipoprotein lipase in the same way as the chylomicrons. The resultant lipoprotein of VLDL is an IDL. Some of the IDL are catabolized in the liver through binding to a specific receptor. The IDL particles that remain in the plasma undergo transformation resulting in the conversion to LDL. In this process, all the apolipoproteins are removed, with the exception of apo-B_{100}. LDL is almost entirely composed of cholesteryl esters surrounded by apo-B_{100}. LDL can be further delipided, resulting in small dense LDL that are more atherogenic. Circulating LDL delivers cholesterol to hepatic and extrahepatic tissues, and the process involves the interaction with a specific receptor in the cell membrane (LDL receptors).

In the liver, cholesterol is converted to bile acids or incorporated into the bile and excreted into the intestine to facilitate lipid absorption. Hepatic cholesterol is also distributed to other tissues as it is incorporated into VLDL. Circulating HDL capture plasma unesterified cholesterol formed from cell degradation and convert it to cholesteryl ester through the action of LCAT. The cholesteryl ester moves to the core of the particle. LCAT is activated by apo-AI, the major apolipoprotein present in the HDL (Figure 3). Major subclasses of HDL are designated HDL_2 and HDL_3 based on density. By the action of LCAT, HDL_3 is produced from discoidal HDL and HDL_2 from HDL_3. HDL_2 also exchange lipids with other lipoproteins (chylomicrons and VLDL fractions) through the action of the enzyme cholesterol ester:transfer protein (CEPT). Hepatic lipase acts on IDL and HDL_2-triacylglycerol and a phospholipase on HDL_2-phospholipid, which generates LDL and HDL_3, respectively (Figure 3). These reactions establish a cycle by which cholesterol is removed and returned to peripheral tissues or is disposed of by the liver.

Requirements

N M F Trugo and A G Torres, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Background

Dietary fat is a term used to designate the major dietary lipids, triacylglycerols. Other dietary lipids are the phospholipids, sterols, waxes, fat-soluble vitamins, carotenoids, and other minor compounds. Fats are required in the human diet to provide energy and essential fatty acids, and to improve the absorption of fat-soluble vitamins, among other functions. They can also enhance food palatability and influence food texture.

Determination of fat requirements as a basis for recommendations is a complex issue owing to the inherent characteristics of fat metabolism and its interaction with energy metabolism. Furthermore, recommendations of desirable ranges of fat intake are influenced by scientific controversies and changing views on both the benefits and risks to human health associated with fat intake. Recommendations may also vary according to the dietary patterns and the prevalence of diet-related noncommunicable diseases in a determined population and in different physiological situations throughout the life-cycle. Most of the data available relating fat intake and health in the general population come from studies in affluent societies and deal with the prevention of chronic diseases, possibly caused by excessive fat intake. An adequate level of fat intake in physiological periods of high and/or special demands has also been of concern. During early development, adequate fat provision will not only influence fetal and infant nutrition but will also have consequences on health in later life.

In this chapter, fat requirements based on current scientific knowledge and the accepted recommendations regarding fat intake for the general adult population, for pregnant and lactating women, and for infants and young children will be specifically addressed.

Fat Requirements for the General Population

Dietary Fat and Energy

Dietary fat intake world-wide is highly variable, ranging from less than 10 to approximately 45% of total energy, being highest among affluent societies. Triacylglycerols present a high digestibility (approximately 95–99%) and the highest energy density among macronutrients (approximately $9\,kcal\,g^{-1}$ or $38\,kJ\,g^{-1}$). Since the metabolic fate of individual fatty acids depends on dietary energy and on energy balance, the intake and requirements for fat and essential fatty acids (EFA) are usually described as the percentage of energy in the diet (en%), rather than total intake (g).

Since the contribution of dietary protein to energy intake shows little variation, low-fat diets are associated with high carbohydrate intakes, and high fat diets with low carbohydrate intakes. Although it is generally assumed that a low fat intake helps to prevent the development of chronic diseases, this may not be necessarily true, since a consequent high intake of carbohydrates can have specific metabolic effects that, in the long term, may lead to chronic diseases, such as type 2 diabetes. Therefore, a compromise should be pursued, regarding an optimal ratio of fat to carbohydrate in the diet. It is currently accepted that dietary fat intake should be moderate: up to 30 en% for sedentary or overweight individuals or up to 35 en% for lean, active individuals, to avoid or minimize the occurrence of chronic diseases associated with high fat intakes. In contrast, fat intake should not be lower than 15 en%, since low fat intakes, common in developing countries especially in rural areas, could limit energy intake and also reduce the absorption of liposoluble vitamins and essential fatty acids.

It has been hypothesized that high levels of dietary fat could lead to obesity. Although it is generally accepted that obesity is the result of a chronic positive energy balance, the homeostatic mechanisms involved in the regulation of energy metabolism discriminate between energy substrates, at both the cellular and whole-body levels. The metabolism of protein and carbohydrates is strictly regulated in the acute and long terms, possibly because of their relatively small storage capacity. Fat, in contrast, has a high storage capacity and is subjected to less efficient homeostatic controls. Additionally, it has been well demonstrated that healthy humans do not synthesize fatty acids *de novo* in appreciable amounts, when eating moderately low and appropriate amounts of fat and carbohydrates, respectively. These evidences lead to the suggestion that high fat intakes *per se* could lead to net weight accretion and obesity. However, an elevated fat consumption alone would not lead to weight gain if not accompanied by a positive energy balance. An elevated consumption of fat is generally associated with high energy intakes, possibly due to a phenomenon known as passive overconsumption or simply due to the elevated energy density of fat. A restriction of dietary fat intake up to the level of 30 en% could help to reduce

energy intake and to improve health. However, fat restriction should be accompanied by total energy restriction and by an exercise plan if weight reduction is to be attained.

Saturated and Unsaturated Fats

The molecular structure of fatty acids will determine their metabolic fate and effects from the cellular level to the whole organism. Fatty acids vary in their chain length, number, position, and geometric configuration of double bonds, which are the main structural differences affecting fatty acid metabolism and, consequently, requirements. Saturated fatty acids are devoid of double bonds, whereas unsaturated fatty acids may have one (monounsaturated) or more (polyunsaturated) double bonds in their carbon chain.

Saturated fatty acids are high in animal fats and palm and coconut oils, and their intake is associated with some of the negative metabolic effects of fats, especially those related to the development of cardiovascular diseases (mainly atherosclerosis and coronary heart disease). The critical links between saturated fat consumption and cardiovascular diseases are total blood cholesterol and low-density lipoprotein (LDL)-cholesterol levels, and thrombosis. Thrombosis is the major determinant of morbidity and mortality from coronary heart disease, and may be caused by elevated saturated fat in the diet. Controlled trials demonstrated that the saturated fat content, as well as the type of saturated fatty acids in the diet, affect serum lipid and lipoprotein levels. The consumption of saturated fatty acids, compared with that of carbohydrates, leads to an increase in total and LDL-bound cholesterol, and it is very likely that high serum cholesterol levels may cause atherosclerosis and coronary heart disease. Therefore, saturated fat intake should be restricted to less than 10 en%. Saturated fatty acids are not equally atherogenic, lauric (12:0), myristic (14:0), and palmitic (16:0) acids seem to elevate LDL-cholesterol levels when compared with carbohydrates, whereas fatty acids with less than 12 carbon atoms (short and medium chain fatty acids) and stearic acid (18:0) seem to have only slight or no effects. These effects are justifiable by the different metabolic fates of these saturated fatty acids. Short-chain fatty acids seem to be oxidized more efficiently than long-chain fatty acids, and stearic acid is probably converted to oleic acid (18:1*n*-9) very rapidly. Although there are differences in the potency of lauric, myristic, and palmitic acids, they are considered the major hypercholesterolemic saturated fatty acids. In case of palmitic acid, its position in the triacylglycerol molecule is also of importance. When bound to the C-2 atom of the glycerol molecule (as in pork lard), it is more hypercholesterolemic than in the C-1 position (such as in palm oil or cocoa butter). A reduction in total saturated fat intake should lead to a decreased consumption of the three aforementioned fatty acids since they are usually the most abundant saturated fatty acids in the diet.

Contrary to saturated fat intake, unsaturated fat intake leads to a decrease in serum cholesterol and LDL-cholesterol levels when substituting for carbohydrates in the diet. The magnitude of this effect is modest when compared with the cholesterol-raising effect of saturated fat. When limiting the intake of saturated fat up to 10 en%, unsaturated fat consumption should increase. The number and position of double bonds in unsaturated fatty acids will influence their effects on serum lipids and lipoproteins levels. The main polyunsaturated fatty acids (PUFA) in the human diet are of the *n*-6 and *n*-3 series, and increasing their intake up to a certain limit should have beneficial effects on human health. However, PUFA are susceptible to peroxidation and generation of reactive oxygen species, which could increase the susceptibility of LDL to oxidation, leading to an increased risk of atherosclerosis, and are also involved in the etiology of certain types of cancer. Therefore, PUFA intake should not be higher than 10 en%.

Although the consumption of monounsaturated fatty acids slightly decreases serum cholesterol and LDL-cholesterol levels, they are generally considered metabolically 'neutral' when compared with polyunsaturated and saturated fatty acids. Therefore, monounsaturated fat intake should account for the remaining of the energy intake contributed by fat, which should correspond to more than 10 en%. However, when the intake of *cis*-monounsaturated fatty acids is elevated (18:1*n*-9/18:2*n*-6 ratio of 10:1), essential fatty acid deficiency may occur.

Essential Fatty Acids

Since animals, in contrast to vegetables, are incapable of synthesizing fatty acids with double bonds at positions *n*-6 or *n*-3, owing to a lack of Δ-12 and Δ-15 desaturase activities, these compounds should be present in the human diet. Linoleic (18:2*n*-6) and α-linolenic (18:3*n*-3), considered essential for humans, are the main fatty acids of the *n*-6 and *n*-3 series in the modern diet. Owing to the high intake of vegetable oils, linoleic acid is present in the diet in higher amounts than α-linolenic acid. PUFA are incorporated into cellular membranes where they present structural functions. In addition, 18:2*n*-6 and 18:3*n*-3 are substrates for the synthesis of long-chain polyunsaturated fatty acids with 20 or 22 carbon atoms (LCPUFA): arachidonic acid (20:4*n*-6;

ARA), dihomo-γ-linolenic acid (20:3*n*-6), eicosapentaenoic acid (20:5*n*-3; EPA), and docosahexaenoic acid (22:6*n*-3; DHA). DHA has an important structural role in the brain and retina, and the LCPUFA with 20 carbon atoms are precursors for the synthesis of eicosanoids, a group of important signaling molecules.

When EFA are not present in the diet in appropriate amounts, deficiency will take place, and various tissues and organs will be affected, owing to EFA ubiquitous structural and regulatory functions. Although its validity has already been questioned, the tissue ratio of 20:3*n*-9 (Mead's acid) to 20:4*n*-6 (triene/tetraene ratio) is still considered a sensitive biochemical marker of essential fatty acid deficiency and should be lower than 0.4 for the human. Mead's acid is the product of elongation and desaturation of oleic acid, which is an important substrate for elongases and desaturases only in the case of deficiency of *n*-6 and *n*-3 fatty acids. Diets with 0.1–0.5 en% of linoleic acid are sufficient to normalize an abnormally high triene/tetraene ratio, but for optimal function of various tissues, much higher intakes of 18:2*n*-6 are necessary. The adequate level of linoleic acid in the diet depends on the criteria used for its determination. It has been recommended that linoleic acid intake should be 1–2 en% to avoid clinical and biochemical signs of EFA deficiency, whereas its intake should be 3–5 en% for the prevention of chronic diseases.

α-Linolenic acid is much less efficient in the treatment of EFA deficiency than linoleic acid, raising the possibility that the former is a conditionally essential nutrient. However, its essentiality for the development and maintenance of normal functions in the retina and brain has now been confirmed, although the adequate level of intake has not yet been strictly determined. It has been estimated that for adult men, the consumption of 2 g day^{-1} of 18:3*n*-3 should provide 75–85% of the 350–400 mg day^{-1} requirement of long-chain *n*-3 fatty acids (20:5*n*-3 and 22:6*n*-3). The intake of approximately 1 en% or 3 g day^{-1} of 18:3*n*-3 and 800 mg of 20:5*n*-3 plus 22:6*n*-3 should provide an adequate supply of *n*-3 fatty acids for healthy adults.

Fatty acids of the *n*-3 and *n*-6 series will compete for the same enzymatic systems: acyl-transferases for incorporation into membranes; elongases and desaturases for LCPUFA synthesis; and lipoxygenase, cycloxygenase and other enzymes for eicosanoid synthesis. Therefore, the balance between tissue levels of *n*-3 and *n*-6 fatty acids will depend on the balance between dietary EFA. Although the optimal ratio of *n*-6/*n*-3 in the diet has been set between 4:1 and 10:1, scientific evidence is lacking to support ratios equal or higher than 5:1. Furthermore, an adequate tissue ratio of *n*-6 to *n*-3 is important to prevent coronary heart disease and stroke, since *n*-6 fatty acids are precursors of eicosanoids that stimulate platelet aggregation and vasoconstriction, in contrast to *n*-3 fatty acids, which are precursors of eicosanoids that stimulate vasodilatation and are much less aggregatory.

Isomeric Fatty Acids

The double bonds in fatty acids may present two geometrical configurations: *cis* (the most common) and *trans*. *Trans* fatty acids are formed during partial hydrogenation of vegetable fats and oils, which are widely used in the food industry for the production of margarine, shortenings, frying fats, among other products. Isomeric fatty acids formed through biohydrogenation in the rumen may be naturally present in meat, milk, and dairy products, which are enriched in *trans*-11-octadecenoic acid (*trans*-11–18:1). The main sources of total *trans* fatty acids in the Western diet are the hydrogenated vegetable fats, which are rich in octadecenoates with double bonds between Δ9 and Δ12.

The consumption of monoenes with a *trans* double bond has long been associated with elevated total and LDL-bound cholesterol in serum, and possibly with reduced levels of high-density lipoprotein cholesterol. In controlled trials in which the *trans* fatty acid intake was increased, an increment in total and LDL-bound cholesterol in serum occurred. It has also been hypothesized that *trans* fatty acids are more potent in eliciting such effects than saturated fatty acids. However, this subject is still a matter of debate, because the dietary levels that would lead to altered serum lipid and lipoprotein levels are much higher than that generally consumed. It is a consensus that *trans* fatty acids intake should be kept low (up to approximately 2 en%), but apparently, there is no need for further limiting when the intake of total fat and of essential and saturated fatty acids is appropriate. However, it should be emphasized that consumers of higher amounts of *trans* fatty acids may present a higher risk of morbidity from cardiovascular diseases.

Other geometrical isomers of unsaturated fatty acids are also present in foodstuffs, the conjugated fatty acids, which are polyunsaturated fatty acids with conjugated double bonds, i.e., double bonds separated by two carbon atoms instead of three. The main dietary sources of conjugated fatty acids are meat and dairy products from ruminants, and the most common are the octadecadienoic or conjugated linoleic acids (CLA). Conjugated linoleic acids have important biological effects that could be beneficial,

even when present in the diet at very low amounts (≤ 1 en%). Effects of CLA range from a potent anticarcinogenic effect to changes in body composition with reduction in the adipose tissue size. Advisable and upper tolerable levels of intake for CLA have not yet been defined, because of the scarce scientific data concerning CLA consumption and its effects in human subjects.

Fat Requirements During Pregnancy and Lactation

Pregnant Women

In the periconceptional period, maternal nutrition is particularly important owing to its influence on the physiological process of fat accretion during pregnancy. Maternal fat stores are critical for placental development and embryonic cell division and differentiation in the first trimester of pregnancy, for the intense fetal growth during the third trimester, and for the production of milk in early lactation. The building up of adequate fat stores requires an increase in energy and fat intakes during pregnancy. The estimated additional energy for pregnant women according to the WHO Report on Energy and Protein Requirements (1985) is 300 kcal day^{-1} for the whole pregnancy, with 30 en% as fat. Dietary energy from fat should not be lower than 20% for women of reproductive age, who might otherwise be exposed to an insufficient supply of EFA and fat-soluble vitamins.

Owing to the demands of EFA for fetal, placental, mammary gland, and uterine growth, and for the increase in maternal blood volume, maternal EFA intake during pregnancy should be increased from 3 to 4.5% of the total energy, and the ratio *n*-6/*n*-3 should be maintained at approximately 5:1.

High consumption of fish and dietary supplementation with *n*-3 LCPUFA are associated with a modest increase in the length of gestation and with reduced incidence of low birth weight and prematurity, suggesting that the dietary consumption of preformed DHA could be advantageous.

Placental transfer of ARA and DHA during pregnancy occurs preferentially in relation to other fatty acids. This can be explained by the presence of a plasma membrane fatty acid-binding protein that presents the highest affinities and binding capacities for both fatty acids, especially DHA. It seems that elongation and desaturation of EFA in human placenta are limited, and the fetus depends on the transfer of ARA and DHA from maternal circulation. There is a substantial increase of ARA and DHA in fetal circulation, and fetal organs such as the liver and brain incorporate large amounts of *n*-3 and *n*-6 LCPUFA into membrane phospholipids by the end of the third trimester. Therefore, the preterm infant will be endowed with a reduced provision of ARA and DHA *in utero*, and will be at a disadvantage concerning fat stores and membrane LCPUFA when compared with term infants.

Prematurity and low birth weight are associated with a high risk of neurodevelopmental disorders and disabilities. An inadequate supply of ARA and DHA during the period of rapid vascular and brain growth could lead to membrane fragility, leakage and breakdown, resulting in ARA peroxidation, vasoconstriction, inflammation, and ischemia, which could explain those disabilities. Fetal exposure to *trans* fatty acids, which are transferred across the placenta, has been related to low birth weight in premature infants.

Lactating Women

The total fat content in human milk is highly variable and is affected by several factors but is secreted in adequate amounts to support infant growth and development in a wide range of maternal nutritional status, unless overt undernutrition is present. The fatty acid composition of the triacylglycerols in milk, however, is dependent on maternal fatty acid intake, body stores, and endogenous synthesis. Gestational age, stage of lactation, nutritional status, and genetic background may also influence the fatty acid composition of human milk.

Saturated and monounsaturated fatty acids are the major fatty acids in human milk, comprising approximately 83% (wt/wt) of the total fatty acids in mature milk. In well-nourished mothers, approximately 11% (wt/wt) of fatty acids in human milk is linoleic acid and 1% α-linolenic, while total *n*-6 and *n*-3 LCPUFA account for 1.2 and 0.6%. Total PUFA accounts for 6% of total energy in milk. PUFA transfer from maternal circulation to milk and the synthesis of LCPUFA from the EFA precursors are a matter of concern, because of their importance for infant growth, neurodevelopment, and visual function. Studies with lactating women using stable isotope methodologies demonstrated that the major part of PUFA in human milk is derived from maternal body stores, which reflect long-term intake, and not from direct dietary transfer. In women on omnivorous diets, about 30 and 12%, respectively, of linoleic acid and ARA secreted in milk were derived from the diet. Endogenous synthesis from dietary linoleic acid accounted for about 3–25% and 1–3% of dihomo-γ-linolenic acid and ARA in milk, respectively.

Assuming an appropriate weight gain during pregnancy, an additional average energy allowance

of 500 kcal day^{-1} is recommended throughout lactation, according to WHO (1985). An additional maternal intake of 1–2% of energy in the form of EFA (3–4 g day^{-1}) is recommended during the first 3 months of lactation, and thereafter a further increase of up to 4% of energy (about 5 g day^{-1}) is required, owing to depletion of maternal fat stores. An inverse correlation between *trans* fatty acids and ARA and DHA in plasma lipids has been reported in infants, suggesting an impairment in LCPUFA synthesis and metabolism. Therefore, maternal intake of *trans* fatty acids is of concern when their intake is excessively high or when EFA intake is low during pregnancy and lactation.

Fat Requirements in Infancy and Early Childhood

Both the amount and quality of dietary fat can affect child growth and development. Breast milk is the best available source of dietary fat and fatty acids for infants, providing between 50 and 60 en% as fat and LCPUFA in adequate amounts for brain development. The human infant should be preferentially breast-fed, but when infant formulas are used, the fatty acid composition should ideally correspond to that of breast milk. Of special concern is the adequate provision of LCPUFA to preterm infants who present an insufficient intrauterine supply of these fatty acids.

LCPUFA are required for adequate brain growth and development. Their requirements are especially high during the last trimester of pregnancy and in the first months of life, when the brain is rapidly developing, and there is a significant deposition of DHA in the central nervous system. The brain gray matter and membranes of the retina present low deposition of EFA but contain high amounts of LCPUFA, which can be incorporated from plasma.

Synthesis of LCPUFA was demonstrated in term infants from the first week of life and even in very-low-birth-weight infants through stable isotope methodologies. However, the contribution of endogenous synthesis to the total plasma LCPUFA pool is small. The rate of ARA synthesis in term infants is low, and it accounts for only about 6% of total ARA renewal in plasma. Therefore, the term infant and especially the preterm infant possibly do not synthesize enough LCPUFA to attain their requirements for brain development during the first few weeks after birth.

Infants fed human milk, compared with infants fed DHA-free formulas, present higher plasma concentrations of LCPUFA and also higher levels of DHA in red blood cell phospholipids and in brain cortex. Clinical trials in premature infants showed beneficial effects of infant formulas enriched in ARA and DHA, such as higher LCPUFA concentrations in plasma, improvement of visual acuity and cognitive abilities, without compromising growth and safety. Several studies with healthy full-term infants indicated that infants fed breast milk or DHA-supplemented formulas presented better visual resolution acuity at 2 months and possibly at 4 months of age than infants fed DHA-free formulas.

A WHO/FAO Expert Committee (1994) based its recommendations for EFA and LCPUFA provision to infants on the composition of breast milk from well-nourished mothers, which provides both parent EFA and their LCPUFA products in apparently adequate amounts to fulfill infants' requirements. The WHO/FAO recommendations described below are similar to those published in position papers of other national and international expert committees.

Total EFA (*n*-6 plus *n*-3) should comprise 5–6 en% (or 0.6–0.8 g kg^{-1} day^{-1}) and LCPUFA 0.8 en%. The total *n*-6/*n*-3 ratio should be in the range of 5:1 to 15:1. To insure tissue proliferation, membrane integrity, and eicosanoid formation, linoleic acid should be supplied as a minimum of 1–4.5 en% or 0.5–0.6 g kg^{-1} day^{-1}, but its intake should be limited to amounts lower than 10–12 en%, since its excess impairs production of the *n*-3 LCPUFA. Arachidonic acid could be considered conditionally essential during early development, owing to its specific neural and vascular functions, the role of its derived eicosanoids in cell regulation, and the interactions between the *n*-3 and *n*-6 fatty acids series. In this regard, 40 mg of ARA should be provided for the term infant, whereas for the premature infant, the amount would be 60–100 mg kg^{-1} day^{-1}, since, in these infants, a low level of ARA is associated with low pre- and postnatal growth.

Total *n*-3 fatty acids should amount to 70–150 mg kg^{-1} day^{-1}, and the intake of DHA should be 20 and 40 mg kg^{-1} day^{-1} for term and preterm infants, respectively. The DHA/ARA ratio should be 1:1 to 1:2, since excess DHA impairs ARA metabolism. Intake of α-linolenic acid should be approximately 1 en% in the absence of intake of EPA and DHA, or 0.5 en% when there is a supply of these LCPUFA, although the bioequivalency of *n*-3 EFA and its LCPUFA products has not yet been determined in infants.

Regarding formulas for preterm babies, a mixture of oleic acid and saturated fatty acids, with a predominance of the former, could provide the required energy from fat, since this mixture would possibly meet the desirable criteria of digestibility and lack of interference with essential fatty acid metabolism.

According to the FAO/WHO (1994) recommendations, during weaning and at least until 2 years of age,

a child's diet should contain 30–40 en% as fat and provide similar levels of EFA to those found in breast milk. Special attention should be given to the complementary foods used in the weaning period in many developing countries, where cereals or tuber-based diets with a low energy density are used, resulting in a drastic drop in energy intake. Low-fat diets with less than 30 en% as fat have been associated with adverse effects on child growth, but this might also have been associated with a low intake of total energy and other nutrients.

The increase of the prevalence and severity of obesity and type 2 diabetes mellitus in the pediatric population is of particular concern, mainly in affluent societies, which reinforces the need for appropriate nutrition, including the quantity and quality of dietary fat, not only in childhood but also in early development.

Fat Replacers

B G Swanson, Washington State University, Pullman, WA, USA

Fat

Reducing dietary fat is a major, if not the primary, dietary goal for many consumers. With encouragement from health groups and government agencies, the public is increasingly choosing foods and beverages naturally low in fat, as well as new, revolutionary low-fat and nonfat foods and beverages. The development and use of a wide variety of food ingredients, known as fat replacers, are making many low fat or nonfat foods possible.

Fat, protein, and carbohydrates are essential components of the human diet. Fat is the most concentrated source of energy, contributing $38\,kJ\,g^{-1}$; protein and carbohydrates contribute approximately $17\,kJ\,g^{-1}$ to the diet. Some dietary fat is essential to enable the body to function properly. Fat is responsible for transporting fat-soluble vitamins A, D, E, and K and is also a source of essential fatty acids necessary for good health. (*See* **Essential Fatty Acids**.)

Most consumers enjoy the taste, texture, and aroma fat gives to foods. Fat consumption, however, is often considered too great by public health organizations and nutritionists since a high intake of dietary fat is associated with an increased risk for obesity, some types of cancer, and possibly gall bladder disease. Epidemiological, clinical, and animal studies provide strong and consistent evidence for a relationship between saturated fat intake, high blood cholesterol, and increased risk for coronary heart disease.

There are two primary types of fat replacers being investigated: 'energy-free fat substitutes' and 'energy-reduced fat mimetics.' Energy-free fat substitutes are neither digested nor absorbed and therefore contribute no fat, calories, or cholesterol to the diet. Fat substitutes are formulated and synthesized to exhibit physical and cooking properties similar to fats or oils, and are expected to replace some or all of the fat in cooking, as well as in foods.

Fat Substitutes

A group of compounds, called sucrose fatty acid polyesters with the trade names 'olestra 7' or 'olean 7,' produced by Procter and Gamble Co., were approved for use in savory snacks by the United States Food and Drug Administration (FDA) in 1996, amidst great controversy regarding the potential health benefits and risks. Recent consumer and industry surveys suggest that the benefits of fat substitutes far outweight the purported risks, and are being favorably received by many consumers. Sucrose polyester fatty acid mono- and di-esters are FDA-approved emulsifiers at concentrations of less than 1% in food emulsions. (*See* **Emulsifiers**: Organic Emulsifiers.)

Carbohydrate (sucrose) fatty acid polyesters are synthesized from fatty acid methyl esters and sugars or sugar derivatives. Fatty acids available from many triacylglycerol sources and sugars, such as sucrose, glucose, raffinose, stachyose, and trehalose, as well as sugar alcohols are combined, with the sugar as the center and the esterified fatty acids extending away from the sugar like spokes in a wheel. Sugars heavily saturated (esterified) with fatty acids, such as hexa-, hepta-, or octa-fatty acid esters of sucrose, are not hydrolyzed by sterically and hydrophobically hindered enzymes in human digestive tracts, are not absorbed, and are poorly metabolized by colonic microorganisms. The steric and hydrophobic hindrance of lipolytic enzymes is in response to the many fatty acids esterified to sucrose, and the accompanying hydrophobic cloud surrounding the ester bonds on the sucrose molecule. (*See* **Carbohydrates**: Metabolism of Sugars; **Triglycerides**: Structures and Properties.)

Prior to petitioning the FDA for approval of olestra 7, Procter and Gamble evaluated olestra 7 in more than 100 animal and 25 clinical studies involving thousands of individuals with no observations of mutagenic, teratogenic, or developmental responses. Carbohydrate fatty acid polyesters exhibit organoleptic and physical properties similar to conventional vegetable oils or animal fats (triacylglycerols), including necessary heat stability for frying.

Structured lipids or medium-chain triacyglycerols are being prescribed for treatment of patients suffering from malabsorption symptoms, pancreatic insufficiency, bile duct obstruction, steatorrhea, and lipoproteinemia, and to bypass surgery patients and infants requiring feeding formulas. Structured lipids are generally triacylglycerols made up of two short to medium-chain (< 12 carbon) fatty acids combined with a single long chain (> 12 carbon) fatty acid. Structured lipids provide the physical and functional properties of fat while contributing approximately one-half the calories or normal edible oils. 'Caprenin 7' and 'Salatrim 7' are structured lipids approved for use as confectionary fats as well as for use in bakery and filled dairy products in the USA.

Malonate esters, synthesized from malonic acid, hexadecane, and fatty acids, were developed by Frito-Lay, Inc. as a calorie-free substitute for high-temperature frying applications. Feeding studies with rats indicate that only trace concentrations are absorbed, and the liver is the primary organ of distribution and elimination.

Esterified propoxylated glycerol is similar to a natural triglyceride, except that oxypropylene is incorporated between the glycerol and the fatty acids. Short-term animal studies suggest that esterified propoxylated glycerol is safe and resistant to hydrolysis.

Trialkoxytricarballate is also similar to natural triglycerides with tricarballylic acid replacing the glycerol and saturated or unsaturated alcohols replacing the fatty acids. Animal studies indicate that trialkoxytricarballates are not digested. Trialkoxytricarballates may be used to replace vegetable oil in cooking applications as well as in food emulsions.

Polyorganosiloxane compounds are also noncaloric, nonabsorbable liquid oils derived from silica that are chemically inert and not toxic. The polysiloxanes are stable, maintain viscosity over a wide temperature range, are resistant to oxidation, hydrolysis, and degradation, and are similar in solubility characteristics to nonpolar lipids.

Jojoba oil and its derivatives have many applications as constituents of cosmetics and pharmaceuticals. Jojoba margarine and mayonnaise have been shown to exhibit functional properties different than controls, but perform acceptably in most food applications. Unfortunately, jojoba oil is sensitive to hydrolysis by pancreatic lipases. The *in vivo* digestibility of jojoba oil may be as much as 20%.

Other fat-based fat substitutes or replacers include Dur-Lo, a vegetable oil mono- and diglyceride emulsifier manufactured by Durkee Industrial Foods Corporation, which can replace all or part of the shortening content in cake mixes, cookies, icings,

and numerous vegetable oil-based dairy products when emulsified with water. Mono- and di-glycerides are considered generally recognized as safe (GRAS) by the FDA. Emulsion systems using soybean oil or milk fat can reduce fat and calories significantly by replacing fat on a one-to-one basis, while utilizing less fat and contributing fewer calories.

Fat Mimetics

Fat mimetics are compounds that help replace the mouthfeel of fats by contributing a greater viscosity to the liquid phase in the mouth, but cannot substitute for fats on a gram-for-gram basis. Fat mimetics do not have the nonpolar chemical properties of fats and cannot be used for frying applications because of water concentration and heat lability.

Fat mimetics are categorized as 'protein-based,' 'carbohydrate-' or 'starch-based', or 'cellulose-based.' Many of the fat mimetics have been marketed and are available in a wide variety of formulations as salad dressings, frozen desserts, and baked goods.

'Protein-based' fat mimetics marketed under product names Simplesse 7, Trailblazer 7, and Finesse 7 are structurally modified natural proteins derived from milk or egg white. Simplesse is the initial protein-based fat replacer prepared with a patented heating and homogenization process of microparticulation in which the proteins are aggregated into tiny, round particles that create the creaminess and mouthfeel of fat. Simplesse cannot be used in heated foods because the protein will congeal and lose the creamy mouthfeel. Traiblazer and Finesse are similar modified protein texturizers prepared with unique and innovative combinations of heat, acidulation, and homogenization of natural proteins, selected carbohydrates, and water.

Carbohydrate- or starch-based fat mimetics are formulated from GRAS oligo- or poly-saccharides chemically extracted and prepared from hydrolyzed, often modified, corn, potato, or tapioca starch. Many calorie-reducing carbohydrate starch-based fat mimetics are available for use as ingredients in low-calorie or 'lite' foods.

Table 1 Selected applications and functions of fat replacing

Specific application	*Fat replacer*	*General functions*[a]
Baked goods	Lipid-based	Emulsify, provide cohesiveness, tenderize, carry flavor, replace shortening, prevent staling, prevent starch retrogadation, condition dough
	Carbohydrate-based	Retain moisture, retard staling
	Protein-based	Texturize
Frying	Lipid-based	Texturize, provide flavor and crispiness, conduct heat
Salad dressing	Lipid-based	Emulsify, provide mouth feel, hold flavorants
	Carbohydrate-based	Increase viscosity, provide mouth feel, texturize
	Protein-based	Texturize, provide mouth feel
Frozen desserts	Lipid-based	Emulsify, texturize
	Carbohydrate-based	Increase viscosity, texturize, thicken
	Protein-based	Texturize, stabilize
Margarine, shortening, spreads, butter	Lipid-based	Provide spreadability, emulsify, provide flavor and plasticity
	Carbohydrate-based	Provide mouth feel
	Protein-based	Texturize
Confectionery	Lipid-based	Emulsify, texturize
	Carbohydrate-based	Provide mouth feel, texturize
	Protein-based	Provide mouth feel, texturize
Processed meat products	Lipid-based	Emulsify, texturize, provide mouthfeel
	Carbohydrate-based	Increase water-holding capacity, texturize, provide mouth feel
	Protein-based	Texturize, provide mouth feel, water-holding
Dairy products	Lipid-based	Provide flavor, body, mouth feel, and texture; stabilize, increase overrun
	Carbohydrate-based	Increase viscosity, thicken, aid gelling, stabilize
	Protein-based	Stabilize, emulsify
Soups, sauces, gravies	Lipid-based	Provide mouth feel and lubricity
	Carbohydrate-based	Thicken, provide mouthfeel, texturize
	Protein-based	Texturize
Snack products	Lipid-based	Emulsify, provide flavor
	Carbohydrate-based	Texturize, aid formulation
	Protein-based	Texturize

[a]Functions are in addition to fat replacement.

Carbohydrate-based fat mimetics are generally digested and absorbed to some extent, contributing 19 kJ or less per gram of carbohydrate. Carbohydrate-based mimetics taste bland, are soluble in water, somewhat pH- and heat-stable, and, most importantly, contribute a smooth, creamy texture and mouthfeel of fat, as well as the spreadability and appearance when replacing all or part of the fat in natural or emulsified foods. General categories of foods, potential fat replacers, and the functions of the fat replacer in addition to fat replacement are presented in Table 1.

Cellulose-based fat mimetics contribute no calories to the diet in contrast to the carbohydrate- or protein-based fat mimetics. One cellulose-based fat mimetic is Avicel, a blend of microcrystalline cellulose and carboxymethyl cellulose. Cellulose-based fat mimetics contribute a creamy mouthful and little taste to foods.

With increasing evidence that fat consumption and obesity are detrimental risk factors for chronic disease, and that reducing the intake of dietary fats and oils will contribute to improved public health, the demand of health conscious consumers for reduced fat foods will continue. Despite medical opinion and media attention to the benefits of reducing fat consumption, many consumers find it difficult to make long-term changes in their eating habits when taste and enjoyment are compromised by reduction in dietary fat. (*See* **Obesity**: Treatment.)

Unique achievements in food science research and technology are resulting in safe ingredients to replace fats in foods. When limiting fats, calories, and sugars in the diet, consumers need to satisfy their basic essential nutritional needs. No fat replacer is a panacea, and additional reduced fat and reduced calorie foods will neither compensate for poor dietary habits nor replace the need for moderation and good overall nutrition. So, the consensus for the need to reduce dietary fat is offset by the difficulty in identifying alternative foods that encourage consumers to make long-term dietary changes. Low-fat and low-calorie foods and beverages formulated from ingredients that replace hidden and obvious fats and oils can help to maintain a healthy, nutritious diet.

Classification

M H Gordon, The University of Reading, Reading, UK

Introduction

Together with proteins, carbohydrates and water, fats represent the major bulk constituents in food and other biological materials. Fats comprise several classes of chemical compounds, termed lipids, that have common solubility properties, i.e., soluble in low-polarity organic solvents such as chloroform, diethyl ether and light petroleum, but sparingly soluble in water. Although these characteristics are valid for many lipids, there is a range of polarity amongst various members of this class and many lipids have a low solubility in nonpolar solvents such as light petroleum. Chloroform is often the best solvent for a wide range of lipids. The term 'fats' may be applied to all lipid-soluble extracts from biological materials,

or a distinction may be made between oils, which are liquid, and fats which are solid. Chemically, fats include many compounds which are fatty acids or esters of fatty acids. However, other components are classified as lipids on the basis of their solubility properties, even though they are not esters of fatty acids. (*See* **Fatty Acids**: Properties.)

Lipids can be classified into three groups: simple lipids, compound lipids, and derived lipids. Simple lipids are esters of fatty acids which produce two classes of compounds on hydrolysis. Compound lipids are esters of fatty acids which produce three or more classes of compounds on hydrolysis. Derived lipids cannot be hydrolyzed to fatty acids.

Simple Lipids

The main simple lipids are triglycerides (also known as triacylglycerols), steryl esters, and wax esters. Hydrolysis of these lipids yields glycerol and fatty acids, sterols and fatty acids, and fatty alcohols plus fatty acids, respectively. The most important of these simple lipids for food scientists are the triglycerides. They are the major components of edible oils and fats, often representing more than 95% of refined oils. Triglycerides are esters of the trihydric alcohol glycerol with three fatty acids (Figure 1). Many of the properties of triglycerides are dependent on the component fatty acids. Thus, the melting point of the triglyceride reflects the melting point of the component fatty acids, with three high-melting-point fatty acids yielding a high-melting triglyceride. Unsaturation in the fatty acids makes the triglyceride susceptible to autoxidation, just as the fatty acid itself would be. (*See* **Triglycerides**: Structures and Properties.)

All triglycerides are susceptible to hydrolysis in the presence of a catalyst. Acids, bases, or enzymes belonging to the hydrolase class, especially lipases, may act as the catalyst for the hydrolysis of triglycerides.

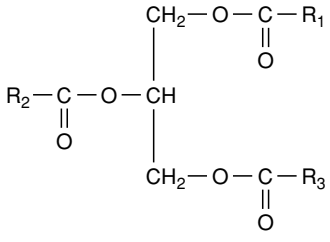

Figure 1 Triglyceride structure. Reproduced from Lipids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

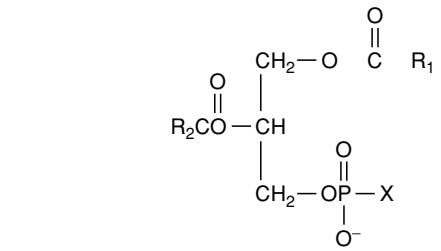
Steryl esters always occur together with sterols in plant, animal, or microbiological tissues. Wax esters may accumulate in considerable amounts in some biological tissues and this class comprises the main constituent of beeswax and jojoba oil.

Compound Lipids

There are many members of this group. Probably the most important compound lipids for food science are the phospholipids.

Phospholipids

Phospholipids are esters of glycerol, fatty acids, phosphoric acid, and other alcohols. The most common phospholipids are phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, and phosphatidylserine. These phospholipids share the common features of fatty acids esterified to the 1 and 2 positions of the glycerol backbone with the phosphate group esterified to the 3 position (Figure 2). (*See* **Phospholipids**: Properties and Occurrence.)



Phosphatidylcholine (Lecithin)	X = —$OCH_2CH_2\overset{+}{N}(CH_3)_3$
Phosphatidylethanolamine (Cephalin)	X = —$OCH_2CH_2\overset{+}{N}H_3$
Phosphatidylserine	X = —$OCH_2CH(\overset{+}{N}H_3)(CO_2^-)$
Phosphatidylinositol	X = Phosphatidylglycerol	X = —$OCH_2CHOHCH_2OH$

Figure 2 Phospholipid structure. Reproduced from Lipids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Whereas triglycerides occur in lipid droplets in storage cells of plants, animals, and microorganisms, phospholipids are the major components of cell membranes. They are always present in small amounts in edible oils extracted from biological tissues. However, the bulk of the phospholipids are removed by degumming during the refining of edible oils. Phospholipids differ from triglycerides in being surface-active and they are used in food products as emulsifiers because they migrate to the interface between oil and water, and reduce the inter-facial tension, thereby stabilizing an emulsion. Commercial phospholipid preparations are called lecithin. (*See* **Emulsifiers**: Organic Emulsifiers.)

Glycolipids

Glycolipids yield fatty acids, glycerol, and carbohydrates on hydrolysis. Monogalactosyldiglycerides (Figure 3) are glycolipids which are commonly found in plant leaves and algae. They contain a high proportion of polyunsaturated fatty acids and appear to play a role in photosynthesis. They are also found in the central nervous systems of some animals. Digalactosyldiglycerides often accompany monogalactosyldiglycerides in the chloroplasts of higher plants and algae, but generally at lower concentrations. Mono- and digalactosyldiglycerides are surface-active compounds which are known to play a key role in the baking quality of wheat flour. They assist the incorporation of air into the dough, thereby increasing the loaf volume, and they also have antistaling properties. (*See* **Bread**: Chemistry of Baking.)

Sulfoquinovosyldiglyceride (Figure 4) is one of the most polar plant lipids. It occurs in the leaves of plants, where it appears to play a role in photosynthesis. It is a significant dietary lipid in green leafy vegetables such as spinach.

Cerebrosides and cerebroside sulfates are further examples of glycolipids. These are discussed further under sphingolipids.

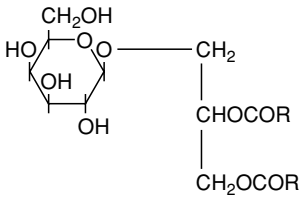

Figure 3 Monogalactosyldiglyceride structure. Reproduced from Lipids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

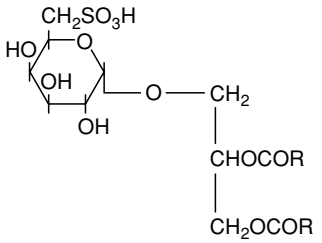

Figure 4 Sulfoquinovosyldiglyceride structure. Reproduced from Lipids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Sphingolipids

Sphingolipids are important membrane components in both plant and animal cells. They are present in especially large amounts in brain and nerve tissue. Mammalian enzymes include those which can catalyze the hydrolysis of sphingolipids. If one of these enzymes is missing, disorders known as lipidosis may occur as the lipid accumulates in the tissues.

Sphingolipids (Figure 5) are derivatives of the amino alcohol sphingosine, which is found in animal tissues, or phytosphingosine, which is found in plant tissues. Lipids derived from other related bases are included in this group. Sphingosine is one of more than 60 long-chain amino alcohols found in animals, plants, and microorganisms. The bases commonly contain between 12 and 22 carbon atoms in the chain. A ceramide, which is an amide formed from a fatty acid and sphingosine, is the characteristic parent structure of all sphingolipids.

The fatty acid groups in ceramides are long-chain, with up to 26 carbon atoms, and are commonly saturated, monounsaturated, or hydroxy fatty acids. Although free ceramides have been found in small amounts in plant and animal tissues, they are generally present as a component of more complex sphingolipids.

Sphingomyelins are the most abundant sphingolipids in the tissues of higher animals. The 1-hydroxyl group of ceramide is esterified with phosphoric acid esterified with choline or with ethanolamine.

Cerebrosides are glycosphingolipids which contain a carbohydrate linked by a glycosidic linkage at the 1-hydroxyl position of the long-chain base. Cerebrosides are the major sphingolipids of plants. Wheat flour contains cerebrosides from at least four classes of amino alcohol. Plant cerebrosides contain only glucose as their component sugar, while animal cerebrosides contain galactose, glucose, or di-, tri- or tetrasaccharides. (*See* **Wheat**: The Crop; Grain Structure of Wheat and Wheat-based Products.)

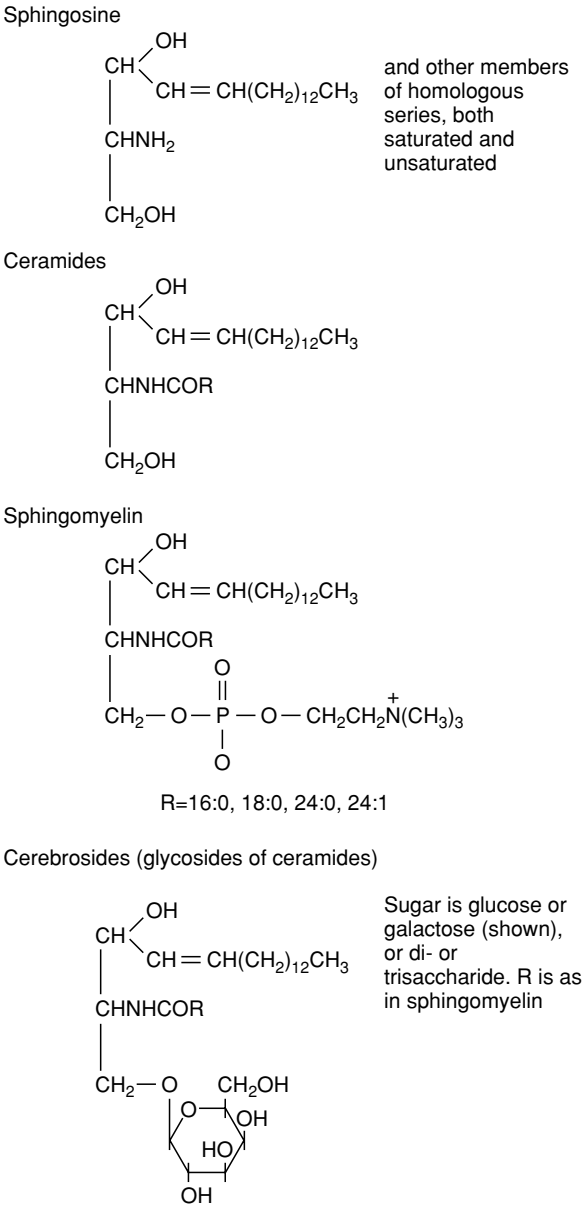

Figure 5 Sphingolipid structure. Reproduced from Lipids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Lipoproteins

Lipoproteins may also be classified as compound lipids. These are compounds of proteins, fatty acids, and alcohols and may include other classes. Lipids and proteins are largely held together by hydrophobic interactions. Transport lipoproteins and membrane lipoproteins are important biomolecules in human physiology. (*See* **Lipoproteins**.)

Derived Lipids

This group of lipids includes a range of compounds which vary widely in their structures. The main derived lipids include: (1) fatty acids, (2) fat-soluble vitamins and provitamins, (3) alcohols – including sterols – (4) terpenoids; and (5) ethers.

Fatty Acids

Although simple and compound lipids are esters of fatty acids, the free fatty acids only occur in relatively small amounts in food and food raw materials. Edible oils usually contain only small amounts of free fatty acids when isolated from the plant, animal, or microbiological source. The concentration of free fatty acids rises in bruised fruit such as palm fruit if the lipases present are not inactivated rapidly by heating.

However, normal values of free fatty acids are below 5% in most crude edible oils. The free fatty acids present are mixtures similar to those present in the triglycerides. Most free fatty acids are removed from crude edible oils during refining because of the undesirable effects on flavor, and the reduction of the smoke point caused by free fatty acids. A refined oil usually contains less than 0.1% free fatty acids.

Vitamin A

Vitamin A is a C_{20} primary alcohol occurring either as vitamin A_1 or vitamin A_2. The vitamin occurs in animal and marine products such as butter (1 mg per 100 g) and eggs (3.7 mg per 100 g). It is commonly used in the form of acetate or palmitate esters as a food additive. Vitamin A can also be formed *in vivo* from some carotenoids such as β-carotene. (*See* **Retinol**: Properties and Determination.)

Vitamin D

The term 'vitamin D' refers collectively to a group of compounds derived from sterols, which are effective in preventing the development of rickets in children. Ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) are the most common compounds with vitamin D activity. Ergocalciferol is formed by the irradiation of ergosterol with ultraviolet light whereas cholecalciferol is formed in an analogous manner from 7-dehydrocholesterol. (*See* **Cholecalciferol**: Properties and Determination.)

Vitamin E

Eight compounds belonging to the tocopherol and tocotrienol classes have vitamin E activity. Vegetable oils in general contain more vitamin E than animal fats, and vegetable oils rich in polyunsaturated fatty acids tend to be good sources of vitamin E. (*See* **Tocopherols**: Properties and Determination.)

Vitamin K

Compounds exhibiting vitamin K activity possess a 2-methyl-1, 4-naphthoquinone ring with differing chain-length polyprenyl substituents at the 3 position. The dietary requirement for vitamin K by the adult human is extremely low, because the vitamin is synthesized in the intestine by intestinal bacteria. The main dietary sources of vitamin K are green vegetables, which commonly contain > 100 μg per 100 g.

Carotenoids

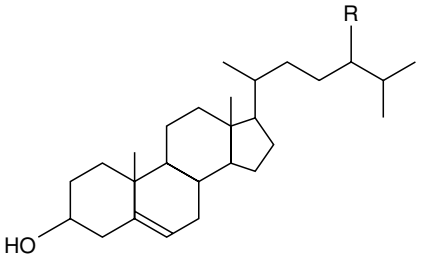
Carotenoids contribute the yellow, orange, or red colors of many fruits and vegetables, such as carrots, peaches, and tomatoes. They are commonly extracted with vegetable oils, including crude palm oil, which is a rich source containing 500 p.p.m. (*See* **Carotenoids**: Occurrence, Properties, and Determination.)

Sterols

Sterols occur in the membranes of plants, animals, and microorganisms and are termed phytosterols, zoosterols, and mycosterols, respectively. Cholesterol is the main zoosterol, but sterols in plants commonly occur as mixtures with β-sitosterol, campesterol, and stigmasterol representing three of the major phytosterols. These sterols are all Δ^5-sterols (Figure 6), but Δ^7-sterols may also be present in small quantities (Table 1). Molecules with a sterol-type structure that lack an endocyclic double bond are termed sterols. Methyl sterols, also known as triterpenyl alcohol, have an additional methyl group at carbon-4 in the A-ring of the molecule. Methyl sterols and dimethylsterols commonly occur with sterols in plant membranes. Bacteria usually lack sterols in their membranes, but yeasts accumulate considerable quantities of sterols, which may represent up to 10% of the cellular dry weight. Algae produce a wide variety of sterols. (*See* **Cholesterol**: Properties and Determination.)

Terpenes

Terpenes are oligomers or polymers of isoprene, 2-methyl-1, 3-butadiene. Monoterpenoids and sesquiterpenoids contain 10 and 15 carbon atoms respectively, and these components occur in essential oils and are very important flavor compounds. Monoterpenoids include acyclic and cyclic hydrocarbons, alcohols, ketones, or lactones such as myrcene, limonene, and menthol. Sesquiterpenoids include



Cholesterol	R = H
β-Sitosterol	R = – C_2H_5
Stigmasterol	R = – C_2H_5 ; Δ^{22}
Campesterol	R = – CH_3
Δ^5-Avenasterol	R = CH – CH_3
Brassicasterol	R = – CH_3 ; Δ^{22}

Figure 6 Sterol structure. Reproduced from Lipids, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

bicyclic or tricyclic compounds such as zingiberene, which is the main constituent of the oil of ginger, or caryophyllene, which occurs in the oil of cloves. (*See* **Essential Oils:** Properties and Uses.)

Diterpenoids include the bitter principles, which are commonly bitter and have physiological effects. Triterpenoids and higher terpenoids have no flavor properties. Triterpene alcohols, which occur in small amounts in edible oils, have been found useful in the identification of oils in blends. Carotenoids are the major tetraterpenoids, while chicle, which is used in chewing gum, is the main polyterpenoid used in foods.

Ethers

Ether lipids occur in which one of the hydroxyl groups of a diglyceride or phosphatidyl ester is linked to an alkyl group. The alkyldiacylglycerols are common constituents of some marine oils while vinyl ethers or plasmalogens are found in blood.

Occurrence

M H Gordon, The University of Reading, Reading, UK

Fats

Fats can be extracted from biological tissues with organic solvents. They comprise complex mixtures of chemical classes, known as lipids, which share the same solubility characteristics. Fats include solid fats and liquid oils. They occur in animals, plants, and microorganisms either as storage lipids, which are potential sources of energy by β-oxidation, or as membrane lipids. Storage lipids mainly comprise triacylglycerols, whereas membrane lipids include phospholipids, sterols, sphingolipids, and glycolipids. (*See* **Phospholipids**: Properties and Occurrence; **Triglycerides**: Structures and Properties.)

Membrane lipids occur in cells in a phospholipid bilayer which has been described as a fluid mosaic. The fatty acid chains of the phospholipids are directed towards the center of the membrane. Globular protein molecules penetrate into either side or extend entirely across the membrane. The membrane is considered to be asymmetric with oligosaccharide chains protruding from glycolipids and glycoproteins on the outer surface of the plasma membrane of eukaryotic cells. Sterols and polar lipids are embedded into the membrane. Phytosterols, including β-sitosterol, campesterol and stigmasterol, occur in plant cell membranes, whereas cholesterol occurs in animal cell membranes.

Fat in Animal Products

Body Fat

The bulk of the meat consumed in the UK is obtained from sheep, cattle, and pigs, with chickens and turkeys being major poultry products. The fat of the adipose tissue of animals usually consists of more than 99% acylglycerols, but fat occurring within the muscles of animals, which are consumed as meat, contains a considerable amount of phospholipids and of unsaponifiable components, such as cholesterol. Palmitic acid, stearic acid and oleic acid are the major fatty acids present in the fat of animals used for meat, and therefore fats derived from animals such as lard and tallow are relatively saturated (Table 1) and consequently semisolid. Fat derived from poultry is more unsaturated. (*See* **Fatty Acids**: Properties.)

Table 1 Major fatty acids in animal fats (% w/w)

Fatty acid	*Lard*	*Beef tallow*	*Bovine milk fat*
4:0			3.3
6:0			1.6
8:0			1.3
10:0			3.0
12:0			3.1
14:0	0.5–2.5	1.4–6.3	9.5
16:0	20–32	20–37	26.3
16:1	1.7–5.0	0.7–8.8	2.3
18:0	5.0–24	6–40	14.6
18:1	35–62	26–50	29.8
18:2	3.0–16	0.5–5.0	2.4
18:3	< 1.5	< 2.5	0.8
20:0	< 1.0	< 0.5	
22:1			

The fatty acid content of depot fat (storage lipid) varies depending on the part of the animal from which the fat is derived. Thus, the oleic acid content of sheep depot fat varies from 19.1 to 35.7%, depending on the anatomical source of the fat. The fatty acid content of depot fats in animals is also dependent partly on the diet since *de novo* synthesis *in vivo* supplies only part of the fatty acids. Unsaturated lipids consumed by ruminants such as cattle and sheep are hydrogenated by rumen microflora before they are incorporated into depot fats. (*See* **Fatty Acids**: Metabolism.)

Milk Fat

Bovine milk contains a complex mixture of lipids, with triacylglycerols representing the major component at 97–98% of the total lipid content. However, diacylglycerols, monoacylglycerols, free fatty acids, sterols, phospholipids, hydrocarbons, and sterol esters are also present. The fat content of milk from cattle reared in developed countries is in the range of 3.4–5.1%. The fatty acid composition of milk fat is extremely complex, with over 400 fatty acids having been identified; the major components are indicated in Table 1. Although the level of linoleic acid (18:2) is normally below 3% due to hydrogenation of dietary linoleic acid in the rumen, the feeding of oil coated with a layer of formaldehyde-treated protein has allowed the linoleic acid content of milk fat to be increased above 15% in experimental animals. The fatty acid composition of milk fat varies with the species of animal. Thus, the oleic acid content of camel milk fat is 38.9% compared with that of horse milk, which is 18.7%, and similar differences are also found in other fatty acids. (*See* **Milk**: Dietary Importance.)

Fat in Vegetable Products

Lipids in plant materials can also be divided into membrane lipids and storage lipids. The composition of membrane lipids varies with membrane function. Cytoplasmic or plasma membranes contain about half the dry mass as lipid. Major components include phospholipids up to 65%, glycolipids up to 20%, sterols up to 5%, and neutral lipids including hydrocarbons, diacylglycerols, and pigments. The main phospholipids are phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol. Mitochondrial membranes contain up to 98% of the lipids as phospholipids. Chloroplast membranes are unique in nature, since the major lipid components of their lamellae are glycosylglycerides and not phospholipids.

Triacylglycerols occur in oil bodies, which are surrounded by a monolayer or half-unit membrane. As the oil content of seeds increases, there is a large increase in the number of oil bodies. Lipids are stored in the oil bodies until required as a source of energy by the growing plant. Storage lipids from plant sources are of considerable industrial importance, with world production of refined plant oils exceeding 50 million tonnes per year. The commercial sources of edible plant oils include: oilseeds, with soya bean, rapeseed, sunflower seed, peanuts, and cottonseed being important commercially; tree and bush products, including palm oil, coconut oil, olive oil, cocoa butter, and palm kernel oil; and grains, particularly corn oil. (*See* **Vegetable Oils**: Dietary Importance.)

The oil content of the oil-bearing material (Table 2) is one of the factors that affects the commercial utilization of the crop. However, other factors include yield per hectare and ease of harvesting. In the case of soya bean oil, the oil is a byproduct in meal production, and therefore it is a very important oil commercially despite having a relatively low oil content in the seed.

Table 2 Oil content of a number of oil-bearing vegetable materials

Oil-bearing material	*Oil content (% w/w)*
Coconut	65–68
Babassu	60–65
Sesame seed	50–55
Palm fruit	45–50
Palm kernel	45–50
Peanut	45–50
Rapeseed	40–45
Sunflower seed	35–45
Safflower seed	30–35
Olive	25–30
Cottonseed	18–20
Soya bean	18–20

Crude vegetable oils are extracted from fruits or seeds by pressing or by solvent extraction, usually with hexane, and in some cases, the two processes are applied sequentially. The extracted crude oil contains minor lipids as well as triacylglycerols. Phospholipids, sterols, sterol esters, tocopherols, free fatty acids, diacylglycerols, carotenoids, chlorophylls and hydrocarbons are commonly present. The fatty acid composition of common plant oils is shown in Table 3. There is considerable research by plant breeders into the development of plant varieties with modified fatty acid composition. This has led to the development of low-erucic acid rapeseed oil, which is considered preferable as a food oil to traditional rapeseed oil, which has an erucic acid content of about 45% of the total fatty acid content. Animal experiments suggest that high levels of erucic acid may lead to fatty lesions in heart muscles. High-oleic sunflower oil has also been developed because of nutritional interest in this type of oil.

Fish Oil

Fish can be classified as marine lean fish, marine fatty fish and freshwater fish. Marine lean fish, including cod, haddock, and hake, have a flesh lipid content of 0.1–1% with little seasonal variation. However, the flesh lipid content of marine fatty fish, including sprats, mackerel, and herring, varies from <1 to $>25\%$ in some species, with considerable variation, depending on the season and the diet. For example, the lipid content of sprats varies from a maximum of 17% in autumn to winter and falls to about 6% in spring to summer. Freshwater fish, including rainbow trout, haplochromis, and rock bass, have relatively low fish lipid contents of $<4\%$. (*See* **Fish Oils**: Dietary Importance.)

In the flesh of lean fish such as cod, 65% of the total lipids are phospholipids intimately associated with muscle protein, and 35% are neutral lipids including triacylglycerols and sterols. In the flesh of fatty fish, a large proportion of the lipids are triacylglycerols present as extracellular globules in the muscle. Sprat flesh contains 8–15% triacylglycerols and 0.6–1.9% phospholipids, whereas rainbow trout contain 2.2% triacylglycerols and 0.9% phospholipids. Both species also contain about 1% sterols. The fatty acid contents of the fish lipids of several species of fish are shown in Table 4. The unsaturated fatty acids are commonly mixtures of positional isomers. Fish oils are of considerable interest as nutritional supplements because of the high level of eicosapentaenoic (20:5) and docosahexaenoic acids

Table 3 Fatty acid composition of plant oils (% w/w)

Fatty acid	Coconut	Palm kernel	Sunflower	Peanut	Corn	Olive	Palm	Cotton seed	Soya bean	Rapeseed	Cocoa butter

(22:6) in some oils. These fatty acids are significant because they are believed to play a role in reducing the incidence of coronary thrombosis. Fats from marine mammals have a similar composition to fish oil.

Microbial Oil

There has been considerable interest in microbial lipids in recent years because of the possibility of commercial production of oils and fats from microbial sources. The lipid composition of microorganisms is also useful in taxonomy.

Bacteria

The major lipids in Gram-positive bacteria are phosphatidylglycerol and phosphatidylethanolamine, in which the acyl chains are mainly odd-numbered branched-chain fatty acids. In contrast, Gram-negative bacteria contain phosphatidylethanolamine with even-numbered straight chain and cyclopropane acyl chains. The lipids in Gram-positive bacteria are limited to the cytoplasmic membranes and the mesosomes, whereas in Gram-negative bacteria and mycobacteria, the lipids are interwoven with the external layers of cells, and there is no clear distinction between membrane and cell-wall lipids. The lipid content of many species of bacteria is rather low, although mycobacteria, corynebacteria, and nocardia may contain substantial amounts, e.g., 23% in mycobacteria grown in glycerol as the carbon source.

Algae

Macroalgae such as seaweeds and phytoplankton have low lipid contents, but microalgae grown in the presence of light and in a nitrogen-poor medium accumulate storage lipids rich in triacylglycerols. Oil droplets are clearly visible in the cells. Lipid contents as high as 70% can be achieved in algae grown under optimum conditions for lipid biosynthesis. Some algae may accumulate relatively high concentrations of derived lipids of commercial interest. Thus, *Dunaliella salina* accumulates more than 10% of its dry mass as β-carotene.

Yeasts

Yeasts vary in oil content with low-oil, medium-oil and high-oil types containing < 5, 5–15 and > 15% oil as percentage cell dry weight, respectively. Oleaginous yeasts have been defined as those that produce

>25% oil. The oil content and composition varies between the various yeast subfamilies, and members of a particular genus, but also varies within strains and depends on the growth conditions. Up to 65% of the biomass of oleaginous yeasts, e.g., *Candida curvata* or *Lipomyces* spp., may comprise oil, if the yeast is grown under nitrogen-deficient conditions.

Molds

There are many examples of oleaginous molds that accumulate > 25% oil. Oil contents up to 75% have been described. Molds show a greater diversity of fatty acid composition compared with yeasts, but most species contain oleic acid, palmitic acid, and linoleic acid as the major acids. Higher proportions of polyunsaturated fatty acids occur in molds than in yeasts, and molds are of interest commercially for the production of oil containing polyunsaturated fatty acids of nutritional interest. Thus, *Mucor javanicus* has been used to produce an oil containing γ-linolenic acid, which has been sold as a nutritional supplement in health food shops.

Fat in Processed Foods

As well as occurring naturally in the membranes of all biological tissues, fats are important in the production of processed foods. The major industrial applications of edible oils and fats are in frying oils, margarine, bakery fats, shortenings, mayonnaise, salad dressings, peanut butter, chocolate, and confectionery products. The oil acts as a heat transfer medium for frying, and it has a major effect on the texture and flavor of the processed foods. Fat-soluble vitamins and pigments are also present in the foods. (*See* **Fats**: Uses in the Food Industry.)

Phospholipids in the form of commercial lecithin are another class of lipids added to processed foods. Lecithin is added in baking formulations, cake mixes, chocolate, confectionery products, icecream, instant foods, margarine, nondairy toppings, and shortenings. The lecithin in these products affects the texture by improving the shortening effect of fat, stabilizing emulsions, reducing the viscosity of sugar in fat dispersions, improving the wettability and dispersion of powders in aqueous solutions, and assisting with foam stabilization.

Other lipids are also important as surfactants or emulsifiers in foods. Thus, mixtures of mono- and diglycerides are the most common emulsifiers used in foods to stabilize water-in-oil emulsions. They also have various roles as surfactants, including retarding the staling of bread, improving the behavior of foods during extrusion cooking, improving the palatability and reducing the stickiness of caramels and toffees, and improving the dispersion of coffee whiteners. Other lipid surfactants include acetylated monoglycerides, sucrose esters, sorbitan esters and polyoxyethylene sorbitan esters. (*See* **Emulsifiers**: Organic Emulsifiers.)

FATTY ACIDS

Contents

Properties

B J F Hudson[†], University of Reading, Reading, UK

Background

Fatty acids, *per se*, do not occur in fresh foods, but comprise very important structural components of virtually all food lipids. They are to be found in the form of esters of glycerol in triglycerides, as esters of phosphatidic acid and its derivatives in phospholipids, and in similar combined forms in glycolipids, sulfolipids, sphingolipids, cerebrosides, etc. Fatty acids also occur in esterified forms in combination with natural aliphatic alcohols in waxes and with sterols in sterol esters. (*See* **Fats:** Classification; **Phospholipids:** Properties and Occurrence; **Triglycerides:** Structures and Properties.)

Free fatty acids are of industrial importance and have many applications. In food, however, their presence is a sign of rancidity as a consequence of lipolytic activity, and this is undesirable as it causes flavor taints.

Fatty acids are all lipophilic in character but in other respects may vary considerably from one another. Their distinctive chemical, physical, and physiological properties carry through to the properties of the lipids in which they occur. Features of particular importance are their melting, crystallization, and solubility behaviors, their type and degree of unsaturation (and hence chemical reactivity) and their potential for *in vivo* conversion to physiologically significant derivatives.

The most important natural fatty acids are listed in Table 1, but many others, probably hundreds, are known, and yet many others have been synthesized. This emphasizes the extreme complexity, in chemical terms, of a natural fat or oil. If it contains two different fatty acids, six triglycerides are possibly present, and for three fatty acids, 18 triglycerides may be present. A more typical oil, e.g., soya bean oil, with at least six fatty acids will contain well over 100 different triglycerides, in greatly varying amounts.

Nomenclature

For practical purposes, natural fatty acids are straight-chain even-numbered aliphatic carboxylic acids that may be saturated ($CH_3(CH_2)_xCO_2H$) or of a similar structure, but unsaturated, with up to six double bonds. The latter are normally arranged along the chain, separated from each other by methylene groups and with *cis*-conformations. The more important fatty acids (Table 1) have traditional ('trivial') names, since their systematic names are rather clumsy. In modern scientific literature, they are described by a shorthand notation. Thus, arachidonic acid is 20:4*n*-6, meaning that it is a straight-chain fatty acid with 20 carbon atoms and 4 *cis* double bonds, the first starting at the sixth carbon from the *end* of the chain, and therefore the other three at the ninth, twelfth, and fifteenth carbons, respectively. This system of nomenclature is now superseding the earlier one in which the positions of the double bonds were described by reference to the carboxyl end of the chain, counting the -CO_2H as carbon no. 1. Thus, by the old system, arachidonic acid was 20:4c6c9c12c15.

Sources

Referring to Table 1, the first five compounds are crystalline solids melting from around 40 to 70 °C and are the most frequently occurring saturated fatty acids. Palmitic and stearic acids occur universally in food lipids and, when comprising a substantial proportion of the total fatty acids, result in a *fat* rather than an *oil*. Lauric and myristic acids occur in

[†]Deceased.

Table 1 The more important natural food fatty acids

Trivial name	*Empirical formula*	*Shorthand structure*
Lauric acid	$C_{11}H_{23}CO_2H$	12:0
Myristic acid	$C_{13}H_{27}CO_2H$	14:0
Palmitic acid	$C_{15}H_{31}CO_2H$	16:0
Stearic acid	$C_{17}H_{35}CO_2H$	18:0
Arachidic acid	$C_{19}H_{39}CO_2H$	20:0
Palmitoleic acid	$C_{15}H_{29}CO_2H$	16:1 *n*-7
Oleic acid	$C_{17}H_{33}CO_2H$	18:1 *n*-9
Petroselinic acid	$C_{17}H_{33}CO_2H$	18:1 *n*-12
Erucic acid	$C_{21}H_{41}CO_2H$	22:1 *n*-9
Linoleic acid	$C_{17}H_{31}CO_2H$	18:2 *n*-6
α-Linolenic acid	$C_{17}H_{29}CO_2H$	18:3 *n*-3
γ-Linolenic acid	$C_{17}H_{29}CO_2H$	18:3 *n*-6
Arachidonic acid	$C_{19}H_{31}CO_2H$	20:4 *n*-6
Eicosapentaenoic acid[a]	$C_{19}H_{29}CO_2H$	20:5 *n*-3
Docosahexaenoic acid[a]	$C_{21}H_{29}CO_2H$	22:6 *n*-3

[a]In these cases, systematic names are given in the absence of trivial names.

certain tropical oils such as coconut and palm kernel oils. Arachidic acid occurs, albeit in small amounts, in a wide range of tropical vegetable fats. Animal fats, in addition to palmitic and stearic acids, contain small amounts of odd-numbered and branched-chain saturated acids. The lower fatty acids from butyric (4:0) to capric (10:0) are significant in ruminant milk fats. (*See* **Palm Oil**.)

The next four items in Table 1 are monounsaturated fatty acids. Oleic acid is universally important in food lipids, in some cases being as much as 80% of the component fatty acids (e.g., olive oil). Palmitoleic acid is also ubiquitous, though in much smaller amounts. Erucic and petroselinic acids, though important in a few seed oils, are of restricted occurrence, the former in the Cruciferae and the latter in the Umbelliferae. Except for erucic acid, these and all the acids referred to later in this section are liquid at ambient temperatures.

Linoleic acid is of almost universal importance in vegetable oils, but it does not occur to a significant extent in animal products. This diunsaturated fatty acid, the only really important one, is the 'essential fatty acid' on which most nutritional studies have been based and is the key member of the widely advertised 'polyunsaturates.'

The triunsaturated fatty acids, α- and γ-linolenic acids, are found, though very rarely together, in many seed oils, the former being the commoner. α-Linolenic acid is the major fatty acid of leaf and root lipids and many seed oils, especially those of northern latitudes. γ-Linolenic acid, though less widespread, is found in the oil seeds of many plant species, in some algae and fungi and certain animal products.

Of the last three fatty acids named in Table 1, arachidonic acid is of exclusively animal origin (e.g., eggs and certain meat offals) whilst the last two occur in substantial proportions in fatty fish (herring, mackerel) and fish liver oils (cod, halibut). (*See* **Fish Oils**: Dietary Importance; **Offal**: Types of Offal.)

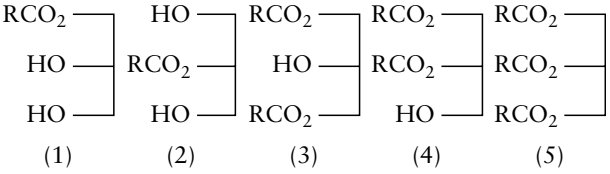
Apart from those listed, and certain isomers and homologs of them, many other fatty acids, though less common, are well known. These may contain conjugated unsaturated systems (e.g., punicic acid), *trans* double bonds (e.g., columbinic acid), triple bonds (e.g., crepenynic acid), homocyclic (e.g., sterculic acid) or heterocyclic (e.g., vernolic acid) rings or substituent functional groups (e.g., ricinoleic acid). Some of these are occasionally consumed in food lipids.

Glycerides

Food scientists and technologists are much more concerned with glycerides than with fatty acids as such. Many, but not all, of the properties of fatty acids are mirrored in those of the nonpolar triglycerides. However, the mono- and diglycerides, in which, respectively, only one or two of the hydroxyls of glycerol are esterified, have both lipophilic and hydrophilic properties. The resulting surface activity enables them to serve as emulsifiers and foam stabilizers in processed foods. (*See* **Emulsifiers**: Organic Emulsifiers; Uses in Processed Foods.)

Mono- and Diglycerides

Monoglycerides containing a fatty acid (RCO_2H) exist in the form of 1-monoglycerides (1) or the isomeric 2-monoglycerides (2). Both forms revert, on storage, to an equilibrium mixture in which the 1-monoglyceride dominates (90%). Monoglycerides, accompanied by diglycerides, are produced by the base-catalyzed interesterification (randomization) of a triglyceride (5) with glycerol. The resulting mixed product is often used without purification, but if high-quality monoglycerides are desired, these can be obtained by molecular distillation of the mixed product. Monoglycerides have important applications in the food-processing industry for the stabilization of both water-in-oil (e.g., margarine) and oil-in-water (e.g., artificial cream) emulsions. (*See* **Margarine**: Methods of Manufacture.)



Diglycerides also exist in two forms ((3) and (4)), the 1,3-diglyceride (3) being dominant in the

equilibrium mixture. They are much less polar than monoglycerides and have few food applications.

Triglycerides

These are the dominant components (more than 90%) of all edible oils and fats. Since they contain about four to 10 significant amounts of different fatty acids, they comprise a very large number of individual triglycerides. The fatty acids are, however, not randomly distributed but tend to follow certain rules.

In oils and fats of vegetable origin, the preferred sites for saturated acids are the 1- and 3-positions, whilst unsaturated acids occupy the 2-position for preference. In animal fats (e.g., lard), the reverse is the case, except for the fats of ruminants (e.g., beef and mutton tallow, milk fat), in which the distribution is approximately random.

The positions of substituent saturated and unsaturated fatty acids in the triglyceride molecule are important in determining the hardness, elasticity, and melting characteristics (Table 2) of fats containing them. These physical parameters control the texture and mouth-feel of foods in which they are major components. Such compositional features are particularly important in the case of monounsaturated disaturated triglycerides, which can be represented as the isomers SUS and SSU.

Relatively hard vegetable fats (SUS-type triglycerides, 30–40 °C), such as cocoa butter melt sharply at, or slightly below, body temperature and hence are ideal components in chocolate, cream fillings, and confectionery couvertures. Admixture with fats of the SSU-type causes a fall in melting point and a marked increase in melting range. Such mixed triglycerides may therefore be well adapted to the formulation of margarines and bakery fats. (*See* **Cocoa**: Production, Products, and Use; **Fats**: Uses in the Food Industry.)

The melting and crystallization characteristics of both pure and mixed triglycerides are also very dependent on 'tempering' (close control of holding time and temperature), since they exist in distinct polymorphic forms, the most stable being that with the highest melting point.

Table 2 Melting points (°C) of fatty acids and derived glycerides

Fatty acid		*1-Monoglyceride*	*1,3-Diglyceride*	*Triglyceride*
12:0	44	63	56	46
14:0	54	70	65	57
16:0	63	77	72	65
18:0	70	81	78	73
18:1 *n*-9 (*cis*)	16	35	21	5
18:1 *n*-9 (*trans*)	44	58	55	42
18:2 *n*-6	−6	12	−3	−13

Natural fats can be physically separated into desirable fractions by various industrial processes, viz. by 'dry,' 'wet,' or 'solvent' fractionation, with appropriate careful temperature control. Fats such as edible tallow, lard, palm oil, palm kernel oil, and coconut oil can, in the 'dry' process, be separated by pressing or filtration into a higher-melting crystalline fraction and a liquid oil. In the 'wet' processes, the fat is mixed with an aqueous solution of a surface-active agent, which disperses the crystalline fraction into the aqueous phase. The separation is more efficient than in the dry processes. The most efficient and selective fractionation process makes use of a volatile solvent, usually acetone, to segregate, to a large extent, glycerides according to their degree of unsaturation: SSS, SUS, SUU, and UUU.

Reactions of Triglycerides

In the context of food, very few intentional reactions are permissible, since both the starting material and the reaction product must be of acceptable edible quality. Thus, only two kinds of reactions are of practical importance – hydrogenation and interesterification. To these, however, must be added lipolysis and autoxidation – undesirable spoilage reactions affecting oils and fats under unfavorable storage conditions, and thus causing rancidity.

Hydrogenation The objects of hydrogenation are (1) by increasing the degree of saturation of an oil or fat to raise its melting point and thus extend its applications, and (2) by reducing its degree of unsaturation to reduce its proneness to autoxidation and thereby to enhance its stability. Hydrogenation is always partial and sometimes only marginal. In chemical terms, it involves not only the saturation of double bonds but also *cis–trans* isomerization and migration of some double bonds to neighboring positions in the fatty chains.

Hydrogenation involves the use of hydrogen and a supported metal catalyst, commonly nickel on Kieselguhr, at temperatures between 100 and 200 °C. Conditions are varied according to requirements. Thus, the use of a fresh catalyst and low temperatures minimizes isomerization, whereas an old ('poisoned') catalyst at higher temperatures promotes isomerization and minimizes saturation. *Trans* fatty acids can be formed in high proportions in hydrogenated fats, with consequent rises in melting points (note the contrast in melting points between corresponding *cis* and *trans* 18:1 *n*-9 compounds in Table 2).

Interesterification The same base-catalyzed reaction, as described earlier for the production of monoglycerides, is applicable to the randomization of

individual fats or to the randomization of mixtures of two or more fats or oils. The process has several advantages. For example, lard, which in its natural form solidifies very slowly on cooling, producing large, 'grainy' crystals, after interesterification, rapidly sets on cooling to a compact mass of very small crystals. Edible tallow, with an inconveniently high melting point, after interesterification with a soft oil, such as soya bean oil, yields a soft fat with a very useful melting range. (*See* **Soy (Soya) Beans**: The Crop.)

Lipolysis Triglycerides are hydrolyzed, albeit very slowly, by aqueous media, but much more rapidly by basic catalysts and, more importantly, by endogenous lipolytic enzymes. Oils and fats (e.g., olive oil, palm oil, tallow) from fruit coats or animal tissues are particularly prone to lipolysis if they are allowed to remain too long in contact with bruised tissue before processing. As a result of such handling, major processing losses are suffered as a result of the need to carry out refining operations to remove harsh flavor taints.

Autoxidation Access of atmospheric oxygen to unsaturated fatty acids or glycerides leads to deterioration through oxidation. Saturated and monounsaturated fatty chains oxidize very slowly and do not as a rule cause problems. Diunsaturated chains, as in 18:2 *n*-6, oxidize more rapidly and polyunsaturated chains very rapidly. Oils such as fish oils are so liable to oxidative degradation that they cannot be used as such in food formulation but must first be hydrogenated. (*See* **Oxidation of Food Components**.)

Autoxidation depends on free-radical chain reactions, which involve the interaction of oxygen with free radicals generated at methylene groups adjacent to double bonds, especially at methylene groups between two double bonds. Hydroperoxides are thus formed, and these, being unstable, break down to fission products, including some of low molecular weight. Equation (1) is a summary of a typical reaction sequence.

$$R_1\text{–CH=CH–CH}_2\text{–}R_2\text{–G} \longrightarrow R_1\text{–CH=CH–CH–}R_2\text{–G} \longrightarrow \underset{\displaystyle \underset{\displaystyle |}{\text{OOH}}}{} \qquad R_1\text{–CH=CH–CHO} + \text{HO–}R_2\text{–G} \qquad (1)$$

(R_1 and R_2 are alkyl and alkylene portions of the fatty chain; G is the nonvolatile glyceride residue.)

The aldehydes and other volatile oxidation products have strong, unattractive odors and flavors, and make a predominating contribution to 'rancidity.' Further, peroxides are toxic food components, so autoxidation must be minimized by all possible means. It can be avoided, or at least greatly delayed, by careful and prompt handling and storage of oils and fats, by avoidance of prooxidative situations such as contact with metals, and by the use of various kinds of antioxidants that inhibit steps in the autoxidation process. (*See* **Antioxidants:** Natural Antioxidants; Synthetic Antioxidants.)

Metabolism

P Muñiz, Universidad de Burgos, Burgos, Spain

Fatty Acid Availability

Fatty acids are the principal form of stored energy for most organisms. Almost all tissues can utilize fatty acids for energy, exceptions being the brain, blood cells, skin, and renal medulla. The fatty acids present two advantages compared with other energetic biomolecules: their high energy density and low solubility. Thus, oxidation of tryacylglycerols releases $37\,kJ\,g^{-1}$ compared with the 16–17 $kJ\,g^{-1}$ for sugars, glycogen, and amino acids, and fatty acids can be stored without water.

Most of these fatty acids are stored in adipose tissue, comprising specialized cells, the adipocytes. Mammals can store 5–25% or more of their body weight in the form of lipids, and 90% of these lipids are tryacylglycerols (TGs). The fat storage is not static, so the tryacylglycerols are in a constant state of turnover. The liver, the major center of lipid metabolism, is largely responsible for regulating lipid levels in the body. Among its important functions are: synthesis of TG from fatty acids, synthesis of other lipids such as phospholipids and cholesterol, desaturation of fatty acids, and catabolism of tryacylglycerols for use as energy.

Since most of the tissues contain only small amounts of storage lipids, energy production depends on a continuous supply of fatty acids. The fatty acids are derived primarily from two sources: exogenous TG obtained from diet and endogenous TG stores mainly in the adipose tissue.

Diet Fatty Acids

Tryacylglycerols are the predominant type of lipid ingested by humans, and they are absorbed as fatty acids from the intestinal mucosa (enterocytes) into the lymphatic system. The free fatty acids (FFAs) inside the enterocytes are reesterified into TGs and packaged with proteins and phospholipids to form chylomicrons. Chylomicrons enter the lymphatic system and eventually into the circulatory system at the thoracic duct.

Most of the chylomicrons are removed from the blood into cells by the action of lipoprotein lipase, an enzyme located on endothelial cell lining the capillaries primarily in adipose tissue, skeletal and cardiac muscle, and the liver. Lipoprotein lipase hydrolyzes the TGs into fatty acids and glycerol, and is taken up into these specific tissues. In adipose tissue, the FFAs are primarily reesterified and stored as TGs, in other organs as muscle and liver, and small amounts of TG are stored intracellularly. The primary sites of FFA oxidation are cardiac and skeletal muscle and liver.

Adipose Tissue Fatty Acids: Lipolysis

Fat stored as tryacylglycerols in adipose tissue and mobilized in the form of plasma free fatty acids is the main source of energy in the absence of dietary substrates; up to 150 g of fatty acids can be liberated daily, corresponding approximately to half of the daily caloric needs.

Hydrolysis of adipose tissue TGs occurs via three consecutive reactions and is catalyzed by two enzymes: the triacylglicerol lipase, also called hormone-sensitive lipase (HSL), and the monoglyceride lipase (MGL). The rate-limiting enzyme in adipose tissue lipolysis is HSL. HSL hydrolyzes TGs and diglycerides, whereas the participation of MGL is required for complete hydrolysis of monoglycerides. Then, the three FFA molecules leave the adipose cell and enter the circulation, where they are transported bound to albumin. The remaining glycerol backbone also leaves the cell, because adipose tissue does not contain the enzyme glycerol kinase, and so glycerol is not reutilized for reesterification in adipocytes.

HSL exhibits a preference, although not absolute, for the (*n*-3/*n*-6) fatty acids from TGs, with approximately three- to fourfold higher hydrolysis rates to the 1(3)-ester bonds than to the 2-ester bond. Fatty acids, i.e., oleic and oleoyl coenzyme A (CoA), and monoacyglycerols have been shown as inhibitors to HSL. This feedback inhibition was proposed to prevent the accumulation of fatty acids and free cholesterol in the cells and to ensure that the capacity of MGL to hydrolyze MGs is not exceeded. Recently, adipocyte lipid-binding protein (ALBP) was shown to interact with HSL, raising the possibility that ALBP sequesters fatty acids resulting from HSL-catalyzed lipolysis, and thus preventing the feedback inhibition by lipolytic products.

Regulation of adipocyte lipolysis Fatty acid concentrations are the result of the balance between the rate of appearance (lipolysis) and the rate of clearance. Today, it is generally accepted that lipolysis is controlled mainly by the activity of the sympatic nervous system and by plasma insulin levels. The main regulator factor of the rate of adipose tissue lipolysis is the activity of HSL.

HSL activity is mainly regulated by the circulating concentrations of insulin and epinephrine. These hormones can change during times of stress, such as

starvation, trauma, or physical exercise, or after feeding, resulting in an alteration in lipolytic rates and FFA concentrations. Insulin decreases the activity of hormone-sensitive lipase, which is responsible for the breakdown of adipose TG and concomitant release of the free fatty acids into the circulation. Epinephrine, norepinephrine, and adrenocorticoids, especially adrenocorticotropic hormone, increase the rate of fat mobilization by stimulating HSL activity.

HSL is hormonally regulated via phosphorylation/dephosphorylation. The hormone stimulated by HSL acts through a membrane-bound receptor and activates the membrane-bound enzyme adenylate cyclase, resulting in an increase in cyclic adenosine monophosphate (cAMP) levels in the adipocyte. cAMP directly activates a protein kinase A (PKA), which phosphorylates and activates HSL. Lipolytic agents generally increase the levels of cAMP far above the concentrations required for maximal activation of protein kinase A.

Epinephrine is the primary stimulator of lipolysis working through a β-adrenergic receptor in the plasma membrane of the adipose cell resulting in phosphorylation and activation of HSL. The physiological state can affect the sensitivity to epinephrine. For example, in short-term (3-day) fasting, the lipolytic responsiveness to epinephrine infusion is enhanced, whereas in obesity, the responsiveness to epinephrine is blunted. Catecholamines are able to stimulate lipolysis via three subtypes of β-adrenergic receptors, which are positively coupled to adenyl cyclase by Gs proteins and to inhibit lipolysis via α2-adrenergic receptors, negatively coupled to the enzyme by Gi proteins. In humans, the interplay between α2 and β-adrenergic receptors plays an important role in modulating cAMP levels in adipocytes.

However, the inhibition of HSL catalyzes its dephosphorylation, and so insulin induces a decrease in cAMP levels and a concomitant decrease in PKA activity, and inhibits HSL, thus catalyzing its dephosphorylation. Glucose is the predominant signal for insulin release, so an effect of glucose intake on lipolysis would be expected. Thus, in humans, an increase in glucose concentration in the plasma stimulates insulin release with concomitant increase in glucose uptake and fatty acid reesterification, and a decrease in lipolysis. The inhibitory effect of glucose on lipolysis is mediated entirely by insulin.

Under most physiological circumstances, the rate of lipolysis is largely determined by the balance between the stimulatory effect of epinephrine and the inhibitory effect of insulin. For example, in short-term fasting, there is a marked increase in the rate of lipolysis, which can be attributed to both a decrease in blood glucose (and thus insulin) concentration and an increase in epinephrine concentration and sensitivity to epinephrine. The striking aspect of the regulation of lipolysis is that the factors that are primary regulators (insulin and epinephrine) are not released in response to a signal related to any aspect of fatty acid metabolism. For example, acute changes in fatty acid concentrations by infusion do not affect insulin, catecholamines, or the rate of lipolysis. Therefore, insulin and catecholamines, rather than being primary regulators of lipolysis, may be considered to be regulators of other physiological and metabolic processes that also affect lipolysis. In fact, the rate of resting lipolysis generally provides fatty acids at a rate that is far in excess of the rate required for oxidation. Fatty acids that are released from adipocytes, but not oxidized, are reesterified, thereby completing a substrate cycle.

Cellular Uptake of Fatty Acid

Fatty acids from the diet or produced by lipolysis are transported, bound to proteins in blood, and their cellular uptake is similar. The majority of complex lipid is hydrolyzed by two related lipases, hepatic lipase and lipoprotein lipase, and this hydrolysis enables free fatty acids to enter cells.

The uptake of fatty acids across the plasma membrane takes place either by diffusive processes, involving partitioning of the fatty acid molecule into the lipid bilayer of the plasma membrane, or by the presence of different lipid-binding proteins in the cell membranes, called plasma membrane fatty-acid-binding proteins (FABPpms).

At least five plasma membrane-associated fatty acid binding proteins were proposed to play a role in free fatty acid (FFA) uptake, a plasma membrane fatty-acid-binding protein (FABPpm, 40 kDa), fatty acid translocase (FAT, 88 kDa), fatty acid transport protein (FATP 63 kDa), caveolin, and 56-kDa kidney fatty acid binding protein. Once inside the cell, fatty acids are bound noncovalently to a family of intracellular fatty acid-binding proteins (FABPs) that may play a role in the transfer of FFAs to intracellular destinations where they are used. FABPs comprise a family of 14–15-kDa proteins that bind long-chain fatty acids.

Catabolism of Fatty Acids

Once within the cell and depending on the tissue and its metabolic demand, fatty acids are either converted to tryacylglycerols or membrane phospholipids, or oxidized in the mitochondria for energy production. Some metabolic routes are common to most of the

cells, like β-oxidation, whereas others are tissue-specific for prostanoid synthesis.

Before being directed into storage or membranes or oxidation, fatty acids are first activated to acyl-CoAs.

Fatty Acids Activation and Transport into Mitochondria

A requisite step for fatty acid entering several metabolic pathways is the formation of fatty acyl-CoA-thioesters, catalyzed by fatty acyl-CoA synthetase, with some substypes showing fatty acid chain-length specificity. The fatty acyl-CoA products of these enzymes are also bound to FABP.

Short- and medium-chain fatty acids are transported into the mitochondria matrix as free acids and form the acyl-CoA derivatives over there. However, long-chain fatty acids are normally activated in outer mitochondrial membrane, but this may also occur at the surface of the endoplasmic reticulum.

The enzyme acyl-CoA synthetase, also called acyl-CoA ligase or fatty acid thiokinase, catalyzes the formation of a thiol ester bound between the fatty acid and the thiol group of coenzyme A (eqn (1)).

$$\text{Fatty acid} + \text{ATP} + \text{CoA-SH} \rightarrow \text{Fatty acyl-CoA} + \text{AMP} + 2\ \text{Pi} \qquad (1)$$

The reaction is accompanied by the hydrolysis of ATP to form AMP and pyrophosphate. The pyrophosphate is rapidly hydrolyzed by inorganic pyrophosphatase to two molecules of phosphate, and the synthetase reaction is strongly promoted.

The long-chain acyl-CoA derivatives cannot be transported into the mitochondria matrix directly. They must be converted to acylcarnitine derivatives and then transported through the inner membrane of the mitochondrion. This transport system consists of the enzyme carnitine palmitoyltransferase I (CPTI) localized in the mitochondrial outer membrane, of an integral inner membrane protein the carnitine:acylcarnitine translocase, and of the enzyme carnitine palmitoyltransferase II localized on the matrix side of the inner membrane as shown in Figure 1. The enzyme CPTI catalyzes the formation of the *O*-acylcarnitine, which is transported across the inner membrane by a translocase. Inside the mitochondria, the enzyme carnitine palmitoyltransferase II (CPTII) transfers the fatty acyl group back to CoA and obtain fatty acyl-CoA.

β-Oxidation Reactions

Once inside the mitochondrial matrix, the fatty acyl-CoA is catalyzed by the enzymes in the β-oxidative pathway, resulting in acetyl-CoA production. Energy produced in the β-oxidation of fatty acids and the oxidation of acetyl-CoA in the tricarboxylic acid cycle is used to generate ATP via oxidative phosphorylation. The fatty acid oxidation begins with the oxidation of the carbon that is in 'β' position to the carboxyl carbon, and so this process has come to be known as β-oxidation.

The mitochondrial β-oxidation of saturated fatty acid acids proceeds by repeated cycles of four reactions (flavin adenine dinucleotide (FAD)-linked dehydrogenation, hydration, nicotinamide adenine dinucleotide $(NAD)^+$-linked dehydrogenation, hydration, NAD^+-linked dehydrogenation, and thiolysis) with chain shortening being achieved by the successive cleavage of a C_2 unit as acetyl-CoA at each cycle until the substrate has been completely converted in acetyl-CoA. This is catalyzed by the sequential action of four enzymes families (acyl-CoA dehydrogenase, enoyl-CoA hydratase, L-hydroxyacyl-CoA dehydrogenase, and L-ketoacyl-CoA thiolase) each with a different substrate specificity for short-, medium-, and long-chain acyl-CoAs.

As shown in Figure 2, the first reaction is catalyzed by acyl-CoA dehydrogenase, a flavoprotein that is present as a family of three enzymes that differ in their specificity for the length of acyl-CoAs. Their mechanism involves the oxidation of Cα–Cβ bound

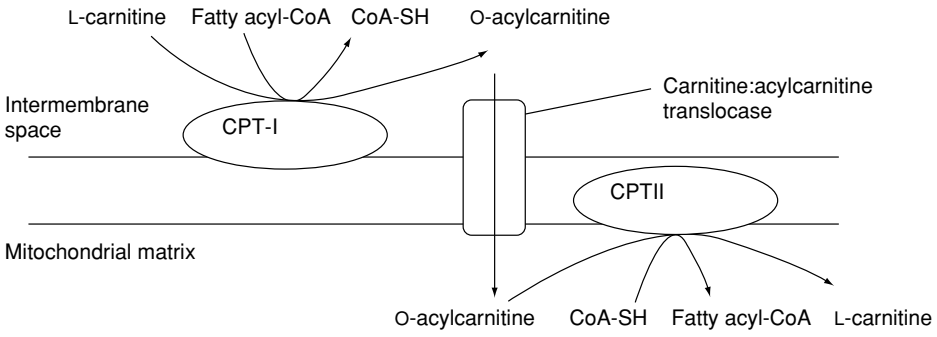

Figure 1 Transport into mitochondria of fatty acid.

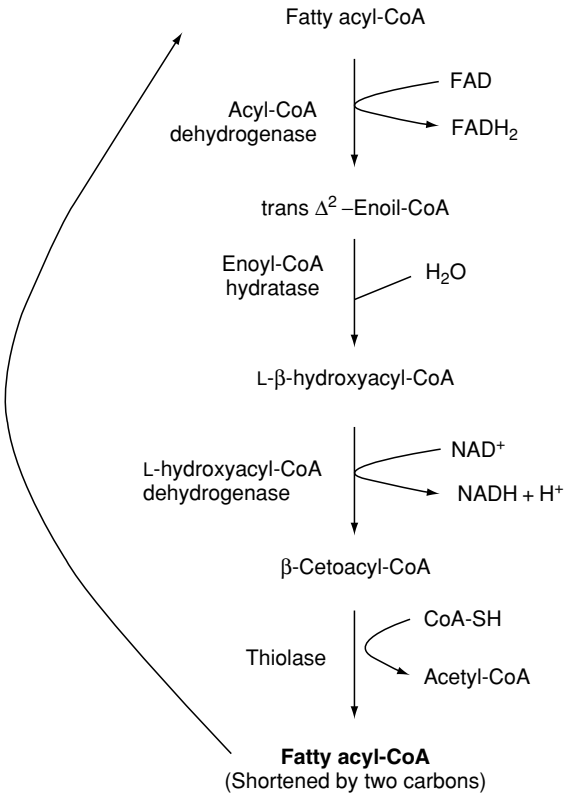

Figure 2 β-Oxidation of saturated fatty acids.

to form a *trans* double bond. During the oxidation of the fatty acid, the FAD is reduced to $FADH_2$, and the electrons are transfered to an electron transfer flavoprotein (ETF). Reduced ETF is reoxidized by a specific oxidoreductase that donates electrons to the electron transport chain at the level of coenzyme Q. The next past is a hydrogenation reaction, catalyzed by the ligase enoyl-CoA hydratase that saturates the new double bond by the addition of a hydroxyl group in the beta position. At least three enoyl-CoA hydratase activities are known. These enzymes present stereospecific and specifically converted *trans*-enoyl-CoA derivates to L-β-hydroxyacyl-CoA. The fourth reaction cleaves the β-keto ester, yielding one molecule of acetyl-CoA and a fatty acyl-CoA shortened in two carbons.

The repetitions of this cycle with the shortened fatty acyl-CoA achieve the complete β-oxidation of fatty acid. At the final step of this cycle, a fatty acid with an even number of carbons yields two molecules of acetyl-CoA.

Fatty acids with an odd number of carbon atoms are rare in mammals but are common in plants and marine organisms. Humans and animals, whose diets include these food sources, metabolize odd-carbon fatty acids via the β-oxidation pathway. The final product of β-oxidation in this case is the 3-carbon propionyl-CoA instead of acetyl-CoA. Three specialized enzymes then carry out the reaction that converts propionyl-CoA to succinyl-CoA, a TCA cycle intermediate that may be oxidized to CO_2.

The oxidation of *polyunsaturated fatty acids* involves the action of two additional mitochondrial enzymes NADPH (nicotinamide adenine dinucleotide phosphate)-linked enoyl-CoA isomerase and $\Delta^2\Delta^4$–enoyl-CoA reductase. They are needed to handle the *cis*-double bonds of naturally occurring fatty acids.

Other Aspects of Fatty Acid Oxidation

Peroxisomes also have a system for the limited β-oxidation of long-chain fatty acids to short-chain acyl-CoA esters and acetyl-CoA. This short-chain product must be transferred to the mitochondria for further breakdown. Peroxisomal β-oxidation is similar to mitochondrial β-oxidation, except that the initial double-bond formation is catalyzed by an FAD-dependent acyl-CoA oxidase.

In *microsomes*, unsaturated fatty acids are oxidized to form eicosanoids and epoxy and hydroxy-fatty acids. Some of these oxidative steps yield regulatory molecules involved in cell signaling. For example, arachidonic acid released from the *sn*-2 position of the membrane phospholipids by the action of phospholipase A_2 provides a substrate for cyclooxygenaxes, lipoxygenase, or monooxygenase.Cyclooxygenase and lipoxygenase products of arachidonic acid (20:4, *n*-6) produce eicosanoids as prostaglandins, thromboxanes, and leukotrienes. These eicosanoids play a critical role coordinating physiological interactions among cells and have an influence in a wide variety of functions, including those of the central nervous system and the contraction of smooth muscles. They also inhibit the mobilization of fatty acids from adipose tissue, have an antiinflamatory effect and modify the blood pressure, aggregation of blood platelets, and cardiac function.

Branched-chain fatty acids are oxidized by α-oxidation pathway. The CoA ester of this metabolic pathway can undergo β-oxidation in the normal way.

Regulation of Fatty Acid Oxidation

Acetyl-CoA formed by mitochondrial oxidation can be oxidized by the citrate cycle. The complete oxidation of fatty acids in peripheral tissues is therefore a major source of metabolic energy and heat in humans. In liver, most of the acetyl-CoA formed by β-oxidation is converted to ketone bodies (acetoacetate and 3-hydroxybutyrate), which are exported as metabolic fuels for extrahepatic tissues. Peroxisomal β-oxidation in the liver is less pronounced than in mitochondria, but it has a key role in metabolizing some very-long-chain fatty acids, although it is

not directly linked to ATP synthesis. The rate of β-oxidation is adjusted to physiological needs. This sequence of events has two potential sites of regulation, (a) transport of fatty acids into the cell, and (b) enzymatic regulation.

Fatty acid transport Long-chain fatty acids can be transferred passively across mammalian cell membranes. A simple diffusion process becomes significant at higher molar ratios of fatty acid to albumin as the concentration of free fatty acid in solution is increased. However, under physiological conditions of low fatty acid to albumin ratios in the circulation, the major fraction of uptake appears to be mediated by a protein component. Therefore, the plasma-membrane-associated and cytoplasmic fatty-acid-binding proteins are involved in cellular fatty acid uptake, transport, and metabolism in tissues. These binding proteins may also act modulate the metabolism of long-chain fatty acids implicated in the regulation of cell growth and other cellular functions.

An acute increase in fatty acid concentration causes a corresponding increase in fatty acid uptake without necessarily increasing fatty acid oxidation. Thus, fatty acid oxidation is more likely to be regulated by factors inside the cell than by limitations in transport.

The FABP exists within both the cytosol and nucleus, which suggests that fatty acids or fatty acid-CoA may be in the nucleus and act as ligands that regulate the activity of specific transcription factors.

Enzymatic regulation When plasma FFAs enter the cells, the first important step in their oxidation is the formation of fatty-acyl-CoA. The enzymatic regulation of CPT-I will then determine whether the fatty-acyl-CoAs will be transferred into the mitochondria for subsequent oxidation.

The reaction catalyzed by CPT-I has been considered to be rate-limiting. CPT-I is subject to regulation at the transcriptional level and to acute control by malonyl-CoA. Thus, the N-terminal domain of CPT-I is essential for malonyl-CoA inhibition.

Malonyl-CoA, which is synthesized by acteyl-CoA carboxylase, is an essential metabolic intermediate in the regulation of fatty acid oxidation. A decrease in malonyl-CoA level results in an increase in CPT-I mediated fatty acid uptake into the mitochondria. As fluctuations in tissue malonyl-CoA content are parallel with changes in acetyl-CoA carboxylase activity, which in turn is under the control of 5′-AMP-activated protein kinase, the CPT-I/malonyl-CoA system is part of a fuel-sensing gauge, turning fatty acid oxidation on and off, depending on the tissue's energy demand.

No allosteric regulation or control of their activities by covalent modification of the other enzymes of the β-oxidation pathway appears to have been described, and it is now recognized that flux control of flux through a pathway is shared between all the enzymes involved, although their individual flux-control coefficients may be very different.

Fatty Acid Biosynthesis. Lipogenesis

Long-chain fatty acids are essential constituents of membrane lipids and are important substrates for energy metabolism of the cell. When total energy intake is in excess of the energy used, fatty acids and triacylglycerol are synthesized.

The synthesis of fatty acids *de novo* is achieved by the sequential condensation of two-carbon units derived initially from acetyl-CoA.

Palmitate, the most abundant acid, is synthesized *de novo* from acetyl-CoA, by acetyl-coA carboxylase (ACC) and fatty acid synthase (FAS) in the cytoplasm.

ACC catalyzes the carboxylation of acetyl-CoA to malonyl-CoA in an ATP-dependent manner. The reaction catalyzed by this enzyme is shown in Figure 3.

Two forms of ACC have been identified. The enzyme that is involved in the synthesis of long-chain fatty acids has a molecular weight of 265 kDa, and the other isoform, with a molecular weight of 275–280 kDa, may be involved in the regulation of mitochondrial oxidation of fatty acids.

FAS plays the central role in *de-novo* lipogenesis in mammals, catalyzing all reaction steps in the conversion of acetyl-CoA and malonyl-CoA to palmitate by enzymatic reactions catalyzed by FAS (Figure 4).

The reaction of FAS involves increasing the length of the acetyl group by C_2 units derived from malonyl-CoA in a stepwise and sequential manner. For instance, in the synthesis of palmitate, there are over 40 steps with at least 30 acyl intermediates. A protein known as acyl carrier protein (ACP) with its 4′-phosphopantetheine prosthetic group was identified as the coenzyme that binds all acyl intermediates as thioester derivatives.

Seven enzymes and reactions are involved in the synthesis of palmitate, as shown in Figure 5. These reactions are essentially the same in all organisms. Acetyl and malonyl are introduced as acyl carrier protein conjugates (reactions 1 and 2). Decarboxylation

(7) Thioesterase	Palmitoyl-ACP + H_2O ⟶ Palmitate + ACP-SH

Figure 5 Reactions and component enzymes of fatty acid synthase.

drives the β-ketoacyl-ACP synthase and results in the addition of two carbon units to the growing chain (reaction 3). The β-ketoacyl derivative is reduced in three consecutive steps (reactions 4–6) to the saturated acyl derivative, which then acts as a primer for further elongation and reduction cycles to yield ultimately a palmitoyl derivative. The latter is either hydrolyzed to free palmitate (reaction 7), as in animal cells and bacteria, or transferred to CoA-SH to form palmitoyl-CoA, as in yeast, or utilized directly in the triacylglycerol and phospholipid synthesis.

In animal cells, the component enzymes of fatty acid synthesis are covalently linked on a single polypeptide chain. From the N-terminus of FAS to its C-terminus, amino acids encoding β-ketoacyl synthatase, acetyl-CoA transacylase, malonyl-CoA transacylase, dehydratase, enoyl reductase, β-ketoacyl reductase, acyl carrier protein, and thioesterase activities are organized into discrete domains in the order indicated. This is in contrast to bacterial and plant FAS, which are multienzyme complexes consisting of discrete monofunctional enzymes and fungal FAS, which has functional components that are distributed between two nonidentical polypeptides.

The most important feature of animal FAS is its multifunctional character. The animal FAS represents one of the more complex multifunctional polypeptide structures discovered to date because a single polypeptide structure contains all the catalytic components required to direct the 37 reactions that lead to the formation of palmitic acid from acetyl and malonyl-CoA. The functional enzyme is a homodimer of the 250-kDa subunits and contains, in separate domains, the seven different catalytic activities and the site for the prosthetic group, 4′-phosphopantetheine, of the acyl carrier protein (ACP). The multifunctional nature of the subunits and their head-to-tail organization produce a highly efficient enzyme complex capable of carrying out multiple reactions leading to the synthesis of a palmitate molecule from one acteyl and seven malonyl moieties. This multifunctional organization of FAS in vertebrates was probably selected in the course of evolution, because it is more efficient and because the partial activities are more easily regulated in a coordinated fashion. The substrates for each reaction can be channeled to the active center of the subsequent enzymatic step within the same polypeptide, thus providing a high efficiency in long-chain fatty acid synthesis. Moreover, regulating production of the single polypeptide has an effect at all the catalytic steps in a concerted manner.

Additional Elongation

Palmitate is the primary product of the fatty acid synthase, but the cells may synthesize many other fatty acids. Shorter chains can be made easily if the chain is released before it reaches 16 carbons in length. Longer chains are made through special elongation reactions, which occur both in the mitochondria and at the surface of the endoplasmic reticulum. The mitochondrial reactions involve addition and subsequent reduction of acetyl units. The endoplasmic reticulum reactions involve the addition of two-carbon units at the carboxyl end of the chain by means of oxidative decarboxylations involving malonyl-CoA.

Introduction of a Single *Cis* Double Bond

Prokaryotes and eukaryotes are able to introduce an unsaturation (one or more double bond) in a fatty

acid. Double bonds in fatty acids are predominantly of the *cis* (or *Z*) configuration. Many prokaryotes introduce double bonds into fatty acids anaerobically, whereas eukaryotes have adopted an O_2-dependent pathway. So, the advent of an aerobic environment several billion years ago allowed eukaryotes, cyanobacteria, and some bacilli to desaturate the methylene groups of long-chain fatty acids using enzymes called fatty acid desaturases. The transition from anaerobic to aerobic respiration yielded more than an order of magnitude of energy efficiency, leaving a surplus available for processes such as oxidative desaturation. In addition, the ability to regulate membrane fluidity controlling the number of double bonds in fatty acids within the membrane in response to changing temperatures probably conferred a selective advantage to organisms capable of aerobic desaturation.

The anaerobic biosynthesis of unsaturated fatty acids involves dehydration of a hydroxy substrate followed by *trans–cis* isomerization of the double bond. The aerobic reaction can occur anywhere in the fatty acid chain without the need to activate the desired bond toward dehydrogenation. Fatty acid desaturation involves an enzymatic reaction in which a double bond is introduced into an acyl chain, and a molecule of oxygen is completely reduced to water. Two classes of fatty acid desaturase enzymes capable of converting saturated to monounsaturated fatty acids are known, one soluble and the other membrane-bound. Desaturase enzymes need the presence of NADH and oxygen, and two other proteins, cytochrome b_5 and cytochrome b_5 reductase, are involved.

Mammals require polyunsaturated fatty acids but must acquire them in their diet. As such, they are referred to as essential fatty acids (linoleic and linolenic acid). However, mammals can add additional double bonds to unsaturated fatty acids from their diets. Three major groups of dietary fatty acids are oleic acid, linoleic acid, and linolenic acid. These fatty acids serve as precursors for the biosynthesis of a long-chain polyunsaturated fatty acid with carbon lengths of C20/C22. These biosynthetic pathways consist of a series of desaturation and chain elongation steps. Desaturation occurs only toward the carboxylic end of fatty acids in mammalian tissues, and there is no direct crossover among unsaturated fatty acids from one group to another.

Regulatory Control of Fatty Acid Biosynthesis

Variations in the composition and quantity of the diet and rates of *de novo* fatty acid and triacylglycerol synthesis are tightly regulated by nutritional and hormonal status to meet the body's requirement for lipid and energy storage.

The activity of the lipogenic pathway is dependent on nutritional conditions, both in the liver and in the adipose tissue. Consumption of a diet rich in carbohydrates stimulates the lipogenic pathway, whereas starvation or consumption of a diet rich in lipids and poor in carbohydrates decreases its function. Flux through the lipogenic pathway depends on the availability both of lipogenic substrates and of cofactors such as NADPH produced by the pentose phosphate pathway. Regulation of the activity of the lipogenic enzymes involves both short-term and long-term mechanisms.

ACC is the rate-limiting enzyme in the biosynthesis of fatty acids. The ACC activity and the rate of fatty acid synthesis fluctuate rapidly in response to various factors such as hormonal, dietary, developmental, and genetic factors. In the regulation of ACC, short-term changes in the enzymatic activity of ACC are through allosteric regulation, phosphorylation/dephosphorylation events and polymerization/depolymerization mechanisms linked to the presence of specific metabolites as Ca. However, long-term regulation mechanisms, particularly those acting at the gene level of ACC, are controlled at a transcription level and involve changes in the concentrations of regulated enzymes, for example, those observed in animals being fasted and then fed.

The expression of the FAS gene is also highly dependent on the nutritional conditions in liver and adipose tissue. Expression of the gene is barely detectable in starved animals and is stimulated by refeeding with a high-carbohydrate, fat-free diet.

Thus, the amount of carbohydrate in the diet appears to be instrumental in turning on transcription of genes coding for lipogenic enzymes in liver and adipose tissue. Rates of expression of the genes for FAS and ACC are stimulated by glucose in adipose tissue *in vivo* and *in vitro*. Expression of FAS and ACC is stimulated in the liver and of ACC in a pancreatic β-cell line. In each case, regulation involves stimulation of transcription, and to stimulate gene transcription, glucose must be metabolized. To date, the role of insulin, either direct or indirect, is still disputed. Indeed, insulin is reported to restore lipogenic enzyme gene expression in diabetic rats, and glucagon (via cAMP) inhibits expression of the genes for lipogenic enzymes. In adipose tissue, insulin increases indirectly the expression of FAS and ACC by stimulating glucose transport.

Although normal tissues have low levels of fatty acid synthesis, a number of recent studies have demonstrated high levels of FAS expression in a wide variety of human cancers, including carcinoma of the colon, prostate, ovary, endometrium, and breast. The widespread expression of FAS in human

cancer suggests that fatty acid synthesis helps promote tumor growth. This is in marked contrast to its role as an anabolic energy storage pathway in liver and adipose tissue, and fatty acid synthesis is now associated with clinically aggressive tumor behavior and tumor-cell growth and survival, and has become a novel target pathway for chemotherapy development.

Gamma-linolenic Acid

F D Gunstone, Scottish Crop Research Institute, Invergowrie, Dundee, UK

Background

Linolenic acid (GLA) is an important member of the *n*-6 family of polyunsaturated fatty acids, being an intermediate in the bioconversion of linoleic acid to arachidonic acid. Since the formation of GLA is rate-determining in this sequence of changes there are several circumstances when it might be desirable to add it to the diet. GLA is available in seed oils of evening primrose, borage, and blackcurrant, and methods of raising the concentration of this acid in these sources have been described.

Structure

γ-Linolenic acid (GLA) is all-*cis*-6,9,12-octadecatrienoic acid and may also be designated as 18:3 (*n*-6).

This later term indicates an acid with 18 carbon atoms and three double bonds starting on the sixth carbon from the methyl group. It is understood that, in the absence of other indicators, the double bonds have a *cis* configuration and are methylene-interrupted, i.e., the unsaturated centers are separated from each other by one CH_2 group.

$$CH_3CH_2CH=\overset{cis}{C}HCH_2CH=\overset{cis}{C}HCH_2CH=\overset{cis}{C}H(CH_2)_7COOH.$$

There are two important families of polyunsaturated fatty acids: the *n*-6 family based on linoleic acid, and the *n*-3 family, based on linolenic acid. Since animals – including humans – cannot produce linoleic or linolenic acids themselves, these acids are essential parts of the diet, obtainable from vegetable sources or from animals that have already derived these acids from a plant source. Once ingested, the two C18 acids can be metabolized to important C20 and C22 acids through a series of changes involving desaturation and elongation. The same enzymes are required for both families of acids, and there is competition for these. The most important acids in these sequences are arachidonic acid (20:4) in the *n*-6 series, and eicosapentaenoic acid (*n*-3 20:5) and docosahexaenoic acid (22:6) in the *n*-3 series. These acids are important components of phospholipid membranes, and the two C20 acids are also precursors of prostaglandins and other eicosanoids.
