The fleshy, thin-skinned tubers are variable in size, shape, and highly branched, and the inside is white with a crispy and watery texture. Tuber colors very from white to yellow and sometimes red or purple. Tuber carbohydrate content ranges from 14.5 to 20%; of this, 65–82% is fructose and the inulin content is 22.4% in some varieties. Only two varieties, Mammoth white French and Sutton's white, are widely grown. V71, D1, D2, Patate Vilmorin, Comber Challenger, and Moder are also important cultivars.

A unique feature of Jerusalem artichoke is the production of inulin, a polymer of fructose (which stores carbohydrate and is a suitable food for diabetics). Tubers are used raw in salad or cooked like potatoes and are also used for animal feeding. Tubers are utilized for sugar extraction, fuel alcohol production, as a source of fructose, and for the preparation of 5-hydroxy methyl furfural.

Tubers are harvested in the late fall when stems are completely senescent or killed by cold temperature. Stems are cut away to facilitate harvesting. Yields vary by 15–40 t h^{-1}. Careful handling during harvest and postharvest is necessary because the thin-skinned tubers bruise easily and are subject to rapid desiccation. Harvested tubers can be stored for several months at 0–2 °C and at 95% relative humidity.

Parsnip: *Pastinaca saliva* l./P. *sylvestris* (2n = 22)

Parsnip belongs to the family Umbellifereae and is native to the Mediterranean region. It was introduced to the West Indies in 1564 but grows well in the tropics, but only at high altitudes. The Romans utilized the wild form for medicine and food.

Parsnips have a sweet taste and a slight mucilaginous texture. The edible portion is a long, tapered,

fleshy axis formed by hypocotyls. Large roots have an excellent, sweet flavor, and can be appreciated better when they are cooked and served cold. Small miniparsnips can be grated raw and served in salad. Smooth-skinned 'Lancer' is a recommended Miniparsnip. Roots have been reported to contain three phytotoxic, mutagenic, and photocarcinogenic furocoumarins that persist through normal cooking. They will melanize skin and have been used to treat depigmented skin and also psoriasis. Workers handling parsnips have frequently reported dermatitis.

Radish: *Raphanus sativus* L. ssp. Salivus (2n = 18)

The radish belongs to the Crucifereae (Brassicaceae), mustard family. It is a popular salad crop for home gardening and fresh market (Table 7). Raphanus is a latinized form of the Greek rephanos, which means 'easily reared.' Radish was a common food crop in Egypt. The eastern Mediterranean region, China, and middle Asia are considered to be the origin of radish. China is the center of origin because wild radish still exists in China. The ancient Greeks prized radishes so much that they made small replicas of them in gold. In 1544, a German botanist reported seeing radishes that weighed 100 lb (45 kg). Radishes were common in England in 1586 and were among the first European crops introduced to America by the Spaniards. By 1629, they were being cultivated in Massachusetts.

Table 7 Classification of radish cultivars depending on the season

Summer radish (approximately 25 days to maturity)	*Cultivar*
Round	
Red	Cavelier, Cherry-Beauty, Comet, Sparkler, Early Scarlet
Red/white	Sparkler
White/yellow	Golden of Globe, Snowboll
Half-long	French Breakfast
Red/white	Icicle
White	
Long-rooted	Cinnicinnati Market, white Icicle, long Scarlet, Short Top, Strasburg, Stuttgart, white Vienna
All-season radish (approximately 45 days to maturity)	Summer cross hybrid
Winter radish (approximately 60 days to maturity)	
Round	
Black	Round Black Spanish
Elongated	
Red	China Rose
White	White Chinese

The varieties evolved in India can broadly be categorized into two groups: Asiatic (tropical) or annual types and European (temperate) or biennial types. Several Asiatic or tropical varieties such as Japanese White, Pusa Desi, Pusa Chetki, and Pusa Reshmi are grown extensively in India. The Indian Agricultural Research Institute (IARI), New Delhi has released Pusa Himani as an improved variety of radish, having white skin, crisp flesh, and sweet flavor. Cultivar CO-1 has recently been released by Tamilnadu Agricultural University, Coimbatore.

The pink color of the radish roots is due to the presence of anthocyanin pigment. The characteristic pungent flavor and taste of radish roots are due to the high content of volatile alkaloid isothiocyanate (*trans*-4-methyl thiobutenyl isothiocyanate: MTB-ITC). For salad purposes, selection is towards low pungency.

Although radish is consumed worldwide, it contributes little to nutrition. Radish is low in calories and is a good source of vitamin C (15–40 mg $100\,g^{-1}$ fresh wt). One serving size of 85 g has only 15 cal and this will provide 30% of the RDA of vitamin C and 20% of the RDA for calcium. Radish contains glucose as the major sugar and smaller quantities of sucrose and fructose. Pectin and pentosans are also reported to be present. Pink-skinned radishes are generally richer in ascorbic acid than white-skinned ones. Radish leaves are a good source of extraction of protein on a commercial scale. The seeds are a potential source of nondrying fatty oil suitable for soap maturing.

Radish roots are eaten raw as salad and as a side item and cooked as vegetables. The very characteristic flavor is popular in Japan, the Philippines, and Hawaii, and roots are used to prepare food products such as takuwan and cabaizuku. It increases appetite, produces cooling effects, and prevents constipation. Radish roots are considered to be good for patients suffering from liver trouble, gallbladder ailments, hemorrhoids (piles), jaundice, and enlarged spleen. The seeds are said to be carminative, diuretic, expectorant, and peptic. The seed oil is used to make soap.

The edible roots become ready for harvesting in about 25–60 days depending on the variety. Radishes grown for the home garden are pulled by hand and laid in bunches of 6–12 in the field and washed to remove soil. They are usually packed in baskets or crates and iced for transport to market. The tops of winter radish are removed before they are stored, Mechanical harvesters are used for commercially grown crops in the USA.

Salsify: *Tragopogon porrifolius*

Salsify is a biennial plant, belonging to the family Asteraceae and native to Europe, North Africa, and Asia. From the appearance of its foliage, the plant acquired the name of 'goat's beard' and from the taste of the root 'vegetable oyster.' It is grown for its long, tapering roots, frequently branched, which are used for flavoring. The long, grass-like narrow leaves form a rosette and the plant can reach 1.2 m (4 ft) in height, with purple daisy-like flowers. Salsify is very hardy and the root may be harvested well into the winter with no damage. Little salsify is grown commercially in the USA. Roots are ready for use in mid-fall to late spring, and are lifted and stored for winter in boxes of sand.

Salsify contains the highest amount of protein (2.9%), carbohydrates (18.0%), phosphorus (66 mg $100\,g^{-1}$), and potassium (380 mg $100\,g^{-1}$) among root salad crops (beet, carrot, radish, turnip, rutabaga, and parsnips).

Roots, leafy shoots (known as chards), buds, and open flowers can be used as raw salad. Salsify is cooked with its peel on and after cooking the peel is removed and the vegetable is served hot or cold with dressing. Flowers as used raw or cooked.

Squawroot: *Perideridia gairdneri* Mathias

Other names: *yampah, epos* root.

The squawroot is perennial, and belongs to the Apiaceae family. It is grown wild in the western USA (southern Oregon, northern California) and British Columbia. Enlarged storage roots are collected in the summer and fall by local people and are eaten raw or cooked. They are also dried for use during summer. Epos was served as food for natives and early settlers in these regions. The starchy dark-skinned roots resemble nuts with a white flesh.

Turnip and Rutabaga: *Brassica rapa* L. ssp. Rapa ($2n = 20$); *B. napus* L. ssp. Napobrassica ($2n = 38$)

These are biennial herbs, belonging to the family Cruciferae, and are cultivated as annual root crops for both animal and human consumption. Rutabaga is evolved as a cross of cabbage (18 chromosomes) with turnip (20 chromosomes), followed by spontaneous chromosome doubling. Turnip and rutabaga have been grown for nearly 4000 years and were known by the Greeks and Romans at the beginning of the Christian era. Their original home is considered to be temperate Europe. They reached Mexico in 1586, Virginia in 1610, and New England in 1628. The early European settlers introduced them to North America in the seventeenth century.

Although both are similar in flavor, most common cultivars can be distinguished by their foliage appearance and root shape, size, and color. The enlarged fleshy storage organ in turnip and rutabaga varies in form, and these may be round, cylindrical, or flattened globes. The exterior may be white, green bronze, or purple color and the interior is white or light yellow. Their nutritional values also differ. Turnip generally has hairy leaves and a small white flesh root, whereas rutabaga has smooth, large leaves with a large, yellow-fleshed root. Turnip is a short-season crop; rutabaga requires a full season.

Purple-Top White Glove and Seven Top are the important cultivars of turnip whereas American Purple-Top and Laurentian are the important cultivars of rutabaga.

A cup of turnip greens provides 165% of the RDA of vitamin C, 182% of vitamin A, one-sixth of iron and thiamin RDA and one-fifth of riboflavin.

Turnips are used in roasts, stews, soups, and casseroles and as a boiled vegetable or sliced in salads. They may be eaten wholes or halved or mashed and served with a variety of sauces. When young and tender, turnip greens are cooked and eaten.

The flavor of rutabaga makes it suitable not only as a cooked vegetable but also in soups, salads, and baked goods. Rutabaga may be boiled or roasted with meat and eaten in pieces or boiled and mashed. Fresh uncooked rutabaga can be shredded into salads.

Rutabagas have much more vitamin A than turnips, considerably more ascorbic acid and more of the other vitamins, but less iron. This comparison refers only to the roots.

Turnip and rutabaga are of best-quality roots (mild and tender) when they are medium-sized, are commonly packed in transparent film bags, and require storage temperatures of 0–2 °C (32–35 °F) and relative humidity of 90–95%.

Yacon: *Polymnia sonchifolia* Poepp. and Endl.

Other names: jiquama, jacon, apple of the earth.

The yacon is perennial, belonging to the Asteraceae family, and is cold-tolerant; overground portions are damaged by frost and reestablish from the underground portion. The crop is grown as an annual for its foliage and as a perennial for the underground tuberous roots. Wild forms of yacon are found in the Andean regions of Colombia, Ecuador, and Peru. Plant height is approximately 1.5 m. Stems are hairy and green with purple markings. Lower auxiliary stems bear yellow or orange flowers. After flowering, the tops become senescent and die. Usually four or more developing tuberous roots form clusters that can be separated. Shapes vary from spindle to round. The thin skins are tan or purplish brown color.

The flesh can be white, pale yellow, or orange and is of varying sweetness.

Moisture and protein ranges are 70–85% and 6–7%, respectively, in roots. Stems and leaves are often fed to animals and can be used as cooked vegetables or eaten raw. Roots are high in potassium. Carbohydrate is stored as inulin, a polymer of fructose, and 65% dry weight is sugar.

Before use, skin must be removed because it is resinous. The crisp-textured tuberous roots are juicy and frequently eaten raw in snacks and salads, and also boiled or baked. The tubers are a rich source of fructose.

Yacon production is more than $20\,t\,ha^{-1}$ and is stored well at 5 °C and in the dark for a few weeks.

Yam beans/jicama: *Pachyrhizus erosus* L. Urban

Other names: sincamas or sinkamas (Philippines), fanko and sargott (China), dolique bulbeus (France), jimaca (Spanish), xicamatl (Nahuatl Indian).

Yam bean is a perennial, belonging to the Fabaceae (leguminoseae) family. It is a native of tropical America, from Mexico to northern South America. It is widely grown for its tuberous roots in these regions, and in the Philippines, and South China and is a domestic crop in Bolivia, northern Argentina, and the Amazon river headwaters.

Jicama (yam bean) is a herbaceous climbing vine. Leaves are entire or lobed rhomboidal shape. The tuberous root shape can be a flattened sphere, much like a turnip, elongated, spindle-like, and lobed. The skin is colored tan to light brown and flesh is white, has a watery crisp texture and sweet taste. In Mexico, two major types are grown:

1. Jicama de leche: this type has a dark skin, slender spindle-shaped root, and a milky taste.
2. Jicama de aqua: this type has a light skin, turnip-shaped root, is very succulent, and has a sweet watery taste.

The young brown-skinned and white-fleshed roots are sweet and watery and often eaten raw as a snack food and appreciated for their mild flavor and succulent crispy texture. Roots are harvested by hand-digging, yielding $15-45\,t\,ha^{-1}$ and can be stored at 13–15 °C for more than a month.

Bulbs

It is monocotyledonous, assigned to Amaryllideceae (Liliaceae), a distinct family of Alliaceae and has bulb or corms, belonging to the *Allium* genus. Scaly leaves are the underground edible portion and are valued for their pungency.

The genus *Allium* contains about 500 widely distributed species. The most important cultivated species are onion (*A. cepa* L.), leek (*A. ampeloprasum* L.), Japanese bunching of onion (*A. fistulosum* L.), rakkyo (*A. chinesensis* G. Don), Chinese chive (*A. tuberosum* Rott. Ex. Spr), chives (*A. schoenoprasum* L.), and shallots (*A. cepa* L.).

These crops are native to the temperate regions of South Africa and the Mediterranean. The alliums have been cultivated for food, medicine, or religious purposes and spices. The best-known feature of the alliums is their characteristic smell and taste.

The remarkable sulfur-containing compounds they contain characterize alliums, giving them their distinctive smell and pungency. In alliums most of the sulfur is in the form of various nonprotein amino acids, including the precursors (*S*-methyl, *S*-propyl, *S*-(1-propenyl) and *S*-allyl) of the volatile flavor compounds. These precursors are odorless, nonvolatile amino acids of the general name 5-alk (en) yl cysteine sulfoxides. When fresh tissue is damaged, flavor precursors react under the control of the enzyme allinase (*S*-alk (en) yl-L-cysteine sulfoxide lyase) to release the highly reactive sulfenic acids plus ammonia and pyruvate. Allium crops are almost totally lacking in starch but store carbohydrates as fractans (polymers of fructose), including sucrose, glucose, and fructose.

Garlic: *Allium sativum* L. ($2n = 16$)

Garlic is a cool-season, bulbous perennial plant of the Alliaceae family. The name comes from the Welsh word garleg, transformed into the English word 'garlic.' Carl Linnaeus gave the name *Allium sativum* to garlic in 1754. The Romans disliked the strong flavor of garlic but they fed it to their laborers and soldiers for strength and courage. In the world of the occult, garlic is believed to be a protection against known and unknown evil. Garlic wreaths hung on an outside door are said to ward off witches.

Garlic is native to middle Asia and the Mediterranean region. Central Asia, in particular the high mountain plateaus of Pamir and Tian Shan, is the original home of garlic. Garlic culture appeared considerably later in Europe and the rest of Asia, and was introduced to North and South America by the Spanish and Portuguese at the beginning of the fifteenth century. Anglo-Saxon settlers cultivated garlic in Australia, neighboring islands, and in Central and Southern Africa at the beginning of the nineteenth century. Garlic was used in Egypt before 2000 BC and in China and India for more than 1000 years. With the increased consumption of garlic in almost all countries, both home and international trade have developed rapidly. China is the highest producer of garlic,

followed by South Korea, Spain, and India. World production of garlic in 1990 was estimated to be 3 012 000 metric tons. Asia leads the world in garlic production, with more than 82% of total world supply, with China producing 63% of world supply.

The biggest exporters of garlic are Spain, Italy, France, and the USA. Fresh garlic and tinned foods are the target of much interest. Garlic for the fresh market was $261.5 million in 1997. Per capita consumption of garlic was 94 g (2.1 lb) per person in 1996. Most of the 37 000 acre of garlic grown in the USA is in California. The Republic of Korea consumes the most garlic.

The garlic bulb is composed of a disk-like stem, thin dry scales, which are the bases of foliage leaves, and smaller bulblets or cloves (usually 10 or more). The edible part of garlic is termed the clove; this is a small bulb that, together with other cloves, forms an aggregate or cluster covered with the outermost leaf, a white or purplish papery sheath. Cloves are formed from auxiliary buds of younger foliage leaves and enclosed by dry outer scales. Each clove consists of a protective cylindrical sheet, a single thickened storage leaf sheath and a small control bud. Garlic leaves have solid, thin blades.

Cultivars There are two different types of garlic: those that send up a seed stalk (hard-neck cultivars) and those that do not (soft-neck cultivars).

1. Rocabole type (hard neck):
   a. Spanish roja produces 6–13 cloves per bulb and cloves are brown to reddish purple and are easy to peel.
   b. Carpathian produces 6–10 cloves per bulb. The bulbs are large and uniform with bulb wrappers that have purple blotches. Carpathian has a hot and spicy flavor.
   c. German Red produces 10–15 cloves per bulb. It is very vigorous and has a deep green large bulb. The cloves are light brown with some purple at the base.
2. Artichoke type (soft neck):
   a. Inchellium Red produces 4–5 clove layers with 8–22 cloves. The bulbs can be over 7 cm in diameter and have a mild, lingering flavor.
   b. California Early produces four clove layers with 10–22 cloves. The cloves can have a tan to off-white color with pinkish blush. The flavor is mild and slightly sweet.
3. Silver Skin types (soft neck):
   a. Mild French produces four clove layers with 13–16 cloves. The color of the cloves is reddish pink blush on a yellow-white background and it is better adapted to hot climate. It has a sharp taste when raw but has a smooth, nutty taste when cooked.
   b. Silver Skin produces 15–20 cloves, usually in five layers. The clove color is off-white to tan with pink blush. It is a good producer of large bulbs that taste mild and sweet.

Two distinct cultivars, Fawari and Royalle Gaddi, are reported from India. Odeskii-13 and Imeruli-23 are grown in CIS. The principal varieties grown in the USA for drying are California Late (Pink and Italian) and California Early (White or Mexican and Creole).

Garlic is largely used fresh and stored as a condiment and a flavoring agent in soups, stews, tomato combinations, spaghetti, sausages, pickles, and salads. Spray-dried garlic products are also available. Garlic is used to enhance the smell and flavor of salted meat and fish. Dried garlic in powdered or granulated form is sometimes used in place of fresh bulbs. A number of garlic products, including capsules, extracts, garlic oil, and tablets, are now marketed and are odor-free. Garlic salt has much wider culinary potential than garlic powder. One tablespoon is equivalent to a clove of fresh garlic. Garlic butter has many uses in home and restaurant cooking and many restaurants offer garlic bread with meals.

Garlic has been used medicinally and there is some belief in its mythical properties. Garlic is a gastric stimulant, and helps in the digestion and absorption of food. Allicin has a hypocholesterolemic action and blood sugar-lowering effect. Garlic possesses antibacterial, insecticidal, and insect repellent properties, as well as nematicidal and larvicidal properties. Ancient folk medicine says that a cold can be cured if a person rubs the soles of the feet with cut garlic cloves or if a tonic of honey and garlic is drunk. Garlic preparations are given in whooping cough, lung disease, stomach complaints (such as to heal intenstinal ulcers) and disorders resulting from childbirth and specifically to treat for sore eyes and earache.

Garlic is harvested when the foliage collapses and starts to senesce. In a warm, dry climate, the bulbs may be left to dry and cure indoors or in windows in the field for about 1–3 weeks, using the foliage to protect the bulbs from sun injury. After drying, plants are tied in small bundles and then stored hanging on bamboo sticks or ropes. Trimmed bulbs can be stored in 2-m-deep bins or stacks provided with forced ventilation, as well as in shallow containers or sacks. Cold air (down to 0 °C) of low relative humidity is best for ventilating the stacks. Garlic cloves are stored best at 1 °C. Garlic cloves sprout most rapidly at 4–18 °C.

Leek: *Allium ampeloprasum* (Porrum group), (2*n* = 4x = 32)

The leek is herbaceous, biennial, and belongs to the family Alliaceae. Leak probably originated in the eastern Mediterranean area and spread to Europe by the Middle Ages; it was introduced to North American by European settlers. Leek are popular year-round as a salad vegetable in northern and western Europe and China. France is the largest producer of leeks in the world. Leeks are especially important in northern European countries such as Belgium, Denmark, and The Netherlands. Wild forms extend into western and southern Russia.

Leek is a tall, hardy robust herbaceous biennial with white, narrowly ovoid bulb and broad flat leaves. It resembles a green onion but is larger and, unlike onion and garlic, it does not form bulbs or cloves. Leeks are made up of sheaths of basal leaves that can be 15–25 cm long and 5 cm in diameter. The leaf base of leek stores some reserve, and has a milder and more delicate flavor than onion. When tender, it is eaten raw; is also cooked with other vegetables or used as a flavoring in soups and stews.

Cultivars Leek varieties have been classified into a number of major types that differ in pseudostem length and slenderness, leaf color, winter hardiness, and the tendency for bulbiness. Types are:

1. Bulgaarse Reuzen cv. Longa: very long, high-yielding leeks with pale green leaves and little frost resistance.
2. Danish cv. King Richard: long, high-yielding types with pale to mid-green leaves, suitable for late summer production and frost-susceptible.
3. Franse Zomer Selections cv. Pancho: long leek with mid-green leaves, limited frost resistance, and a tendency to form bulb.
4. Swiss Giant Selections cv. Tilina: medium to long leaves, with pale to mid-green, rather spreading leaves, frost-resistant.
5. Blauwgroene Herfst cv. Verina: medium shank length, dark leaf varieties, tendency to form bulb.
6. Autumn Mammoth selection cv. Goliath: medium shank length, mid-green, spreading leaves, little bulbing, very frost-hardy, high-yielding.
7. Giant winter cv. Winterreuzen: variable in appearance between varieties; all have good frost resistance.
8. Blauwgroene Winter cv. Bleu Star: short leeks with dark leaves and a high degree of bulbiness, very hardy, low-yielding.

The cultivars listed by American seedmen include London Flag, American Flag, Elephant or Monstrous, Carentan, Giant Nussenburgh, and Lyon. Acadia, Derrick, and Electra are suitable for fall cultivation in Belgium, while Alberts, Brizzard, and Carina are better for winter. Longa, Odin, Kilima, Goliath, Cyberia, and Artico are promising cultivars in Canada. Highest yield of leeks was obtained from King Richard, Verina, Tivi, Kazan, Kilima, and Albana.

Commercially important leek cultivars include the following:

- Carina has heavy thick, long white shanks and is good for overwintering.
- Titan is an extra long, early type that has vigorous growth. The leaves are dark green with white stems.
- Alaska has dark blue-green foliage and is tolerant to subfreezing temperatures.
- Pancho is considered an early leek, has thick white shanks, and resists bulbing.
- American Flag is very hardy and cold-resistant, and has large, thick shanks; it blanches to clear white with blue-green leaves.

Slender minileeks, which are very tender, may be eaten raw or cooked. The sharp flavor of leeks disappears upon boiling. They are used extensively in soups and stews because of their mild flavor and mucilaginous character.

Compared to onion, leek contains more protein and minerals. The energy value of 100 g of edible portion of leek is also higher than that of onion.

Leeks are harvested when their stalks reach a size of 2.5 cm or more in diameter and are tenderer. Hydrocooling, icing, or vacuum cooling to preserve the freshness of harvested leeks has been adopted. Leeks can be stored at near 0 °C (32 °F) and about 90% relative humidity for 2–3 months.

Onion: *Allium cepa* (2*n* = 2x = 16)

The onion is a biennial herbaceous, belonging to the Alliaceae family, and is typically grown for bulbs as annuals. Onions are native to southern Asia and the Ural mountains and have long been valued in China and India for their pungent flavor. The onion is an essential ingredient of the cuisine of many regions; it was the staple food of workers at the pyramids in Egypt; it has been worshipped since before the Christian era; and it has also been used in ancient Druid rites. The onion is the oldest salad crop known to humans.

Onions have been grown in England for centuries. The onion was introduced into the West Indies by the Spanish and spread to all parts of America, including California, Oregon, Colorado, Texas, and Georgia. China, India, CIS, Turkey, Japan, Pakistan, Mexico,

Egypt and Chile and Spain are the major producers and exporters of onion, whereas Malaysia, United Arab Republic, Canada, Japan, Lebanon and Kuwait are the major importers.

India, Indonesia, the former Soviet Union and the USA are the leading producers of onion. Onion is a major commodity of international trade. Imports in 1987 by Germany, France, the UK, and the USA were valued at US$265 m. Annually, the US onion crop is the third most valuable commercial vegetable ($426 m in 1988). Onion production for fresh market and processing increased from $581.5 m to $648.4 m in 1997.

The size, shape, and color of skin and flesh, single centers, skin retention, firmness, dormancy, pungency, and concentration of soluble solids are important quality traits for bulb production. Onions are becoming the mainstay of our diets. The bulbs may be white, red, brown, or yellow; round, piriform, or flat, soft, or firm. Dormancy is important because onions are often stored and marketed when prices are higher. Higher soluble solids are important to the dehydrating industry, producing onion chips or powder, which is used as seasoning.

Consumers in the USA prefer a less pungent onion, whereas many tropical onions are prized for their strongly pungent flesh.

The edible part of the onion is the bulbs, which are composed of concentric, fleshy, enlarged leaf bases or scales. The outer leaf bases lose moisture and became scaly. The inner leaves generally thicken as the bulb develops.

Table 8 lists important onion cultivars, and Table 9 gives a classification.

Starlite, Sunlite, BRI, Buffalo, Utalian Red Torpedo, California, Early Red, and Sweet Sandwich are important onion cultivars. Kyoto market

Table 8 Important onion cultivars

Country	*Cultivars*
India	Pusa Red, Pusa Ratnar, Nasik Red, Patna Red, N404, N207-1, white Patna, N-53, N2-4-1, Bellary Red, Bellary Big Onion, B-780, Udaipur 101, Udaipur 103, Hisar-2, Hisar-II, Kalyanpur Red Round, Arka Pragati, Arka Niketan, Arka Kalyan, Bangalore Rose and Punjab 48, Udaipur 102, Pusa White Round, Pusa White Flat, Phule Safed, Phule Suwama, Basawant 780
Pakistan	Phulkara, Faisalabad, Early and Desi Red, Local White (Kasmir)
Bangladesh	Faridpuri Vati, Taherpuri
Egypt	Giza6, Beherl
Israel	Haemek, Moab
Spain	Babosa, Valenciana, Temprana
South Africa	De Wildt, Pyramid, Bon Accord, Hojein
Mexico	Cojumatlah
Brazil	Baia Performe, Grano 502, Texas Early Grand
USA	Brigham Yellow Globe, Yellow Globe Danvers, Early Yellow Globe, Mountains Danvers, Ebenzer, Red Wethersfield, South Port Red Globe, California, Early Red, South Port White Globe, White Cresole, White Portugal or Silverstein, Yellow Bermuda, Crystal Wax, Early Grano, Yellow Sweet Spanish, White Balbosa, White Sweet Spanish, Barletta, Beltsville, Bunching and White Lisbon

Table 9 Classification of onion cultivars

Day length	*Scale color*	*Pungency*	*Representative cultivars*	*Characteristics*
Short (European type)	Brown	Sweet	Awahia	Very mild, soft-fleshed, and unsuitable for storage
	Red	Sweet	Red Granex	
	Red	Pungent	Red Creole	
	White	Sweet	White Granex, Crystal Wax	
	Yellow	Sweet	Grans, Granex	
	Yellow	Pungent	Yellow Croele	
Intermediate	Brown	Moderate	Cochise Brown	Relatively soft-fleshed and primarily used for the fresh trade
	Red	Moderate	Stockton Early Red	
	White	Moderate	Fresno White	
	Yellow	Moderate	Riaeto	
Long (American type)	Brown	Pungent	Australian Brown	Very pungent, hard, and store well
	Red	Pungent	Carmen, South Port, Red Globe	
	White	Pungent	White Lisbon, Ivory	
	Yellow	Sweet	Fiesta, Sweet Spanish	
	Yellow	Pungent	Autumn Spice, Downing Yellow Globe	

(multistem), Ishikuro, and White Evergreen are the best known and Paris Silver Skin, Barletta, Brunswick (Reddish Brown), and Purplette (Purple) are important traditional cultivars.

Bulb onions may be sliced and used in sandwiches and tried as onion rings or blooming onions. They are used at both immature (spring onion: bulbs are rudimentary) and mature bulb stages as a vegetable and spice as well as food for cattle and poultry. Onion can be eaten raw or cooked. Mild-flavored, colorful bulbs are often chosen for salads. Onions have many uses as folk remedies and recent reports suggest that onions play a part in preventing heart disease and other ailments. In many countries pickled *Allium* bulbs are eaten in large amounts. Onion is liked by the rich and the poor alike as a vegetable and for flavoring and pickling. Onions for pickling are either common yellow-brown-skinned varieties or special white Silver Skin types.

1-propenyl-sulfenic acid is produced on cutting; it spontaneously rearranges its chemical structure to form the tear-inducing thiopropanal *S*-oxide. Onion bulbs boiled whole, without previously damaging the tissue, lack flavor, since the enzyme will be destroyed before it has access to the flavor precursors.

Onions are generally dried and pickled. In some parts of West Africa, fermented preparations are made from crushed onion leaves and tops. These products are used to flavor food at times when onion is not available. Onion scales may be sun-dried for this purpose. Commercially prepared onion products include dried flakes and powder, usually made from white cultivars, with high dry-matter contents and high pungency. Onion oil has a flavor strength 500 times and onion juice 10 times that of dried products.

Canned and bottled onion is used in industries in North America. Onion rings are common products in fast-food industries. Pickled onions are popular in the UK: onions covered in vinegar and pasteurized are used. Onions are said to be stimulant, diuretic, and expectorant. Onion oil is used to treat stomach ulcers, eye disorders, gastrointestinal disturbances (flatulence), high blood pressure, malarial fevers, scorpion bites, and intestinal worms. The onion is known to possess insecticidal, antibacterial, antifungal, anti-tumor, hypoglycemic, hypolipidemic, and antiatherosclerotic properties. This has been attributed to its sulfur-containing compounds.

Onion bulbs are harvested when the tops fall over and begin to turn yellow. The ideal diameter of an onion bulb is 5–10 cm. Onions are dug and allowed to dry out in the open sun for a few days to toughen the skin. The dried soil on the bulb is removed by gentle brushing. The stems are cut, leaving 5–7 cm attached to the bulb. Onion bulbs are thoroughly covered before being stored in crates; these crates, filled with topped bulbs, are usually stacked in the field or in open curing sheds, and covered with boards, and roofing paper to protect the onions from injury by sun and rain. For fresh usage, a temperature of 0 °C and relative humidity of about 65–75% for storing are recommended. Onions can also be stored at high temperatures of 29.2–34.7 °C: 3–5% O_2 plus 10% CO_2 is superior to storage in air at 4.4 °C.

Shallot: *Allium cepa* (Aggregatum group)

A multiplier onion is an onion-like plant, which originated in western Asia, and is popular in southern USA and some European countries – France in particular. In the tropics, shallots are often grown in areas where onion culture is difficult because the climate is humid. The shallot has a very short growing season of only 2 or 3 months. The term shallot refers to the vegetatively propagated forms of *Allium cepa* var. ascalonicum. Bulbs usually propagate the crop. A single plant produces a cluster of from two to more than 15 distinct small bulbs at the base. Shallots ripen earlier than onion grown from seeds and generally give a lower yield. Shallots are reasonably hardy; they have a distinctively flavored onion-like bulb, and are a good substitute for onion as they are easily grown and fast-maturing, and most cultivars store for an exceptionally long time, much longer than onions. The shallot grows well where temperatures are too high for bulb onions over 30 °C (86 °F). They are normally roundish in shape, but there are some long and banana-shaped forms. The flesh is reddish or creamy (yellow). Red is considered to be better-flavored but it is smaller, slower-growing, and may not store as well.

Varieties/cultivars There are number of different forms of shallots:

1. The Old Shallot: bulbs are small, about the size of a walnut, 2.5 cm in diameter, 2.75 cm high and with an irregular pyriform shape. When ripe, the outer skin is silvery green or brownish, and the inner scales are tinged with purple or brown. The bulbs are produced in clusters of 5–8 or 10. Leaves are about 30 cm tall and bright green in color. This is the earliest variety, and it keeps well and is rarely cultivated.
2. Large Brown: bulbs are about 5 cm in diameter, 6 cm high, the outer skin is reddish brown, and the inner skin is tinged deep purple and fleshy. Leaves are 45 cm long, erect, and deep green.
3. Jersey Shallot: bulbs are fairly large, uneven, and irregular, often divided into side bulb and divided crowns.

4. Yellow or Dutch shallots: bulbs are round or slightly flattened, scales are greenish before drying, and straw-colored when ripe.

Ampenan, Cloja, Bima, Bima Kuning, Bauji, Balizo, Suminep, Bawang Lambung, Betawi Cipenos, and Hejakuning cultivars are reported from Indonesia.

Traditional cultivars Traditional cultivars include Long Keeping Yellow; Long Keeping Red, Hative de Niort, New Yellows. Sarite Atlantic Creation (grown for seed), New Reds: Pikant and Deli Cato.

Shallots are used in salads and cooking. Used as bulb onions, they are superb pickled. Shallots may contain more fat (Suminep) and soluble solids. Shallots are also used in certain sauces. In Ethiopia small local red shallots are highly valued in a traditional sauce to accompany injera bread made from wheat flour.

Shallots are pulled by hand, when 70–80% of the leaves have turned yellow. The outer skin is peeled off and the roots are trimmed after washing, and they are tied into 1.5-kg bunches. Shallot bulbs are dried for 5–14 days in the field and stored in warm conditions (30 °C or 86 °F).

SALMONELLA

Contents

Properties and Occurrence

C Wray, Greendale Veterinary Laboratories Ltd, Knaphill, Woking, UK

Background

The clinical and postmortem picture of typhoid fever was first accurately described by French workers in the early nineteenth century. The most striking contribution on the natural history of typhoid before the opening of the bacteriological era was the work of William Budd, who elucidated many of the epidemiological aspects of the disease. Ebert had observed in 1880 the typhoid bacillus in autopsy specimens from a patient who had died from typhoid and the organism was isolated in 1884 by Gaffky. Calf paratyphoid was first recorded as an endemic disease in northern Europe in the middle of the nineteenth century and in 1885 the organism now known as *Salmonella choleraesuis* was first isolated from pigs by Salmon and Smith, who considered the organism to be the cause of swine fever (hog cholera). *Salmonella* was first shown to be the cause of food poisoning by Gartner in Germany, who isolated an organism which he called *S. enteritidis* from the meat of a cow that had diarrhea and was slaughtered, and from the spleen of a man who had eaten about 800 g of meat from the cow and died a day later. Subsequently *Salmonella* were isolated from other species of animals and the new strains were initially named after the disease condition (e.g., *S. abortusovis, S. typhimurium*) and each was considered a different species. With the refinement of serological techniques for identification, the serological subdivisions have increased and the number of new *Salmonella* serovars continues to increase annually. Each newly recognized serovar is now customarily named after its place of isolation.

Taxonomy and Serological Classification

The genus *Salmonella* belongs to the bacterial family Enterobacteriaceae, whose definition is: straight rods, generally motile with peritrichous flagella, grow on nutrient agar, facultatively anaerobic, ferment glucose often with the production of gas, reduce nitrates to nitrites, and the oxidase test is negative. Some serovars have peculiarities, e.g., the avian serovar *S. gallinarum* is nonmotile and nonmotile variants of other serovars are occasionally observed. The classification of *Salmonella* has been controversial for many years, and according to the latest nomenclature, which reflects advances in *Salmonella* taxonomy, the genus consists of only two species: *S. enterica* and *S. bongori*. *S. enterica* is divided into six subspecies which are distinguishable by certain biochemical characteristics. These subspecies are:

Subspecies I = subspecies *enterica*
Subspecies II = subspecies *salamae*
Subspecies III = subspecies *arizonae*
Subspecies IV = subspecies *diarizonae*
Subspecies V = subspecies *houtenae*
Subspecies VI = subspecies *indica*

Thus the full correct nomenclature of an isolate would be, e.g., *Salmonella enterica* subspecies *enterica* serovar Enteritidis, rather than, as in the past, *Salmonella enteritidis*. This, however, is cumbersome and the concept that is currently in use at many laboratories is to write *Salmonella enteritidis*.

Most isolates of *Salmonella* from domestic animals belong to subspecies *enterica*, whose behavior is, with few exceptions, regular and may be classified as typical for the species. The principal biochemical tests by which *Salmonella* can be identified are given in Table 1. It should be pointed out however that variable test results may occur because, with a few exceptions, no test is 100% positive or negative.

Strains of *Salmonella* are classified into serovars by the characterization of their surface antigens, as described in the Kauffmann–White–Le Minor scheme. The identity, known as the *Salmonella* serovar, is designated by the identification of two sets of antigens. The somatic antigens, known as the O antigens, are present on the main body of the organism. They are polysaccharide antigens, identified by agglutination with specific antisera, usually prepared in

Table 1 Biochemical reactions of typical *Salmonella enterica* subsp. *enterica* strains

Test	*Reaction of typical strains*	*Test*	*Reaction of typical strains*
Motility	+	Fermentation of:

O-nitrophenyl-β-D-galactopyranoside	−		

rabbits, to give the serogroup, e.g., *S. typhimurium* is a group B *Salmonella* due to the presence of the O4 somatic antigen. Most *Salmonella* possess two phases of flagellar antigens (termed H), which are present on the protein flagellar structures that extend from the surface of the bacterium and such antigens are described as diphasic. Some serovars possess only one flagellar antigen and are described as monophasic. Examples of antigenic formulas are:

Group B (O4)	*S. agama*	O 4,12 : H i : 1,6	Diphasic
	S. typhimurium	O 1, 4, (5), 12 : H i : 1,2	Diphasic
Group C1 (O7)	*S. bonn*	O 6,7 : H 1,v : e,n,x	Diphasic
Group D1 (O9)	*S. enteritidis*	O 9,12 : H gm : –	Monophasic

Currently *c*. 2500 different *Salmonella* serovars have been identified, although only a limited number are encountered in practice. Some *Salmonella* serovars possess a capsular polysaccharide which is termed the Vi antigen. It is only of practical importance in *S. typhi* and *S. paratyphi*, when its presence may mask agglutination with somatic antiserum.

Salmonella also possess fimbriae, which are a family of polymeric proteinaceous surface organelles, but until recently little was understood about their variety and functions. Several different fimbrial types may be expressed during the organism's lifetime and it is believed that some may assist intestinal colonization and others assist their survival.

Further subdivision for epidemiological studies of the more frequent serovars may be obtained by phage typing, which evaluates the degree of susceptibility (or resistance) of isolates to a set of selected bacteriophages (viruses active against *Salmonella*). Such schemes are in routine use in many laboratories for the subdivision of *S. typhi, S. typhimurium*, and *S. enteritidis*, and other serovars of more local importance. Other methods used to show the relatedness of isolates during disease outbreaks include biotyping, antibiograms, and molecular genetic techniques to examine plasmid and chromosomal DNA. In recent years, many different molecular genetic techniques have been used to fingerprint *Salmonella* during disease outbreaks, but it should be pointed out that while one method may work with a particular serovar, it may not work with a different serovar.

Antibacterial Resistance

In general the prevalence of antibacterial resistance in *Salmonella* is low and to some extent relates to the serovar. However over the years different phage-types of *S. typhimurium* have become resistant to a range of antibacterials and caused epidemics in humans and other animals. Often the resistance genes are carried on mobile genetic elements, e.g., plasmids, and thus may be transmissible to other serovars and other bacterial species. Recently there has been an epidemic in many different countries of a multiple-resistant clone of *S. typhimurium* DT104 in which the resistance genes are incorporated into the chromosome.

Detection of *Salmonella*

Conventional isolation of *Salmonella* is accomplished by using cultural methods, which are often based on its phenotypic properties. *Salmonella* and other members of the Enterobacteriaceae are more resistant to novobiocin, selenite, tergitol, and bile salts, especially desoxycholate, than other bacteria. *Salmonella* are also more resistant than other Enterobacteriaceae to some dyes, e.g., brilliant green and malachite green; however, these properties are not sufficient for a true selective isolation and no medium is presently available that would allow the isolation of only *Salmonella* and no other bacteria. Because of this drawback, most differential media often include

lactose, sucrose, and salicin with a pH indicator, since most *Salmonella* fail to produce acid from these substrates. (*See* ***Salmonella***: Detection.)

Rapid Methods for the Detection of *Salmonella*

The time span that is necessary to obtain a negative result can thus take up to 96 h when the whole cultural method has to be applied and presumptive positive results may take up to 48–96 h. Many alternative methods have consequently been introduced in recent years to reduce analytical time and also save staff time and media requirements. These may include modification of conventional methods by including specific substances to media used either for isolation or confirmation or the development of tests to detect specific characteristics of *Salmonella*. Other rapid methods do not involve the isolation of the organism and only provide a presumptive result. This allows negative samples to be screened out, but positive samples still have to be investigated further for confirmation. Of these methods, techniques based on electrical conductance and impedance are in use in many laboratories. When microbial growth and metabolism take place in a culture medium, changes in conductance of the medium occur but the reliability of the method largely depends on the performance of the selective medium used for the assay. Immunological techniques comprise the largest group of alternative methods and many test kits are available. These techniques include immunodiffusion, enzyme-linked immunosorbent assays (ELISA), and the use of specific antibodies to 'capture and concentrate' the organism. Nucleic acid-based assays are also available, including the use of DNA probes to detect the organism and the polymerase chain reaction (PCR) to amplify a targeted region of the *Salmonella* genome. Rapid methods, however, still require up to 24 h and for many of the methods no worldwide standardization for the validation and approval of the technique is available.

Epidemiology

Although primarily intestinal parasites of human beings and other animals, *Salmonella* are widespread in the environment and commonly found in human sewage, farm effluents, and any material subject to fecal contamination. Salmonellosis has been recognized in all countries of the world, but appears to be most prevalent in areas of intensive animal production, especially in poultry and pigs. Although the disease may affect all species of domestic animal, young animals and pregnant animals are the most susceptible. Many animals may be infected but show no clinical signs. People are also highly susceptible to infection, either by direct contact with infected animals or through their products, as occurs in foodborne salmonellosis.

Host Range

While all *Salmonella* are considered to be potentially pathogenic, different serovars differ widely in their host range and pathogenic syndromes that they produce. Some serovars show a degree of host adaptation and primarily infect only one species of animal. Thus *S. typhi* and *S. paratyphi* A, B, and C usually infect only human beings and typhoid and paratyphoid are considered as human disease entities. *S. choleraesuis, S. abortusovis*, and *S. gallinarum/pullorum* occur in pigs, sheep, and poultry respectively, and *S. dublin* appears to have a predilection for cattle. In contrast, *S. typhimurium* affects all species of animals and is one of the most common causes of human food poisoning. Companion animals are a source of *Salmonella* infection; the serovars relate to their feed and the extent to which they scavenge. *Salmonella* have been isolated from wild animals and birds, reptiles, fishes, and insects.

Animal Infections

Most *Salmonella* infections in farm animals are likely to be acquired from the same species of animal, especially the host-adapted serovars. Purchased animals may acquire infection on their home premises, in transit, in markets, in collecting centers, or in lorries. Poultry may be infected vertically by egg-borne transmission of *Salmonella* when the contents or the shell may be contaminated or in the hatchery by cross-contamination. *Salmonella typhimurium* and other serovars may be introduced into herds and flocks by contaminated feedstuff. Many batches of animal protein, e.g., meat and bone meal, fishmeal, pelleted feeds, and vegetable proteins have been found to be contaminated with *Salmonella* and many new serovars have been introduced into countries in imported feed ingredients. Recontamination of feedstuffs after processing is a major problem and heat treatment, e.g., pelletization, and treatment with organic acids, e.g., propionic or formic acid, is used to produce a *Salmonella*-free product.

Infection may also be introduced by other domestic animals as well as by feral animals and birds. Rats and mice may acquire *Salmonella* infection; available evidence suggests that they do not play a major role in the spread of disease but that they may prolong the persistence of infection on a farm.

Environmental Considerations

Salmonella may survive for long periods in infected feces and slurry, where their survival depends on a

number of factors, especially the climatic conditions. Intensive livestock production has created problems of excreta disposal. The number of animals per unit area of land has vastly increased in many countries and it has been necessary to increase application rates of animal waste on to the land. One survey found that 10% of cattle slurry samples contained *Salmonella*, with survival periods ranging from 11 to 12 weeks.

Biological treatment of human sewage removes most of the suspended and dissolved organic matter, but it does not necessarily remove pathogenic bacteria. Where sewage sludge is used as a fertilizer, many samples have been found to be contaminated with *Salmonella*. There are numerous reports of the isolation of *Salmonella* from rivers and streams and of their pollution by sewage effluent and slurry runoff. Further spread from contaminated environments may also take place by wild animals and birds.

Transmission to Humans

Typhoid fever usually follows the ingestion of drinking water contaminated by human carriers of *S. typhi* or food prepared or handled by such carriers who do not take adequate hygienic precautions.

In contrast, acute gastroenteritis (foodborne disease/poisoning) is usually acquired from consumption of foods which may be directly or indirectly contaminated with *Salmonella*. A wide variety of animal species have been shown to be capable of harboring the organisms, and in the developed world turkeys, chickens, swine, and cattle have often been found to be infected in abattoir studies. Cross-contamination may readily occur during transport to the abattoir and during slaughter. Modern poultry-processing plants are designed with emphasis on speed, and during the slaughtering process there are many points where cross-contamination may occur. Recent surveys have found that up to 30% of chicken carcasses may be contaminated with *Salmonella*. Table eggs have been found to be an important vehicle for the transmission of *S. enteritidis* to humans and undercooked or raw eggs or dishes made from them, such as mayonnaise or mousse, have been responsible for many outbreaks of food poisoning.

The progressive trend toward mass processing and distribution of food products has been an important factor in the increased incidence of *Salmonella* foodborne disease. Milk has also been shown to be an important source of infection and has been associated with massive outbreaks of human salmonellosis. Most outbreaks have been associated with the consumption of raw milk, although pasteurization plant failure has also resulted in large outbreaks. Salads and other vegetables which have been contaminated in washing or 'freshening' with polluted water have also been shown to be associated with human salmonellosis. Many other products, e.g., beansprouts, chocolate, have been found to be the source of *Salmonella* infection and dried milk became contaminated with *Salmonella* when the production machinery was contaminated. Whatever the source, many outbreaks occur as a consequence of the delay between preparation/cooking and consumption of the food, which allows the numbers of *Salmonella* to increase rapidly. The important food-associated risk factors are inadequate cooking or reheating, storage at inappropriate temperatures, and cross-contamination from raw to cooked food.

Person-to-person spread has been demonstrated on many occasions and may be of importance in young children and groups living under poor socioeconomic conditions where effective sanitation is lacking. In these situations, flies may serve as vectors for *Salmonella* transmission. Dog and wild animal feces on footwear have been implicated as a route by which infection can be carried into households. Person-to-person spread may also occur in hospitals, nursing homes, and mental institutions, where a number of large outbreaks have occurred. Amplification of infection in these institutions may occur from contaminated food or from asymptomatic carriers; babies are at special risk. Likewise, contaminated equipment has been shown to be vehicles of infections.

Causation of Disease

Salmonella cause disease by invading the intestinal mucosa and multiplying in the gut-associated lymphoid tissue. From the infected tissue the organisms are drained to the regional lymph nodes, where further spread is usually prevented if the host defense mechanisms are successful. In humans nontyphoidal *Salmonella* serovars usually cause a localized disease which is manifest as an acute gastroenteritis. If, on the other hand, the host's defense mechanisms are unable to prevent the spread of the organism, systemic disease results, as commonly occurs with typhoid. The etiology of diarrheal disease is poorly understood, and although several putative toxins, e.g., enterotoxins, cytotoxins, have been described, their significance is far from clear. (*See* ***Salmonella***: Salmonellosis.)

Whether infection follows exposure to any pathogenic microorganisms depends in part on the number of organisms that enter the host's tissues. From volunteer studies in humans, it has been suggested that large inocula of *Salmonella* are necessary to cause illness. However, investigations of outbreaks of *Salmonella* foodborne disease have suggested that the

infective dose is often low; in six of the 11 outbreaks the actual dose ingested was calculated as $< 10^3$ organisms. However, many factors may affect the infective dose, not least of which are strain variations, e.g., S. *choleraesuis*, although a rare cause of human infection, may cause serious disease. Children and older people are more susceptible; other concurrent illnesses (e.g., acquired immune deficiency syndrome (AIDS)) may increase susceptibility. The use of antibiotics for other indications may predispose to foodborne salmonellosis, even when the *Salmonella* are sensitive to that antibiotic. There is a fivefold increase in risk when the *Salmonella* are resistant.

Prevention of Transmission

The overall quality of meat and edible byproducts depends heavily on their microbiological quality. This is very dependent on the contamination level of the production equipment, as well as on the skin and intestinal microflora of animals and on the technology and techniques used in slaughtering and processing. The fecal microflora of animals is the predominant source of pathogens on the final dressed carcass, and the modern slaughter line offers many risks of cross-contamination. In general, such cross-contamination is much less pronounced with carcasses of beef and sheep than with pork and poultry carcasses. A system to insure quality and safety must be designed for the entire chain of operations, from the farm to the consumer. This system must include the identification of potential microbiological problems and control measures at all stages of the entire meat production chain, as well as the development of Hazard Analysis Critical Control Point procedures. Although the hazards may differ from country to country and vary with animal health, slaughter procedures, type of meat products, and storage and distribution, the main areas of focus are the slaughter process itself and disinfection of tools and equipment.

Pasteurization will prevent milk-borne salmonellosis, although outbreaks have occurred on a number of occasions when faults have developed in plants. One of the most effective end-product treatments is gamma-irradiation, which can destroy *Salmonella* on poultry carcasses and prolong shelf-life, although possible changes in flavor and texture may occur. There may be some consumer resistance toward the use of nuclear energy.

Equally important is the education of caterers and domestic consumers in all aspects of hygienic preparation of food. Cross-contamination may occur readily in kitchens, especially when raw and cooked foods are prepared on the same surfaces.

Public Health Aspects

In many countries the results of tests which identify the presence of *Salmonella* in animals have to be reported to the appropriate government department and, in addition, separate orders may relate to animal feeds.

Likewise, on the human side, it may be necessary to report if a patient is suffering from or is suspected of having foodborne disease. Following the reporting of *Salmonella* incidents in both humans and animals, further investigations may be carried out. Regulations may also apply to the production and sale of food.

Economic and Social Impact

The financial costs of *Salmonella* infections are not only associated with investigations, treatment, and prevention of human illness; they may also affect the whole food production chain.

In the public sector, resources are necessary for surveillance, treatment of patients, and investigations of outbreaks. Financial burdens may be imposed on industry, especially the food industry. Likewise, the cost to affected individuals may be extremely high, especially should death result from *Salmonella* infections. The costs associated with Salmonellosis may be subdivided into tangible costs, which can be measured in monetary terms (e.g., medical costs and loss of work), and intangible costs, such as loss of leisure, pain, discomfort, etc., which cannot be readily costed. A study of infectious intestinal disease in England between 1993 and 1996 suggested that the true rate of salmonellosis in the community was 220/100 000 population and the estimated cost per human case was £660.

An analysis of five *Salmonella* outbreaks in North America gave direct costs which ranged from $36 400 to $62 million. In the UK, an outbreak of *S. ealing* infection associated with powdered milk was estimated to have cost £14.6 million in the late 1980s.

There have been few studies into the costs and benefits of preventing *Salmonella* infection, but it has been suggested that for every £1 spent on investigation and curtailment of an outbreak, there is a saving of £5.

Detection

T Humphrey, PHLS Food Microbiology Research Unit, Heavitree Exeter, Devon, UK
P Stephens, Oxoid Limited, Basingstoke, Hampshire, UK

Detection

In the developed world, the majority of cases of human salmonellosis is zoonotic and results from the colonization/infection of food animals and resultant contamination of products derived from them. *Salmonella* are also ubiquitous, and a diverse range of foodstuffs – including dried milk, fermented sausage, beansprouts, chocolate, and yeast-based flavoring – have been implicated as vehicles for human salmonellosis. In the UK, and elsewhere in the last decade, most cases or outbreaks of *Salmonella* infection have resulted from the consumption of contaminated eggs or poultry meat. Natural water systems, particularly those receiving human and animal waste, are also frequently contaminated.

The ubiquity of *Salmonella* and the wide range of materials with which they have been associated have meant that numerous media and techniques have been developed for their isolation. It is not the intention in this chapter to go into detail on the possible virtues or disadvantages of individual methods. Attention is focused instead on the fundamental aspects of the isolation and detection of *Salmonella*, particularly from food and environmental samples. Special emphasis is given to sublethal injury and its impact on recovery of the bacteria and the possible inhibition by other organisms. The application of rapid methods is also discussed. (*See* **Food Poisoning**: Tracing Origins and Testing.)

Sublethal Injury and its Impact on Detection

Salmonella are primarily enteric organisms and, whether in the gut or on contaminated foodstuffs, they are usually present as part of a mixed microbial population. Exceptions to this are seen with invasive, host-specific strains such as *S. typhi* in humans and *S. enteritidis* in poultry. The latter organism, for example, can be isolated in pure culture from both the tissues of infected chickens and the contents of intact shell eggs. It is generally necessary, however, to apply techniques which selectively encourage the growth of *Salmonella* and to use agars which permit the organism to produce characteristic colonies. The similarity in antibiotic resistance patterns between *Salmonella* and other enterobacteria has largely precluded the use of antibiotics and selection has relied upon the use of chemicals such as selenite, tetrathionate, and deoxycholate.

When microorganisms, particularly Gram-negative bacteria, are exposed to unfavorable conditions such as high or low temperature, they may become sublethally injured. This can be defined as 'a sensitivity to either selective agents or conditions to which normal cells are resistant.' In *Salmonella*, injury can be manifested by, for example, lowered resistance to the chemicals mentioned above. The organisms may also be less able to grow, particularly in selective media, at elevated incubation temperatures, such as 43 °C, which are used to improve the selectivity of isolation media when samples like sewage are examined.

Techniques used routinely for clinical specimens when large numbers of the target pathogen may be present and where it is relatively unaffected by its environment are not suitable for use with either food or environmental samples. These might have been exposed to conditions damaging to bacteria and they may also contain only low numbers of *Salmonella*. The direct inoculation of food or environmental samples into selenite broth or another selective medium may lead to false-negative results.

The principal site of injury in the bacterial cell is the outer membrane, and alterations in permeability allow the ingress of selective agents that are normally excluded. If cells are exposed to more extreme conditions, damage can also be caused to the chromosome and ribosomes. Much work remains to be done on the

response of *Salmonella* to adverse conditions and on the full impact of the exposure of these bacteria to different environments and their subsequent ability to grow in culture media. *Salmonella*, like other bacterial cells, are able to repair the lesions causing sublethal injury, either partially or completely, if they are incubated in a nonselective medium at 37 °C. Two media, buffered peptone water (BPW) and lactose broth, are the most commonly used, with the buffering capacity of BPW giving it an advantage over the other medium – particularly when foods containing fermentable substrates are examined.

Studies have demonstrated that the isolation rate from selective broth cultures is greatly improved if they are inoculated with an actively growing population of *Salmonella*. It is thus essential that initial incubation in BPW allows the organism both to overcome the effects of sublethal injury and to multiply.

The period of recovery or repair is often referred to as preenrichment. Incubation is usually for 18–24 h, although some workers have reported improved isolation rates when preenrichment is extended to 72 h. This is dependent on the material under investigation. *Salmonella* do not appear to be able to compete well with some other bacteria. Recovery media, by necessity, are nonselective and permit the growth of the majority of aerobic and facultative organisms present in the sample. Where this encourages the proliferation of either *Proteus* or *Pseudomonas* spp. – as with liquid raw egg and chicken meat – or lactobacilli – as with dairy products – *Salmonella* may be inhibited. This can be particularly pronounced when incubation is prolonged (Table 1).

The addition to BPW of novobiocin and cefsulodin, which inhibit *Proteus* or *Pseudomonas* spp., respectively, but have little effect on the growth of *Salmonella*, was found to improve the isolation rate of *Salmonella* from naturally contaminated samples of raw liquid egg (Table 1). The recovery of *Salmonella* from dried milk can also be improved if, after 2–4 h initial incubation, brilliant green at a final concentration of 0.0002% is added to the preenrichment culture.

Table 1 The influence of period of preenrichment and the addition of novobiocin and cefsulodin on the isolation of *Salmonella* from samples of liquid raw egg

Culture medium	*No. of* Salmonella*-positive samples*[a] *after incubation for*	
	24 h	*48 h*
Egg/BPW only	32	14
Egg/BPW plus novobiocin (5 μg ml^{-1}), cefsulodin (10 μg ml^{-1})	74	70

[a]110 samples were examined. Rappaport–Vassiliadis broth was used as the selective medium.
BPW, buffered peptone water.
Data from Humphrey TJ and Whitehead A (1992).

The presence of any number of *Salmonella* in a processed or cooked food is regarded as being potentially hazardous and most microbiological guidelines suggest an absence of the bacteria in 25 g of product. There is also evidence that, with some foodstuffs, particularly those rich in fat, and with certain vulnerable individuals such as the very young or the elderly, the infective doses of *Salmonella* may be low. Recent studies have also demonstrated that sublethally injured cells of *Campylobacter jejuni* are capable of repair in the intestinal tract. *Salmonella* may also be able to do this and it is important that sensitive techniques are used for their detection in the laboratory. In this respect, the importance of effective preenrichment cannot be overemphasized. As a general rule, it is prudent, when examining food and environmental samples from any source, to carry out primary incubation in BPW at 37 °C for a full 24 h. The ratio of sample to medium should be at least 1:10 and, where appropriate, the growth of competing flora may be suppressed by the addition of antibiotics.

Selective Culture

The necessity for selective culture techniques in microbiology has been recognized for over 100 years and much of the early work was centered upon *Salmonella*. Selective isolation is usually in two stages: growth in an enrichment broth followed by plating on a selective agar. Selective media make use of either dyes or chemicals. A formulation much in use in clinical laboratories is based on selenite. It is believed that this compound inhibits bacteria either by reaction with sulfhydryl groups or by the formation of analogs of sulfur amino acids. Selenite broth has been used successfully for many years and modifications to improve the isolation rate have included the addition of cystine and the incorporation of fermentable sugars, such as either mannitol or lactose, which prevent increases in the pH. Selenite is less selective at alkaline pH values.

Selenite can be used for direct inoculation with specimens such as feces or used following preenrichment. It is probably less suitable, however, for the latter when compared to other media. The medium can inhibit many bacterial types, but two important exceptions – *Proteus* and *Pseudomonas* spp. – can cause problems, particularly as they are capable of preventing the growth of *Salmonella* and can also resemble them on selective agars.

Salmonella have been shown to possess the enzyme tetrathionate reductase, which is absent in many

other bacteria. This provides a selective advantage and has been used in the development of another commonly used enrichment medium, tetrathionate broth. Tetrathionate is usually employed in combination with brilliant green and bile salts, the medium being known as Müller–Kauffman tetrathionate broth. It is probably more selective than selenite, but more care may be required in the control of incubation temperatures.

Malachite green, in combination with high concentrations (4%) of magnesium chloride and a medium pH of 5.0–5.2, has been shown to be effective for the isolation of *Salmonella*. The medium was originally developed for use with feces but modifications in the last 10–15 years, which have seen a reduction in the malachite green concentration from 0.012% to 0.004% and use of soya peptone rather than tryptone, have meant that the formulation, usually known as Rappaport–Vassiliadis (RV) broth, is more suitable for selective culture following preenrichment. This medium is probably the one of choice in the examination of nonclinical samples and numerous studies, on many different materials, have confirmed the superiority of RV broth over both selenite and tetrathionate.

The selective nature of the above broths is often finely balanced and can be disturbed by either a large inoculum, relative to broth volume, or overlong incubation. A change in incubation temperature can also profoundly affect the toxicity of the medium.

An inoculum-to-broth ratio of 1:10 is recommended for both selenite and tetrathionate broths, although following preenrichment culture there would appear to be no reduction in sensitivity if smaller volumes of BPW are used. The size of the inoculum is critical with RV broth and its ratio to the medium should be at least 1:100. With this medium, studies have indicated that more samples are *Salmonella*-positive after 48 h rather than 24 h incubation, although the differences are often not significant. In contrast, extended incubation significantly reduces the effectiveness of tetrathionate and selenite broths and, with the latter, overgrowth of competing flora occurs frequently. These media can also become more toxic to the target organism and *Salmonella* may die if incubation is continued much beyond 24 h. Care also has to be taken in controlling incubation temperature. Selenite and tetrathionate can be used at either 37 °C or 43 °C and are more selective at the higher temperature. Some studies have shown, however, that *Salmonella* will not always survive in these media at 43 °C. Initial studies on RV broth recommended 43 °C but it is now accepted that incubation at 41 ± 0.5 °C increases sensitivity.

Studies with particular samples or in particular situations have demonstrated that one selective medium may be superior to another. No one medium, however, can be relied upon always to maximize the isolation rate with all samples. There may thus be advantages in using two selective broths (**Figure 1**).

An important disadvantage with traditional culture techniques is the time taken to confirm whether a food sample is *Salmonella*-positive or -negative. There have been many attempts to make *Salmonella* testing more rapid and some of the newer methods are discussed below.

At first sight, it would seem possible to reduce the length of either preenrichment or selective broth culture, but in the past this approach has been largely unsuccessful. A number of publications have stated that recovery from injury is complete within 8 h at 37 °C. This is dependent on the culture medium used and the degree of cellular damage. In some systems, lag times of up to 72 h have been reported, and other studies have indicated that repair of damaged cells is not complete until some hours after growth has begun. Thus, subculture of preenrichment broths after 6 h rather than 24 h incubation was found to reduce the isolation rate. Newer work, however, has suggested that it may be possible to shorten traditional culture methods without any loss of sensitivity by using a combination of delayed release of selective agents into an optimized recovery medium. The new method makes use of a peptone-based medium that contains oxygen-consuming sterile outer membrane fragments from *Escherichia coli*, which protect bacteria by reducing oxidative stress. This allows damaged *Salmonella* cells to recover more rapidly than with conventional media. The method also makes use of delayed release capsules that release the selective components of RV broth after about 5 h at 42 °C. Trials to date indicate that this method is at least equivalent in performance to standard methods.

Selective agars should be so formulated that the competing flora is suppressed while the target organism is able to form discrete, characteristic colonies. A degree of selectivity is achieved by the addition of either dyes like brilliant green or chemicals such as sodium deoxycholate. The resistance of *Salmonella* to selective agents is similar to that of many other bacteria and this can create difficulties in media formulation. Thus, the detection of *Salmonella* on selective agars relies heavily on diagnostic aspects. Principal among these is the inability of most strains to ferment lactose and the production of hydrogen sulfide from thiosulfate at a neutral pH (leading to black colonies). More recently, the advent of affordable chromogenic substrates has led to the development of a number of new selective differential media for *Salmonella*. These

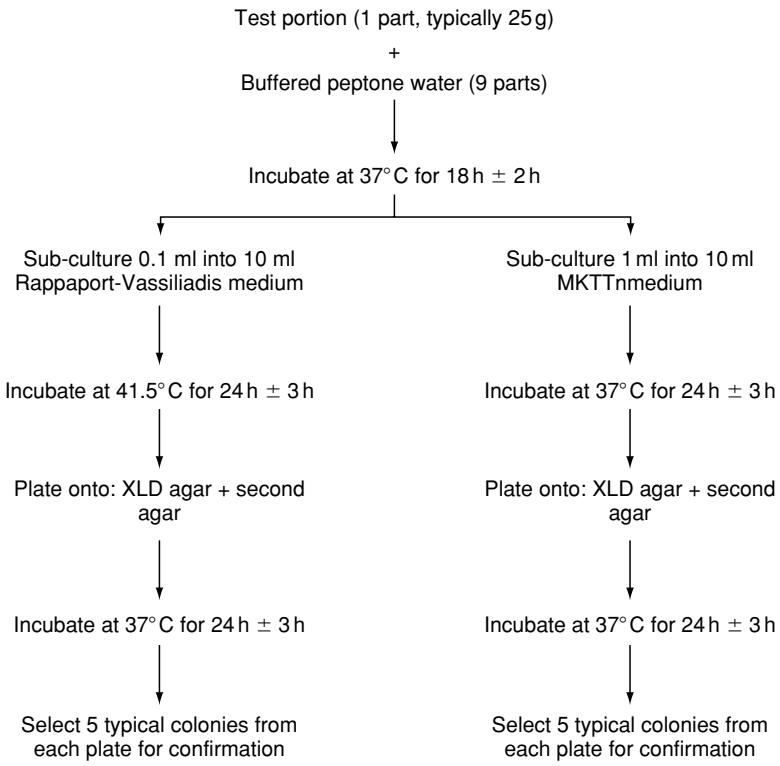

Figure 1 International Standards Organization (ISO) standard method for *Salmonella* isolation (ISO 6579:1997). BGA, brilliant green agar; XLD, xylose lysine deoxycholate.

new media often utilize a combination of traditional diagnostic markers with new substrates for the detection of galactosidase, glucoronidase, and esterase activities. Additionally, old diagnostic tools such as acid production from carbohydrate utilization have been applied to new substrates, e.g., propylene glycol utilization by *Salmonella*.

As with enrichment broths, many selective agars are available, but none has been shown definitively to be suitable for all applications and the best course of action would be to use two agars in parallel. The most commonly used media appear to be bismuth sulfite, xylose lysine deoxycholate (XLD), and brilliant green agar (BGA).

Many workers have attempted to improve selectivity by the incorporation of antibiotics and/or other selective agents. Of these, novobiocin, which prevents the growth of *Proteus* spp., seems to be the most useful.

Confirmatory Tests

Other organisms, particularly members of the family Enterobacteriaceae, can resemble *Salmonella* on selective agars and confirmation of '*Salmonella*-like' colonies is necessary. Tests take the form of biochemical confirmation, which usually involves assessment of urease and lysine decarboxylase activity, fermentation of dulcitol, indole production, growth in the presence of potassium cyanide, utilization of sodium malonate and, more recently, pyrrolindonylarylamidase (PYR) activity. These reactions, in combination with serological tests, are usually sufficient for identification, but additional tests may sometimes be necessary. If these are to form part of a laboratory routine, the use of commercial kits may be cost-effective. Antibodies against somatic (O) and flagella (H) antigens are used to confirm/identify *Salmonella*-like isolates. Somatic antigens are composed of polysaccharide, while those from the flagella are proteinaceous. Testing will usually comprise slide agglutinations with polyvalent O and H antisera, followed by the use of sera raised against specific antigens.

Rapid Methods

The time taken to confirm or deny the presence of *Salmonella*, especially in food and environmental samples, can create difficulties and, with perishable foods, can mean that products may be distributed and consumed before test results are known. It is not surprising that considerable attention has

been paid to the development of rapid methods of detection.

The new methodologies can be divided into two broad categories. There are those designed to detect or isolate viable cells and those that detect cellular components such as DNA. There are concerns that the latter methods may detect either dead cells or DNA released from them and that cultural techniques may lack the required sensitivity.

Conventional culture techniques, as discussed earlier, can be long-winded, cumbersome, and expensive. How much better it would be if it were possible to detect pathogenic bacteria by the direct application of a test to a food sample. *Salmonella* spp., and presumably other foodborne pathogens, appear to have unique DNA sequences that could allow detection. *Salmonella*-specific DNA probes and polymerase chain reaction (PCR) methods have been developed.

These techniques compare well to conventional culture when used on enrichment broths. The above studies were designed to obviate the need for selective culture and serological/biochemical identification. There are other examples, and various automated PCR-based systems are now available. Most of them require an enrichment period which delays results but sensitivity can be of the order of 3 CFU per 25 g of food.

Other new approaches include flow cytometry. These methods have faced the criticism that they are still too slow for the rapid pace of modern processed-food production methods. Tests would be much easier to perform and much more rapid if the modern technologies could be applied directly to samples. Such an approach, which continues to be investigated, is not without problems. One is due to the fact that DNA is heat-stable. Thus, intact DNA will be present in processed foods. DNA in both a free form and within dead cells of *Salmonella* can also survive for considerable periods in sea water. One possible way to overcome this problem is to include a culture step as a means of detecting viable cells. Not only will this increase the length of the test but it may not be sufficient to allow the growth of more severely damaged cells, as discussed earlier.

An alternative nucleic acid target to determine viability would be an RNA molecule that exists as many copies in a cell and which exhibits rapid turnover. Messenger RNA (mRNA) may prove to be a suitable target as it has a reported half-life of 2 min or less, and PCRs have been published for the detection of viability in *Escherichia coli* and the thermophilic *Campylobacter* spp. The rate of degradation of the mRNA is influenced by the method of inactivation, however, and this has to be considered when assessing food-processing conditions.

'Rapid' methods clearly have a place for the detection of *Salmonella* spp. in food samples. With many of the current tests, time is saved because selective plating and biochemical and/or serological confirmatory tests are not necessary. 'Rapid' tests would appear to offer advantages over traditional culture systems. It is likely that improvements will be made in both speed and sensitivity. This may encourage a wider use of the new technologies. If this is the case, it is to be hoped that people continue to bear in mind the vital roles of proper sample handling and the importance of using initial culture systems, which facilitate the recovery and growth of injured organisms.

Salmonellosis

C Wray, Greendale Veterinary Laboratories Ltd, Knaphill, Woking, UK

C A Hart, University of Liverpool, Liverpool, UK

Introduction

Salmonellosis is the general term for human illness caused by members of the genus *Salmonella*; however from the epidemiological point of view it is necessary to differentiate the enteric fevers caused by *S. typhi* and *paratyphi*, A, B, and C from foodborne gastroenteritis caused by any of the other *Salmonella* serovars. The infectious nature of typhoid fever has been known for more than a century and the causative organism was one of the earliest to be isolated and characterized. The transmission of *S. typhi* occurs most often by water which has been contaminated by feces or urine from infected human carriers or food prepared and handled by such carriers who do not take adequate hygienic precautions. The organism appears to be only a parasite of humans and the higher apes and the link between poor sanitation and other epidemiological aspects of the disease was elucidated by William Budd before the opening of the bacteriological era.

In contrast, gastroenteritis (foodborne disease) is usually acquired from consumption of foods which may be directly or indirectly contaminated with *Salmonella*. Whether infection follows exposure to any pathogenic microorganism depends in part on the number of organisms (infective dose) that enter the host's tissues. Factors that may predispose to human salmonellosis are given in **Table 1** and the following section. There are four main clinical patterns of *Salmonella* infection in humans: (1) typhoid (enteric fever); (2) acute gastroenteritis; (3) septicemia, with or without localized infection; and (4) asymptomatic infection.

Table 1 Factors affecting the infectious dose of *Salmonella*

Bacteria-associated factors
Serovar, genotype
State and nature of contaminated material ingested (dry, moist, liquid, and does it allow bacterial multiplication?)
Resistance to antibacterials
Stress status of the bacteria
Host-associated factors
Age of host (very young and aged are most susceptible)
Effect of therapy (prior treatment with antibacterials, antacids, etc.)
Presence of other disease (malaria, human immunodeficiency virus (HIV), etc.)
Immune status of the host
Genetic status of the host

Enteric Fevers

Typhoid and paratyphoid fevers usually follow ingestion of drinking water contaminated with feces containing *S. typhi/paratyphi* A, B, or C, or food prepared or handled by a person who is a carrier of the organism. Direct transmission from one individual to another may occur via the fecal–oral route, especially in children, because of their poor attention to personal hygiene. While large-scale epidemics of typhoid fever have been traced to human fecal contamination of food, poor sanitary practice resulting in contamination of drinking water by fecal material containing *S. typhi* appears to be a major factor in many countries. Of foodborne outbreaks, 504 cases of typhoid occurred in Aberdeen; this was caused by the ingestion of tinned corned beef from Argentina. The meat was contaminated in Argentina, where river water containing unprocessed sewage was used to cool the containers after sterilization. The water seeped through the seams of the cans and reached the contents. In Aberdeen, infection developed in individuals who ate the corned beef, but also in those who ate meat that became contaminated by the machine that had been used to slice the corned beef.

In Mexico, in the early 1970s a large outbreak of typhoid was caused by a chloramphenicol-resistant strain of the organism, which had contaminated water. The lack of susceptibility of the organism to chloramphenicol was responsible for the death of many patients who were infected with it. The resistance determinant was a useful epidemiological marker when the organism caused disease in the USA, and a number of European countries.

Clinical Findings: Typhoid Fever

Typhoid fever is the best-studied form of salmonellosis and is well-described in the literature. It is potentially fatal for young children, particularly during the first year of life, and for the elderly, but in endemic areas a degree of immunity may develop in the population. Clinically, paratyphoid tends to be less severe than typhoid.

Illness usually occurs 7–10 days after consumption of infected water or food, and the initial symptoms tend to be both vague and variable. Headaches tend to be common, as does a general feeling of lethargy, along with abdominal pain/discomfort, and constipation is more usual than diarrhea. The fever increases progressively during the first week, and then decreases, although a biphasic response may be seen. Rose spots representing cutaneous vasculitis may be seen on the abdomen and enlargement of the spleen may be felt on abdominal palpation. The initial symptoms resemble those of acute gastroenteritis and *Salmonella* may be isolated from the feces. Then for a week or more the organism may not be isolated from the feces, although blood cultures are positive. This is then followed by further fecal shedding. In about 25% of patients *Salmonella* may be isolated from the urine. Fatalities usually arise from perforation of the intestine after the bacteria have been localized in the Peyer's patches, and/or pneumonia, but otherwise the disease runs a slow course over 5–6 weeks and then leaves the patient in a longer period of gradual convalescence.

The pathogenesis of the disease is of interest. From the small intestine the organisms pass via the lymphatics to the mesenteric lymph nodes, where, after a period of multiplication, they invade the blood stream via the thoracic duct and the liver, gall bladder, spleen, kidney, and bone marrow become infected during this bacteremic phase in the first 7–10 days of the disease. From the gall bladder a further invasion of the intestine occurs and lymphoid tissue, particularly Peyer's patches, are involved in an acute inflammatory reaction, followed by necrosis, sloughing, and the formation of the characteristic typhoid ulcers. Hemorrhage of varying degree may occur and, less frequently, perforation through a necrotic Peyer's patch may complicate the illness and result in death. *S. typhi* is present in large numbers in the inflamed tissues in the ulcers and it may localize in the kidneys and be found in other lesions that occur as a complication or sequela of typhoid fever, e.g., acute suppurative periosteitis, renal and hepatic abscesses, bronchopneumonia, and ulcerative endocarditis.

In 2–5% of convalescents the organism persists in the body, sometimes for an indefinite period, and in such chronic carriers the organism is most commonly found in the gall bladder or, more rarely, in the urinary tract.

Diagnosis

Typhoid fever should be suspected in any patient who has visited an endemic area; the diagnosis is confirmed by recovering the organism from the feces, urine, blood, or other tissues. Blood cultures are positive in about 80% of patients and in the early stages of illness, i.e., 7–10 days, it is the most reliable diagnostic test. Bone marrow cultures and skin biopsies of rose spots are, however, more likely to be positive for *S. typhi* than blood cultures. *S. typhi* and *paratyphi* can be isolated from the feces throughout the illness but are most frequently found during the second and third weeks. Repeated examination of the feces may be required before isolation is successful. The tube agglutination test (Widal reaction) for detecting antibodies to the somatic, flagellar H and the envelope Vi antigen has been used for the serological diagnosis and positive titers occur about day 7–10 after infection. Occasionally positive titers develop earlier, but they may be delayed and a negative result at an early stage of the illness therefore may be inconclusive (cross-reactions with other bacteria and previous typhoid may give false-positive results). Other serological tests, such as enzyme-linked immunosorbent assays (ELISAs) have also been developed to detect different antigens of the bacillus. Vaccination may give rise to false-positive serological reactions and, if the patient has a history of vaccination, it is advisable to take a second sample a week or so later to determine whether there is a rising titer.

Chemotherapy

The treatment of enteric fevers necessitates the use of antibacterial drugs. Chloramphenicol, ampicillin/amoxicillin, trimethoprim/sulfamethoxazole are the drugs of choice against sensitive *Salmonella*. Multiple drug-resistant (MDR) isolates of *S. typhi*, resistant to the first three antimicrobials (chloramphenicol, ampicillin, and co-trimoxazole) have emerged in Southeast Asia and in 1998 in Kenya. Therapeutic options include fluoroquinolones or azithromycin. Thus, because MDRs of *S. typhi* have been reported, all isolates should be tested for their antimicrobial susceptibility. Proper management of the fluid and electrolyte balance is important in all patients, especially the young and the old.

Immunoprophylaxis

Vaccines have been available for the prevention of enteric fevers for many years. The classic inactivated vaccine TAB protects against both typhoid and paratyphoid A and B and extensive field trials in endemic areas have shown a good degree of protection, although a high percentage of vaccinates develop local and systemic reactions.

In recent years, two new typhoid vaccines have become available. A vaccine prepared from the Vi capsular polysaccharide antigen has given good results in field trials. One dose protects for 3 years and it has a low incidence of side-effects. It is not licenced for

children less than 18 months of age because they may have a suboptimal response.

A live oral preparation produced from an attenuated strain (Ty 21a) of *S. typhi* is available in enteric-coated capsules; it is administered in three doses on alternate days. Significant side-effects have not been reported, but transient mild nausea, vomiting, abdominal cramps, diarrhea, and urticaria may occur in less than 1% of vaccinates. In mass trials it has not proved as effective as the previous vaccines.

Acute Gastroenteritis

Acute gastroenteritis is usually acquired from consumption of foods which may have been directly or indirectly contaminated with *Salmonella*. A wide variety of animal species have been shown to be capable of harboring the organisms without showing clinical signs, and in the developed world, turkeys, swine, chickens, and cattle have often been found to be infected in abattoir studies. Animal products such as milk and eggs have also been shown to be important vehicles of infection. Many other foodstuffs, including vegetables and salads, have also been found to be associated with *Salmonella* outbreaks. It should also be remembered that person-to-person spread may also be of importance.

Clinical Findings

The incubation period ranges from 8 to 48 h following the ingestion of contaminated food. The most common symptoms are diarrhea, abdominal pain, fever, and headache. Extremely fluid stools persist for 3–4 days, and these may contain mucus and occasionally blood. The temperature may be slightly elevated in most patients but usually returns to normal within 1–2 days. In the young and the elderly the symptoms may be more severe and last for a week or more.

Salmonella gastroenteritis is usually a self-limiting illness and fatalities are uncommon. Sigmoidoscope and biopsy examinations have demonstrated that the colon is the major site of infection. The changes in the colon range from edema of the lamina propria with a focal or diffuse inflammatory infiltrate to a more intense inflammation with disruption of the surface epithelium and multifocal microabscesses. In more severe cases, edema, vascular congestion, infiltration of the lamina propria with polymorphonuclear leukocytes, and abscess formation have been recorded.

Chemotherapy

Although *Salmonella* are usually sensitive *in vitro* to many antibiotics, their use for the treatment of uncomplicated gastroenteritis until recently has generally been contraindicated by the lack of favorable effect on the course of disease and by a prolongation of *Salmonella* shedding. Following the introduction of the fluoroquinolones, a number of clinicians have advocated their use for the treatment of *Salmonella* gastroenteritis because of their efficacy in reducing the severity of symptoms, the duration of illness, and *Salmonella* shedding. However, this has been followed by increasing development of resistance.

Salmonella Bacteremia (Septicemia)

A transient bacteremia may occur in patients with gastroenteritis caused by *Salmonella*, although periods of longer persistence occur in the blood of individuals with one of the forms of enteric fevers or those suffering from underlying disorders. Chronic bacteremia is commonly associated with *S. choleraesuis* infection, and the fatality rate is usually two to three times that caused by typhoid fever. Metastatic infectious foci, of which the most important are intravascular lesions, osteomyelitis, and meningitis, are common complications of disease caused by *S. choleraesuis*. This organism may lie dormant in some tissues, usually bone marrow, and then later become activated.

The serovar most commonly associated with bacteremia is *S. typhimurium*. This is perhaps not surprising because it is the most frequent cause of salmonellosis in humans and other animals. The high-grade bacteremia suggests the presence of focal intravascular infections in either the large arteries or the endocardium, but whether this is a primary or secondary effect is not certain. In sub-Saharan Africa, non-typhi *Salmonella* (NTS) are the most common isolates from blood culture in children (< 50% of isolates). This is not related to human immunodeficiency virus (HIV) infection but occurs in the malaria season and especially in children with severe malarial anemia. In HIV-infected adults NTS bacteremia is an early acquired immunodeficiency syndrome (AIDS)-defining illness: relapse after therapy commonly occurs.

Focal infections, such as osteomyelitis, arthritis, and meningitis, are not uncommon sequelae to *Salmonella* infections. Any area of the skeleton, especially the long bones, may be invaded. Two types of arthritis have been described: bacteremia may give rise to suppurative arthritis with the organism in the joint fluid, or a sterile inflammatory reaction involving the synovia may occur as a sequel in about 2.5% of cases of gastroenteritis.

Chemotherapy

Chemotherapy is usually similar to that for typhoid fever, although prolonged antibiotic therapy for

localized infection, e.g., osteomyelitis, may give rise to resistant organisms.

The Salmonella Carrier State

Although *Salmonella* carriage occurs more commonly after illness, it may also occur in individuals who have not been ill. All patients with *Salmonella* gastroenteritis usually shed up to 10^6–10^9 organisms per gram feces early in the course of disease and excretion generally persists for 2–4 weeks, with 0.2–0.6% of cases continuing to shed the organism for 1 year or more. The persistence of *Salmonella* does not relate to the severity of the disease.

A number of factors are involved in the pathogenesis of chronic carriage. Age is important: young children tend to be prolonged convalescent carriers but do not usually develop the chronic state. Adults in their sixth decade or older are likely to become carriers, with the biliary tree believed to be the site of multiplication.

Pathogenesis of Infection

There is little information concerning the number of organisms involved in many outbreaks of naturally acquired disease. Volunteer studies indicated that *c.* 10^6–10^9 organisms were necessary to cause disease in 50% of the healthy individuals participating. In the case of *S. typhi*, none of the individuals became ill when given 10^3 organisms: of those given 10^5, 10^7, and 10^9 organisms, 25, 50, and 95% respectively developed disease. The clinical manifestations did not vary with the size of the inoculum, although the incubation periods were longer in those receiving the smaller doses. However, volunteer studies in healthy adults involving only a few serovars may not be directly transferable to naturally acquired infection. Where it has been possible to obtain the vehicle, e.g., chocolate, cheese, and desserts, the number of *Salmonella* have often been $< 10^2\,g^{-1}$, especially in foods with a high fat content or a good buffering capacity which may protect the *Salmonella* from the gastric acidity. It has also been demonstrated that people on antacids, where gastric acidity has been lowered, or on antibiotics, which may alter the gut flora, are more susceptible to infection. The minimal infective dose can also vary with age and the state of health. Factors which help to determine the infective dose of *Salmonella* are given in Table 1.

Following ingestion of *Salmonella*, the organisms pass through the stomach where the bactericidal activity of the stomach produced by the low pH of gastric juice regulates the number of organisms entering the small intestine. The course of events then depends on multiple factors, of which the most important is probably the serovar of the *Salmonella*. Thus, *S. typhi* after an initial period of multiplication invades the intestinal mucosa, primarily it is thought in the M cells of the Peyer's patches of the distal ileum, where a cellular reaction may take place in the lamina propria. Although the infiltrate is composed of mononuclear cells, in the case of *S. typhi*, it contains predominantly polymorphonuclear leukocytes when other noninvasive *Salmonella* produce infection. It has been suggested that differences in phagocytic effectiveness of the two types of phagocytes may explain the high incidence of bacteremia with *S. typhi* and the relatively low occurrence with other non-invasive *Salmonella*. The major factor for intestinal penetration is encoded by genes that are clustered in a large (40 kb) area of the chromosome, designated *Salmonella* pathogenicity island 1 (PI 1). In *Salmonella* there are at least five PIs, of which two are associated with type III secretion systems, which export proteins in response to bacterial contact with cells. Although the onset of systemic and localized infection is fairly similar, the symptoms produced are not identical. Localized infection is usually manifested as acute gastroenteritis, whereas only one-third of typhoid patients develop diarrhea, usually several days after the onset of fever. The contribution of toxins in the etiology of diarrhea has never been conclusively demonstrated, although several putative toxins have been described, and it is now suggested that the type III export system on PI 1 secretes one or more proteins with enterotoxic activity.

To cause bacteremia, *Salmonella* must have strategies to overcome each of the host's deep-tissue defenses, including resistance to phagocytic cells, complement, specific antibodies, and cellular immunity. It must be able to reach its preferred site of replication, i.e., the liver and spleen, where intracellular multiplication occurs, which protects it from the host's defense mechanisms. If the bacteria are not contained, they may then invade the blood and replicate rapidly.

SAMNA

S A Abou-Donia and E I El-Agamy, Alexandria University, Alexandria, Egypt

Introduction

Although similar to ghee and other concentrated milk fats, samna is of especial importance to the dairy industry in Egypt. This article deals specifically, therefore, with the production and properties of samna as traditionally manufactured in the rural areas of Egypt.

Samna is pure, clarified milk fat, produced in Egypt. It is generally prepared from buffuloes' milk or cows' milk, which constitute 63.5% and 35% respectively of total milk output in Egypt, while small amounts of samna are prepared from sheeps' milk and goats' milk, which constitute 1% and 0.5%, respectively, of total milk output.

The main object of the primitive dairy industry in the rural districts of Egypt is to separate milk fats for making butter, and to make the remainder into products which are consumed as such or, after storage, throughout the year. In lower Egypt, farmers put fresh milk in shallow or deep earthenware pots, martrad or shalia, and leave it undisturbed in a warm, dark place till the cream rises and the milk coagulates. The cream layer is removed and beaten into butter, which is converted into samna. The presence of earthenware pots, such as used in cream-making, in the tomb of king Horaha of the first dynasty (3200 BC), indicates that the art of samna-making was known to the Ancient Egyptians.

Samna making by the Traditional Method

Samna is usually made from butter produced from ripened cream; however, nowadays, in some cases, it can be made using cream prepared from salted or unsalted whey. The resulting samna is called whey-cream samna.

The traditional process of samnamaking depends primarily upon the properties of the butter with respect to its acid degree value, taste, odor, and weight. Weight is important to determine both the yield of the samna and the amount of salt to be added to the butter prior to the making process.

Liquefaction of Butter and Addition of Salt

Butter is placed in a stainless-steel or aluminum vat; iron or copper pans should not be used, for if the samna is contaminated with heavy metals, oxidation of the fat is accelerated. The butter is then heated with continuous stirring until liquefied (50–60 °C), and the salt is added at a rate of about 2–4% of butter weight.

The addition of salt leads to the following: (1) a decrease in the water content of the resultant samna because the salt increases the boiling point of the water in the butter; (2) it helps in the fat separation that arises from the difference in density between fat and nonfat phases; (3) it increases the quantity and shelf-life of the byproduct (morta); (4) it plays an important role in the precipitation of the proteins in butter during boiling. In addition, some makers of samna believe that the addition of high levels of salt during the making of samna is necessary in order to store samna for a long time. This view is misguided for the following reasons: (1) salt is not a fat-soluble material and hence does not have a preservative effect; (2) contamination of the salt with heavy metals, e.g., iron or copper, accelerates fat deterioration; (3) salt is a good absorber of water, and thus the presence of salt in samna can increase the moisture level and hence risk of rancidity. In general, after the butter has been heated and salted, it is filtered through a cloth, such as cheesecloth, to remove any foreign matter mixed with the butter. In the case of a good-quality butter, this step is omitted.

Butter Boiling and Ripening

Butter boiling and ripening are the most important parts of the process of samnamaking with respect to the quality of the resultant product. They are performed as follows. The liquefied butter is heated further to 90–96 °C and, in the course of heating, a foam is produced which is known as the boiling foam. At this point, the level of heating should be reduced.

After the disappearance of the foam, regular boiling or simmering of the fat starts. After a certain time, floating particles appear, which are principally composed of proteins and phospholipids.

Some makers prefer to remove the floating particles, but others do not. In general, at 103–107 °C most particles precipitate to the bottom of the vat. At 107–110 °C the amount of nonfat particles increases. At 110–115 °C all the nonfat suspended particles are precipitated to form morta, which has the same color as samna, i.e., bright yellow. At 115–125 °C, the color of morta becomes dark and the characteristic cooked odor of samna starts to appear. Moreover, a foam suddenly appears, at which point the heating should be stopped (this foam is called the 'ripening foam'). Excessive heating after this stage leads to the following: (1) production of a darker product; (2) the precipitated nonfat particles start to disperse and suspend again and will be difficult to separate; (3) the samna acquires an undesirable flavor; (4) the keeping quality of the resultant samna is very poor, owing to the weak body derived from the crystallization of the fat.

The quality of samna depends on the control of the boiling and ripening processes and the expertise of the maker. For example, continuous stirring during boiling is very important to avoid any overcooking defects, as is the time at which the heating and stirring should be stopped. All these aspects must be controlled by the samnamaker.

Decantation and Filtration

Decantation and filtration are carried out when the samna is slightly hot. The clear fat layer is decanted by pouring it into another vat until just above the level of precipitated particles (morta). The latter portion of samna is passed through cheesecloth at least twice, to retain any precipitated particles, and the clear fat is then added to the rest.

Packaging of Samna

The packing of samna is considered a vital process. Samna should be filled into storage cans with sufficient temperature to expel air bubbles inside the cans.

Many different containers can be used for packaging samna, e.g., jars of dark-colored glass to avoid light-induced oxidation, tin-cans free of rust, or there are special pots (which are known as barany and mostly used in Egypt) made from clay with a glazed inner surface.

Too hot ambient temperatures and direct light should be avoided for samna storage.

Factors Affecting the Keeping Quality of Samna

1. An increase in the acidity of the butter or cream decreases the keeping quality of samna.
2. The heat treatment of the fat during the manufacturing process should be not less 110 °C and not more than 125 °C, since heat treatment (115–125 °C for 20 min) causes noticeable changes in the fatty acid contents and induces changes in unsaponifiable matter components.
3. The presence of traces of heavy metals, e.g., iron and copper.
4. The presence of air or oxygen inside pots or cans.
5. The storage temperature.
6. The exposure of samna to light during storage.
7. A high level of moisture and/or nonfat matter in the samna.
8. The presence or absence of natural antioxidants.
9. The source of cream prepared for buttermaking, since samna results from whey cream has a lower keeping quality due to higher rancid flavor and increase in peroxide, thiobarbituric acid, and acid values.
10. Samna produced in winter has a better keeping quality than that made in summer, spring, or autumn. This is presumably due to the higher phospholipids and unsaponifiable matter content and lower levels of unsaturated fatty acids.
11. The keeping quality of cows' milk samna is better than that of buffaloes' milk due to the higher contents of phospholipids and vitamin E in cows' milk fat. The chemical composition of samna is shown in Table 1.

Characteristics of Good-Quality Samna

1. Samna produced from cows' milk fat has a golden-yellow color (owing to the high content of β-carotene), but in the case of buffalo milk fat, the product has a white, slightly greenish color.

Table 1 Chemical composition of samna

Constituent	*Cows' milk samna*	*Buffaloes' milk samna*
Water	0.3–1.0%	0.3–1.0%
Fat	98–99%	98–99%
Solid not-fat	0.2–0.3%	0.2–0.3%
Phospholipids (mg 100 g^{-1})	93.2	76.6
Sterols (mg 100 g^{-1})	241	316
Cholestrol (mg 100 g^{-1})	33.05	42.66
Carotenoids (μ g^{-1})	4–15	0.2–1.0
Vitamin A (μg g^{-1})	3–8	3–8
Vitamin D (μg g^{-1})	7–10	7–10
Vitamin E (μg g^{-1})	30–45	20–30
Vitamin K	Traces	Traces

Table 2 The fat content of samna made from cows' milk and buffaloes' milk

Fat constant	*Cows' milk samna*	*Buffaloes' milk samna*
Reichert–Meissl value	≥22	≥25
Polenske value	≤2.7	≤2.7
Kirschner value	≥19	≥22
Saponification value	≥220	≥222
Iodine value	29.65	37.90
Butyrorefractometer reading	40–44	40–43

Sometimes hydrogenated oils or other fats are added to samna and to detect this kind of adulteration, milk-fat constants should be measured, e.g., Reichert–Meissl, Polenske, Kirschner, iodine, and saponification values.

2. The samna should be free of cooked, slightly sweet flavor and it should be free of rancidity.
3. It should have a gritty texture at 10–20 °C.
4. The fat content should be not less than 99.5%, the moisture not more than 0.3%; the expected chemical properties of fat(s) are shown in Table 2.
5. The main flavor compounds in samna are methyl ketones, 2-enals, and 2,4 dienals.

Antioxidants used in Samnamaking

The most common cause of deterioration in samna is oxidative rancidity resulting from exposure to light. To prevent this phenomenon, antioxidants are added. These are categorized as follows:

1. Natural antioxidants, which are present in samna, derived from milk, e.g., phospholipids and vitamin E (tocopherol).
2. Antioxidants derived from nonfat matter (proteins) during the heat treatment process of samnamaking, e.g., sulfhydryl groups (–SH groups).
3. Some natural materials that may be added to certain brands of samna during packaging, e.g., soya bean and wheat flours, dried date, fenugreek grains, and safflower at a rate of 0.5–1%.
4. Chemical substances, e.g., propylgallate at a rate of 0.01–0.003%, but these materials are rarely used.

Nutritive Value of Samna

Samna is mainly composed of pure fat and thus it is considered a good source of energy. Moreover, samna provides significant quantities of fat-soluble vitamins, e.g., A, D, and E. In addition, the use of samna in cooking improves the taste of meal, and hence overall intake may be increased.

The Byproduct (Morta) of Samnamaking

Morta is a byproduct of samnamaking and, if butter rather than cream is used, the amount of morta is usually equivalent to 6% of the weight of butter. During boiling of butter, more than 85% and 75% of cows' and buffaloes' butter cholesterols were separated with morta respectively. The composition of morta depends primarily upon the steps in and conditions of samnamaking but it is generally as follows:

- water: 10–18%
- fat: 40–65%
- nonfat solids: 10–25%
- ash and salt: 10–15%
- cholesterol: buffaloes' milk samna 131.6 mg $100\,g^{-1}$ versus 193.6 mg $100\,g^{-1}$ in cows' milk samna

The nutritive value of morta is mainly attributable to the high content of phospholipids. Morta is consumed as is, or used in making mish cheese.

SANITIZATION

P N Hoffman, Public Health Laboratory Service, London, UK

Principles

Sanitization is usually defined as those disinfection processes appropriate to use in the context of food. Disinfection is 'the elimination of microorganisms such that they may remain only at levels that are not harmful to health', but there are, in practice, many minor variations on this general definition. This elimination may be by removal through cleaning, by killing in processes such as by chemicals or heat, or a combination of these methods. Such a definition is, in practice, reliant on the context in which it occurs and outlined in the following paragraph.

The level of microorganisms designated as a 'safe' level will vary according to their location: more bacteria could be present on a 'safe' floor than on a 'safe' chopping board. It will also depend on the type of microorganism present: for a pathogen such as *Shigella*, where very small numbers can give rise to infection, only a total absence would be safe; for nonpathogenic (i.e. which do not cause disease) spoilage organisms, low numbers present neither a threat to health nor any immediate threat to quality. The process of disinfection does not normally include the killing of bacterial spores. These are highly resistant dormant forms in the life cycle of members of the genera bacillus and clostridia, such as *Bacillus cereus* and *Clostridium botulinum*. These are normally only eliminated by the more stringent process of sterilization, that is the total elimination of all microbial life, preferably in a process that has a high quality assurance. Some chemical disinfectants are capable of killing bacterial spores and are termed 'sporicides.'

Mechanisms and Kinetics

Chemical disinfectants kill their target microorganisms by reaction with one or more components vital to the internal integrity and function of that cell. This reaction can be chemical, physico-chemical, or both. A chemical reaction is one where covalent bonds within molecules are broken or formed or where the charge on an ion is altered. A physicochemical reaction is one where non-covalent bonds, i.e., areas of hydrophobic affinity or of noncovalent polarized attraction are disrupted. These reactions follow the kinetics of chemical reactions in general; thus, the killing of microorganisms by disinfectants can be similarly categorized. As the end effect, the death of microbes, may be the result of a single reaction or, more likely, of a combination of many reactions, the kinetics of microbial death can become somewhat more complex than the more simple chemical reactions. The death of microorganisms in these circumstances approximates to the kinetics of a first-order chemical reaction; the rates of microbial death occur in a logarithmic manner. To illustrate this, if 1 000 000 bacteria are acted on by a lethal chemical agent, they will lose a proportion, rather than a set number, of their population with each unit of time. If a lethal agent kills nine out of 10 of a particular bacterium every minute (i.e., one base ten logarithmic reduction per minute), 1 000 000 bacteria at time zero (i.e., the start of the reaction) will be reduced to 100 000 after 1 min; to 10 000 in 2 min, and so on. After 6 min, there will be one bacterium left. After 7 min there will be (in theory) 0.1 of a bacterium remaining. A tenth of a bacterium does not exist, but in statistical terms, this means one-tenth the chance of a surviving bacterium, or one bacterium surviving in every 10 samples processed. This continues, so that at 12 min from the start, there will be one-millionth of a bacterium left; in effect, one bacterium in every million samples. Thus, the concept of disinfection, as with the concept of safety, takes on a statistical element.

Microbial Resistance to Chemical Disinfectants

Microbial resistance to chemical disinfectants is a less well-defined phenomenon than the better-known analogy of microbial resistance to antibiotics. With antibiotics, the concentration of an agent achievable in the body will determine the so-called 'break point.' This provides a naturally set level of antibiotic concentration against which to judge resistance. If an organism is killed or inhibited below this break point, it is considered sensitive; if it can grow at or above the break point, it is resistant. Attainable concentrations of chemical disinfectants are not similarly fixed and usually can be varied within any given use situation. Thus, 'resistance' to chemical disinfectants has to be considered within these constraints but can still be a useful concept.

There are several possible mechanisms by which resistance to chemical disinfection exists.

- Innate resistance: This implies that there is either no susceptible target within the microbial cell or that the microbial cell is in some way impermeable to the agent. An example of the former is the resistance of viruses that comprise only nucleic acid and protein (such as the picornaviruses, a group of viruses that include a number of viruses that infect by ingestion, an example of which is poliovirus) to disinfectants such as phenolics and quaternary ammonium compounds. An example of the latter is the high resistance of bacterial spores to most disinfectants. Bacterial spores are a 'survival' form of certain bacterial genera that show extreme resistance to chemical and physical inactivation. Only a few chemical disinfectants (sporicides) are capable of inactivating bacterial spores.
- Acquired resistance: In this form of resistance, certain bacteria can adapt to survive or grow in the presence of a particular disinfectant. This can be through a process of 'training', whereby a bacterium is exposed to a sublethal concentration of a disinfectant and can then bring in to play a variety of phenotypic adaptations, such as capsule production, that can enable it to survive increasing concentrations of the disinfectant. Another mechanism is by the acquisition of transmissible genetic elements that confer resistance to lethal agents. Although this is better known with bacterial resistance to antibiotics, it does also exist with disinfectants.

Reasons for Disinfection Failure

It is not only genuine resistances, as above, that can result in failures of a disinfection process. Many other factors can affect the performance of a disinfectant and lead to a suboptimal disinfection result:

- Neutralization of a chemical disinfectant can occur by chemical or physical reaction. Disinfectants, by their very nature, will react with molecules in a microbial cell and thereby disrupt its vital functions. They will similarly react with nonliving organic matter, removing disinfectant molecules from effective solution. If there is an excess of organic matter and the disinfectant has a high affinity for it, this can lead to a disinfection failure due to neutralization of the disinfectant. The disinfectant will have reacted with nonliving organic matter, leaving insufficient for microbicidal purposes. Although excess organic matter is the most commonly encountered disinfectant neutralizer, others do exist. There can be reactions between disinfectant and neutralizing compounds, converting the disinfectant compound to a nonmicrobicidal reaction product. These are specific chemical reactions and tend to occur in unusual circumstances. The other main source of disinfectant neutralization is from physical reaction with surfactants, charged, or polarized large molecules, again removing disinfectant molecules from active solution. Disinfectants that are especially susceptible to this are those whose activity depends on charge or polarization within their molecule. This makes them both prone to these charge-based interactions and also means that, once their charge or polarization has been disrupted, their microbicidal capacity is neutralized.
- Failure to make contact with the target organism is a common source of ineffective disinfection. Organic matter, as well as neutralizing disinfectants (see above), can form a barrier to disinfectants, shielding microorganisms within and facilitating their survival. In this way, microorganisms can withstand a disinfection procedure that, to the operator, should have been effective, i.e. the correct concentration of disinfectant applied for the right time to act against a microorganism innately susceptible to that disinfectant. Some disinfectants, mainly those with innate or added surface active capabilities, are better able to overcome shielding barriers whilst others, especially those that coagulate proteins, are particularly prone to this shortcoming. However, even those disinfectants with surfactant properties cannot be expected to penetrate thick layers of viscous or solid matter. A clean surface is an essential prerequisite to routinely efficient disinfection. Organisms within crevices in surfaces are usually protected from contact with disinfectants. This protection is enhanced by the presence of organic matter. In situations when it may be difficult for a disinfectant to penetrate a crevice, it will probably be impossible for it to penetrate that crevice when it is also filled and protected by organic matter. So, not only an absence of soiling, but also a crevice-free surface, is needed. Crevices can be innate, as in the grain of a wooden chopping board, a result of poor design, as in machinery or pipework or a byproduct of use, as in knife scours in a plastic chopping board.

Another situation where disinfectants do not work due to a failure to make contact with their target is that of poor-quality application such that the agent does not make contact with all the surfaces intended for disinfection. On an accessible surface, this could be a result of human error, perhaps due to inept or badly instructed staff, to equipment that does not apply disinfectant to areas that are difficult to reach, or to failure to remove extraneous objects that

may shield a surface from a directly applied or sprayed disinfectant. Inaccessible surfaces, such as those within pipework or other enclosed vessels, present a more substantial problem. Ideally, the application of disinfectants should be considered at the design stage, in the form of either a modification allowing free access to all surfaces or 'cleaning in place'-style dispensing nozzles as permanent internal features.

The concentration of a disinfectant will also determine the microbicidal efficacy. Disinfectants are formulated to work at a specific concentration. Sometimes, different concentrations for different situations are stated, for example, in the presence or absence of organic soiling. If the concentration is too low, inefficient microbicidal action will result; if the concentration is too high, the consequences could be wasted resources, corrosion problems, or taint and toxicity problems. Disinfectants should be made up for use accurately. A 'splash in a bucket' approach cannot insure accuracy. Similarly, if a disinfectant is going to become substantially diluted during its use, it should be formulated to be near its designated use concentration after, rather than before, this dilution.

All disinfectants need adequate time in which to work. The exposure time of a microorganism to a disinfectant can be determined by the method of application; for example, it is very convenient to use a volatile surface disinfectant, such as alcohol, in the form of a wipe. The surface to be disinfected will be dry and useable within seconds. The very convenience of this form of application is also what can make it a less effective method.

Another factor that will determine the efficacy of surface disinfection is the wetting ability of a disinfectant. When a disinfectant without a detergent or other surface active agent (i.e., which has no wetting ability) is spread on a surface, the film that it forms will turn rapidly into discrete droplets with dry areas in between these droplets. No substantial disinfection will occur in these dry areas, which will comprise the majority of the area to which liquid was initially applied. A wetting agent, usually a detergent, will allow the disinfectant to remain as a continuous film on the surface and exert its full action until it is taken out of effective solution by drying and so becoming unavailable to microbial cells. The wetting ability also enhances a disinfectant's ability to penetrate or remove layers of organic matter.

As with chemical reactions in general, the temperature at which a disinfectant acts will affect the speed of its activity. Unless otherwise specified, disinfectants are formulated to work around normal ambient temperatures. There are use situations where they might be expected to work at low temperatures, for instance, in a refrigerated food production unit or out of doors in a cold climate. For a disinfectant to work effectively in such situations, it will need a higher concentration, a longer exposure time, or both. From the same principles, if the temperature is higher than normal ambient, a more rapid and efficient disinfection will occur. Temperature itself starts to become lethal to vegetative bacteria (not bacterial spores) and other microbes around 60–65 °C, at which temperatures, the time needed for heat disinfection is in the range of several minutes to hours. At 80 °C, disinfection will occur far more rapidly, needing only seconds for susceptible microbes to be killed at this temperature.

Other Factors to be Considered in Disinfectant Choice

Chemical disinfectants have a high reactivity with biological systems, this being an integral part of their microbicidal mechanism. As living systems share many biochemical similarities, it is not unusual for disinfectants to have a toxic effect on humans. Toxicity may occur through one or more routes of contact, such as through the skin, ingestion, inhalation, or absorption into mucous membranes of the eyes, nose, etc. There are two separate considerations to the use of chemical disinfectants in catering and the food industry: risk to the user and risk to the consumer.

The major toxic risk is to the users of chemical disinfectants. It is they who will handle concentrated disinfectant solutions or solids, where any toxicity will be many times that of the use dilution; who will make up the use dilution, involving splash and skin contact risks during this process; who will apply the disinfectant with attendant risks of skin contact and inhalation; and who will dispose of the disinfectant, with more contact and inhalation risks. Chemical disinfectants, especially in their undiluted form, must always be assessed for hazard before use. Any hazard must be eliminated by handling procedures insuring minimal contact (especially uncontrolled contact such as splashing), and use of effective and appropriate personal protective equipment (gloves, eye protection, etc.), where contact cannot be ruled out. As a general rule, prevention of operator contact with toxic agents by containment of the agent is preferable to the use of personal protective equipment.

Consumer toxicity, whilst much rarer, is a serious consideration in terms of the number of people affected as well as commercial considerations. The dilution factors of disinfectants that find their way from food-processing areas to consumers via a food product will be immense. Nevertheless, the

consequences of such an occurrence are equally immense in terms of the potential numbers of people affected, as well as commercial considerations. Control is achieved by segregation of significantly toxic chemicals from food-handling areas or routes into those areas.

Taint is a problem allied in many ways to toxicity in terms of origin and consequences. The problem here is that certain disinfectants can impart characteristic and undesirable taints to foods. Taint can be caused by extremely low concentrations of these chemicals, usually in terms of a few parts per billion of a contaminant in food. The disinfectants most implicated in taint problems are those with phenol-derived molecules in them. These should be regarded with suspicion unless an assurance of lack of taint can be given. As with toxicity, such disinfectants are best excluded from use in food-handling areas completely.

Some disinfectants, particularly those of an oxidative nature, can cause or accelerate corrosion of a variety of metals. Whilst this is not directly connected to microbicidal issues, it is a factor that must be considered in the wider context of the practicalities of disinfectant use. Particularly implicated in this are hypochlorite disinfectants, which can start rusting carbon steels in minutes. Corrosion is dependent on a combination of factors, mainly: the disinfectant, its constituents and concentration; the materials that are in contact with the disinfectant; and the contact time and temperature.

Characteristics of Commonly Used Disinfectants

Hypochlorites

These have a wide applicability in food-associated use. Their advantages are a low toxicity, low taint, wide microbicidal spectrum, and low cost. Their disadvantages are corrosivity to some metals (good-quality stainless steels are usually fairly resistant to corrosion) and ready inactivation of low-hypochlorite concentrations by organic matter. Hypochlorites are available as sodium hypochlorite, a liquid ('bleach') or sodium dichloroisocyanurate ('NaDCC') and chloramines, both soluble solids. Hypochlorites will decay in liquid solution, dependent on exposure to light, elevated temperature, and the presence of impurities. The solid hypochlorites are stable on dry storage.

Iodine

The advantages of iodine are a low toxicity, low taint, and a wide microbicidal spectrum. The disadvantages include some corrosion to metals (though less than hypochlorites), ready inactivation of low-iodine concentrations by organic matter, and their comparatively high costs. Relatively insoluble in water, iodine preparations are usually supplied as a complex with polyvinylpyrrolidone ('PVP') or solubilized with detergents. Iodine dissolved in potassium iodide ('Lugol's iodine') or alcoholic solutions ('tincture of iodine') are available for medical use but have no role in food hygiene.

Quaternary Ammonium Compounds (QACs)

The advantages of these are a low toxicity, low taint, cheapness, and noncorrosivity. They all possess some cleaning ability and are convenient to use. Their disadvantages are a ready inactivation by a wide range of materials and an often incomplete microbicidal spectrum. They are useful as general hygiene agents but must be used with care if disinfection is a critical step. Benzalkonium chloride is the most commonly used QAC.

SAPONINS

G P Savage, Lincoln University, Canterbury, New Zealand

Background

Saponins are a heterogeneous group of glycosides that are widely distributed in plants of agricultural importance, particularly legumes. Many of these legumes are staple items of the human diet. Foods particularly rich in saponins are soya beans (*Glycine max*), chickpeas (*Cicer arietinum*), and beans derived from *Phaseolus vulgaris*. (*See* **Beans; Cereals**: Dietary Importance; **Legumes**: Legumes in the Diet; **Pulses; Soy (Soya) Beans**: Properties and Analysis.)

When saponins are agitated in water, they form a soapy lather. Other properties generally ascribed to this wide group of compounds are hemolytic effects on red blood cells, cholesterol-binding properties, and a bitter taste. These properties characterize particular types of saponins and are not necessarily shared by all members of the group. From a biological point of view, some of these properties are beneficial, whereas others are considered to be adverse.

Of particular interest is the observation that dietary saponins reduce plasma cholesterol levels in primates, thus having the potential to lower the risk of coronary heart disease in humans.

Chemical and Physical Properties of Saponins

Saponins consist of an aglycone unit linked to one or more carbohydrate chains (Figure 1). The aglycone or sapogenin unit consists of either a sterol or the more common triterpene unit. In both the steroid and triterpenoid saponins, the carbohydrate side-chain is usually attached to the 3 carbon of the sapogenin.

Saponins possess surface-active or detergent properties because the carbohydrate portion of the molecule is water-soluble, whereas the sapogenin is fat-soluble. The stability and strength of forage saponin foams are affected by pH, and this may have an effect on the development of bloat in ruminants. Saponins are remarkably stable to heat processing, and their biological activity is not reduced by normal cooking.

Isolation of saponins from plant material involves extraction with a polar solvent after removal of lipids, with petroleum ether or chloroform, followed by various purification techniques. A number of chromatographic procedures have been used to separate individual saponins. (*See* **Chromatography**: Principles.)

The analysis of saponins is complex and potentially subject to considerable errors during their isolation, separation and quantification stages. Thus, many early reports of the saponin content of food plants and processed food should be treated with caution. The data presented in Table 1 were obtained using rigorous methodology and are the most reliable data available at present. More recent studies have shown that many legume seeds contain several saponins, e.g., five different saponins have been separated from soya beans.

Biological Effects of Saponins

Ingested saponins can influence animal performance and metabolism in a number of ways.

Sensory Properties of Saponins

Recent studies have shown that a bitter or astringent taste is related to amounts of soya saponin I isolated from pea and soya flour. It is possible that saponins are a contributing factor to the undesirable organoleptic properties that humans associate with some legumes and legume products. The bitter taste of saponins may be responsible for the low palatability of lucerne to ruminants and may explain the reduced feed intake observed in many experiments when using this material as a forage. Many stock will discriminate against feeds containing high levels of lucerne meal.

Erythrocyte Hemolysis

Saponins have pronounced hemolytic properties when given intravenously, the degree of effect on the red blood cells varying among different mammalian species. The release of hemoglobin from red blood cells is the direct result of the interaction of saponins with membrane-bound sterols, which causes an increase in the permeability of the plasma membrane, bringing about the destruction of the cell. (*See* **Sensory Evaluation**: Taste.)

The hemolytic activity of saponins has been widely used as a means of detecting and assaying saponins in plant materials. The potentially toxic effects of

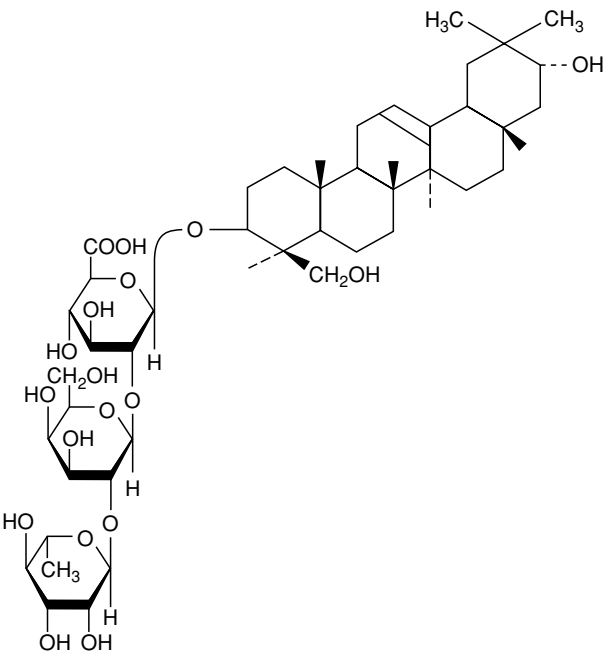

Figure 1 Structure of a typical saponin (from soya beans). Reproduced from Saponins, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Table 1 Saponin content of some legume seeds

Legume	*Saponin content (gram per kilogram of dry matter)*
Chickpeas (*Cicer arietinum* L.)	2.3
Green pea (*Pisum sativum*)	1.8
Haricot bean (*Phaseolus vulgaris*)	4.1
Kidney beans (*Phaseolus vulgaris*)	3.5
Lentils (*Lens culinaris* Medik.)	1.1
Mung bean (*Vigna radiata* L.)	0.5
Runner bean (*Phaseolus coccineus* L.)	3.4
Soya beans (*Glycine max* L. Merrill)	6.5
Yellow split pea (*Pisum sativum*)	1.1

intravenous injection of saponin extracts have resulted in this class of compounds being regarded as antinutritive factors in foods. Their low oral toxicity and the potentially useful nutritive value in foods have only recently been appreciated.

Effects on Blood and Tissue Cholesterol Levels

Since many legume saponins form insoluble addition complexes with cholesterol, the effects of dietary saponin on cholesterol might be expected. Saponin in the diet of chicks has been reported to reduce plasma cholesterol in cholesterol-fed animals. Saponin extracted from *Quillaia saponaria* has been shown to reduce liver (but not plasma) cholesterol levels in chicks. An exhaustive series of experiments, with a variety of saponins, have consistently demonstrated cholesterol-lowering effects. These include the feeding of lucerne saponins to rats, rabbits, and monkeys. Some workers have suggested that dietary saponins do not have any effect on plasma cholesterol concentrations. This is perhaps to be expected in experiments with rats that received no dietary cholesterol.

Experiments on humans have produced variable results. Different saponin levels in a dietary supplement based on soy flour had no effect on plasma cholesterol levels in hypercholesterolemic men. As the experiment was conducted on free-living subjects, it cannot be guaranteed that the subjects actually consumed the experimental diets.

In a more closely supervised trial, with subjects having normal blood cholesterol levels, it was found that a dietary supplement containing saponins did not have a significant effect on plasma cholesterol level. Increased fecal excretion of bile acids and neutral sterols was observed. Foods containing saponins, or diets supplemented with saponins, have been shown to reduce blood cholesterol levels in humans under conditions that would be expected to induce high levels of blood cholesterol. (*See* **Cholesterol**: Role of Cholesterol in Heart Disease; **Fats**: Digestion, Absorption, and Transport.)

Mode of Action

Saponins remain within the gastrointestinal tract. Some interact directly with dietary cholesterol, producing an insoluble complex that prevents the cholesterol being absorbed. Others appear to affect cholesterol metabolism indirectly by interacting with bile acids. An increased fecal excretion of bile acids is observed in response to feeding additional saponins in the diet. Bile acids thus diverted from the enterohepatic cycle would be replaced by hepatic synthesis from cholesterol. (*See* **Bile**.)

In the digestive tract, saponins form mixed micelles with cholesterol and bile salts; their hydrophobic triterpene or steroid groups stack together like small piles of coins. These micelles are then too large to pass through the intestinal wall.

Bile salts normally pass through the wall of the small intestine by both passive diffusion and active transport. Passive diffusion takes place along the entire length of the ileum and jejunum; active transport is confined to the terminal ileum. Saponins can interact with cell membranes, as shown by their hemolytic activity. It is possible that they may also have an effect on the cell membranes of the intestinal mucosa. However, the effects of saponins on both passive absorption and active transport can be

explained simply as being due to the reduction in the concentration of free bile acid, because bile acids assist lipid absorption. Low concentrations of free bile acids would also impair the efficiency of lipid absorption and presumably affect the absorption of fat soluble vitamins. Thus, there may also be a significant metabolic effect within the animal as well as in the digestive tract.

Effects on Growth

When lucerne saponin was added at high levels to the diets of monogastric animals, reduced feed efficiency and growth rates were observed. It is clear that species differ considerably in their responses to dietary saponin, e.g., poultry are more sensitive than rats. In contrast, soya bean saponins had little effect on the growth rate of experimental animals. Some saponins increase the permeability of the small intestinal mucosal cells, thereby inhibiting the active transport of some nutrients, but at the same time, they facilitate the uptake of materials to which the gut would normally be impermeable.

The biochemical mechanism that accounts for the growth-depressing effects has not been fully identified. In at least one experiment, the addition of 1% cholesterol to the diets of chicks completely overcame growth depression produced by 0.3% saponin.

It is possible that, in addition to their effects on lipid absorption, saponins also affect chymotrypsin and trypsin activity, which would affect the absorption of protein. (*See* **Protein**: Digestion and Absorption of Protein and Nitrogen Balance.)

In addition to observing reduced intestinal uptake of cholesterol in rat intestinal perfusates on the addition of soy saponin extracts, some workers have also observed a significant reduction in cholate and glucose uptakes. It was observed that the saponins could be washed out of the intestinal lumen, suggesting that inhibition, at least in the short term, was not caused by modification of, or damage to, the intestinal mucosa.

Metabolism of Saponins

Toxicity studies indicate that only very low levels of saponin absorption occur. Saponins are between 10 and 1000 times more toxic when administered intravenously than when given orally. Destruction of saponins in the digestive tract of both ruminants and monogastric animals has been observed. Saponins are degraded by rumen bacteria and by microflora found in the cecum of rats, mice, and chicks. Since saponin in the cecum is past the major sites of absorption, the release of sapogenins and sugars is considered to be insignificant.

Conclusions

The substantial evidence that saponins from a number of plant species can reduce plasma cholesterol levels in man is likely to encourage further interest in these plant foods. It is generally recognized that the overall nutritional value of many Western type diets would be considered improved if more legumes or legume-based products were consumed regularly. The acceptance of more legumes in Western type diets is limited by undesirable taste characteristics, some of which may be due to the higher levels of saponin found in many legume seeds.

There is little doubt that saponins can be incorporated into human diets at levels that can give a beneficial effect and would not entail a risk of acute toxicity. The fact that saponins can increase the permeability of intestinal mucosa raises the possibility of interesting nutritional and pharmacological uses.

SATIETY AND APPETITE

Contents

Food, Nutrition, and Appetite

D A Booth, University of Birmingham, Edgbaston, Birmingham, UK

Introduction

Appetite for food and drink is the momentary disposition of an individual to seek and ingest edible or potable materials. The concept of having an appetite for food and drink has been widely misunderstood. Appetite has often been assumed to be a subjective phenomenon, private to a person's consciousness. The view has been held that appetite can be measured by a rating procedure, such as marking a visual analog scale (a line labeled at each end, e.g., with the phrases, 'extremely hungry' and 'not at all hungry'), or magnitude estimation (assigning numbers to the strengths of a named aspect of awareness).

A measure of appetite, whether based on ratings, behavioral patterns, or intakes, is an objective

estimate of the strength of influence of specified current determinants on the disposition to seek and consume food. Appetite is a publicly observable relationship between the tendency to ingest and the sensed food composition, the culturally interpreted context, and the bodily state of the eater or drinker.

Appetite has also been restricted to facilitatory influences that come from food, or at least from outside the skin. In such terminology, facilitation from under the skin is often called hunger (and only the inhibition of eating from truly physiological sources is called satiety). Alternatively, appetite is in the mind, and hunger in the body.

However, appetite is not one sort of influence on eating behavior – external, mental, or other. Ingestive appetite is the causal structure by which all influences are momentarily affecting eating and drinking. It is sometimes necessary to distinguish appetite for food (hunger) from appetite for drink (thirst). The subjective experience of hunger can be referred to external sources, as in a food craving or the desire to eat at the usual time, not just to bodily sensations such as the epigastric pang.

Aspects of Appetite

The immediate causes of eating and drinking might be crudely divided into three categories, which can be dubbed sensory, somatic, and social. This subdivision is not entirely coherent, however, because appetite is an integral whole. Not only do sensed food factors interact among themselves in the consumer's mind but also the sensory configuration interacts with physiological factors and economic, cultural, and interpersonal factors, in determining a momentary decision to accept an item of food or drink.

It is therefore scientifically and practically unwise to study one factor by itself, especially out of the normal context of eating (or of food purchase or preparation). Moreover, it cannot be assumed that sensory, social, and somatic groups of factors independently add into the disposition to eat or purchase a food. Thus neither theory nor application is sound if based solely on economics or physiological or sensory research. (*See* **Food Acceptability**: Affective Methods.)

Sensory Aspects of Appetite

The influences on eating or drinking that arise immediately from the sensing of the food or drink have traditionally been called palatability. However, incorrect assumptions are made in many uses of this term; one such assumption is that palatability is an invariant property of the food or drink itself. Palatability is not inherent to the food; it is an effect of the food on the eater. This effect can vary, not just between people, but within a person in different contexts of eating.

The ordinary person regards foods as having constant palatabilities, even if varying from person to person. It is natural to deny that one stopped eating because the food became less palatable; cessation of eating is generally attributed to feeling full or to having had an appropriate amount to eat.

Many scientific investigations and theories have also treated palatability as a constant sensory effect. In physiological psychology, for example, the standard account of the control of meal size is that accumulating satiety subtracts from constant palatability until insufficient facilitation of eating exists to continue the meal. It is more likely, however, that the sensory facilitation differs between the contexts of starting and ending a meal. When the sensory facilitation of eating is actually measured during or from before to after meals, it typically decreases to a minimum at the end of eating and for some while afterwards. Moreover, at the anecdotal level, a savoury course is not expected to be as palatable after a sweet dessert as it would be before the dessert.

Measurement of sensory preferences Any measure of the sensory aspect of appetite must compare the responses to two or more foodstuffs differing in known sensed characteristics, unconfounded by any other differences that might affect the responses. Whether the responses are concrete (such as selection among the foods) or symbolic (such as numerical or line rating of liking, pleasantness, or likelihood of choice), and whether the food samples are presented simultaneously (e.g., triadic test) or successively (i.e., monadically), the relative acceptances give an estimate of the sensory preference of that assessor in the context of testing.

Attention must be given to the basic psychological mechanisms operative in sensory effects on food choice. The most preferred version of a food for a consumer in a given context is always a particular physicochemical configuration of its sensed characteristics. In fact, the individual's ideal point is a more precise sensory level than a descriptive verbal anchor (such as 'extremely strong') and is often no worse than a familiar physical standard. Taken with a second sensory anchor, such as apparent absence of the characteristic or perhaps a presence so weak (or so strong) as to be unacceptable, the ideal point defines a sensory scale as objectively and precisely as any purely descriptive rating. The crucial requirements are that each tested sensory level is described by the assessor or identified by the investigator as above or below the ideal level and that the preference-anchored responses are scored according to

sensory level, not for degree of preference. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods; Food Acceptability and Sensory Evaluation.)

The raw sensory preference scores and the slopes of plots of these scores against physical levels are as meaningful as conventional descriptive scores and slopes (or psychophysical power function exponents). They can be averaged across a panel and tested statistically for differences between samples. This amounts merely to data analysis, however; it is not scientific measurement of the strength of influences on food perception or appetite. The most direct step towards efficient design of palatable foods, rather, is to use the effect of levels on score to measure causal strength: the sensitivity of each assessor's preference to a physically measured factor should be calculated from the slope and residual variance of a linear plot of responses against sensory levels, using general psychological theory of the mechanisms by which different responses are given to different signals (Figure 1). (*See* **Sensory Evaluation**: Sensory Rating and Scoring Methods.)

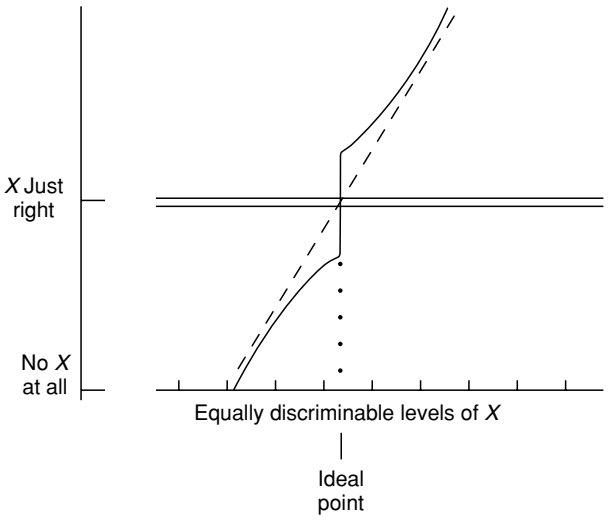

Figure 1 Effect of equally discriminable differences in level of a described sensory or other influence on appetite on the strength of that factor, rated from too weak to be recognized to ideal strength, in a context where other factors are at inappropriate levels. The response line is in the Euclidean distance of the factor level from ideal, i.e., the square root of the sum of the square of the difference of a test sample from the influence's ideal level and a constant that represents the square of the size of the contextual defect; its discontinuity around the ideal point is the truncation of the preference peak by this defect. Reproduced from Satiety and Appetite, Food, Nutrition, and Appetite, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

A great advantage of this approach is that sensitivity of perception or preference to each investigated factor can be estimated when the other foods, or the social and somatic contexts of the test, depart moderately from the combination in which the tested food is normally eaten or purchased. If tolerably low and high levels of a factor are well and equally represented among the responses, the ideal level and the sensitivity can be interpolated with fair accuracy. Moderate inappropriateness in the context of testing creates a Euclidean discontinuity which is virtually confined to the midrange of the theoretical linear function (Figure 1).

The sensitivities of a preference response to different factors can be used to identify how those factors interact in the individual's mind in the test situation, potentially enabling understanding of how a food works in dietary habits. Preference characteristics can also be aggregated across a panel of representative consumers. This could be used to give a physically and behaviorally objective market-response surface from which one or more popular products could be designed.

Somatic Aspects of Appetite

Somatic influences on appetite include physiological signals of hunger, thirst, and satiety from the digestive tract or from tissues such as the liver or the brain itself, as well as these and other postingestional effects of foods that induce sensory preference or aversion.

As already indicated, even a physiological signal of hunger or satiety (such as gastric motility or distension) is likely to operate through particular sensory configurations when the eating situation is familiar. There is evidence that appetite from an empty stomach is stronger for an entrée than a dessert, and vice versa for a partly filled stomach. Similarly, we should expect conventions about foods that are appropriate to particular times of day (such as breakfast) to affect hunger from an empty upper intestine or the satisfaction of appetite arising from stimulation of the intestinal wall or hepatic metabolism, although such hypotheses remain to be tested physiologically. Investigation of behavior at ordinary meals is necessary to elucidate the normal operation of somatic factors in appetite. Evidence for particular physiological signals has been obtained with unusual foods at imposed times but that leaves open the role of a signal in everyday eating and drinking.

Those physiological factors which alter food preferences by associative conditioning or other forms of learning are interacting with sensory factors. It must be noted that they are interacting quite differently

from the contemporaneous mixing of factors considered elsewhere in this article. Indeed, a preference acquired by the association of certain sensory characteristics with a physiological consequence might be unaffected if the conditioning physiological event recurs when the conditioned food stimuli are also present. In psychology, this distinction in mechanisms is referred to as the difference between reinforcement and motivation, or between learning and performance. The distinction is crucial to the understanding of learned behavior such as normal appetite.

The same metabolic signals that inhibit appetite may also induce preferences for food flavors and textures presented shortly beforehand. This is the main basis for the desire for familiar foods, ranging from the appetite for a staple food, such as potatoes or bread, to the craving for an indulgence item such as chocolate. Association with these reinforcers enables bodily states (such as a partly full stomach) and external situations (such as lunchtime, or a party atmosphere) to acquire a learned power to motivate or de-motivate eating or drinking.

The temporal pattern of appetite suppression following the consumption of a particular type of menu also appears to be learnt. Such expectations of satisfaction may be at least as important as physiological signals in the sensation of fullness and in the rise of appetite before the next meal.

Additional physiologically mediated psychological effects of foods are suspected to condition sensory preferences or to create functional expectations of sensorily identified foodstuffs or beverages, although conclusive evidence is lacking. These appetite-reinforcing somatic factors include the stimulant action of caffeine and the sedating action of a heavy meal or of alcohol. However, cultural stereotypes and personal experience can create stimulant, soothing, or cheering effects from consumption of a drink or food, without any specific physiological basis.

A somatic factor in appetite can only be identified if the study disconfounds variations in the physiological effect from variations in both social and sensory effects. Neglect of this point has led to ill-founded claims of measuring physiologically specific aspects of appetite, such as carbohydrate craving, protein selection, protein- and fiber-induced postingestional satiety signals, and gastric distension satiety. The technical difficulties are daunting, but there is no gain in knowledge from neglecting these variations.

All relevant sensory and social factors, as well as somatic factors, must be specifically manipulated and/or measured as perceived by the individual, and shown to be uncorrelated with the physiological effect(s) of interest. Only then can the sensitivity of appetite to that somatic factor in that context be estimated, or indeed even a qualitative effect of the factor be established.

Social Aspects of Appetite

Interpersonal, cultural, and economic factors in appetite appear to influence food choices by modulating the effects of sensory factors. It may be feasible to investigate a range of foods or drinks for general effects of factors such as price, declared sweetener type, or use by children, on appetite at the point of purchase, serving, or ingestion. However, effects may be specific to a food.

Social influences on appetite are often present in a symbolic form, e.g., the category of eating occasion or type of company at the meal, a brand logo, an advertising picture, compositional information, or the price label attached to a food item. Social factors do not differ from rated sensations generated by foods or in the body: descriptive scores that relate to physical factors can be used to model sensory and somatic aspects of appetite; hence the procedure for scaling a social factor and estimating its strength of influence on appetite is the same in principle as that for other factors.

Psychology, Society, and Nature

Appetite is a psychological phenomenon, an aspect of the mental processes organizing an individual's behavior. Hence the cognitive approach to food consumption should be capable of yielding general explanations of the anthropology of cuisine and the microeconomics of the food market. The constructs about cooking and eating held in common among individuals from a social group are evidence of their shared culinary culture. The effects of price, pack label, and shelf display on the personal disposition to purchase a food item will aggregate across consumers into sales of that brand in the shops. The performance of selective eating behavior provides challenges to scientific explanation that go beyond the physics and chemistry of foods and their biochemical and physiological effects. Each individual has his or her own causally structured behavior beyond the food materials, the nutritional physiology, and the socioeconomic systems.

Development of the quantitative behavioral science of food choice and intake is needed. With fundamental understanding of the determinants of eating habits at the level of the causal processes in the mind of the consumer, we would be able to bring together knowledge of the socioeconomic, physicochemical, and biochemical–physiological processes into a coherent

science and effective practice of food design and dietary health.

The Role of Satiety in Nutrition

D A Booth, University of Birmingham, Edgbaston, Birmingham, UK

Introduction

Satiety, a transient lack of interest in further ingestion, is a dispositional state of the individual. This state may limit how much food and drink is consumed on one occasion. It may also delay the next occasion of consumption. The satiating effect of a food is thought to contribute to that food's acceptability, by serving as part of the satisfaction to be gained from eating it. However, there are few relevant hard data, and thinking on this matter is confused.

Scientific Concept of Satiety

Satiety is specifically the inhibitory effect of dietary consumption on appetite. The decrease in hunger or thirst must, by definition, have been caused by some consequence of ingestion. In studies of satiety it is not sufficient to record satiety ratings alone. These may be graded expressions of the sensation of abdominal fullness, the wish to eat only a small amount, an awareness of how much was eaten and how recently, or some other measure of the disposition to refuse food. The origins of the lack of appetite must be shown to include an effect of eating for the rating to be a true measure of satiety. (*See* **Satiety and Appetite: Food, Nutrition, and Appetite.**)

Scientific analysis of satiation requires identification of the influence(s) from eating that reduce appetite. Satiety is not a response but the operation of a type of mechanism.

What Role does Satiety have in Food Acceptability?

It is reasonable to expect that short-term satisfaction of hunger by particular foods increases the acceptability of those foods. Another attraction of a food or meal could be a longer postponement of the need to eat. Understanding satiety mechanisms could be considered to have broad relevance to the formulation and marketing of foods.

However, there has so far been little scientific investigation in humans of the role of satiety in palatability and choice of foods. A considerable body of data in experimental animals has shown that the satiating effect of eating food carbohydrate induces sensory preferences for foods eaten shortly before

absorption of the carbohydrate begins. Sensory preferences are also acquired by association with the effects of absorption of amino acids and of digested fat, under conditions where it is less clear that these nutrients are contributing to satiety. Experiments in humans on the acquisition of sensory preference by association with carbohydrate or protein also indicate that satiety may influence the learning of palatability. (*See* **Sucrose**: Dietary Importance.)

What Role does Satiety have in Weight Control?

Satiety is widely assumed to play a major role in weight control. However, there is a dearth of data on the mechanisms by which satiety can inhibit food consumption in the short term, or on how such effects influence energy intake and long-term energy balance. Research methods are not generally attuned to the concept of satiety as a disposition integrated from sensory, physiological, and cultural mechanisms, or to daily energy intake as an epiphenomenon of diverse sequences of complex dietary selection decisions. (*See* **Obesity**: Treatment.)

As a result, satiety mechanisms are not effectively exploited in established ways of attempting weight control. This is a potential explanation for the fact that obesity has not been prevented, and generally reliable procedures have not been found to reduce unhealthy overweight. There are sound reasons for expecting satiety to have some part to play in weight control. The satiating effects of foods or meals could operate within the framework of certain patterns of eating in ways that help to reduce habitual daily intake, making excess energy intake over expenditure less likely.

Understanding satiety mechanisms is crucial for extrapolating to common eating patterns in order to identify foods and drinks that support successful long-term weight control. Unfortunately, most frequent research on human satiety has attempted only to test foods and food components for effects on appetite ratings and nutrient intake, without measuring the foods' mechanisms of action or their effects on eating habits. As a result, the role of satiety in weight control remains largely a matter of speculation.

Food-Specific Satiety Mechanisms

Satiety is essentially sensory: it is a disposition to reject foods or to accept them in limited amounts. In principle, inhibition of eating could be similarly strong for all foods. Alternatively, it is conceivable that the strength of inhibition may vary with the sensed identity of the food. Such satiety with a degree of specificity to a food is called sensory-specific satiety. The Greek form of this term was applied to a taste-selective satiety that is claimed to depend on the nutrient consumed: negative alliesthesia (literally, a change in sensation – negative in the sense that the food is less attractive). The sensory impression does not necessarily change; the loss of interest is not because the taste seems weaker or different in gustatory quality. The change is in the reaction to the taste (or other sensory characteristics of the foodstuff).

There is evidence from experimental animals that hypertonic sugar solutions (which can be nauseating in people) cause a temporary loss of the sensual pleasure obtained from sweetness. In humans, however, suppression of a pleasurable reaction to foods has yet to be distinguished from a reduced disposition to consume them. Whether eating is motivated only by pleasures and pains, or by other things as well, is an empirical issue for cognitive psychology.

There are at least two sorts of food-specific satiety. One is caused by immediately preceding exposure to food having the consequently satiated sensory characteristics. The other is a learnt reaction to those sensory characteristics in conjunction with a particular physiological signal, such as a partly filled stomach: it is not necessary for the particular food to have been ingested previously in that meal; the reaction is acquired from experience at one or more earlier meals.

Habituation Satiety

Satiation for a food induced by recent exposure to that food meets the basic criteria for the behavioral change known as habituation. This is a decline in a specific response (eating) during and shortly after repeated or continuous exposure to a specific stimulus (the food). The decline is not fatigue in the sensory pathways or in the eating movement circuits but involves a decline in effectiveness of central connections between these two neural systems. At the sensory end the rated strength of the sensation of, for example, flavor does not decrease, at least not by as much as the decrease in the rated pleasantness of eating the food.

Introduction of a new stimulus disrupts habituation and the original response reemerges, an effect called dishabituation. In the case of satiety, this disruption is known as the variety effect. Presenting a food that was not in the preceding meal can reactivate eating and its rated pleasantness. Switching foods can provoke eating a larger meal than switches between samples of the same food in experiments with rats and with human subjects.

If the larger meal is compensated by omission of a subsequent snack or by a smaller following meal,

body weight should not be affected. There is no conclusive evidence that marketing a wide variety of flavor variants contributes to obesity.

The mental processes involved in habituation satiety remain to be elucidated. Boredom with a food seems to be more complex than mere fatigue in a central neuronal connection; yet it could still be based on a subconscious decline in a particular sensory facilitation of eating.

Habituation in invertebrates is mediated by a decline in effectiveness of synapses on the motor neurons from the repeatedly stimulated sensory pathway. Similarly, taste-specific satiation in monkeys involves no changes in the taste pathways through to the cerebral cortex: changes in line with the satiated behavior occur only beyond the sensory cortex, towards the food-selection pathways.

Habituation also has a long-term component. The short-term habituated response recovers completely within an hour or so of the end of repeated stimulation. When the same stimulus is repeatedly presented on a later occasion, the decline in response is more rapid. Long-term habituation (i.e., more rapid rehabituation) may contribute to boredom with the same meal presented day after day.

There are indications of the more complex processes in the attractions of long-term variety. While the main item that characterizes a course in a meal might have to be varied, the same staple food (such as potatoes or bread) can be eaten day after day. In addition, drinks seem to show less item-specific satiation than many foods. Conventions about menus or personal dietary habits may contribute to cessation of eating one food or to starting to eat a different food.

Famine relief may provide only two or three foodstuffs, albeit in ample quantities. This diet might become tedious even to the chronically hungry who are being offered culturally appropriate staples. There is some evidence that intake increases when a variety of flavorings is provided with the basic commodities.

Conditioned Satiety

The second known type of food-specific satiety has been learned from experiences in the past. Satiety learning processes have the basic form of associative conditioning – stimuli elicit a reaction that they have not previously evoked, because they have been associated with consequent stimuli. Repetition is not enough; the stimuli must be paired with conditioning consequences.

The Russian behavioral physiologist Pavlov demonstrated conditioning of appetite when the ringing of a bell in hungry dogs was paired with feeding or a food taste; after that, ringing the dinner bell when the dogs had empty stomachs elicited salivation and orientation to the food provider or food bowl before the food was presented. The bell and the empty stomach predict the taste of food. The dog associated this cue or conditioned stimulus (CS) with the consequence or unconditioned stimulus (US).

The conditioning of satiety follows the same principles. A food stimulus and a partly filled stomach (the CS) are paired with subsequent strong satiation, such as a mildly bloated sensation (the US). When the food or flavor is presented again later, while the stomach is just as full, the food flavor has become less attractive or even slightly repulsive. To the extent that this loss of interest comes to consciousness, it will be expected that particular foods or meals will be regarded as satisfying.

A key difference from habituation satiety is that conditioned satiety does not depend on the sensory characteristics of the food that has just been eaten. The loss of interest can apply to a food that had not been presented before on that particular occasion, because the satiety had been learned on earlier occasions. All foods to which satiety has been previously conditioned will become less attractive when the stomach begins to fill.

Integration of Satiety Processes

Conditioned elicitation of loss of interest in eating by cues from food and from the digestive tract suggests that satiety in familiar situations is a learnt response. If internal signals can become part of the food-specific satiating pattern, external cues such as emptied plates may also come to suppress appetite.

Experiments on satiety risk missing the normal mechanisms of satiety when they impose unfamiliar or extreme conditions. Eating would stop when visceral or social discomfort is strong enough, independently of prior learning. Therefore, to elucidate postingestional and social satieties, the role of any one satiety mechanism must be examined in its normal range and within the learnt complex a person has established for his or her dietary habits.

Postingestional Satiety Mechanisms

The effects of food arise in sequence as the ingested food passes down the digestive tract, from sight and aroma, through texture, temperature, irritation, taste, and retronasal aroma in the mouth, to stimulation of the gut wall, and the stimulation of tissues such as the liver and the brain itself as the food is absorbed. The traditional assumption in the physiology of ingestion has been that inhibitory stimuli subtract from facilitatory stimuli. Intake of sugar solutions in rats has an intestinal effect which

subtracts from the palatability of the sweetness; however, these fluids are not familiar parts of the subjects' diet.

Linear or additive interactions are not the norm in neurophysiological studies, or in experiments on the interactions of mechanisms in the ingestion or rating of ordinary foods and drinks. There is no convincing evidence for interactions among satiety mechanisms that justify the use of the term cascade. The evidence is consistent with satiety arising from recognition of the accustomed pattern of eating, postingestional stimulation, and social constraints, with reduced satiety in the absence of any one element in that learnt pattern.

Cultural and Interpersonal Satiety Mechanisms

Appropriate proportions of food items on a plate (e.g., meat and vegetables) and the total amount (e.g., for a man or at the price) are subject to cultural variation, although these in turn may be influenced by average physiological requirements.

The process of eating in company can influence food intake. For example, a dieter may inhibit eating. This social satiety for food is likely to have been integrated with physiological and sensory satiety, at least in situations about which sufficient has been learned from personal experience.

Satiety Disruption in Dieting

Reducing dietary intake may evoke desires for more food and, possibly, cravings for forbidden foods. Cognitive bases for food cravings are more likely than hormonal imbalances or nutrient deficiencies.

Small meals are less likely to create satiety and will allow the hunger pattern in the viscera and within the memory of that meal to form sooner than after a larger meal. Sufficiently severe restriction of food at meals, even when the gut and the tissues adapt, will activate innate mechanisms of distress, readily labeled hunger by the dieter. The temptation to look for food will be increased, as will the temptation to eat when food is available.

Satiety Manipulation in Weight Control

Permanently successful weight control will depend on keeping satiety as normal as possible in the new lifestyle required to maintain target weight.

Satiety Synapses and Antiobesity Drugs

The pathways in the brain over which the inhibitory effects of food on eating are transferred are poorly understood. Satiety signals, such as distension of the stomach, chemical stimulation of the upper intestine, and oxidation of energy substrates in the liver, have been investigated in isolation from stimuli from food. Reactions to these food stimuli constitute the disposition to eat that satiety suppresses. Neural signals from the viscera and sensors of the circulation at the surface of the brain have their first relay at the back of the brainstem. It is not known where or how they interact there and higher in the brain with the sensory control of eating in the inhibition of appetite.

Visceral signals are relayed to the hypothalamus at the head of the brainstem; this has complex connections with the forebrain, where incoming and past information from different sources is put together. For example, gastric distension affects neuronal activity in the ventromedial hypothalamic nucleus. Yet this is not evidence that this region mediates satiety, because the hypothalamus has many autonomic and endocrine functions to perform. These are liable to affect eating behavior indirectly (via neural circuitry elsewhere in the brain). In fact, it has been found that the ventromedial hypothalamic region is not crucial to any of the appetite-suppressant effects of food that have been tested.

These tests were carried out to evaluate the theory that the obesity seen after destruction of this region of the hypothalamus arises from a defect in satiety resulting from destruction of 'the satiety center.' Since satiety mechanisms operate normally in rats made fat by lesions in this area, the hypothalamus is unlikely to contain any such center.

The effects of drugs on the sizes of meals in experimental animals have inspired theories that particular monoamine neurotransmitters operate in the pathways on the brain that mediate satiety. A region of the hypothalamus forward from, and above, the originally supposed satiety and appetite centers appears to contain some of the synapses at which transmission alters meal sizes.

Norepinephrine (noradrenaline) appears to be the transmitter at synapses in this region that increases meal sizes and even restarts eating in a satiated animal. Analysis of the different possible mechanisms implicates a disruption of conditioned satiety.

However, it may be a localized effect of the arousal system that has norepinephrine (noradrenaline) synapses in many brain regions. This may be experimental isolation of the effect of distraction or excitement on normal moderation of eating. Conceivably, therefore, disruption of learnt satiety is related to emotional eating. This is amenable to psychological management and does not need drug treatment.

Drugs that activate synapses using serotonin (5-hydroxytryptamine; 5-HT) decrease the size of the first meal that a rat takes after it has been deprived

of food for a while. This has been interpreted as an augmentation of satiety. However, starved rats tend to eat fast and long at this initial meal. Serotonin is a transmitter in the brainstem circuits that organize chewing and other tactually guided movements. Hence these drugs may simply be slowing movement or making chewing and swallowing more difficult; they have been shown to alter the effects of food textures on preference and intakes in rats. Serotonin is also important in sleep circuits; indeed, when these drugs are having their greatest impact on people's eating, they are also having their strongest sedative effect. The classic meal-size decrease in these circumstances may have nothing to do with satiety.

Serotonergic drugs that have been used to aid rapid weight reduction may exert part of their effect peripherally. Serotonin is one of the most important transmitters in local neural control of the contractions that pass food down the digestive tract. These and other drugs therefore slow gastric emptying under some conditions, prolonging the satiating action of food and reducing the temptation to snack. They may even postpone the next meal.

Satiety in Dietary Treatment and Advice

There is a medical consensus that energy from starchy foods should not be decreased. Where energy is needed to replace that removed by reduction in fat intake, starch intake should be increased. Readily assimilated carbohydrate, particularly in the earlier stages of meals, is likely to play a major role in immediate satisfaction following the meal. This function and its training of expectations and palatability are important for acceptability of the diet.

In addition, intake of low-energy bulky foods, such as pulses, grains, and vegetables and fruit that provide nonstarch polysaccharides, is recommended. The satiating effect of normal amounts of fiber is probably mediated by learning by association with intestinal and metabolic effects such as those of glucose and fructose from the starch and sugar present in high-fiber foods. Therefore the sugar that is often required to make high-fiber foods edible also has a role in their satiating effects. Alternatively, some of the starch may be rapidly assimilated. However, much of the starch will be in slowly assimilable forms, potentially delaying the return of hunger.

Enthusiasm for a nutrient, a diet product, or a dietary regimen by a professional or in another dieter can convey itself to the dieter or at least lead to it being tried in desperation. For example, it seems obvious that high-fiber foods are filling, and these foods have acquired a nutritious image. This sensory satiety can suggest visceral satiety, and these expectations may be fulfilled as long as sufficient energy is included with the fiber. The assumption is that sufficiently high doses of fiber augment satiety by postingestional mechanisms such as slower gastric emptying and slower absorption of nutrients through soluble fiber gels in the small intestine. These theories remain to be critically tested, by studies of normal eating with sensory factors dissociated out.

Satiety in Psychological Weight Therapy

Eating slowly is a standard part of behavior modification for weight reduction, although its effectiveness has not been evaluated.

Part of the rationale has been to 'satisfy the taste buds.' Perhaps savoring all the food that is eaten helps to ward off the sense of restriction that makes forbidden eating more tempting. Another idea is that more prolonged sensing would augment food-specific satiety.

A different rationale for slow eating has been that it would fill the stomach more effectively and so satiate with less food. However, there is no evidence that gastric distension plays such a precise or dominant role in meal termination. Furthermore, if the eating were as slow as gastric emptying, the stomach would not begin to fill.

A variety of other suggestions have been made as to how to strengthen the influence of satiety but none has yet been taken up seriously, let alone tested for efficacy.

SCURVY

T K Basu, University of Alberta, Edmonton, Alberta, Canada
D Donaldson, Chemical Pathology Department, East Surrey Hospital, Redhill, Surrey, UK

Etymology

'Scurvy' is the current word in the English language for what has at various times in history been referred to as skurvie, scurvie, skirvye, scurvey, scurby, skyrby, scorbie, and scorby. The same word, in varied forms, has also been used to refer to scurf, i.e., dandruff. Confusion has also arisen because one sign, the petechiae (small hemorrhages in the skin), that are a feature of scurvy and many hematological disorders, has been referred to loosely and quite incorrectly as scurvy, because they are confused with purpura. In addition, many of the early references to scurvy are almost certainly erroneous as only later was it possible to differentiate this clinical disorder from other diseases of close or superficial resemblance. Further confusion and lack of clarity were caused by reference to patients with mixed disorders such as rickets as a comorbidity as scurvy, when the disease might in reality have been just a portion of the whole clinical presentation. Scurvy is a clinical syndrome caused by vitamin C deficiency which is associated with a derangement of collagenous protein synthesis; this is rapidly reversed with vitamin C supplementation.

History

The Ebers Papyrus from Ancient Egypt (*c.* 1500 BC) contains a reference to what could well be scurvy. In Ancient Greece Hippocrates referred to a disease occurring in soldiers and comprising pain in the legs, gangrene of the gums, and the consequent loss of teeth. During the Middle Ages 'land scurvy' was

recognized to be both commonplace and seasonal throughout the whole of Europe, usually being seen in the winter months, long after the cessation of availability of summer fruits and vegetables.

'Land scurvy' became 'sea scurvy' during the 14th and 15th centuries at the time of a rising spirit of adventure, catalyzed by new technical developments in ship design and advancements in navigational instrumentation, and compounded by growing and powerful commercial interests in the trading of silk and spices. These factors cleared the way for longer sea voyages of weeks or months in duration, without the opportunity for the crew to land at ports where fresh vegetables and fruits would be available. The diaries of Commodore George Anson's voyage of 1740–44, during which he attempted unsuccessfully to circumnavigate the world and on which 1051 of his 1955 men died – the majority from scurvy – referred to the fact that 'the scars of old wounds, healed for many years, were forced open again' and stated 'many of our people, though confined to their hammocks, ate and drank heartily and were cheerful, yet having resolved to get out of their hammock, died before they could well reach the deck.'

Vasco da Gama sailed from Lisbon on 9 July 1497 with about 140 Portuguese sailors. He reached the south-eastern coast of Africa 7 months later; the records indicated 'many of our men fell ill here, their feet and hands swelling and their gums grown over their teeth so that they could not eat.' On 6 April 1498 came the opportunity to purchase oranges from Moorish traders. Just 6 days later it is stated 'all our sick recovered their health for the air of this place is very good.'

In the winter of 1536, on the frozen St Lawrence River, the North American Indians taught the French explorer Jacques Cartier and his men the value of boiling the bark and leaves of the white cedar tree in water and then drinking the juice and dregs. Three doses on alternate days were sufficient 'miraculously' to cure their loss of strength and their swollen and inflamed legs.

The introduction of the potato to Europe from South America, where it had been cultivated for nearly 1500 years, was effected in the second half of the 16th century by the Spaniards who invaded that country. It is now seen to have provided a ready means of combating the problem of low vitamin C status in the winter months.

In 1617 John Woodall, Surgeon-General of the British East India Company, wrote *The Surgions Mate*, which contained a 23-page chapter on the subject of scurvy. He emphasized at that time the necessity of providing the crews of ships with the juice of oranges, lemons, or limes. He added a recommendation of two to three spoonfuls of lemon juice as a medicine against scurvy, and as a preventive too, if enough could be spared. This suggestion preceded the work and publications of James Lind, which did not appear until the following century.

James Lind was born in Edinburgh in 1716 and eventually became Physician-in-charge of the 2000-bed Haslar Hospital near Portsmouth, the largest and newest of the naval hospitals, in which there was the opportunity to study 300–400 cases of scurvy at a time. The famous experiment of his earlier days, in 1747, involved six groups of two men each, treated as follows: group 1 with cider, group 2 with elixir vitriol, group 3 with vinegar, group 4 with sea water, group 5 with two oranges and one lemon each day over 6 days, and group 6 with garlic, mustard seed, balsam of Peru, dried radish root and gum myrrh, together with barley water, tamarinds and cremor tartar. All received the same diet apart from the above 'medicines.' The best response was from group 5 by the sixth day, and group 1 came second at 2 weeks; the other 'remedies' proved to be of no value. Lind published his famous book *A Treatise of the Scurvy* in 1753, in Edinburgh. Nevertheless, it was not until 1804 that the Royal Navy decreed that lemon or lime juice must be provided daily; limes were later substituted for lemons as they were cheaper and could be obtained from the new West Indian colonies, although they are now known to contain less vitamin C. Hence the origin of the term 'limeys' for British sailors. In retrospect, one can now say that James Lind made one major error in preparing his 'rob of oranges' by evaporating juice down to 10% of its original volume, as heat is now known to destroy vitamin C; moreover, further storage following the preparative procedures permits yet greater deterioration in the vitamin C content.

The history of vitamin C is strewn with anecdotes such as these. Others should be briefly mentioned; they include Captain James Cook's 1768 voyage to the South Pacific in which his crew avoided scurvy by his insistence on the consumption of various fresh vegetables. An outbreak of scurvy at the National Penitentiary at Millbank in London in February 1825, following drastic reduction of the diet of the inmates, responded to the simple prescription of three oranges a day; however, neither the kitchen staff nor the prison officers suffered!

The Great Potato Famine of 1845–48 involved not only the UK and Ireland but also France and Belgium; many cases of scurvy were being reported in the British medical literature from 1847 onwards. Scurvy, not surprisingly, was seen in the general population and in the prisons and hospitals, too. The Royal Navy's Arctic expedition, which returned in 1876, suffered

badly from scurvy in spite of the availability of lime juice. However, lime juice had not been supplied on sledging expeditions, and even when it had been taken, the bottles had frozen solid, causing them to break on thawing over the evening fire.

In 1928 Albert Szent-Györgyi isolated a sugar from cabbage and lemon juice, and also from the adrenal gland. He was not permitted by the editor of the *Biochemical Journal* to call it 'ignose' or 'godnose' and had to call it 'hexuronic acid' instead. In 1932 CG King and WA Waugh identified the antiscorbutic factor from lemon juice to be the same as hexuronic acid; the name ascorbic acid was adopted. In 1933 Sir Norman Hawarth and his colleagues in Birmingham, UK, established the chemical structure of ascorbic acid. Also in 1933 both Sir Norman Hawarth's team and the team led by Tadeus Reichstein in Switzerland succeeded in synthesizing vitamin C.

During the latter part of World War II, at the time when many of those captured in the Far East were in Japanese prisoner-of-war camps, it was accepted that deficiency of vitamins A and B was commonly seen; however, deficiency of vitamin C did not occur. The reason for this was that the prisoners themselves prepared and drank 'jungle juice,' a mixture of the green leaf tops of sweet potatoes, kang kong (a vegetable eaten by the local natives in Borneo), leaves of the tapioca tree, and onion leaves for flavoring, all boiled up quickly in water. Grass, which was in abundance, and which is now known to contain weight-for-weight more vitamin C than citrus fruits, was never used as it was thought to have no nutritional value.

Species-sensitivity

Most animals do not develop scurvy since they are able to synthesize vitamin C from glucose by the reactions in eqns (1–3).

$$\text{D-Glucose} \xrightarrow{\text{NADPH.H}^+} \text{D-Glucuronic acid} \longrightarrow \text{D-Glucuronolactone} \quad (1)$$

$$\text{D-Glucuronolactone} \longrightarrow \text{L-Gulonolactone} + O_2 \xrightarrow[\text{oxidase}]{\text{gulonolactone}} \text{2-Ketogulonolactone} + H_2O_2 \quad (2)$$

$$\text{2-Ketogulonolactone} \longrightarrow \text{L-ascorbic acid} \quad (3)$$

The only known species unable to synthesize vitamin C are the primates (including humans), guinea pigs, the red-vented bulbul, the fruit-eating bat (*Pteropus medius*), the rainbow trout and the coho salmon. They lack the enzyme gulonolactone oxidase, which is necessary for the conversion of L-gulonolactone to L-ascorbic acid. Hence, these species are dependent on dietary sources (**Table 1**) for the vitamin. (*See* **Ascorbic Acid**: Physiology.)

Table 1 Vitamin C content of foods and plants

Food or plant	*Vitamin C content (mg per 100 g or 100 ml)*
Fruits	
Apples	4
Banana with peel	7
Citrus fruits	25–60
Gooseberries, fresh	60–65
Strawberries	58
Vegetables	
Broccoli	90
Cabbage	
Fresh	45–60
Boiled	24–30
Peas	
Sprouting	25–50
Dried	0
Potatoes	
Uncooked	10–30
Baked in skin	15
Boiled	5–15
Boiled and reheated	2–8
Sauerkraut	
Stored 1 month	10–15
Tomatoes	20
Animal origin	
Adrenal glands	100–200
Eggs	Trace
Meat or fish, well cooked	Trace
Milk	
Cows', pasteurized	1
Human breast milk	30–55
Botanical	
Scurvy grass	66–100
Spruce pine needles	65–200
Gramineae (grasses)	140–173
Liquids	
Apple cider, fresh unpasteurized	4–5
Blackcurrant syrup	60
Lemon juice, fresh	45
Lime juice, fresh	30
Orange juice, fresh	48
Rosehip syrup	150–200

Pathophysiology

Vitamin C deficiency causes failure to maintain the cellular structure of the supporting tissues of mesenchymal origin, such as bone, dentine, cartilage, and connective tissues. As a consequence, vitamin C deficiency is characterized by weakness and fatigue, hyperkeratosis of the hair follicles, perifollicular hemorrhages, petechiae and ecchymoses, swollen bleeding gums, delayed wound healing, and the easy fracturing of bone. These are the characteristic clinical features of scurvy.

The clinical manifestations of scurvy are the result of complete vitamin C deprivation of 100–160 days'

Table 2 The consequences of withdrawing vitamin C from the diet

200	< 1	< 6	< 2	< 11	< 0.1	< 0.6	Dyspnea, edema, and very rapid progression

duration (**Table 2**). During deficiency the vitamin C pool of the body is depleted at a daily rate of about 2.6% of the existing pool; 92% is lost after 100 days and symptoms of mild scurvy are evident when the pool is less than about 300 mg.

Fibroblasts play a central role in the wound-healing process. In vitamin C deficiency the fibroblasts proliferate but in an unimpeded manner. These proliferating cells generally remain immature, however, and fail to synthesize collagen molecules, which are the 'building blocks' of tissue repair. The impaired fibroblastic activity is essentially responsible for the delayed wound healing in vitamin C deficiency. Moreover, in vitamin C deficiency cartilage cells of the epiphyseal plate, at the end(s) of the diaphysis of long bones, continue to proliferate and line up in rows. The cartilage between these rows is calcified where osteoblasts do not migrate, resulting in the development of compressed and brittle bone.

Ultrastructural studies in scurvy show distinct alterations of the ribosomal and polyribosomal pattern. The endoplasmic reticulum shows considerable dilation and loss of ribosomal granules. The polyribosomes are disaggregated, unbeaded fibrillar material being seen in the extracellular space.

Biochemical Aspects

The characteristic feature of scurvy is an inability of the supporting tissues to maintain the synthesis of collagen, the intercellular substance. The collagen molecule consists of three linked popypeptide chains of amino acid residues. For the collagen molecule to aggregate into its triple helix configuration, the proline and lysine residues of newly synthesized collagen must be hydroxylated. Formation of the triple helix is important because it is in this configuration that the procollagen is secreted from the fibroblast. Hydroxylation of both proline and lysine occurs after the amino acids have been incorporated into the peptide chain; vitamin C is required in these reactions. The essential process mediated by vitamin C is the formation of hydroxyproline from proline and of hydroxylysine from lysine, as shown in the following reactions:

$$\text{Proline} + \text{ascorbate} + O_2 \xrightarrow{\text{proline hydroxylase}} \text{OH-proline} + \text{Dehydroascorbate} + H_2O \quad (4)$$

$$\text{Lysine} + \text{ascorbate} + O_2 \xrightarrow{\text{lysine hydroxylase}} \text{OH-lysine} + \text{Dehydroascorbate} + H_2O \quad (5)$$

Vitamin C appears to act as a cofactor for peptidyl proline and lysine hydroxylases, possibly by keeping copper and iron in a reduced state. Defective hydroxylation within the synthesizing fibroblast gives rise to the formation of an abnormal collagen precursor called protocollagen. Unlike the normal precursor (tropocollagen), this substance may not be extruded from the cell. If it is extruded it polymerizes into an abnormal collagen which lacks tensile strength. In addition to its requirement for collagen synthesis, vitamin C is believed to be an essential cofactor in forming the intercellular cement substance which binds the lining cells of blood vessels not only to their basement membrane but also to each other. (*See* **Coenzymes.**)

Occurrence of Scurvy

Scurvy is now a rare condition but isolated cases can still be seen in certain population groups. The at-risk groups are often the elderly (not so much in North America), food faddists, alcoholics, those living in institutions, and patients with psychiatric disorders.

Outbreaks of scurvy occur in poor nomadic populations in arid or semidesert districts when there is a threat of famine or a long-standing drought. There is also isolated evidence that long-term administration of large doses of vitamin C could lead to adaptation which might be responsible for developing scurvy, following sudden cessation of the extra vitamin intake. The conditioning effect is more pronounced during intrauterine life than either following birth or in adults. Overdosing with vitamin C during pregnancy may thus be contraindicated.

SELENIUM

Contents

Properties and Determination

G F Combs Jr, Grand Forks Human Nutrition Research Center, Grand Forks, ND, USA

Introduction

The chemical properties of the trace element selenium are similar to those of sulfur; however, unlike sulfur, which tends to be oxidized in biological systems, selenium tends to undergo reduction in the tissues of microbes, plants, and animals. Selenium is present in most biological tissues at very low concentrations where it is almost exclusively bound to proteins, mostly as analogs of the sulfur-amino acids. Several methods are available for the analysis of selenium; the most commonly used ones are electrothermal atomic absorption spectrophometry, and a chemical procedure based on the formation of a fluorescent,

piazoselenol derivative. These methods are useful for the quantitation of total selenium in tissues; however, more sophisticated methods, such as those involving high-performance liquid–liquid partition chromatography linked with mass spectrometry, are required for the chemical speciation of tissue selenium.

Chemical Forms of Selenium

Selenium is in group IVa of the periodic table of elements. This group includes the nonmetallic elements sulfur and oxygen in the periods above selenium and the metallic elements tellurium and polonium in the periods below. By period, selenium lies between the group Va metal arsenic and the group VIIa nonmetal bromine. Thus, selenium is considered a metalloid, having both metallic and nonmetallic properties. Its atomic properties are listed in Table 1.

Elemental selenium shows allotropy; that is, it can exist in either an amorphous state or in one of three crystalline states. Amorphous selenium in a hard, brittle glass at temperatures below 31 °C, is vitreous at 31–230 °C, and is a free-flowing liquid above 230 °C. The increased viscosity of amorphous selenium at temperatures less than 230 °C results from the formation of polymeric chains. Crystalline selenium can take several forms: flat, polygonal (often hexagonal) crystals called γ-monoclinic or red selenium; needle-like, prismatic crystals called γ-monoclinic or dark red selenium; or spiral polyatomic chains variously called metallic, gray or black selenium. Of these forms, the most stable is the hexagonal, crystalline form to which both monoclinic forms convert at temperatures above 110 °C and to which amorphous selenium converts spontaneously at 70–120 °C.

Elemental selenium can be reduced to the −2 (selenide, Se^{-2}) oxidation state or oxidized to the +4 (selenite, Se^{+4}) or +6 (selenate, Se^{+6}) oxidation states. Hydrogen selenide (H_2Se) is a fairly strong acid with a pK_a of 3.8 in aqueous systems. It is a colorless gas with an unpleasant odor. The gas is highly toxic (the LC50 for 30 min exposure for guinea pigs is 6 p.p.m.); however, Se^{-2} is also a pivotal metabolite in animals and at least some microbes, being the obligate precursor to selenocysteine at the active centres of a number of physiologically important selenoenzymes. Hydrogen selenide can be produced by heating elemental selenium (Se^0) to temperatures above 400 °C, but it decomposes in air to form the element and water. It is fairly soluble in water (270 ml per 100 ml of water at 22.5 °C). It reacts directly with most metals to form insoluble metal selenides. Organic selenides are ready electron donors; thus, they are readily converted to higher oxidation states.

In the +4 oxidation state, selenium can exist as selenium dioxide (SeO_2), selenious acid (H_2SeO_3), or selenite (SeO_3^{2-}). Selenium dioxide is formed by burning elemental selenium in air, or by reacting it with nitric acid. It is readily reduced to the elemental state by ammonia, hydroxylamine, sulfur dioxide, or a number of organic compounds. It is soluble in water (38.4 g per 100 ml at 14 °C) and forms selenious acid when dissolved in hot water. Selenious acid is weakly dibasic (pK_a 2.6), and dissolved selenite salts exist as biselenite ions in aqueous solutions at pH 3.5–9. In contrast to the organic selenides, selenites readily accept electrons from their environments and are, therefore, easily reduced. At low pH, selenite is readily reduced to the elemental state by such

Table 1 Atomic properties of selenium

Atomic number	34
Atomic weight	78.96
Stable isotopes (natural abundance)	^{74}Se (0.87%), ^{76}Se (9.03%), ^{77}Se (7.58%), ^{78}Se (23.52%), ^{80}Se (49.82%), ^{82}Se (9.19%)
Radioisotopes (emission; [a]half-life)	^{70}Se (γ^+, EC; 44 months); ^{71}Se (γ^+, EC; 5 months), ^{72}Se (EC; 8.4 days), ^{73}Se (γ^+, EC; 7.1 h), ^{75}Se (γ-; 120.4 days), ^{77m}Se (IT; 17.5 s), ^{79}Se (γ-; 6.5 × 10^4 years), ^{81m}Se (IT; 57 months), ^{81}Se (γ-; 18.6 months), ^{83m}Se (γ-; 70 s), ^{83}Se (γ-; 23 months), ^{84}Se (γ-; 3.3 months), ^{85}Se (γ-; 39 s)
Electronic configuration	Ar3d^{10} 4$s^2$2p^4
Atomic radius	1.40 γ
Covalent radius	1.16 γ
Ionic radius	1.98 γ
Common oxidation states	−2, 0, $^+$4, $^+$6
M-M bond energy	44 kcal mol^{-1}
M-H bond energy	67 kcal mol^{-1}
Ionization potential	9.75 eV
Electron affinity	−4.21 eV
Electronegativity	2.55 (Pauling's scale)

reducing agents as ascorbic acid and sulfur dioxide. Selenites in soils are strongly bound by hydrous oxides of iron, forming insoluble complexes at moderate pH.

In its highest oxidation state (+6), selenium can exist as selenic acid (H_2SeO_4) or selenate (SeO_4^{-2}) salts. Selenic acid is a strong acid. It is formed by the oxidation of selenious acid or elemental selenium with strong oxidizing agents in the presence of water. It is very soluble in water, as are most selenate salts. Selenates tend to be rather inert and are very resistant to reduction.

Six stable isotopes of selenium exist in nature and 13 radioisotopes of the element can be produced by neutron activation or radionuclear decay (Table 1). The stable isotopes ^{74}Se, ^{76}Se, and ^{80}Se have been employed in the study of the metabolism of selenite and selenomethionine by humans; these can be detected by mass spectrometry or neutron activation analysis. The short-lived radioisotope ^{77m}Se (half-life 17.5 s) has been used in the neutron activation analysis of the element in biological materials. Due to its emission of γ-radiation and to its relatively long half-life (120 days), ^{75}Se has proven widely employed in biological experimentation and in medical diagnostic work.

Selenium is a semiconductor that exhibits photoconductivity; that is, excitation with electromagnetic radiation can increase its conductivity. This property has made selenium compounds useful in photovoltaic cells and in xerography. As a result of the many practical utilities conferred by this property, the literature on the chemistry of inorganic and organic selenium compounds is large.

The selenium compounds of greatest relevance in biology are listed in Table 2. It should be noted that, whereas some dietary supplements and fortificants of foods and livestock feeds include selenium compounds of higher oxidation states (e.g., selenate [Se^{+4}]), the major metabolites are in the reduced (Se^{-2}) state.

Chemical Properties of Selenium

The chemical properties of selenium, like its physical properties, are very similar to those of sulfur. The two elements have similar outer valence shell electronic configurations and similar atomic sizes in both the covalent and ionic states. Their bond energies, ionization potentials, and polarizabilities are virtually the same. Despite these similarities, the chemistry of selenium differs from that of sulfur in two important respects which distinguish the elements in biological systems: their oxyanions are not similarly reduced, and their hydrides have different acid strengths. For these reasons, selenium behaves very differently from sulfur in biological systems.

In biological systems, selenium compounds tend to be metabolized to more reduced states while sulfur compounds tend to be metabolized to more oxidized states. For example, quadrivalent selenium (Se^{+4}) in selenite tends to undergo reduction to Se^{-2}, being metabolized first to H_2Se and, ultimately, being methylated to a variety of excretory forms. In contrast, quadrivalent sulfur in sulfite tends to undergo oxidation. This difference is demonstrated by the ability of selenious acid to oxidize sulfurous acid: $H_2SeO_3 + 2H_2SO_3 \rightarrow Se^0 + 2H_2SO_4 + H_2O$.

Although the oxyacids of selenium and sulfur have comparable acid strengths (pK_a 2.6 versus pK_a 1.9, respectively, for the quadrivalent species; pK_a 3 for both of the hexivalent species), the hydride H_2Se is much more acidic than H_2S (pK_a 3.8 versus 7.0, respectively). This difference in acid strengths is

Table 2 Biologically important selenium compounds

Oxidation state	*Compound*	*Biological relevance*
Se^{-2}	H_2Se	Obligate metabolic precursor to selenoproteins
	Methyl selenol, CH_3SeH	Excretory form (lung) shown to be anticarcinogenic
	Dimethyl selenide, $(CH_3)_2Se$	Excretory form (lung)
	Trimethyl selenonium, $(CH_3)_3Se^+$	Excretory form (kidney)
	Selenomethionine	Common food form; form in nonspecific Se-containing proteins (e.g., albumin); metabolized to selenocysteine
	Selenocysteine	Common food form; form in selenoproteins; metabolized to H_2Se
	Se-methylselenomethionine	Form found in some foods; metabolized to CH_3SeH
	Se-methylselenocysteine	Form found in some foods; metabolized to CH_3SeH
	Selenobetaine	Metabolic precursor of CH_3SeH
	Selenotaurine	Form found in some foods
Se^0	Selenodiglutathione	Reductive metabolite of selenite/selenate with anticarcinogenic activity
Se^{+4}	Na_2SeO_3	Commonly used feed supplemental form
Se^{+6}	Na_2SeO_4	Potential food/feed supplement form

reflected in the different dissociation behaviors of the selenohydryl group (–SeH) of selenocysteine (pK_a 5.24) and the sulfhydryl group (–SH) of cysteine (pK_a 8.25). This, while thiols such as cysteine are mainly protonated at physiological pH, selenols such as selenocysteine are predominantly dissociated under the same conditions.

Selenite (Se^{+4}) can readily react with nonprotein thiols and with protein-sulfhydryl groups to undergo reduction to Se^0 with the concomitant formation of 1,3-dithio-2-selane products of the form RS-Se-SR, called 'selenotrisulfides.' In this reaction, $4RSH + H_2SeO_3 \rightarrow RS\text{-}Se\text{-}SR + 3H_2O$, four sulfhydryl sulfur atoms (S^{-2}) are oxidized to the disulfide state (S^{-1}) with the concomitant reduction of a single selenium atom from the selenite state (Se^{+4}) to the zero oxidation state. However, because the electronegativities of selenium and sulfur are very similar, the –2 charge may be distributed across the selenotrisulfide bridge, yielding an effective oxidation number of –2/3 for each of its members. A similar reaction can occur between selenite and free sulfhydryl groups of proteins to yield selenodisulfide (RS-SeH) and selenotrisulfide-type oxidation products that, in some cases, can inhibit enzymatic activity. Indeed, such reactions are thought to play a role in selenium toxicity.

Analysis of Selenium

The analytical challenge for determining selenium in biological samples, i.e., plant and animal tissues, is to detect quantitatively the element over at least three orders of magnitude of concentration. The nutritional assessment of selenium status calls for analytical procedures capable of measuring plasma/serum selenium levels in individuals who may be adequately nourished (> 80 p.p.b. selenium), marginally nourished (40–80 p.p.b.), frankly deficient (< 40 p.p.b.), or potentially intoxicated (> 1000 p.p.b.). The analysis of selenium in foods and feedstuffs calls for methods capable of measuring the element in the range of 20–500 p.p.b., while the detection of selenium in nonprotein-bound fractions of animal/human tissues calls for detection capability of 1–5 p.p.b.

Several procedures are available for the quantitative determination of selenium; however, some that have industrial utility do not lend themselves to biological applications due to their relatively low sensitivities. Such methods include both gravimetric (e.g., after reduction and quantitative precipitation with acid or electrolytic deposition with copper) and colorimetric ones (e.g., titration with oxidizing agents after reduction with thiocyanate; measurement of selenium hydrosols after reduction by hydrazine, stannous chloride, or ascorbic acid; measurement of azo-compounds formed by the reaction of aromatic amines with diazonium salts produced by the oxidation of organic compounds by selenite; measurement of complexes of Se^{-2} with phenyl-substituted thicarbazides or semicarbazide after reduction of selenium). The limit of detection of none of these methods is less than 0.5 p.p.m. and, for the gravimetric methods, they can be several parts per million. None of these procedures is free of interferences that can give false-positive results; other elements can coprecipitate with selenium to affect the results of gravimetric methods, and other oxidizing agents that can affect the colorimetric methods.

Other methods have been found to be more useful for the determination of selenium in plant and animal tissues. These include: (1) fluorimetric measurement of selenium, after nitric-perchloric acid digestion and conversion to Se^{+4}, using diaminonaphthalene (DAN) to form benzopiazselenol; (2) atomic absorption spectrophotometry; (3) instrumental neutron activation analysis; (4) mass spectrometry; (5) atomic fluorescence spectroscopy; (6) inductively coupled plasma emission spectroscopy; and (7) proton-induced X-ray emission spectrometry. Each of these approaches can yield sensitivity less than 5 p.p.b. Of these, the methods most widely employed in biomedical applications have been the DAN-fluorimetric and electrothermal atomic absorption methods.

The chemical determination of selenium by the DAN-fluorimetric method is of lower cost with comparable sensitivity (2–5 p.p.b.) compared to most other methods. This method necessitates the quantitative conversion of the selenium in the sample to Se^{+4}. Because most, if not all, selenium in biological tissues occurs as Se^{-2} compounds, this is achieved using nitric-perchloric acid digestion to oxidize organic matter and form Se^{+6}. This is followed by treating the sample with hydrochloric acid to reduce any Se^{+6} that may be present to the +4 oxidation state. Se^{+4} is reacted with DAN, yielding benzopiazselenol which is extracted into cyclohexane and measured fluorimetrically (excitation 390 nm; emission 520 nm). The DAN-fluorimetric method has two points of vulnerability: effect that impairs the conversion of selenium to Se^{+4}, and factors that produce fluorescence interference. One potential source of the first type of error is the loss of volatile H_2Se formed in the transition, particularly in the presence of large amounts of organic matter such that sample charring can occur (e.g., fatty materials such as egg yolk or adipose tissue). Because H_2Se is volatilized from acid solutions by reducing agents, this loss can be avoided by maintaining strongly oxidizing conditions during digestion and by using low heat such that

the oxidation of Se^{+4} to Se^{+6} proceeds relatively slowly (this can be achieved by gradually raising the temperature of the perchloric acid solution to 210 °C). When the nitric-perchloric acid digestion is controlled and carefully attended, it produces satisfactory conversion to Se^{+4}, even of such forms as trimethylselenonium which is resistant to oxidation by nitric acid alone. The second type of problem involves fluorescence interference caused by degradation products of DAN. This can be avoided by purifying DAN prior to use either by recrystallization from water in the presence of sodium sulfite and activated charcoal, or by hexane extraction after hydrochloride stabilization.

Although conventional atomic absorption spectrophotometry (AAS) does not yield satisfactory sensitivity for most biological applications, two variant methods do so. The best results are obtained using electrothermal AAS which avoids the problems associated with wet digestions by employing high-temperature oxidation and antomization in a graphite furnace. This reduces interferences due to nonspecific absorption of organic compounds and nonselenium salts, but introduces the problem of selenium volatility under such conditions and can also be prone to 'matrix' effects, particularly due to phosphate. These sources of interference can be effectively reduced by using a palladium-based matrix modifier to reduce the volatility and, thus, permit the vaporization of nonselenium compounds at lower furnace temperatures than those used to vaporize and quantitate selenium. Also effective is background correction by the Zeeman effect, in which a magnetic field is used to split the resonance line into its Zeeman components, converting a single beam into a double one, the wings of which can be monitored with polarizers to assess the background while the central portion is monitored to assess the analyte. In practice, electrothermal AAS with the use of automatic Zeeman-effect background correction can achieve a sensitivity of 2 p.p.b. A less sensitive AAS technique involves the pretreatment of the sample with sodium borohydride and acid to convert selenium to H_2Se. This method requires selenium to be in solution as Se^{+4}, which can be achieved by nitric-perchloric acid digestion of the sample, after which the hydride generation step can be automated. This approach yields a limit of detection of only 50–100 p.p.b. and is subject to interferences due to other elements that can also form hydrides, particularly copper.

Investigators with access to research atomic reactors have found instrumental neutron activation analysis of selenium to be very useful, as it offers the advantages of applicability to small samples, ease of sample preparation, and nondestruction of sample. The greatest sensitivity, about 20 p.p.b., by this method is obtained by measuring ^{75}Se; however, the use of that radioisotope requires relatively lengthy periods of irradiation (100 h), postirradiation holding (60 days) and counting (2 h), making it relatively expensive. Greater economy and increased sample throughput are achieved through the use of the short-lived ^{77m}Se which can be produced by only 5 s of irradiation, and counted (25 s) after only 15 s of decay using an automated system. Nevertheless, this fast method is limited by its relatively low sensitivity, rendering it unsuitable for accurate quantitation of such low amounts of selenium as are found in tissues of animals chronically deficient in the element.

Selenium can be measured by mass spectrometry, which method offers the distinct advantage of being able to distinguish between the major stable isotopes of the element. There is, therefore, great interest in developing mass spectrometric techniques for use in metabolic studies in which ^{74}Se, ^{76}Se, or ^{82}Se are used as tracers. Mass spectrometric procedures have been developed for determining selenium in biological samples by isotope dilution. These involve the analysis of the naturally abundant ^{80}Se in addition to ^{82}Se which is used as an internal standard. Samples spiked with known amounts of the internal standard are treated by nitric-perchloric acid digestion to convert all of the selenium in the sample to Se^{+4}. The latter can be chelated using *o*-nitrophenylenediamine, extracted into an organic solvent, and subjected to gas–liquid partition chromatography–mass spectrometry to determine the ratios of ^{82}Se to ^{80}Se, comparing that ratio to the ratio of the one naturally occurring in the sample. Mass spectrometry can yield limits of detection for selenium as low as 1 p.p.b. The technique known as inductively coupled plasma mass spectrometry (ICP-MS) involves coupling using mass spectrometry inline after ionizing the sample in a high-temperature plasma.

Selenium can be measured by emission spectrophotometry using either a flame or high-temperature plasma to atomize selenium. A very sensitive atomic flame fluorescence spectrophotometric method uses automated hydride generation of a predigested sample. This method has not been widely used, but offers very good specificity, in as much as only a few elements can form volatile hydrides and as the fluorescence emission wavelength can be measured selectively. The method offers impressive sensitivity with limits of detection on the order of 2–5 p.p.t.; the sample dilution usually required for hydride generation reduces the working limit of detection to the 20–50 p.p.t. range, which is still superior to other methods. Selenium can be measured by inductively

coupled plasma emission spectrometry, which offers the advantage of the simultaneous determination of other elements. This method can yield limits of detection of about 1 p.p.b., but is limited by spectral interferences of the dimeric argon formed in the plasma.

The measurement of selenium by proton-induced X-ray emission (PIXE) spectroscopy offers the potential advantage of simultaneous analysis of other elements. This method involves proton bombardment of target atoms to cause loss of the latters' inner-shell electrons which are consequently replaced by electrons from the outer shell. The X-rays emitted during that transition are characteristic of the energy differences between the respective electron shells and are, therefore, identifiable and quantifiable. The sensitivity of the PIXE procedure for the determination of selenium is about 10 p.p.b., making it useful for some biological purposes but not sufficiently sensitive for the accurate determination of very low tissue levels of the element.

Chemical Speciation of Selenium

Most selenium naturally present in biological materials appears to be in the reduced (selenide) state, Se^{-2}. There is, however, little information available concerning the various chemical forms in which that Se^{-2} occurs in plant and animal tissues. Studies have shown that the selenium in wheat and corn grown on seleniferous soils is predominantly protein-bound; in wheat half or more occurs as the selenium analog of methionine, selenomethionine. Because plants cannot synthesize the cysteine analog selenocysteine, it is generally thought that selenomethionine is the predominant form of the element in plant tissues in which it acts as a methionine mimic in general protein metabolism. This is not the case for animals and at least some microorganisms, which can biosynthesize selenocysteine from H_2Se. In fact, it is as selenocysteine in specific selenoenzymes that selenium serves its nutritionally essential metabolic functions. Therefore, the tissues of selenium-fed animals and humans typically contain both selenocysteine from the biosynthesis of selenoproteins as well as selenomethionine derived from the diet and used nonspecifically in general protein synthesis. In addition to these two main forms, it is clear that plant tissues can contain smaller amounts of certain derivatives, including Se-methylselenomethionine and Se-methylselenocysteine, and that animals produce metabolically both H_2Se as well as a number of methylated excretory metabolites thereof (methylselenol, dimethylselenide, and trimethylselenonium); however, there are virtually no data currently available concerning the amounts of these metabolites in animal or human tissues.

The chemical determination of selenium species is the next frontier in the analytical chemistry of selenium. Recent efforts in this area have involved the use of gas–liquid partition chromatographic separation techniques coupled with atomic plasma emission detection methods for the simultaneous detection and quantitation of selenoamino acids; of ethylation derivatization to separate volatile organoselenium compounds; and of ion-pair, reverse-phase, high-performance liquid–liquid partition chromatography couple to ICP-MS for the determination of selenoamino acids, selenoxides, and other selenium derivatives. Future efforts in this field are likely to employ molecular mass spectrometry.

Physiology

C D Thomson, University of Otago, Dunedin, New Zealand

Introduction

Selenium first attracted attention in the 1930s as a toxic trace element that caused 'alkali disease' in livestock consuming high-selenium plants. In 1957, selenium was shown to be essential for animals when traces of this element prevented liver necrosis in vitamin E-deficient rats, and later to prevent a variety of economically important diseases such as white muscle disease in cattle and sheep, hepatosis dietetica in swine, and exudative diathesis in poultry. The demonstration in 1973 of a biochemical function for selenium as a constituent of the enzyme glutathione peroxidase helped to explain the interrelationship between selenium and vitamin E. The importance of selenium in human nutrition was highlighted in reports in 1979 of the selenium responsive condition, Keshan disease in China, and selenium deficiency in a patient on total parenteral nutrition in New Zealand. Considerable research during the last two decades has provided information on the molecular biology, metabolism, and importance of selenium in human nutrition, leading to a much greater understanding of the functions of selenium and the establishment of recommended dietary intakes.

Metabolism of Selenium

Comparatively little is known about the forms of selenium in foods. The major form in cereals and other plants is selenomethionine, while the most likely form in animal foods is selenocysteine, as this is the active form in functional selenoproteins in the mammalian body. Inorganic forms are often used in experimental diets and as supplements, but the extent of occurrence of inorganic or other forms of selenium in foods is not clear. The metabolism of selenium, including absorption, transport, distribution, excretion, retention, and transformation to the active form, is very much dependent on the chemical form and amount of selenium ingested, and on interacting dietary factors. There is considerable species variation in many aspects of selenium metabolism.

Absorption

Selenium is absorbed mainly from the duodenum. Selenomethionine and methionine share the same active transport mechanism, but little is known about the transport of selenocysteine. Absorption of inorganic forms of selenium such as selenite and selenate is via a passive mechanism.

While the absorption of selenium is generally high in humans, probably about 80% from food selenium, selenomethionine appears to be better absorbed than selenite. Absorption of selenium is unaffected by selenium status, and there appears to be no homeostatic regulation of absorption. Selenium is better absorbed from a high-protein diet, and the absorption of selenomethionine may be influenced by the methionine content of the diet.

Bioavailability

As well as absorption, utilization of a nutrient may also include transformation to a biochemically active form, which, for selenium, is assessed from changes in tissue glutathione peroxidase. Few studies have been made in humans of the bioavailability of selenium, but animal studies show a wide variation in the availability from different foods. In rats, the bioavailability from mushrooms, tuna, wheat, beef kidney, and Brazil nuts is 5, 57, 83, 97, and 124%, respectively, in comparison with sodium selenite. In humans, the bioavailability of selenium from fish is low in comparison with wheat. Human studies also show differences among various forms of selenium such as selenate, wheat, and yeast, but this also depends upon the criterion of measurement used for availability, indicating the need to consider several variables, including short-term changes in glutathione peroxidase activity, long-term retention of tissue selenium, and metabolic conversion to biologically active forms.

Transport

Little is known about the transport of selenium in the body, although it appears to be transported bound to plasma proteins. A selenium-containing protein called selenoprotein P, isolated from rat and human plasma,

has been suggested as a transport protein, and plasma also contains extracellular glutathione peroxidase, but lower-molecular-weight forms of selenium are more likely to act as transport proteins.

Metabolism and Distribution

An outline of selenium metabolism is shown in Figure 1. In animal tissues, selenium occurs in association with protein, and is present in two main compartments or forms. The first is selenocysteine, which is present as the active form of selenium in selenoproteins, including the selenoenzyme glutathione peroxidase. The second is selenomethionine, which is incorporated in place of methionine in a variety of proteins, unregulated by the selenium status of the animal.

Selenium levels in tissue are influenced by dietary selenium intake; this is reflected in the wide variation in blood selenium levels of residents of countries with differing soil selenium levels (Figure 2). The total amount of selenium in the body ranges from 3 to 20 mg, depending on intake of selenium. Retention of selenium is also profoundly influenced by the form administered, with selenomethionine being much more effective in raising blood selenium levels than sodium selenite or selenate. Selenomethonine appears to follow the same metabolic pathway as methionine and is incorporated nonspecifically into protein in its place. This contributes to tissue selenium, where it may in fact accumulate, but has no physiological function and is not available for synthesis of functional forms of selenium until it is catabolized. Selenate is reduced to selenite, then selenide, and in this oxidation state (−2) is introduced into selenocysteine, the active form of selenoproteins. The selenium from inorganic selenium, or from catabolism of selenomethionine or selenocysteine, is incorporated into selenocysteine, which enters regulated selenium metabolism and is then incorporated into selenoproteins. Selenium intake from selenate, selenite, or selenocysteine, unlike that from selenomethionine, will be excreted in urine if in excess.

Incorporation of Selenium into Selenoproteins

All functional mammalian selenoproteins contain selenocysteine at the active site. Selenium is incorporated by replacement of oxygen into serine to form selenocysteine, while serine is attached to a unique tRNA (transfer ribonucleic acid). Selenocysteine is encoded by a unique stop codon UGA on the mRNA specific for the selenoprotein. Regulation of selenoprotein synthesis appears to be via individual mRNAs (messenger RNAs) at the transcriptional or posttranscriptional levels in response to selenium availability, as well factors such as the chemical form of selenium and oxygen exposure. However, there is differential depression of selenoprotein synthesis in response to an inadequate selenium supply with preservation of the metabolically most important proteins. This has been termed the 'hierarchy' of importance of functional selenoproteins.

Excretion

Urine is the principal route of excretion of selenium, followed by feces, which mainly contain unabsorbed selenium. Homeostasis of selenium is achieved by regulation of its excretion. Daily urinary excretion of selenium is closely associated with plasma selenium and dietary selenium intake and has been used as an indicator of selenium status. Balance studies show

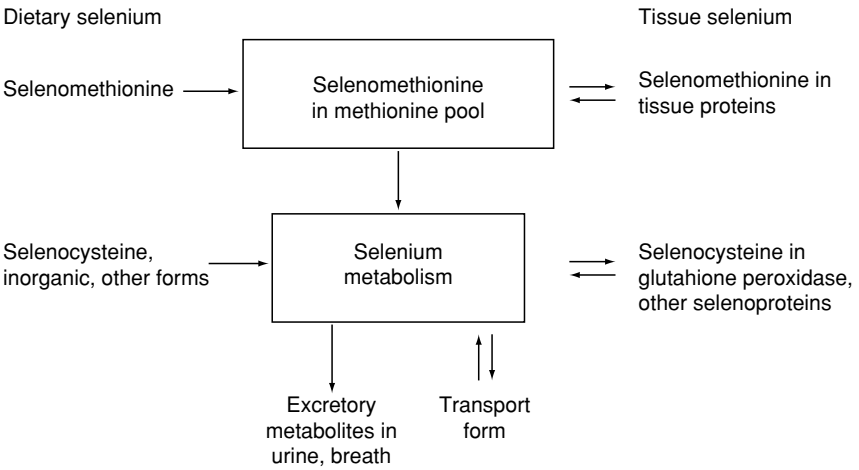

Figure 1 Outline of selenium metabolism.

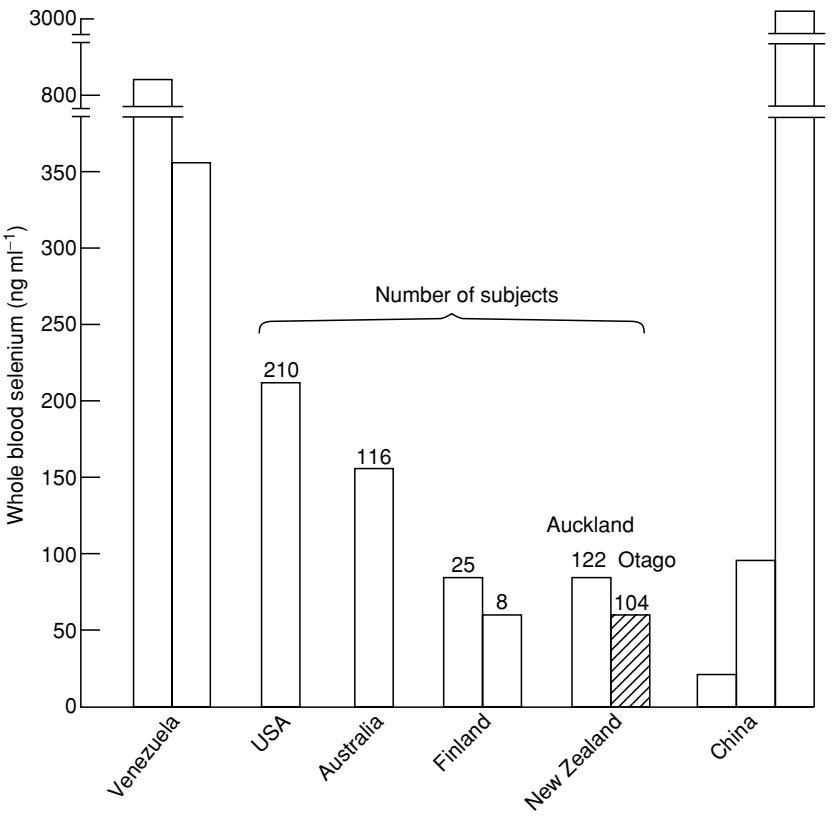

Figure 2 Blood selenium concentrations of healthy adults in Venezuela, the USA, Australia, Finland, New Zealand, and China (low- and high-selenium areas). (To convert nanograms of Se per milliliter to micromoles per liter, multiply by 0.0127.)

that over a wide range of intakes, urinary excretion accounts for 50–60% of the total amount excreted. Measurement of the plasma renal clearance of selenium, which expresses its rate of excretion in the urine in terms of the amount contained in a unit volume of plasma, shows that the kidneys of residents of the low-selenium country, New Zealand, excrete selenium more sparingly than those of North Americans, and Chinese from low-selenium areas have an even lower renal clearance. This indicates a possible adaptation to low selenium status.

Trimethylselenonium ion, one of several urinary metabolites, was once thought to be a detoxification product of selenium and appears to be a minor metabolite in humans. Another methylated metabolite, methylselenol, may constitute a larger proportion of urinary selenium. Small losses of selenium occur through the skin or hair or, at high intakes, in expired air as volatile dimethylselenide.

Excretion of Selenium in Milk

Most of the selenium in human milk is protein-bound; at least nine selenium-containing proteins have been detected in milk with glutathione peroxidase accounting for 15–30% of total selenium.

Role of Selenium in the Body

Selenoproteins

Selenium exerts its biological effect through several selenoproteins, of which there may be upwards of 30 in mammalian systems. Identification and characterization of many of these proteins in recent years have resulted in major advances in our understanding of the function of selenium. The following selenoproteins have been purified and studied.

- glutathione peroxidases;
  - cytosolic, cellular
  - gastrointestinal
  - plasma
  - phospholipid hydroperoxide
- selenoprotein P;
- iodothyronine 5′-deiodinases;
- sperm capsule selenoprotein;
- selenoprotein-W;
- thioredoxin reductase;
- selenophosphate synthetase;
- 58-, 56-, and 14-kDa Se-binding protein.

Glutathione peroxidases The first of these selenoproteins to be characterized was glutathione

peroxidase, which consists of four identical subunits, each containing one selenocysteine at the active site. Activity of this enzyme can be reduced to less than 1% in tissues of selenium-deficient animals. Glutathione peroxidase present in cells (including erythrocytes), plasma, and the gastrointestinal tract may function *in vivo* to remove hydrogen peroxide, thereby preventing the initiation of peroxidation of membranes and oxidative damage. However, the significance of this function in the body is uncertain, and it seems likely that the oxidant defense role for selenium is exerted more through other selenoproteins. Glutathione peroxidase may have more specific functions in arachidonic acid metabolism in platelets, microbiocidal activity in leukocytes, and the immune response mechanism or perhaps as a storage protein.

Another selenium-containing enzyme, phospholipid hydroperoxide glutathione peroxidase, is different from the classic glutathione peroxidase in that it can metabolize fatty acid hydroperoxides that are esterified in phospholipids in cell membranes. This enzyme can inhibit microsomal lipid peroxidation and is most likely the basis of the selenium/vitamin E interaction in the pathogenesis of several deficiency diseases in animals.

Selenoprotein P A plasma protein designated selenoprotein-P has been purified and characterized from rat and human plasma and is also associated with endothelial cells. Selenoprotein-P is a glycoprotein containing selenium as selenocysteine, and its concentration in rat plasma falls to less than 10% of the control in selenium deficiency. Its function is unknown, but it may have an extracellular oxidant defense role because its presence correlates with selenium protection of selenium-deficient rats against diquat-induced lipid peroxidation and liver necrosis. A transport role has also been suggested for this protein.

Iodothyronine deiodinases The discovery that type I iodothyronine 5′-deiodinase and, more recently, type II and type III deiodinases are selenoproteins indicates a role for selenium in the metabolism of thyroid hormones that are essential for growth and development. This enzyme catalyzes the conversion of thyroxine (T_4) to its active metabolite triiodothyronine (T_3) in the liver and kidney, and selenium deficiency results in an increase in levels of plasma T_4 and a corresponding decrease in levels of more active T_3. Selenium is preferentially supplied to this enzyme rather than glutathione peroxidase when the selenium supply is inadequate. The interactions of selenium and iodine deficiencies have implications for both human and animal health and livestock production. In humans, selenium deficiency can either exacerbate or ameliorate the effects of concurrent iodine deficiency as has been observed in the development of iodine deficiency disorders in Zaire.

Thioredoxin reductase A recent addition to the list of selenoproteins is thioredoxin reductase, an NADPH-dependent flavoenzyme that reduces the disulfide of thioredoxin. This enzyme regenerates ascorbic acid from dehydroascorbic acid. The activity of thioredoxin reductase declines in selenium deficiency, and there is evidence that selenium is present in the active site as selenocysteine.

Selenoprotein W Selenoprotein W is a selenoprotein found in muscle and other tissues. Its concentration decreases during selenium deficiency, and it may be involved in the development of muscular degeneration in selenium-deficient sheep.

Other selenoproteins Several other selenium-containing enzymes have been identified in microorganisms, and other selenoproteins have been found in animal tissues, suggesting further functions for selenium. These include a specific selenoprotein in prostate tissue, a mitochondrial selenoprotein in sperm, and a 14-kDa and 56/58-kDa selenium-binding protein. One of two selenophosphate synthetases recently identified contains selenocysteine, and it is possible that this enzyme may be involved in the regulation of selenium homeostasis.

Selenium and Host Defense Towards Viruses

The seasonal nature of Keshan disease suggested the likely involvement of an infectious agent, which led to recent work on host response to myocarditic and amyocarditic strains of Coxsackie virus B_3 in mice. Selenium deficiency potentiated cardiotoxicity of myocarditic strains, but in addition, the amyocarditic strain caused heart lesions in selenium deficient mice. This indicated that this specific nutrient deficiency allowed a benign virus to become virulent, apparently as a result of a change in the viral genome. The observation that selenium deficiency may accelerate viral evolution may help to clarify the etiology of Keshan disease and may also be applicable to other RNA viruses. Vitamin E deficiency had effects similar to those observed with selenium deficiency, which suggests the involvement of antioxidant properties of the two nutrients. This is the first reported instance of an influence of host nutritional status on the genetic composition of the pathogen.

Selenium and Immune Function

Adequate selenium is essential for a variety of aspects of the immune function. Selenium is necessary for the development of the acquired immune system, and has a role to play in the defense system of animals against bacteria and other infections. The recent finding of a role for selenium in cell-mediated immunity to Coxsackie virus in mice indicates a protective effect of selenium against viral infection. The mechanisms for the involvement of selenium in the immune system are likely to be related to its antioxidant function through one of the antioxidant selenoproteins glutathione peroxidase, phospholipid glutathione peroxidase, or selenoprotein-P.

Deficiency

Interaction between selenium and vitamin E is observed in the etiology of many deficiency diseases in animals and pure selenium deficiency is in fact rare. Thus, selenium deficiency may only occur when low selenium status is linked with an additional stress such as chemical exposure, increased oxidant stress due to vitamin E deficiency, exercise, or increased dietary intake of polyunsaturated fatty acids. Although residents in some low-selenium areas have low blood selenium, glutathione peroxidase activity, and Selenoprotein P levels, there is little evidence that these are suboptimal or have resulted in any noticeable oxidative damage or changes in other oxidative defense mechanisms. Moreover, people have not shown noticeably improved health when glutathione peroxidase activity is saturated by selenium supplementation. However, an exception to this general rule may be found in the problem of Keshan disease in China. Whether any of the newer functions of selenium are suboptimal in persons with low selenium status is being investigated.

Selenium-responsive Diseases in Humans

Keshan disease, an endemic cardiomyopathy occurring in low-selenium areas of China, was reported in 1979 to be responsive to supplementation with sodium selenite. The principal pathological finding is multifocal necrosis of the myocardium that causes cardiac enlargement, congestive heart failure, cardiogenic shock, and death. The disease is associated with low selenium intake and low blood and hair levels, and affects mainly children and women of childbearing age. It is probably the only case of naturally occurring selenium deficiency. Because some features of Keshan disease (e.g., seasonal variation) cannot be explained solely on the basis of a very low selenium status, Chinese researchers have suggested that other factors may be involved, such as a virus, mineral imbalance, or environmental toxins. Recent research on Coxsackie virus B-induced myocarditis in selenium-deficient mice supports a possible viral involvement in Keshan disease. Another disease that has been associated with poor selenium status in China and Russia is Kashin–Beck disease, an endemic osteoarthritis that occurs during preadolescent or adolescent years. Again, other etiologic factors such as contamination of grain by fungi and high concentrations of organic matter (e.g., fulvic acid) may be contributing factors. The main features of the disease are shortened stature and joint deformation, resulting from multiple focal necroses in the growth plate of tubular bones.

Selenium deficiency has been associated with long-term intravenous nutrition, because of the low levels of selenium in the fluids. Clinical symptoms of cardiomyopathy, muscle pain, and muscular weakness are responsive to selenium supplementation, but are not seen in all patients with extremely low selenium status, indicating that there may be other interacting factors. Furthermore, children on very low selenium synthetic diets for inborn errors of metabolism such as phenylketonuria do not develop selenium-deficiency syndromes.

It is not clear whether syndromes in animals such as the selenium-responsive muscular dystrophy observed in sheep are related to human diseases. Although persistent anecdotal reports from New Zealand farmers in low-selenium areas indicate their conviction that selenium relieves the farmers' muscular aches and pains, double-blind trials have failed to give a clear-cut answer.

Selenium and Cancer

Several lines of scientific enquiry suggest that an increased risk of cancer occurs as a result of low levels of selenium in the diet. An association between selenium and cancer was first proposed 30 years ago when it was observed that regional cancer mortality rates in the USA correlated with selenium exposure, as reflected by concentrations in plants. Evidence for the role of selenium as an anticarcinogenic agent comes from *in vitro* and animal studies that suggest that selenium is protective against tumorigenesis at high levels of intake and from case-controlled prospective studies in human subjects. However, epidemiological evidence linking a low selenium status with an increased incidence of cancer is conflicting. Few intervention studies in humans have been carried out. In Linxian China, a significant effect of a combination of vitamin E, β-carotene and selenium was observed on mortality, particularly from esophageal cancer. Recently a 10-year controlled clinical trial to test the efficacy of selenium in preventing skin cancer

was completed in the USA. There was no effect of daily supplementation with 200 μg of selenium on the primary endpoint skin cancer, but there was a statistically significant reduction in several additional endpoints such as total cancer mortality (50%), and incidence of cancer of the prostate (63%), lung (46%), colorectal (58%), and total cancer. Further studies are needed to confirm these observations.

Selenium and Cardiovascular Disease

Similarly, dietary deficiency of selenium has been implicated in the etiology of cardiovascular diseases, but the evidence at present is less convincing than for cancer. Although a large case-control study in Finland suggested that selenium was an independent risk factor for myocardial infarction in a low-selenium population, evaluation of prospective epidemiological studies has failed to provide sufficient evidence to implicate selenium deficiency in most aspects of cardiovascular disease. While some investigations have observed a relationship between low serum-selenium levels and risk of coronary disease, others have not. However, selenium may have some role in protection against thrombosis and low-density lipoprotein oxidation, in particular in individuals such as smokers at risk from increased oxidant stress. Further evidence must come from controlled intervention trials to clarify any possible role for selenium in atherosclerotic disease.

Toxicity

The margin between an adequate and toxic intake of selenium is quite narrow. Overexposure or selenosis may occur from consuming high-selenium foods grown in seleniferous areas in Venezuela and some areas of China. People following long-term liberal megadosing can also attain an undesirably high selenium status. The most common sign of poisoning is loss of hair and nails, but lesions of the skin, nervous system, and teeth may also be involved. Garlic odor on the breath is an indication of excessive selenium exposure resulting from expiration of dimethylselenide. Sensitive biochemical techniques are lacking for selenium toxicity, which is at present diagnosed from hair loss and nail changes. Some effects of selenium toxicity are seen in individuals with dietary intakes as low as 900 μg, and the maximum safe dietary intake has been suggested as 400 μg per day.

Assessment of Selenium Status

Blood selenium concentration is generally considered a useful measure of both selenium status and intake, but other tissues are often assessed as well. Plasma selenium reflects short-term status and erythrocyte selenium long-term status, but blood selenium concentrations are influenced by the chemical form of selenium ingested as a result of the different patterns of absorption and retention outlined previously. Toenails are often used, but selenium-containing shampoos restrict the use of hair. Urinary excretion can also be used to assess selenium status, and total dietary intake is estimated as twice the daily urinary excretion.

The close relationship between blood or red-cell glutathione peroxidase activity and selenium concentrations (**Figure 3**) is useful for assessment in people with a relatively low status, but not once the saturating activity of the enzyme is reached at blood selenium concentrations above $100\,\mu g\,l^{-1}$ ($1.27\,\mu mol\,l^{-1}$). More recently, mesurement of selenoprotein P has been used to assess selenium status, and there is the potential for measurement of other enzymes as functional markers. However, their use is limited at present by the lack of simple assay techniques. Furthermore, the conclusions drawn from measurement of one selenoprotein may not apply to all biological functions of selenium because of the differences in responses of tissues and these proteins to deficient, adequate, or high levels of selenium in terms of their 'hierarchy' of importance. Therefore, there may be no single indicator of functional selenium status, but rather a series of markers that apply to specific problems associated with suboptimal selenium status. The situation is further complicated by the large number of interacting factors, including, protein, methionine, polyunsaturated fatty acids and other oxidant stressors, vitamin E, other trace elements, and heavy metals such as mercury, cadmium, and lead.

Dietary Intake

Food is the major source of selenium; drinking water contributes little. Dietary intake varies with the geographic source of foods and eating habits of the people. Plant food concentrations reflect selenium content of soils and its availability for uptake, as plants do not require selenium for growth; cereals and grains grown in soils poor or rich in selenium may vary over 100-fold in selenium content. Animal foods vary less. Fish and organ meats are the richest sources followed by muscle meats, cereals, grains, and dairy products, with fruits and vegetables mostly poor sources. Average daily dietary intakes vary considerably, depending on the levels of selenium in soils (**Table 1**), ranging from 10–20 μg of selenium in low soil-selenium areas of China where Keshan disease is endemic, 30–60 μg in New Zealand, and up to 200 μg

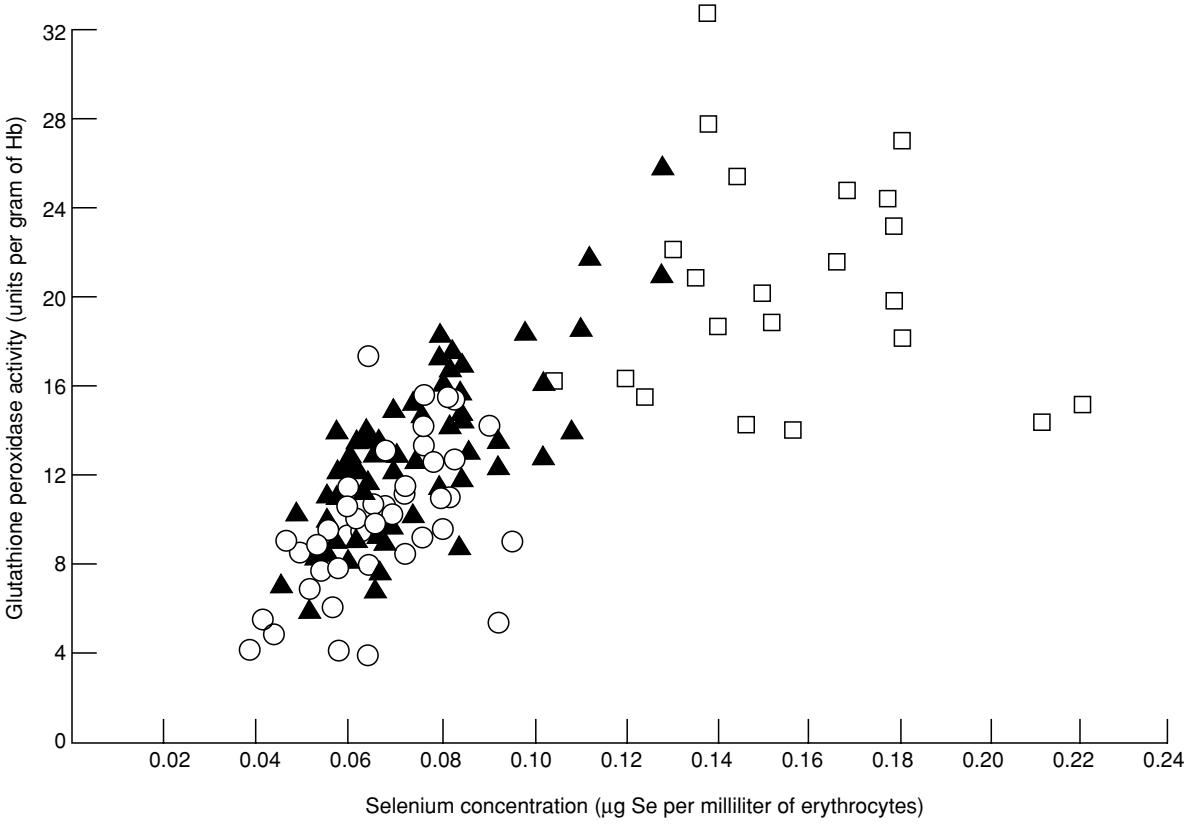

Figure 3 Relationship between selenium concentration of erythrocytes and glutathione peroxidase activities for New Zealand residents: Otago patients (○): Otago blood donors (▲) and overseas subjects (□). (To convert nanograms of Se per milliliter to micromoles per liter, multiply by 0.0127.) in seleniferous areas in Venezuela. In 1985, selenium was added to fertilizers in Finland to increase selenium intake throughout the population, and the daily intake rose from 40 μg to close to 100 μg per day, resulting in an increase in serum selenium in healthy individuals from 65–70 $\mu g\,l^{-1}$ in 1985 to 120 $\mu g\,l^{-1}$ in 1989–1991. In New Zealand, intakes are increasing due to increasing importation of Australian wheat, and selenium status is rising accordingly. However, this increase is greater than expected from the increase in wheat selenium, indicating that other dietary factors are involved. These differing intakes in various countries are reflected in the wide range of blood selenium concentrations found in residents of these countries (Figure 2).

Requirements and Recommended Dietary Allowances (RDAs)

Many countries have proposed recommended dietary intakes based upon estimates of requirements from Chinese intakes for endemic and nonendemic Keshan disease areas, as well as intakes at which maximal levels of plasma glutathione peroxidase activity occurred. The recommended dietary intake for Australia was the first set in the world in 1986 and may have been cautiously on the high side at 85 and 70 μg

Table 2 Recommended intakes of selenium for adults (μg/day)

	Australia (1990) RDI	*USA & Canada (2000) RDA*	*UK (1991)*		*Germany, Austria, Switzerland (2000) RNI*	*WHO*[a] *(1996) NR*
			LNRI	*RNI*		
Men	85	55	40	75	30–70	40
Women	70	55	40	60	30–70	30

selenium for Australian men and women. Others, including the recommended intakes of the USA, the UK, and other European countries, are summarized in Table 2. Each set of recommended intakes can be met from habitual diets in each country. Whether optimal health depends upon saturation of glutathione peroxidase activity has yet to be resolved, leading to disagreement regarding the use of this approach for assessing selenium requirements. The US RDAs are based on the desirability of the full activity of glutathione peroxidase, whereas a WHO group concluded that only two-thirds of the maximal activity was needed, based on the observation that abnormalities in metabolism of hydrogen peroxide in blood cells is apparent only when enzyme activity falls to one-quarter or less of normal. This has led to a wide range of dietary recommendations, with the WHO recommendations approaching intakes in countries with a naturally low selenium status such as New Zealand. In the future, several of the newly discovered selenoproteins might be used as endpoints for determining selenium requirements. However, the maximal activity of some of these proteins occurs at dietary intakes of selenium less than those needed for maximal glutathione peroxidase activity. This would no doubt lead to dietary recommendations lower than current values.

SENSORY EVALUATION

Contents

Sensory Characteristics of Human Foods

R York, Canadian Food Inspection Agency, Winnipeg, Manitoba, Canada
M Vaisey-Genser, The University of Manitoba, Winnipeg, Manitoba, Canada

Background

Satisfaction with the sensory features of foods and beverages is a major determinant of the consumer's nutritional status. If something does not taste 'good,' it is not likely to become part of the food habit. However, the colloquial term 'good' is a reflection of an integrated response to the several food features that are considered in detail in following sections. The present discussion is an introduction to sensory evaluation that focuses on its ongoing evolution as a discipline.

Definitions

Early work in sensory evaluation was referred to as organoleptic testing, a term that was discarded in the 1960s because it failed to recognize the complexity of the sensory impression. In 1975, the US Institute of Food Technologists defined the subject as a scientific discipline used to evoke, measure, analyze, and interpret reactions to those characteristics of foods and materials as they are perceived by the senses of sight, smell, taste, touch, and hearing. This definition has since been extended to include the purpose of providing information for decision-making with economic consequences. As the field increases in sophistication, the term 'sensory science' is becoming the descriptor of choice rather than sensory evaluation. The sequence and the strategy for sensory science measurements is illustrated in Figure 1.

Justification

Sensory measurements provide a unique resource of information for the evaluation of foods. Humans are sensitive and complex instruments capable of measuring and integrating simple and complex stimuli, repeating measurements after a brief resting stage, and differentiating relevant from irrelevant information. Accordingly, most physical tests for 'ideal' product characteristics are based on human definition. The results are reliable and repeatable as long as the test conditions are controlled.

History

Among sensory features, aroma seems to have captured major interest in early times, perhaps reflecting the importance of spices for foods and of other aromatics used in perfumes and oils. In 320 BCE (Before the Common Era), a treatise on odor was put forth by Theophrastus in Greece. That was followed by the occasional classic on the nature of smell capped by Linnaeus, odor classification, which appeared in 1756. Over time, the 'expert taster' became relied upon within specific commodities, most notably teas, wines, and other alcoholic beverages.

Sensory evaluation as we know it today stems from the attention to methodology that began in the latter part of the nineteenth century. This included methods as simple as the score card to monitor commodity quality and as sophisticated as the Weber–Fechner Law, which related the sensory response quantitatively with incremental changes in a physical stimulus. This spawned the discipline of psychophysics, a

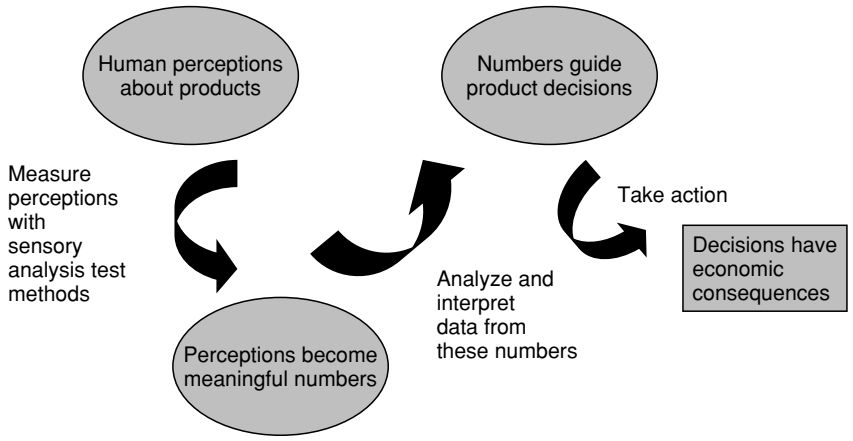

Figure 1 Sequence and strategy of sensory science measurements.

hybrid of psychology and physiology. The late nineteenth century saw the introduction of statistical methods for handling sensory data.

There were two sensory landmarks in the twentieth century: the development of statistically sturdy measurement methods and attention to the selection, training, and performance monitoring of sensory panelists. In the early 1930s, rating scales were developed to measure the intensity of specific food qualities such as the tenderness of meat, and concurrently, paired comparison and rank order methods were introduced. The early 1950s was marked by the introduction of the flavor profile system for the qualitative analysis of foods by the Arthur D. Little Company (ADL) in Massachusetts. ADL introduced training of selected members from an industry in the systematic 'descriptive analysis' of their products.

The mid-1950s saw further advances in statistical methods for both design and analysis as well as the launch in the USA of forced-choice methods such as duo–trio and the triangle test, which originated in the USA and Sweden, respectively. These tools are still widely used by industry for sensory testing in their quality control laboratories. A singular contribution from this era was the nine-point hedonic scale for measuring how much a food was liked or disliked. Developed by the food acceptance branch of the US Quartermaster Food and Container Institute in Chicago, this tool has been used far beyond its original purpose, which was to assist the development of more acceptable rations for the military. It remains a worldwide standard tool for food-preference measurement.

The momentum in sensory evaluation continued throughout the 1960s marked by three major events: (1) the 1961 formation of Committee E-18 within the American Society for Testing of Materials (ASTM), (2) the publication in 1963 of the Texture Profile Method by scientists at General Foods Corporation led by Alina Szczesniak, and (3) the 1965 Academic Press publication of *Principles of Sensory Evaluation of Food*, written by Amerine, Pangborn, and Roessler at the University of California in Davis, a book that promptly became a standard text. Further steps forward were the 1968 opening of the Monell Chemical Senses Center in Philadelphia to concentrate on basic research of the senses under the leadership of physiologist Morley Kare, and the 1969 introduction of the *Journal of Texture Studies*.

In the early 1970s, the International Organization for Standardization/Organization Internationale de Normalisation (ISO) formed a subcommittee, TC34/SC12, for Sensory Evaluation with the aim of having internationally agreed upon standards for sensory methodologies. This group currently includes representatives from 17 countries as members and 30 countries as observers.

During the 1970s and 1980s, newer methods of data handling erupted with the maturing of the computer age. Multivariate analyses became the norm, facilitating methods such as response surface and principal-component analyses. Communication worldwide was sparked by international symposia such as the Mediterranean Odor Conference in Cannes in 1970 followed by the later conferences in Switzerland, Sweden, and the UK. New journals such as 1974s *Chemical Senses and Flavor* (now *Chemical Senses*), and later, in 1986, the *Journal of Sensory Studies* emerged followed by *Food Quality and Preference* in 1988. The 1990s saw the formation of the Sensometrics Society for the development of the special methodologies and statistical methods, which were needed by the fields of sensory and consumer science.

By the 1990s, electronic mail encouraged speedy interaction among sensory scientists worldwide. Other tools continued to evolve. The beginning years of the twenty-first century are bringing intriguing tools such as the electronic nose to the challenge of sensory research.

Disciplines

Figure 2 describes the root disciplines involved in sensory evaluation together with those that have been most active in its applications. This picture confirms the interdisciplinary nature of the field. As each of these grows in sophistication, so does sensory science.

Some examples of the contributions of each of the basic areas are:

- *Psychology/Psychophysics*: the study of the laws of sensory perception, basic information on testing methodologies and the requirements for effective testing (from ballot design to sample presentation to testing protocols), sources of psychological error in sensory testing, the study of cognitive functions in the development, and use of terminology in sensory testing.
- *Physiology*: the functioning of the sensory systems, sources of physiological error in sensory testing.
- *Statistics*: the data analysis methods used to date and the development of new methods specific to sensory analysis.

Further examples from the applied areas include:

- *Home economics/food science*: applications of sensory analysis to the production of foods as basic commodities and in processed forms including product stability, product quality, consumer preference.
- *Chemistry*: the instrumental techniques for the analysis of foods and other products tested in sensory science.
- *Management/marketing*: methods for the assessment of consumer behavior.
- *Engineering*: the development of sensor-based technology in the forms of the electronic nose and the electronic tongue, and of neural networks.

Classifications of Areas of Sensory Testing

The most fundamental division of sensory measurement is determined by whether the subject is asked how they 'fit' relative to the stimulus or whether the subject is required to make an analytical judgement of the stimulus. This is given in sensory analysis by the terms subjective and objective testing (see Table 1). Answering a question using sensory analysis requires the development of a strategy for the approach, including the identification of the question that is really being asked and formulating an experimental plan to obtain appropriate data.

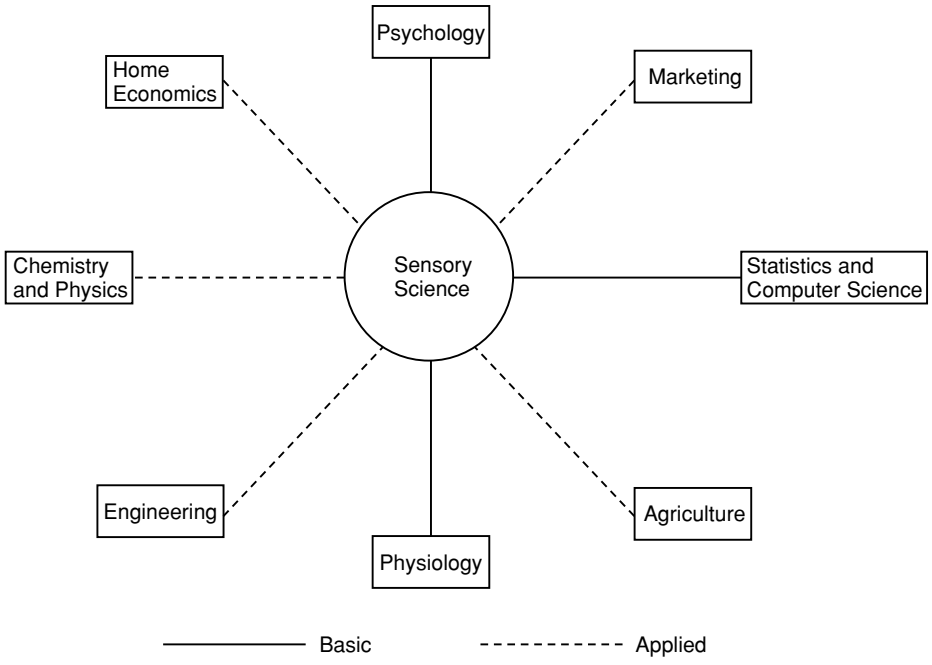

Figure 2 Disciplines contributing to sensory science.

Table 1 General characteristics of subjective *vs.* objective tests

	Subjective test	*Objective test*
Measures properties of:	Person (opinion)	Products (level or intensity of attribute)
Approach to test:	Emotional	Analytical
Assessor selected for:	Represents a population segment or a group with particular product experience	Demonstrated ability to perform sensory measurement tasks
Training level:	Untrained (naïve response)	Trained (educated response)
Number of assessors:	Many (30–50 for preliminary test, up to several hundred for final test)	Few (usually four to 10)
Performance evaluation of assessors:	No	Yes
Terms used on ballot:	Value judgements (like/dislike, good/bad, accept/reject)	Descriptive of phenomena (sweet, salty, red, tough, etc.)
Method described in early sensory evaluation literature as:	Organoleptic testing	Sensory analysis

Subjectivity and Objectivity

Subjective tests are those that evaluate the behavior of the assessor relative to the sample, i.e., they measure the opinion of a person who is using a product and are more commonly referred to as 'consumer tests.' They imply a response that is affected by personal bias, emotional background, etc., and describe the individual. These tests are not necessarily validated through demonstration of sensory ability. The term subjective is often incorrectly used to describe all sensory tests.

Objective tests are those that measure the presence and/or intensity of specific characteristics within a sample. These tests imply a response that is based on external phenomena or events, and the approach of the panelist is expected to be detached, impersonal, and unprejudiced. This term is used in sensory evaluation to define those tests that are based on demonstrated results with selected, trained judges appropriate to the test procedure.

Sensory test methodologies have been classified in different ways – by the overall purpose of sensory testing, by format of test methodologies, and by the type of primary 'tool' used, i.e., the type of sensory assessor.

For example, Michael O'Mahony in 1988 classifies the world of sensory evaluation into four types of testing, based on test function and experimental goals:

- Sensory Evaluation I: sensory evaluation used as a basic tool to study chemical and physical characteristics of food systems, e.g., a change in a flavoring would result in a change in a volatile chemical and thus a perceived change in odor. Judges are selected for sensory ability.
- Sensory Evaluation II: testing with consumers to measure the degree to which product changes can be detected by untrained assessors. Assessors can be trained in sensory methodology, but not in the product characteristic.
- Consumer testing: preference testing, etc.
- Sensory psychophysics: studies of testing methodologies and assessor sensitivities.

Several workers have used a classification system by the type of assessor chosen. In this classification, there are four basic types of assessors:

1. Naïve untrained assessors: consumer testing; used to measure subjective opinions about a sample.
2. Selected assessors trained for specific short-term tasks: laboratory tests for specific attributes; objective tests including the difference tests and the rating scales that measure specific product characteristics.
3. Descriptive analysis panels: groups selected and highly trained assessors that work as an expert group; objective procedure to evaluate specific products or product groups for complete ranges of product characteristics.
4. Expert assessors: selected, highly trained, and employed to work as individuals; objective testing of specific product or product group by an individual who has responsibility for the samples and the data about them.

Sensory Science and Psychophysics

Psychophysics defines those aspects of sensory science that include the way in which stimuli are perceived and the way in which they are measured. Some of the pioneering work in psychophysics was done by the psychologist L. L. Thurstone, mainly in the areas of psychology, but also in applications to food testing. Psychophysics itself has been defined as 'concerning the functional relationship between stimulus and response.' Work in this area includes not only the relationship between the perceived intensity and physical intensity of the stimulus, but also the ways in which judge sensitivity can change in test situations, the nature of language and terminology development

and its relationship to everyday language, and the development and processing of sensory concepts.

An example of the understanding this discipline provides is from the work by Stevens, which categorized sensory measurement as involving three parameters – the task undertaken by the assessor, the manner of the stimulus, and the statistical measure used to describe the data.

The task undertaken by the assessor was further defined by four groupings, which are generally accepted as defining the data collected in sensory testing:

1. Classification or nominal data: where the observer judges whether the stimulus is present or not. The data consist of meaningful categories that can be clearly differentiated. No numerical values are associated with the categories within this group – the data analysis includes frequency data only. One example of these data is given by the numbers on football jerseys – numerical handling of these data, e.g., a mean of the numbers, is meaningless.
2. Order or ordinal data: consisting of meaningful categories that can be clearly differentiated and placed in order of magnitude, e.g., greater or lesser of some defined characteristic, ranked data.
3. Interval data: involving judging the apparent difference between two or more perceptions and assigning values to the intensity of the perceptions using a continuum that is divided into apparently equal intervals.
4. Ratio or magnitude data: involving reporting the ratio of magnitude between two or more perceptions or the apparent magnitude of a perception.

Another example of the contribution of psychophysics is the development of a numerical expression of the relationship between the physical intensity of a stimulus to its perceived sensory intensity. This began with the Weber Fraction and Fechner's semilog relationship between these phenomena. This evolved into the development of Stevens' Power law as the basis for sensory work with the definition:

$$I = kS^n,$$

where I = perceived intensity; S = stimulus intensity; n = the exponent of the power function; k = a constant. Once this function was established, Stevens' Law offered useful predictive power for the study of sensory perception and the relation to other product attributes.

Work on the application of Thurstonian methods to sensory data analysis is currently underway through the activities of one of the ASTM E18 Subcommittees and will result in a standard for this application.

Sensory Science and Advancements in Methodology Development

Developments in data collection methodologies in the evolution of sensory science have included landmarks such as the nine-point hedonic scale, category scaling systems for descriptive analysis, the line scale method of Quantitative Descriptive Analysis, ratio scaling methods for both perception and preference, and the labeled magnitude scale, first developed for the study of pain perception and now applied to odor and taste measurements as well as to preference measurements.

Advances in sensory methodology have been enhanced by the recent advances in computer technology and the easy availability of both hardware and software for the complex analyses that are often required. This has provided sensory testing with a greater flexibility in data collection and analysis. The sensory laboratory is no longer limited to paper ballots and the more cumbersome manual handling of data. Laboratories can now be equipped with data acquisition hardware and software in the form of computer terminals that allow the ballots to be presented and recorded as data without requiring manual handling of the data. Other systems allow the collection of consumer information using telephone and internet formats.

Consumer testing has evolved greatly since its first uses in sensory science with the work of the US Quartermaster Corps and the evaluation of military rations. Part of this was the development of the nine-point hedonic scale and the application of this to preference testing. While this method is still used, the current work in this field now includes greater breadth in the considerations given to the information which is needed to make product decisions from consumer responses. This includes the interactions of preference with underlying sensory mechanisms and with various cultural experiences that cause preference to vary between different groups. These groups can be characterized by factors such as sensory acuity to particular stimuli and particular demographics such as age, cultural background, etc. This has led to the developments in methodology such as sensory segmentation, preference mapping, applications of advanced design methods such as conjoint analysis, and structural equation modeling.

The use of expert assessors has developed as well. Expert sensory panels for complex descriptive analysis have evolved in both training and application systems. The use of expert assessors in regulatory and industrial applications is well established and, in current practice, relies on the basic knowledge of sensory science methodologies.

Resources in Sensory Science

Sensory evaluation is currently recognized as an established discipline with courses and/or programs in many universities all over the world. Major international food corporations have units specializing in sensory analysis. Additionally, there are independent companies with facilities specializing in sensory applications and advice in different areas of application.

Two contemporary international events especially for sensory scientists are the Pangborn Sensory Science Symposium and meetings of the Sensometric Society, which are now scheduled for alternate years. Historical attendance at these meetings has been impressive, with 600 registrants for the 2001 Pangborn Symposium in France.

Publications are keys to communication in any discipline. *Chemoreception References* circulated by the European Chemoreception Research Organization since 1984 has proved to be a particularly valuable resource for sensory scientists. In 2002, the Sensometric Society chose *Food Quality and Preference* as its official journal. The primary criterion for acceptance for this journal is that the work include some form of human measurement. Standards for, and information on, testing methodology have been developed by the ISO and ASTM and can be ordered through their respective websites.

Conclusion

Sensory evaluation is a good example of an interdisciplinary success. Its maturation has been relatively rapid in the history of science, due to the strong leadership provided by imaginative researchers spanning a range of traditional and applied disciplines. Its evolution continues in all areas in which human perceptions are used to evaluate food and other products.

Food Acceptability and Sensory Evaluation

J M Murray, Quest International Australia, Smithfield, Australia
I A Baxter, Food Science Australia, North Ryde, Australia

Background

Food acceptability is affected by many factors, which may be related to the individual, the food, or the environment in which the food is consumed. Acceptability is a subjective measure based on hedonics

(pleasure), which in turn is influenced by the sensory properties of the food, previous exposure to it and subsequent expectations, contextual factors, an individual's culture, physiological status (i.e., hunger, thirst, and presence/absence of illness), and many other variables. The measurement of food acceptance is highly complex and relies on psychometrics (scales) and/or behavioral models (food-choice models). This article aims to discuss some innate factors that impact on foods' sensory acceptability and how these can be measured and understood using sensory evaluation.

Food Properties and Sensory Acceptability

The acceptability of a food in sensory terms is influenced by the intrinsic properties it possesses, that is, the appearance, aroma, flavor, texture, aftertaste, and auditory attributes of the food. The interaction between these variables is also an important consideration, and the manifestation of sensory attributes can be affected by factors such as temperature, portion size, and so on.

Appearance of a food provides cues regarding its acceptability, e.g., indicating freshness or lack of (the turgid appearance of lettuce, the wrinkled skin of an apple that is past its best, the appearance of green mold on cheese), ripeness (greening in tomatoes), or skill in preparation (e.g., absence of burning, absence of lumps in mashed potato). Color affects acceptability, influencing taste thresholds, taste perception, expected food pleasantness, and acceptability. For example, certain colors are associated with particular flavors so that a yellow sweet may taste 'sour' as it is associated with lemons, and foods that are intensely colored may be perceived as more intense in flavor.

Aroma suggests the flavor to be expected when eating foods and thereby influences acceptance. Volatile compounds are generally responsible for aroma and vary from one food to another; for example, brussel sprouts are rich in volatile sulfurous compounds that contribute to their characteristic odor and flavor, thus influencing acceptance among many consumers. Aroma is also a good indicator of the freshness of a product; think of yourself sniffing a carton of milk to check the freshness before using it. In this respect, aroma can also be regarded as a 'defense mechanism,' by providing the consumer with information about the safety of a food prior to consumption.

Flavor is frequently regarded as the most influential attribute for sensory acceptance, and perception of flavor is a complex process involving the sense of smell, taste, and chemesthesis. A distinction is often made between the terms 'taste' and 'flavor.' The former refers to the four basic tastes, sweet, sour, salty, and bitter (a fifth, umami has also been proposed), and the latter refers to a combination of 'taste' and 'aroma,' with the volatile components of the food mainly contributing to the overall perception. Other sensations such as 'chilli burn,' perceived by the trigeminal nerve, and the 'cooling' sensation of foods such as mints contribute to the overall flavor.

The acceptability of a 'flavor sensation' changes throughout life, and genetic components have been proposed for sensitivity to certain bitter compounds, e.g., phenylthiocarbamide (PTC) and 6-*n*-propylthiouracil (PROP), with consumption of bitter-tasting foods being inversely related to sensitivity. Humans are born with particular taste preferences, indicated by newborns whose facial expressions show a preference for sweet, indifference to salt, and negative reactions to bitter flavors. Evidence suggests that these are innate responses, whilst throughout the development of a child to adulthood, a combination of innate and learned responses determine food acceptability. Aging has a diminishing effect on our taste and aroma thresholds and the ability to differentiate particular flavors, and thus ultimately influences acceptability. Cultural differences in the perception of flavor have also been suggested but have yet to be proved. Flavor perception and release has been the subject of a vast amount of research in the last 10 years and is influenced very much by the food matrix and individual characteristics of the consumer (e.g., rate of saliva production in the mouth). The interaction between flavor and texture is vitally important, with the perception of a flavor changing, depending on the texture of the food. For example, the same amount of cheese flavor on a hard and crunchy corn chip will be released and perceived differently to that on a puffed (extruded) chip.

Texture is perceived by the senses of sight (visual texture), touch (tactile texture), and sound (auditory texture), and its contribution to overall food quality can be relatively simple (a cup of coffee, puréed soup) or complex (steak, potato chip). Consumers use texture information for classifying foods, but they do not normally volunteer comments on texture, unless it is definitely different from the consumers' expectation, it has been suggested that texture awareness is usually on the subconscious level, with awareness heightened only when expectations are violated, or nonfood associations are triggered. Auditory texture in some foods is critical for overall acceptability: dried breakfast cereals that do not snap, crackle, and pop, cola that does not fizz, or snacks that do not crunch would lose their inherent identity and acceptability. The

acoustic properties of foods are also reliable indicators of freshness; imagine an apple that did not crunch when first bitten.

Visual texture contributes significantly to overall acceptability and suggests the texture to be perceived upon consumption. Visual texture can suggest the freshness of the food; for example, a cut slice of cake may look moist or dry and thus may be perceived as stale or fresh. Tactile texture perceived upon consumption is related to the food matrix and size and shape of the food being consumed. Mouthfeel characteristics (which can be, for example, viscosity-, carbonation-, or body-related) impact significantly on acceptance depending on the food, and factors such as melting are vital attributes for categories of food such as icecream and chocolate. The perception of texture is dependent mainly on the teeth and masticatory musculature. Infants are able to consume only liquids until the musculature has developed sufficiently to allow them to ingest semiliquid (puréed) foods. The development of teeth affords children the ability to deal with foods that need biting, tearing, and chewing. In adulthood, most texture challenges can be dealt with, but ageing and the subsequent decline in the quality of dentition and musclature impact on the acceptability of certain textures.

The manifestation of sensory properties can also be affected by factors such as the temperature and portion size, and thus influence perception and acceptability. Changes in temperature can alter the viscosity of a sauce (and thus the texture sensation). The perception of the basic tastes can also be altered: a cold, sweetened beverage is perceived to be less sweet as the tongue is cooled, but as the temperature of the drink rises, the tongue is not cooled, and the drink's sweetness seems to increase. The amount of food placed in the mouth also affects perception: flavor may be perceived as more intense when a larger piece of food is eaten, and less intense with a smaller portion.

Determining Acceptability by Sensory Evaluation

Many complex variables of the food interact with the consumer to influence sensory acceptability, and as such, objective measurement of sensory acceptability proves difficult. However, there is an increasing requirement to understand and measure sensory preferences *reliably* within the food industry. As the focus of most food manufacturers' product development, quality assurance, and formulation efforts, it is vital to ensure that the results of these sensory tests are valid. Attention must therefore be paid to the type of outcomes required from the test, the design of the experiment, sources of bias in sensory evaluation, and the use of appropriate participants. Today, there are a number of approaches that can be used for eliciting both qualitative and quantitative information relating to foods sensory properties and their subsequent acceptability. These range from simple, 'I like it, I don't like it' tests, to complex modeling procedures that uncover sensory reasons for preference and relate these to the physical and chemical properties of the food. Both qualitative and quantitative techniques are described below for measurement of sensory acceptability.

Hedonic Testing

Hedonic trials are performed in order to obtain quantified information on, for example, how much people like a product or how much a new prototype is preferred over the others. They are conducted with large representative samples of the population and encompass both preference and acceptability tests.

Preference Tests

The most commonly employed preference test is the *Paired Preference test*, which is used when one wants to examine the preference of one product directly against a second, as in the case of product improvements, or determine parity or preference over a competitive brand. Participants in a paired preference test receive two samples simultaneously, and the panelist is asked to identify the sample that is preferred. The major advantage of this test is that it is simple, and participants can easily grasp the task. The *Nonforced Preference test* is identical to that described above, except that it allows a no-preference option. This can yield valuable insights into the consumer's state of mind, as there may be participants who genuinely do not have any preference; however, this option does complicate the analysis, the power of the test is decreased, and it can give some consumers an 'easy way out,' as they do not have to, and do not, make a choice. In the case of *Preference ranking tests*, consumers are asked to rank several products in either descending or ascending order of preference or liking. The advantage of this test is, again, that it is intuitively simple for the consumer and can be conducted quickly and with very little effort, but the data from different sets of overlapping products cannot be compared. Visual and tactile rankings are normally quite straightforward, but multiflavor and taste comparisons can be fatiguing.

Acceptability Tests

Acceptability tests still investigate liking for products but do not provide a direct comparison of liking over

other products. The most common acceptability scale is the nine-point hedonic scale, which has labeled categories for indicating a level of like or dislike. The advantages of this scale is that it is simple and easy to use, with a reportedly high level of reliability and stability independent of region and, to some extent, panel size. The neutral 'neither like or dislike' category is a valid response for some consumers, although some do show 'end use avoidance,' where the participants avoid using the extremes of the scale. This serves as a warning to those who may be tempted to truncate the scale further to seven or even five points. Hedonic measurements can also be achieved using scales such as smiley faces, but the pictures may be distracting to the participant, and the results often prove unreliable. Acceptability ratings may also be given on unstructured line scales, anchored by a like or dislike at each end, and magnitude estimation scales have also been proposed for the measurement of food acceptability. Variations on acceptability scaling include the just-right scale, which measures the desirability of a specific attribute, e.g., a scale may be anchored with 'not sweet enough' at the left, 'just right' in the center, and 'much too sweet' at the right. However, as consumers must have a consensus as to the understanding of the attribute in question, the use of this scale is often confined to a few simple attributes that are widely understood. The analysis of this scale can also pose some problems, and the assumption is made that the population is homogenous when in fact there may be two or more consumer segments that prefer different levels of the attribute(s) in question.

Preference Mapping: Internal

Internal preference mapping is based solely on the acceptability information gained from hedonic tests (commonly the nine-point hedonic scale) and provides a multidimensional representation of the samples and the position of consumers in relation to the samples. It provides an illustration of the consumer samples likes and dislikes, and the intensity of these, and additionally allows a visual segmentation of the samples likes and dislikes to be made. An internal preference map may be derived by multivariate statistical techniques such as principal-components analysis and is relatively straightforward to interpret. However, one potential limitation of this method is that it assumes that sensory perception is equal over all consumers and that differences in the rating assigned to products are due to varying preferences and not differences in perception. Figure 1 illustrates an internal preference map for eight cheeses; the further a consumer is from the center of the plot, the more discriminatory their evaluation was. From the plot, we can determine that

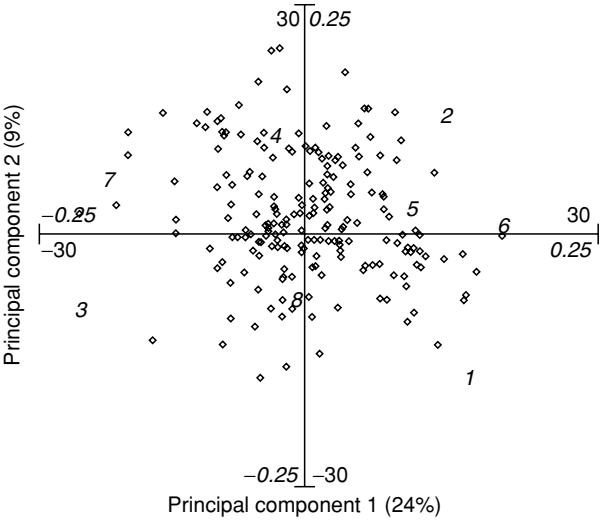

Figure 1 Internal preference map illustrating consumer preference for cheeses (consumers are represented by dots, and products are represented by numbers).

cheese 3 was the least liked, and cheese 8 was most liked.

Whilst an invaluable part of determining food sensory acceptability and preference, hedonic tests and their representation by internal preference mapping give no indication of why a product is liked and thus are sometimes combined with other sensory tests, such as a descriptive sensory analysis in a procedure known as *External Preference Mapping*, or analytical information, such as that obtained from gas chromatography–mass spectrometry experiments.

Preference Mapping: External

The technique of external preference mapping (PREFMAP) requires an objective characterization of products' sensory attributes, achieved by descriptive sensory analysis (conducted using qualified and trained panelists), which is then related to hedonic acceptability ratings for the product obtained from a representative sample of consumers. Descriptive sensory analysis has been recommended as the most appropriate sensory tool to provide the sensory attribute measures, because there is no prior knowledge concerning the most important sensory characteristics. Statistical modeling of the data, using techniques such as response surface analysis or partial least-squares regression, allows the complex nature of the relationships between consumer preference data and descriptive data to be established.

There are a number of models/approaches that can be used for external preference mapping. The most simple of these is the vectorial model, which operates on the assumption that 'more of attribute X is better'.

In practice, this model has obvious limitations as liking for a product attribute will increase until the point of maximum pleasantness (the 'bliss point'), beyond which an increasing intensity may begin to impact negatively on acceptability. The ideal point model, which is more complex, identifies the optimum combination of product attributes ('X and Y are ideal') for maximum liking and assumes that some products have too much of an attribute, and some products have too little. This technique is useful for market researchers who are involved in new product development and trying to identify gaps in the market place (i.e., the map can indicate consumer groups whose preferences are not currently met by any of the products on the market place). Less commonly used and more complex models used for external preference mapping include the elliptical ideal point model, and the elliptical ideal point model with rotation.

Consumers are inherently complex, and thus attempting to describe consumer behavior using a limited number of models is difficult, with a large number of consumers who are not explained by the resultant maps. To overcome this problem, the AUTOFIT model was developed, which selected the most acceptable model for each consumer, with some consumers fitted by the vectorial model, some by the ideal point model, and so on. However, this method results in 30–50% of consumers still not being explained in the analysis and has obvious limitations. The question of discarding consumers for the reason that they do not 'fit' the analysis has also been debated and should be considered carefully.

Preference mapping can also be combined with segmentation techniques, such as cluster analysis. These analyses are conducted prior to creating the external preference map, and the scores assigned by each of the consumer segments input into the analysis. This allows consumers with similar preference behavior to be identified. An example of an external preference map for Cheddar cheese, using clustering, is illustrated in Figure 2. In this trial, few consumers liked the light cheese, which was perceived as 'bitter' and 'rubbery.' Some consumers (cluster 4) liked premium and vegetarian cheese, whose preference appeared to be driven by a 'buttery' flavor and 'smooth' texture. The map also illustrates consumer needs not met by the products currently on the market. One group of consumers (cluster 5) would prefer sweeter and more caramel-like cheese.

In general, these statistical modeling techniques have brought a wealth of information about product liking; however, some practical considerations are worthy of mention here. At present, at least six products must be used in the external analysis, and all consumers must assess all products, as missing values

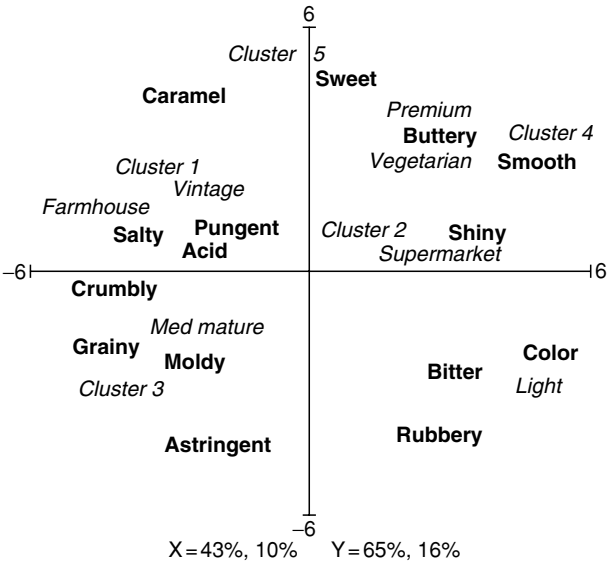

Figure 2 External preference map illustrating consumer clusters' preference for cheeses and their associated sensory attributes.

cannot be accounted for. The sample range must also be considered, and their properties in the context of each other evaluated. The reliability of the preference map result is dependent on the quality of the external (trained panel) data, and often it is necessary to weight all attributes equally (standardise), as some attributes that are highly discriminating (e.g., color) can skew the analysis. Whilst most commonly used to understand sensory preference, preference mapping can also be used to understand physical or chemical reasons for consumer preference. Finally, when choosing a modeling method, it is worthwhile to remember a commonly used rule of thumb: '80% of the modeling benefit comes from the first 20% of model complexity.'

Overall, preference mapping is increasingly being used within the food industry as a tool to reduce the risk of failure in new product development, increase liking, and secure market share for existing products.

Focus Groups

Focus groups are an increasingly common method for eliciting qualitative information about foods' sensory properties and how these may relate to food acceptability. The group should be a carefully planned session designed to obtain the maximum amount of relevant information on the product/attribute of interest. A moderator skilled in consumer research and the nuances of group dynamics should coordinate the effort to ensure that the result is a balanced and informative representation of all the participants' views. The information from focus groups is often

used as a starting point in sensory research and can be used as the basis for developing sensory questionnaires/tests in order to elicit quantitative acceptability information about products.

Repertory Grid Method

Individual or one-to-one interviews are an alternative method for eliciting qualitative information about products' sensory attributes and acceptability in situations where group dynamics, are perceived to be a problem. The repertory grid method (RGM), which has its origins in the field of psychology, is now commonly used to collect qualitative sensory data on product attributes and acceptability. The interviewer should be trained and familiar with the method in order to ensure that the maximum amount of product information is gained. Products are presented to the interviewee in triads (groups of three), and the interviewee is subsequently asked to describe the similarities and differences between the products in terms of their sensory properties. When no more attributes can be generated, the next triad of products is evaluated. The proposed advantage of RGM is that the continually changing frame of reference to which the participant is exposed allows a greater insight into the details and intricacies of the product attributes than simply asking the participant to 'describe the sensory properties of this product.' The qualitative information gained from this procedure is often used as the basis for quantitative research, for example in free-choice profiling studies (discussed below) or for further sensory questionnaires/tests.

Free-choice Profiling

Free-choice profiling (FCP) is a variation of descriptive sensory analysis and can also be combined with acceptability information to ultimately determine foods sensory acceptability. FCP allows consumers to generate their own terms to describe product perceptions, as in the case of descriptive sensory analysis and PREFMAP; the information can then be related to hedonic measurements, thus allowing an understanding of the sensory attributes driving acceptability.

Generally, for the attribute elicitation stage, a method such as RGM is used to maximize the amount of information gained. Once the vocabulary of attributes to use has been decided upon, participants score products for the attributes on line scales. In addition, consumers rate the acceptability of the product. The attribute data are then analyzed by a procedure known as generalized procrustes analysis (GPA). Through stages of translation, scaling, and rotation/reflection, the GPA adjusts for several sources of variation, such as assessors using different levels and ranges of the measurement scales. The resulting plots demonstrate consumer perceptions of products, which are then further analyzed in conjunction with the hedonic data in order to determine reasons for consumer preference. Figure 3 illustrates children's preference for the sensory attributes of vegetables. Children used FCP and generated individual vocabularies to describe vegetables and rated these attributes on line scales. In addition, they were also asked to rate the acceptability of the vegetables. Sensory attribute data were then analyzed by GPA, and the subsequently identified consensus attributes were then correlated with the first two preference dimensions of an internal preference map (produced using the acceptability data). Vegetables perceived as 'big' and 'hard,' such as cauliflower were least liked whilst those perceived as 'soft' and 'small' were most liked.

The advantage of using FCP to determine acceptability is that the descriptive sensory measurements (conducted using highly qualified panellists who can be expensive to maintain) are not required. Participants need only to be able to use a scale and be consumers of the product under evaluation. It also provides a more 'consumer orientated' opinion on the products. However, sometimes, the handling of individual ballots for each participant in an FCP study can prove time-consuming, and the interpretation of the results by the sensory analyst can also be challenging. Although, ultimately, the attribute information is not as discriminatory as that obtained from a trained panel, FCP measurements when related to hedonic information in this way provide valuable acceptability information about product sensory attributes.

Future Role of Sensory Evaluation in Determining Food Acceptability

The area of sensory evaluation and its role in determining food acceptability have increased rapidly and will continue to do so for many years to come. The use of validated statistical models will increasingly allow the results of sensory tests (such as FCP, descriptive analysis, time–intensity flavor evaluations) to be related to hedonic measurements of acceptability, uncovering not just the 'what is liked' but the 'why.' Reverse control modeling, which allows a feedback loop to be established between chemical/physical, sensory, and acceptability data will be used increasingly to understand product acceptability. The integration of the sensory analyst into both the technical and marketing departments of organizations will extend further the boundaries of the sensory science discipline. Already, we have research that

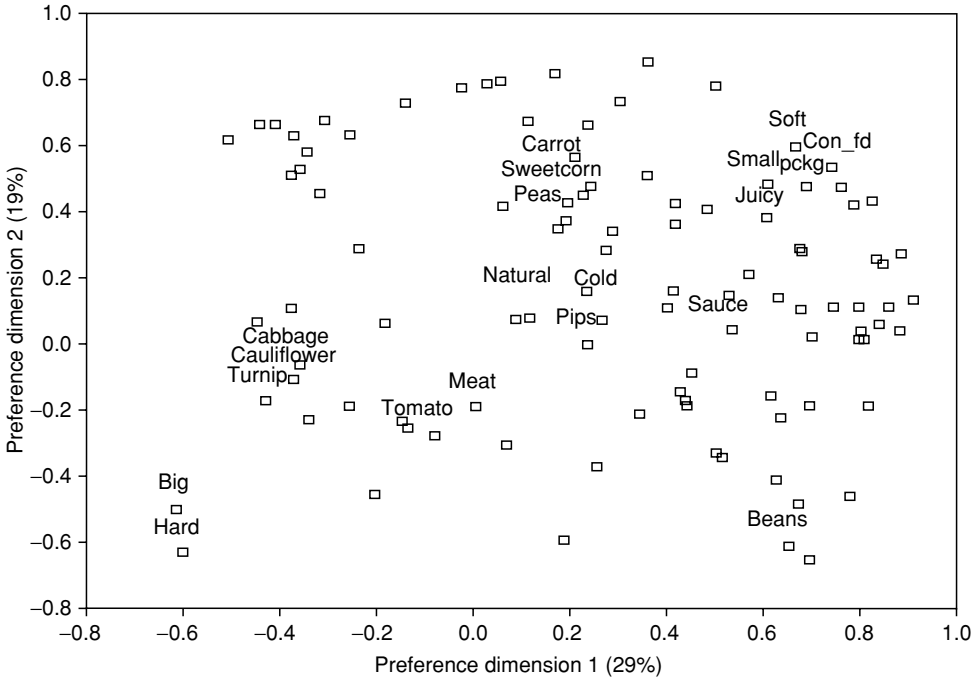

Figure 3 Plot illustrating children's preference for the sensory attributes of vegetables, obtained through correlation of consensus attributes (identified by generalized procrustes analysis) with the first two preference dimensions of an internal preference map (consumers are identified by squares).

illustrates how generated product concepts 'fit' the sensory characteristics of products, and how these may be matched better. Such techniques will be used increasingly in order to minimize risk in an increasingly competitive and global food industry.

Practical Considerations

E Chambers and B McGuire, Kansas State University, Manhattan, KS, USA

Background

Many of the most common applications of sensory analysis are in the consumer goods industries. For those purposes, the basic aim of sensory analysis is

to provide information about how the sensory characteristics of products, ingredients, or other related information and services are related to perceived quality characteristics and consumer liking. How do you make a peanut butter 'creamier' or a facial tissue 'softer'? How do you describe the fragrance of a fine perfume? How easy is it to push the pump on a spray deodorant? When does a potato chip start to taste 'stale'? These are just some examples of what sensory analysis can do.

Setting Objectives

Given numerous applications of sensory analysis, the practical considerations associated with effective testing must begin with the objectives. In short, what information is needed, or 'What do you want to know?'

Consider the following hypothetical situation. You own an icecream company. Your supplier of vanilla tells you to expect a substantial increase in price. You do not want to make consumers pay more for your icecream, so you find a different provider at a lower price. Your biggest concern is providing the same great flavor to your consumers. Therefore, an initial question is: 'If the new vanilla is used, can people distinguish between the products?' or 'If I use the new vanilla flavor, do I still have a great product?'

A key practical consideration is to realize that those two questions are fundamentally different. The first question is an issue of difference; the second is an issue of liking or preference. If you decide that people should not be able to detect any difference in the product, you have set a very different criteria than if you determine that the product can taste different as long as consumers like the new product as much as, or more than, current product.

Part of setting the objectives in a sensory test is risk management. Every person who will buy the product will not be asked to test the product (see section Resource Management); nor will it be tested in every situation in which people eat icecream. You have to identify an objective and select a test protocol that addresses how much risk you are willing to accept. If you want to be especially sure that a consumer will not find any differences in the icecream, you need to specify that in the objective and use a large population of people who are able to discriminate differences in icecream. If you just want to be pretty sure that you still have a good icecream that will be acceptable to the average user, specify this objective and test a population of typical users to make sure that the icecream still scores high in acceptance.

Deciding on the objective(s) of the sensory test *and* getting everyone to agree on the objective(s) is the first practical consideration in sensory testing. If this is done poorly, the rest of the test may be meaningless. If the objectives are set correctly, and everyone has agreed in advance, the test and the reporting of results will be much easier.

Resource Management

The next practical consideration in sensory testing is managing the test to provide the key information in a cost-effective, timely way. Although it is possible to conduct sensory studies in many ways, the best ways will be those that provide appropriate answers to key questions as quickly as possible using the minimum amount of resources. It is very easy to overplan or overconduct studies. Commonly, tests are conducted that either are not required or that try to answer too many questions simultaneously.

If we go back to the icecream company, an initial question might be, 'Is there an obvious difference if we change to the new vanilla?' If there is, then difference testing is a waste of time. Initial benchtop screening can help to answer those questions. Although lab personnel and other employees are not representative of the typical user population, they can be a cost-effective way to initially screen products to determine whether further testing is needed.

If the company decides, after benchtop screening, that testing is needed, an appropriate test is required. While it might be nice and interesting to find every consumer of our icecream and ask them to taste the two samples, such an enormous study would make little sense from the perspective of cost or time and would provide no information that we cannot gain from a smaller more focused study. It would be a huge waste of resources to ignore the practical issues of resource management.

Sampling

Another key practical consideration is sampling of the population. It is important that participants in sensory test are the people we really need to answer the questions. Caution must be exercised that the testers do not have biases that would affect their testing. Thus, the first step in obtaining a group of people who are representative of the product's consumers is acknowledging that employees of the company often do not meet these criteria. The potential biases, both good and bad, that employees may bring about their companies products often disqualify them from making a real assessment of the quality of the product. Although employees provide a cheap and

convenient source of people to test, and may be suitable for a screening test, their views should not be used as a final decision-maker when deciding what consumers really think about the product(s) in question.

For descriptive sensory tests, the appropriate people are those who have a good ability to sense attributes and have been trained in some way to describe what they are testing. Panelists trained to have a common vocabulary make the task of translating sensory perceptions into meaningful information for product scientists much easier.

Consumers usually are screened to help assess their potential to represent either potential users or current users of the product. Screening questions may include: age, gender, product related behaviors (e.g., use in the past 3 months), or attitudinal and other factors that help to identify people who are likely to use, or do use, the product or other products in the category.

There is no 'magic' minimum number of consumers required for any specific consumer test. The number of respondents should be large enough to be representative of the consumer population and to provide the statistical power needed to differentiate the products. This is a fine balance. The tendency is to test too few people 'to control costs' or to test too many people 'just to be sure.' Historical information on the consumer population, often obtained from marketing or purchase data, and information on statistical variability can help to determine the number of consumers for the test that balances resources and risk management.

The second major part of sampling is the product. The range of products or samples tested can have an impact on the test. For example, testing a high-fat vanilla icecream with a reduced calorie vanilla icecream will result in different sensory scores than testing the high-fat product against other similar high-fat products. In the end, the results obtained from testing are dependent on the samples evaluated.

The second major concern in product sampling is making sure that the product being tested represents the product that actually is manufactured. Too often, incorrect conclusions are drawn from a test because 'early prototypes' (that is, samples that are different from the actual final product) are used in the test, for example, testing a product from one manufacturing plant when three plants product the product using different equipment and ingredients suppliers, or when products have been mishandled. In those and similar cases, the products in the test are not representative of the product that consumers actually see when they 'purchase off the shelf.' If the product does not really represent 'the product,' the test results are meaningless.

Issues associated with sampling are critical practical considerations in sensory testing. Ensuring that the right product is tested and that the correct population of people tests the product are essential to providing actionable data.

Analysis and Reporting

Time and resources are limited, finite properties. Within this context, the use of appropriate analysis and reporting is the essence of practical considerations for sensory analysis. Proper analysis and appropriate reporting of well-conducted studies provide timely information that is actionable and concise.

The use of appropriate data analysis is an extension of the first practical consideration – clear objectives. 'How is this analysis related to the specific objectives?' is a question that should precede all statistical applications. One advantage of basing analysis and reporting on specific objectives is that it refines the scope of analysis that is appropriate. For example, analysis of results from common difference tests may require only the use of standard tables, whereas analysis of results for data that attempt to 'explain' liking data on the basis of descriptive sensory properties is more complex. Appropriate analysis concludes with obtaining all findings that are directly relevant to the stated objectives.

At the end of almost every study, people want three basic questions answered: 'What did we learn?', 'Why is this information important?', and 'How can we use this information?' In reality, after testing is complete, and the data have been analyzed, some findings are not as important as originally thought, some will require further investigation, and some may provide several possible courses of action. Within this context, quality reporting, whether written or oral, provides specific, concise answers with supporting details when needed. Reporting that leads the audience to wonder 'so what?' is misguided and will be ineffective. Further, quality reporting does not mean that everyone is happy with the answers: it means that everyone is clear on what the answers are, the relative confidence in these answers, and how they are actionable.

The basic purpose of a report is to communicate information related to specific goals. Thus, clarity and brevity are key considerations in appropriate reporting. If the relevance of the information presented cannot be clearly understood by the reader or listener, the value of the work will not be maximized. Further, acknowledgement that people have a finite attention span is key to effective communication, especially for complex sensory information. This emphasizes the importance of stating key findings early

so that the audience can focus on the meaning of the information presented.

Sensory analysis can answer a wide range of different questions provided that practical considerations such as clear objectives, resource management, appropriate sampling, and efficient analysis and reporting are used effectively. Without those key considerations, any sensory testing is likely to be misguided and wasteful. The following examples have been provided to illustrate how these common themes apply to the different areas of sensory analysis.

Do You Want to Know if Consumers can Distinguish Products?

Consider the following hypothetical situation. You own an icecream company. Your provider of sweetener tells you to expect a substantial increase in price. You do not want to make consumers pay more for your icecream, so you find a different provider at a lower price. Your biggest concern is providing the same great flavor to your consumers. Therefore, an initial question is: 'If the new sweetener is used, can people distinguish between the products?'

There are numerous tests that can be used for this purpose, collectively referred to as discrimination or difference tests. Difference tests do not answer the question 'How much consumers like a product?' or 'How are these products different?' Difference tests answer one simple question, 'Can people distinguish samples?'

Difference tests often test 30 or more known discriminators in order to determine whether differences that are found can be attributed to random variability or are product-based. Both the analysis and reporting for these tests are straightforward. Simple, test specific tables (often based on binomial distributions) are available to determine the likelihood that the difference between the samples is product-based. A concise way to report these findings is to state the percentage of people who could distinguish the products, followed by the likelihood (a statistical p-value) that this difference can be attributed to random variability. For example, results might be summarized as 'In the paired difference test, 51% (24 out of 47) selected the different sample, which is less than the number required to find a significant ($p = 0.05$) difference in the products. This suggests that consumers will not perceive icecream with the new sweetener as different.'

Are You Interested in Exploring Consumer's perceptions?

Again, let us imagine that you own the icecream company, but now you are interested in understanding more about how your product is packaged. Your main competitor uses different colors and a different shape, and some consumers have noted that their package is more 'exciting' and 'appealing.' You are interested in knowing the specific characteristics of the package that are related to how 'eye-catching' the product is. What are the key factors – the color, the material, the shape, the advertising on the product?

Focus groups or one-on-one interviews are effective for initially exploring consumers' perceptions. This research is described as qualitative because the objective is to answer the questions, 'What is important to consumers and why?', instead of quantifying 'how much.' Qualitative consumer research allows for in-depth discussion of consumers' attitudes and perceptions.

As with any technique, the first step is using qualitative methods to define the specific objective. The fundamental challenge of qualitative research is to obtain relevant information from the consumer. Given this, it is essential to develop a guide of how the conversation (discussion) with the consumer will proceed that will lead them to provide answers to issues but will not bias their response. A well-prepared guide is an important asset in managing resources and obtaining the desired information and is more than just an outline. It can provide the interviewer or moderator with transitional statements between topics, anticipate potential problem areas, and provide ideas for 'follow-up' questions.

In qualitative consumer research, acknowledging possible factors that may bias the sampling is important. Because the basic purpose of qualitative research is to better understand consumers ideas, any influence that causes an inconsistency between what consumers communicate and what they actually believe may lead to inaccurate conclusions being made. There are many potential sources of bias, including: the facility used, the attitude of the moderator, how questions are asked, and the interaction among participants. Effective focus groups, for example, generally involve a comfortable, distraction-free room, with the discussion led by a moderator, who promotes an environment in which all participants feel comfortable expressing and discussing their ideas and opinions.

Because of the nature of qualitative research, analysis and reporting of findings are different than with quantitative data. An effective way to analyze qualitative data is to begin by reviewing all discussion and finding 'common themes' that are related directly to the objectives. For each theme, specific comments from as many people as possible that illustrate these

themes are noted. For reporting, the use of bulleted points outlining the themes with some illustrative quotes can be a concise, effective way to present findings.

Do You Want to Estimate How Much Consumers Like Products?

Now, consider the situation: same icecream company, only now you would like to sell more icecream. You decide that a 'fruity raspberry' icecream is the best new product because consumers like the flavor, and your main competitor is having success with a similar product. In short, you want a 'fruity raspberry' icecream that consumers like more than your main competitor's. You produce a small amount of a new 'fruity raspberry' icecream, but how do you determine how much consumers like it?

This objective requires a quantitative consumer acceptance test. Consumer acceptance testing is a generic phrase that describes a group of different methods for estimating how much consumers like products. In acceptance tests, consumers generally evaluate multiple samples and are asked questions including: overall liking and liking of basic product characteristics (for example, sweetness, creaminess, or raspberry flavor).

One important key to using acceptance tests is to ask questions that are directly related to the specific objectives of the test and to include the products that are necessary. Because testing can be expensive, clarity of objectives is important because cost constraints likely will limit the number of consumers who can be tested or the number of questions that can be asked. For example, in addition to overall liking, is it important to obtain feedback on the overall flavor, specific flavors, color, texture, aroma, meltdown? Since one of the goals of this example is to determine whether the product is liked more than the competitor, samples that represent the competitors' product(s) are a prerequisite for testing.

Keep the questions simple. Consumers generally do not have the level of interest or attention that people who work with the product every day have. For these reasons, their willingness to think about confusing issues, or respond to complex questions, may be limited. If consumers do not understand the question, or interpret a question in different ways, the results are unlikely to be an accurate measure of the characteristics that the questions were intended to answer.

It is crucial that the participants in an acceptance test are representative of the larger consumer population. One of the best ways to ensure this is to test only people who have been identified as potential consumers of the products. In general, a consumer acceptance test will collect responses from at least 100 consumers, but the actual number is dependent largely on the decision being considered and may range into the hundreds or, on rare occasions, into the thousands.

Although the analysis of acceptance tests is more complex than difference testing, the emphasis on addressing the specific objectives and brevity is no less important. In this case, reporting the mean liking scores and comparing the company's new product with that of the competition is usually the main area of emphasis. If the new product does not score highly, a review of the other consumer data is essential to understand why.

Do You Want to Describe and Measure the Sensory Properties of a Product?

Let us use the icecream company one last time. You are receiving complaints that your vanilla icecream has a 'funny,' 'off,' or 'bad' flavor. You attempt to have consumers provide a more specific description of the flavor, but they are unable to do this. That is not surprising; consumers are great at communicating what they like or dislike, but they are not as good at describing why. Descriptive sensory analysis, using highly trained assessors, is more appropriate for this task because those assessors are able to reduce complex perceptions that often involve multiple senses into simpler senses that can be defined and measured.

In our example, you have determined that the icecream is close to, but not past, the 'best if used by' date. You are concerned that the shelf-life of the product may be too long, but you need a better description of the flavor and its intensity during storage.

Product orientation and the use of appropriate methods are important resource-management tools in descriptive sensory testing. Allowing the panelists to work briefly with products similar to what they will test allows the panelists to become oriented with the product and helps you and the panelists decide on the best way to evaluate the products. Specific methods and scales that are used for descriptive sensory analysis are described extensively in the literature and are dependent on the product being tested and the objectives of the study.

Appropriate analysis and reporting for descriptive sensory analysis again are dependent on the objectives. The objective of the sample study would be to provide information on how the sensory properties of the products are changing as storage time increases. Thus, a chart that tracks changes in specific attributes over time is a simple, effective method for evaluating the changes.

Conclusion

Sensory analysis integrates many different sciences to understand better the sensory properties of products and consumer response to these properties. Because sensory analysis has a broad range of applications, start with the basic questions: 'What do you want to know?', 'What resources are available?', 'Who needs to conduct the test?', 'What products will you use?', and finally, 'What answers do you need?' Answering these questions will lead you to a consideration of the practical aspects of conducting any sensory study.

Sensory Difference Testing

B Rousseau, The Institute for Perception, Davis, CA, USA

Introduction

This article describes our current knowledge on the topic of sensory discrimination testing. The general objectives of the commonly called 'difference tests' are first emphasized, the main objective being the scaling of sensory magnitudes. Then, the traditionally encountered discrimination protocols are described in terms of the nature of the instructions given to the subject. The common data analysis based on binomial tables and its limitations are mentioned. An approach based on an index of perceptual differences, called d' and pronounced 'd prime,' is introduced. It is shown how the results using this index are consistent across methods. A comparison of the power of the traditional discrimination tests is presented, showing which tests are less likely to fail to detect nonnegligible sensory differences between food products.

The field of sensory evaluation has been commonly divided into three categories: sensory discrimination testing, descriptive analysis, and hedonic studies. The sensory discrimination tests are traditionally used to investigate whether two food samples can be perceived as significantly different by a group of panelists. Descriptive analysis will provide qualitative information regarding the difference among food samples, by focusing on particular sensory attributes inherent to the products under study. Hedonic testing will be used in order to study the acceptance and preference of food samples by consumers.

Discrimination testing is sometimes considered as a straightforward data collection method, with results providing useful but limited information. One will use a difference test in order to determine whether the sensory characteristics of two samples, for instance a standard product and its reformulation, can be distinguished. Assuming that a proper experimental design is used, the similarity or difference of the two products will be concluded. However, this reasoning can appear unsatisfactory. It could be easily argued that two products with different physical and chemical characteristic will never be perceived as identical. If a large enough sample size is used, any sensory difference will be detected.

This brings us to the notion which will be used in the present article. Instead of merely answering the question: 'Are my products the same or different?,' we will show how discrimination test results can be

used as a tool to answer the following question: 'How large is the sensory difference between my products?' These results will permit the scaling of sensory magnitudes and sensory differences, information thought until now to be provided only through the use of rating methods.

Traditional Protocols Used in Discrimination Testing

There is no limitation on the number of different discrimination tests that can be used to study sensory differences. The list which will be given here is not exhaustive, and alternative discrimination methods can easily be created. The issue is then to develop the proper model to conduct statistical analyses.

The discrimination protocols can be classified into two main categories: those that require the nature of the sensory difference to be specified in the instructions and those that do not.

The protocols described here will be illustrated by the comparison of two cookies *A* and *B*, *B* being slightly sweeter than *A*. The samples are presented blind, and no other difference (visual, textural, temperature) is assumed to be present. A subject will perform several tests in succession, or a group of subjects will perform one test each. From the results of the test, the similarity of the difference between the two samples will be concluded with a given level of confidence, depending on the sample size (number of tests) involved in the comparison.

Directional Difference Tests

These methods require the nature of the difference to be specified in the instructions. Table 1 gives details for each method.

The chance probability represents the probability of getting the answer right if the subject cannot discriminate between the products. For the sorting protocols, it is important to keep in mind the fatiguing nature of food samples and the memory requirements that might significantly hinder subjects' performance. These tasks are best suited to textural and visual investigations.

Nondirectional Difference Tests

Those are the most commonly used methods in sensory discrimination testing, even if their statistical power can be up to 100 times inferior to that of the directional difference tests (Table 2).

Traditional Data Analyses

The traditional way of analyzing data extracted from difference tests involves no consideration of the psychological processes occurring at the time a response is generated. This is what is called a response-based analysis. The information obtained from this rather limited statistical analysis is either 'Yes, the products are different,' or 'No, they are not different.' No information is obtained regarding the size of the sensory difference. This can yield inconsistent results and this issue will be discussed later.

Table 1 Directional difference tests

Test	*Number of samples*	*Instructions*	*Chance probability*
2-AFC	Pairs of samples: *A*: 1, *B*: 1	 Find the sweeter cookie	1/2
3-AFC	Triads of samples: *A*: 2, *B*: 1 or *A*: 1, *B*: 2	 Find the sweetest cookie or  Find the least sweet cookie	1/3
A/Not *A*	Single sample: *A* or *B*	 Is it *A* or is it Not *A* (*B*)?	1/2
Sorting	*n* samples: *A*: $n-p$, *B*: p	Find the p sweetest samples	$\frac{p!(n-p)!}{n!}$

AFC; alternative forced choice.

Table 2 Nondirectional difference tests

Test	*Number of samples*	*Instructions*	*Chance probability*
Triangle	Triads of samples: *A*: 2, *B*: 1 or *A*: 1, *B*: 2	 Find the different sample	1/3
Duo–trio	Triads of samples: Reference: *A* and *A*: 1, *B*: 1 or Reference: *B* and *A*: 1, *B*: 1	 Find the sample more similar to the reference	1/2
Same–different	Pairs of sample: *AA*, *BB*, or *AB*	 Are the samples the same or different?	1/2
p-out-of-*n*	*n* samples: *A*: $n-p$, *B*: p	Make one group of $n-p$ similar samples and one group of p similar samples	If n is odd: $\frac{p!\,(n-p)!}{n!}$ If n is even: $2\times\frac{p!\,(n-p)!}{n!}$

In discrimination testing, one is concerned with two types of error. The first one is the type I error: concluding that the products were significantly different while they were not. The second is the type II error: failing to detect an existing sensory difference. Statistical tests are conducted at a particular α level, usually 0.05, describing the type I error. An α level of 0.05 means that we have only a 5% chance of concluding that the products were different while they were not. For the type II error, described by the parameter β, the level used is usually 0.2 or 0.1. The statistical power of the test is defined by: Power $=1-\beta$. A power of 80% implies that a test has 80% chance of detecting a difference of a given size. The issue of power will be discussed later.

Binomial Analysis

For a given protocol, the number of correct tests is compared to the number that would be expected by chance. This type of model is called a guessing model. It assumes that if the subject cannot discriminate between the samples, he or she will pick a sample or an answer randomly. We are testing the H_0 hypothesis that the two products are identical. If rejected, we will accept the H_1 hypothesis that the products are different. For instance, if a study with 20 tests was run using the two-alternative forced choice (2-AFC) protocol and 14 were performed correctly, this result would be compared to an expected chance result of 10. Tables have been published indicating the minimum number of tests correct for a given sample size to be significant at a given α level, usually 0.05. In our example, to be significant at the 5% level, we would need 15 tests correct. Therefore, we cannot conclude that the two cookies were significantly different. We cannot reject H_0.

It is critical to be aware that we are not concluding that the cookies are the same. We can only conclude that they are not different. Had we used a larger sample size, we might have obtained a significant result. In order to accept H_0, it is necessary to consider the power of the test.

χ^2 Analysis

This analysis is traditionally used with tests yielding results in a contingency table, such as the *A*/Not *A* and same–different tests. An example of a contingency table is shown in Table 3. A study between

Table 3 Results of a same–different test conducted with 100 consumers

Presentation	*Response*	
	'Different'	*'Same'*
Same	20	30
Different	35	15

the two cookies *A* and *B* was conducted with 100 consumers, each getting either a different pair (*AB* or *BA*) or an identical pair (*AA* or *BB*).

A χ^2 value can be calculated and we find that $\chi^2 = 9.1$. Looking in a table for the significance of χ^2, we find that a χ^2 of 9.1 and 1 degree of freedom is significant at the 1% level.

Therefore, here we can reject the null hypothesis H_0 and conclude that the products are different.

Taking into Account the Degree of Difference Between the Products: Thurstonian Models

The data analyses discussed above only provide one type of information from discrimination testing: 'Are my products significantly different or not?' We never mentioned the magnitude of the difference between the products. Was it a large difference or a small difference? How does it compare to results from previous studies? In order to answer these questions, it is necessary to introduce new notions, such as an index of perceptual difference, called d'. We are first going to show why it is essential to consider this index when comparing products.

Insufficiency of the Guessing Model: The Paradox of Discriminatory Nondiscriminators

It has been reported numerous times in the literature that, while using the same subjects and the same products, the null hypothesis could be rejected using some protocols but not others. The most illustrious example is the result discrepancy between the 3-AFC and triangle tests. While the two tests have the same design and only very slightly different instructions, subjects' performance is significantly greater in the 3-AFC than in the triangle test. With a 3-AFC test, it might be concluded that the products are significantly different, while we would not be able to reach that conclusion with the triangle test. Which result is right? Or are the two methods giving two versions of the same information, i.e., the magnitude of the difference between the two products? With the triangle test, nonnegligible sensory differences might not be detected because of insufficient statistical power. This might result in the release of reformulated products in the marketplace that will be rejected by consumers.

These experimental results underscore the insufficiency of relying on the number of correct answers in a given test to determine how different two products are. It is essential to take into consideration two very important aspects of sensory evaluation: variability and behavior. These aspects are taken into account in Thurstonian modeling.

Thurstonian Models

These models are very similar to those encountered in the field of psychology and discussed in signal detection theory.

Thurstonian modeling assumptions

Variability Let's take our sweet cookie example again. The idea behind perception variability is that, when tasting the same cookie several times, the perceived sweetness will not always be the same. On average it will have a certain intensity, but at any given moment, the perceived intensity can be slightly stronger or slightly weaker (Figure 1). Several reasons can explain these variations: first, there is always some random noise in the nervous system due to the spontaneous firing of nerves. Second, the number of compounds binding with the sweet receptors can be slightly different each time. Third, there might be variation in the cookie itself: the sweet compounds might not be evenly distributed on the cookie, or the subject might take bites of slightly different sizes every time.

The likelihood of each sweetness magnitude occurring for the cookie can be represented by a distribution. This distribution is usually assumed to be normal, even though alternative models have been published using other types of distributions. Figure 2 illustrates this concept. The height of the distribution at each intensity level represents the likelihood of this intensity occurring in a given tasting. The intensity at the mean of the distribution is the most likely. The further away the intensity is from the mean, higher or lower, the less likely it is to occur.

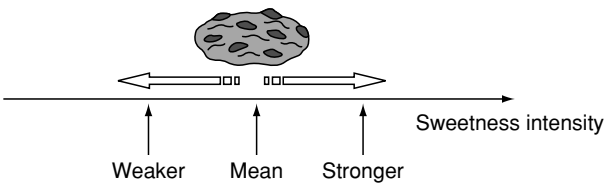

Figure 1 Representation of variable sweetness intensities for a cookie.

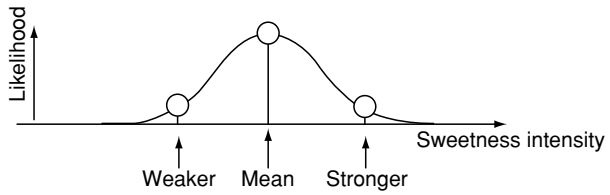

Figure 2 Normal representation of the likelihood of sweetness perception.

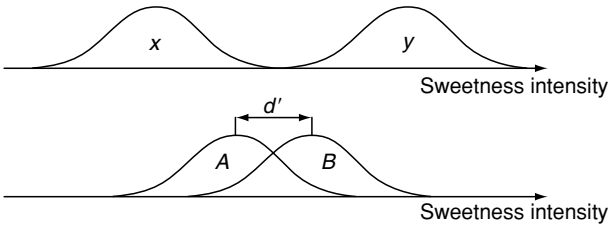

Figure 3 Thurstonian representation of two products differing in sweetness.

When performing a discrimination test, the two products to be compared can be represented by two normal distributions. This is shown in Figure 3.

In the top picture, product *Y* is always sweeter than product *X*. In this situation test, a subject will always get 100% tests correct in a difference test. Discrimination testing is not even necessary in this case; *X* and *Y* are totally discriminable. In the bottom picture, there is some overlap between the two distributions. Overall, *B* is sweeter than *A* and will be perceived as such most of the time, but on some occasions, *B* will be perceived as less sweet than *A*. This will happen when the *B* intensity is on the lower part of its distribution and the *A* intensity is on the higher part of the distribution. The measure of the extent of the overlap is called d' and is the distance between the means of the two distributions measured in terms of their standard deviation. A d' of 1 means that the two distributions are 1 standard deviation apart. The bigger the d', the more different the products. A d' of 0 means that the products are undistinguishable. N.B.: a d' of 1 corresponds to 76% tests correct in a 2-AFC test. In psychophysics, this would correspond to the definition of a detection threshold.

We now have an index measuring the magnitude of a difference, something we did not have when using the guessing model. Let's see now how we can obtain a d' value when using discrimination tests. For this, we need to take into account the behavioral aspect of discrimination testing, namely the decision rule, or cognitive strategy, used by the subject when performing a discrimination test.

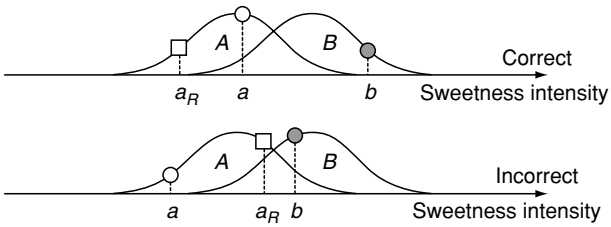

Figure 4 Correct and incorrect answers in a duo–trio test. Square, reference; circle, alternative sample.

Behavior The guessing model assumes that subjects make mistakes when they cannot tell the difference between the products and make a wrong guess about the answer. We will see that this is not how incorrect answers arise.

Duo–trio example Let's imagine that a subject performs a duo–trio test between two cookies *A* and *B*, the less sweet cookie, *A*, being the reference. A trial is described in Figure 4.

In the top picture, the subject tasted the reference and perceived a sweetness on the left-hand side of the distribution (a_R). He then tasted the two alternative samples and perceived the *a* and *b* sensations. When asked which of the two is more similar to the reference, he will choose *a*, since it is closer to a_R. His answer will be correct.

In the bottom picture, we can see that the sensations perceived will yield an incorrect answer. This time, *b* is closer to a_R than *a* is, thus the subject will pick *b* as more similar and his answer will be wrong, even if he gave the right answer based on the sensations perceived. We see that the error was not made because the subject guessed, but because the perceived sensations happened to be in such locations that a wrong answer was generated.

Over repeated trials, the top situation will occur more often than the bottom one, resulting in the measure of a d' value and the conclusion that the products are different.

The d' values can easily be calculated from discrimination test results. Tables have been published that provide the correspondence between d' and proportion of correct answers for the most traditionally used protocols.

Main cognitive strategies For each discrimination protocol, a subject will use a specific cognitive strategy. The two main cognitive strategies are the comparison of distances strategy and skimming strategy. Figure 5 illustrates these two decision rules with the triangle and 3-AFC tests.

Figure 5 represents a triadic test where two *A* and one *B* samples were presented. In the triangle test, the

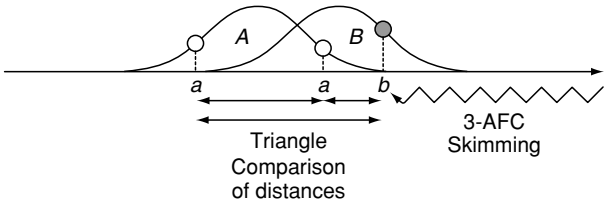

Figure 5 Comparison of distances and skimming strategies in the triangle and three-alternative forced choice (3-AFC) tests.

subject will compare the distances to determine which of the three samples is most different from the other two. We see that the subject will select the *A* sample furthest left and his answer will be recorded as incorrect. For the 3-AFC, the subject needs only to select the sample with the largest magnitude. Therefore he will pick the *B* sample (most intense) and his answer will be recorded as correct. This example illustrates why subjects' performance will be lower in the triangle than in the 3-AFC test.

We can generalize this example to the other protocols described earlier. For directional discrimination tests (*m*-AFC tests), subjects will use a skimming strategy. For the nondirectional protocols (triangle, duo–trio), subjects will use a comparison of distances strategy. The *A*/Not *A* and same–different tests use alternative strategies, since the instructions require the use of a psychological criterion (How strong does a sample need to taste before I call it '*A*'? How different do two samples need to taste before I call them 'Different'?) The *A*/Not *A* test has a strategy analogous to a skimming strategy, while the same–different test has a strategy analogous to a comparison of distances strategy.

Protocols with a skimming strategy are statistically more powerful, i.e., not as likely to fail to detect a nonnegligible difference as a test using a comparison of distances. This was illustrated earlier with the triangle and 3-AFC tests.

When using d' values, results from discrimination tests now become independent of the protocol used. This is what we would predict, as discrimination tests are merely an instrument to measure product differences. Simply calculating the proportion of tests correct and using the binomial test will provide bias and unstable information.

Practical aspects of Thurstonian modeling Now that we have ways of measuring a degree of difference between food products, we need to set up the experimental parameters that will allow us to detect it accurately. This brings us to the issue of power.

Power In order to define the power of a test, we need to decide what degree of difference we want to be able to detect. This will require some general knowledge of the magnitude of the difference that usually needs to be detected and can be determined using past data and converting them in terms of d' values. The power of a test can be illustrated by calculating the sample size needed to detect a given d' with a given confidence. The smaller the sample size required, the more powerful the test. Equations have been published providing the sample size needed for a given d' value, α level, and power. Tables can be constructed and an example is shown in Table 4.

Table 4 Sample size required to detect a given degree of difference (d') for given α and power levels and discrimination protocol

d'	α	*Power*	*2-AFC*	*Duo–trio*	*3-AFC*	*Triangle*
0.5	5%	0.8	78	3092	64	2742
1.0	5%	0.8	20	225	15	197
1.5	5%	0.8	9	55	6	47
0.5	1%	0.8	128	5021	103	4441
1.0	1%	0.8	34	366	25	318
1.5	1%	0.8	16	91	11	76
0.5	5%	0.9	108	4283	89	3810
1.0	5%	0.9	27	310	21	276
1.5	5%	0.9	12	76	9	66
0.5	1%	0.9	165	6511	135	5776
1.0	1%	0.9	43	473	32	416
1.5	1%	0.9	20	117	14	100

AFC, alternative forced choice.

Here is the way to read the table. For the 2-AFC, first line: if we run 78 tests and detect a significant difference at the 5% level, we are 95% sure that a difference exists between the products. If we do not detect a significant difference at the 5% level, we are 80% sure that the d' was less than 0.5. In order to reach the same confidence level for the duo–trio, 3-AFC, and triangle tests, we need a sample size of 3092, 64, and 2742 respectively. These variations in sample size indicate the larger power of the protocols using the skimming strategy.

The same–different and *A*/Not *A* tests cannot be included in this table because of the issue of response bias. A power value would need to be calculated for each criterion location and size. However, as a general rule, the same–different test is slightly more powerful than the triangle and duo–trio tests but less powerful than the 2- and 3-AFC tests, while the power of the *A*/Not *A* test is closer to that of the 2-AFC test. N.B.: power tables have been published using the proportion of discriminators in the population. This notion is flawed (it is directly linked to the proportion of correct answers, which we've seen is not a reliable measure of the degree of difference between products) and such tables should be used with extreme caution.

The power of a test is also shown in the calculated variance of d': the more powerful the test, the smaller the variance of d'. This variance is very useful when comparing several d' values (for instance, when comparing a standard to several reformulations) in order to determine whether they are significantly different from each other.

Replicated testing Considering the sample sizes required for the duo–trio and triangle tests, it would be more suitable to use the 2- or 3-AFC protocols. If it is impossible to use the directional difference tests, the power of the triangle and duo–trio tests can be somewhat increased by replicating the number of tests per subject. However, combining data from different subjects brings the issue of overdispersion. References in the Further Reading section at the end of this chapter should be consulted in order to insure accurate data analysis.

Experimental variables Under certain conditions, d' values obtained from discrimination tests may not correspond exactly. This may be due to the effect of experimental variables such as memory and sequence/adaptation effects which are not considered in the models. Since a larger d' value requires a smaller sample size to be detected, it may be beneficial to use protocols providing larger d' values. Experimentally, it has been found that memory requirements can significantly hinder subjects' performance and thus product discrimination. Under certain conditions, tests with only two samples (2-AFC, same–different) have been found more sensitive (higher d' value) than those with more stimuli (3-AFC, triangle).

This aspect of difference testing should also be considered when selecting a protocol to conduct a discrimination study.

Conclusion

For an unaware scientist, the topic of discrimination testing can be perceived as deceptively simple and limited. However, we showed here that proper knowledge from psychology, physiology, and statistics is necessary in order to insure proper data collection and analysis. Furthermore, discrimination testing can provide very valuable information by not limiting the information to a mere yes/no answer regarding the existence of a difference. This can be achieved by calculating d' values and their variances from widely available tables, and by determining the magnitude of the difference between the samples.

This chapter summarized the scope of this topic. The reader is advised to refer to the review articles cited at the end of this section in order to build a more general knowledge about the topic of discrimination testing.

We still need to mention that the concepts of sensory magnitudes and d' values are not limited to sensory difference tests and that they can easily be extended to ratings on category scales and consumer preference and hedonic data. This approach is extremely useful for sensory science since it allows the connection of all kinds of sensory measurements in a common structural framework.

Purpose of Rating and Scoring Methods

Rating and scoring methods provide the basis for quantification of sensory information. Although these two terms are sometimes used interchangeably by sensory scientists, they have different meanings.

Rating refers to the quantification of information by the use of ordinal categories, while scoring is a more defined form of rating as it uses a numerical interval or a ratio scale, of which the properties are known. A scale can be defined as a measurement continuum divided into successive units according to the properties associated with it.

There are many different rating and scoring methods used in sensory analysis, as illustrated both here and in other articles. In each case, these scales are physical measurement tools used to measure some sensory phenomenon perceived by individuals. Thus, implicit in using rating and scoring is that these scales provide meaningful representations of some psychological process or processes.

When considering rating and scoring methods, the reader should be aware that the experimental design considerations given to sensory analysis procedures should be observed. In this article, example forms are given with the illustrations of different scales to aid the reader in designing appropriate questionnaires.

Type of Scale

Four types of scale can be used to collect data: nominal scales, ordinal scales, interval scales, and ratio scales.

Nominal Scale

A nominal scale is one where data collected are categorized by a name or a number. Each observation collected using these scales must fall within one of the categories. For example, 'canned,' 'frozen,' 'dried,' 'chilled,' and 'fresh' are five categories used to describe methods of food preservation. These categories have no logical ordering and, thus, the key point about nominal scales is that the different categories have no quantitative relationship.

Ordinal Scale

An ordinal scale is one which allows observations to be ordered according to whether they have more or less of a particular attribute. Successive numbers or words are used to indicate more (or less) of the attribute being measured. Ordinal scales do not allow the amount of difference between observations to be quantified. The nine-point hedonic scale (described later) is ordinal, as are ranked data.

Interval Scale

An interval scale is one where the distance between points on the scale is quantifiable. In many instances, the distance or intervals between points on a scale will represent an equal perceptual distance. For example, if the perceptual distance between 1 and 2 on a seven-point scale of sweetness was the same perceptual distance as between 2 and 3, 3 and 4, and so on, then this scale would have interval properties.

Ratio Scale

A ratio scale is one where the observations collected can be expressed as a percentage or ratio of each other. For example, a person eating 100 g of chocolate a day eats twice as much as a person eating 50 g day^{-1}. An example of a ratio scale in sensory analysis is magnitude estimation, which will be discussed later. The main difference between interval and ratio scales is that the latter has a true zero, whereas the zero point of an interval scale is arbitrary.

Data Collection Methods and Data Analysis

Nominal Data

Nominal data can be collected in a number of ways (Figure 1), but common to all nominal data is that each observation can only fall into one category. A logical first step in analysis and interpretation of the data, therefore, is to produce a histogram indicating

Please taste the sample coded 457, and identify which of the four basic tastes you perceive.

Sweet _____
Sour _____
Salt _____
Bitter _____
Unable to Identify _____

Please taste the sample coded 943, and rate the sweetness intensity by placing a tick in the appropriate box below.

Not sweet	Slightly sweet	Moderately sweet	Very sweet	Extremely sweet

Figure 3 Evaluation of the taste attribute sweet, using a verbal category scale.

the frequency of occurrence of each category. The next step is to determine whether more observations fall in one category than another, or if the distribution of counts for one sample is the same as for another. In either case, the usual method of analysis is by the χ^2 (chi-squared) test.

A more advanced method for treating nominal data is the technique of multiple correspondence analysis. This method produces a multidimensional spatial representation of the relationship between samples and attributes, which is often a useful summary of the data.

Please taste the sample coded 183, and indicate how much you like or dislike the flavor by placing a tick by the appropriate descriptor.

_____ Like extremely
_____ Like very much
_____ Like moderately
_____ Like slightly
_____ Neither like nor dislike
_____ Dislike slightly
_____ Dislike moderately
_____ Dislike very much
_____ Dislike extremely

Rating Methods

Rating methods involve the quantification of perceived sensations by the use of scales.

Category scales Category scales are widely used in sensory analysis, both for objective assessment and affective (related to preference or liking) response. Category scales for objective sensory measurement are most often unipolar, as it is the amount of a particular attribute which is being measured. An example of a unipolar scale for firmness is given in Figure 2. A category scale may also be constructed such that each category has a verbal label attached to it, as illustrated in Figure 3. Bipolar scales can be used to measure attributes such as texture, e.g., substitute the two anchors of Figure 2 with 'soft' and 'firm,' respectively. While these scales give the appearance of having interval properties, care should be taken in making this assumption without experimental evidence. Generally speaking, category scales provide ratings and not scores; thus, category scales provide ordinal data.

A well-known scale for affective measurement is the nine-point hedonic scale (Figure 4). Variations of this rating scale exist, comprising fewer categories and the absence of the middle category.

Continuous line scales Continuous line or visual analog scales take the form of an unstructured line, as illustrated in Figure 5. Such scales are usually unipolar and measure the two extremes of an attribute, the extremes of which are represented as anchor points at the left and right of the scale. The length of the line is often 100 mm, although this may be longer or shorter according to need. However, research conducted by both psychologists and market researchers has indicated that 100 mm is satisfactory. A line that is too short may decrease the discrimination achievable by the assessors, while beyond a particular length it is unlikely that an assessor will provide more precise information.

Continuous line scales are often used with trained sensory panels as they allow the assessor to be more discriminating than with the category scale. Data collected on rating scales are measured by an interval ruler; however, strictly speaking the data should be considered ordinal, as it is usually impossible to prove

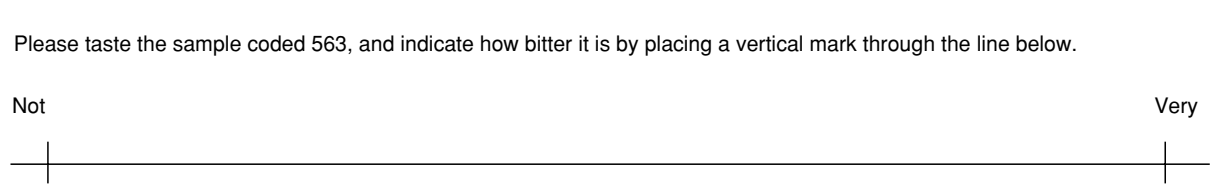

Figure 5 Evaluation of the taste attribute bitter, using a continuous line scale.

the linear (interval) properties of every continuous line scale used for sensory measurement.

With a trained sensory panel, continuous line scales are usually assumed to be linear with the understanding that the extremes of the scale may be slightly curved due to end effects. If continuous line scales were truly interval, then the data would be scores rather than ratings. It would be unwise, however, to make this assumption with an untrained panel or a consumer panel without justification.

Data analysis Data that have interval properties can be analyzed using parametric statistical methods, providing certain assumptions are satisfied. These methods assume that the data are normally distributed, which implies a symmetric distribution (i.e., the mean, median, and mode are equal) and that the data have interval or ratio properties. Parametric methods of analysis are powerful methods for sensory interval data as they enable more precise interpretation to be made of the results. There is a wide range of statistical methods available for interval data, depending on the question being asked. The simplest form of analysis is to calculate means and standard deviations, which measure the location and spread of the data, respectively.

This can be taken one step further by calculation of a standard error and confidence interval for the mean. This allows the sensory analyst to make inferences about the mean of a sample with respect to the attribute being measured, or to test a hypothesis that the mean is equal to a particular value. *t*-tests can be used to test the hypothesis that two samples have different mean values for a particular attribute, while analysis of variance will test whether more than two samples have different mean values.

When several attributes are being evaluated, multivariate analysis procedures are often adopted. Techniques that can be used include principal component analysis (PCA), generalized Procrustes analysis, factor analysis, discriminant analysis, canonical variate analysis, and cluster analysis.

Whilst data collected by rating methods are mostly ordinal, it is a common practice to use the univariate parametric statistical methods discussed. However, these methods assume that the data are derived from an underlying normal distribution, which assumes that the data are continuous, i.e., they have interval or ratio properties. Clearly, by definition, ordinal data cannot be continuous. In fact, for each of the above-mentioned parametric statistics there is a nonparametric equivalent. These are medians (means), interquartile ranges (standard deviations), Mann–Whitney *U*-test and Wilcoxon paired test (*t*-tests), and the Kruskal–Wallis and Friedman rank test (analysis of variance).

Multivariate analysis on ordinal data can be achieved through correspondence analysis (CA), which reduces the dimensionality (number of measured attributes) to a smaller number of dimensions, which effectively describes the correspondence between samples and attributes. However, there is little evidence to suggest that CA is better than PCA for sensory profile data collected on ordinal scales.

Magnitude estimation

Method Magnitude estimation is a form of ratio scaling where the perception of a specified attribute in one sample is measured as a ratio of the perception of that attribute in another sample. Stevens introduced this method in 1953, and one of its first applications in sensory analysis was to evaluate pleasantness of odors.

There are two main methods of collecting ratio data by this method. In the first method, one sample is designated the standard and allocated a whole positive (not zero) number (e.g., 100) to present the perception of a specified attribute. The perception of this attribute in subsequent samples is represented as a fraction or multiple of the standard number. For example, if the sample evaluated is twice as sweet as the standard then it is allocated the value 200, if it is a quarter as sweet than it is allocated the value 25. It is often recommended that the standard sample should be one-third of the way along in the range of samples to be used in the experiment.

In the second method, the assessor allocates a positive (not zero) number to the first sample, and evaluates the perception of that attribute in subsequent samples as a ratio of the first sample. Whichever approach is adopted, magnitude estimation usually requires more training than the other methods of

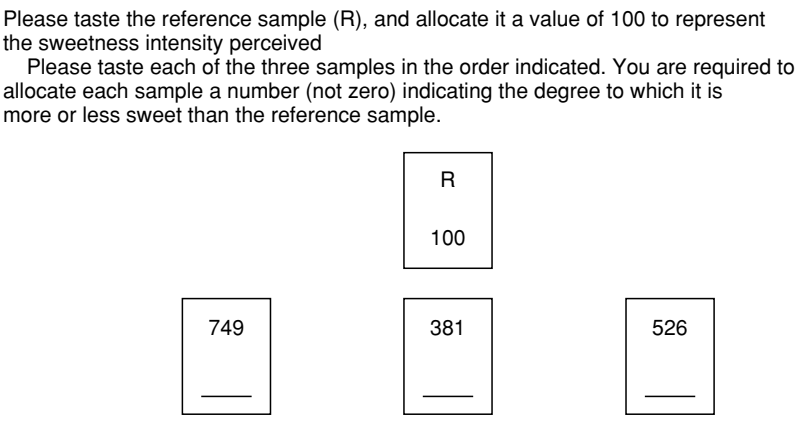

Figure 6 Flavor assessment by magnitude estimation, where 100 represents the reference against which other samples are evaluated.

data collection. An example of a magnitude estimation form is given in Figure 6.

Data analysis Data collected on a ratio scale, by magnitude estimation, require additional thought as they have to be transformed before analysis. In considering data analysis, it is important to recall that the data are ratios for each individual. Further, as each individual may have used his or her own range within the ratio scale, the distribution of the data will differ from individual to individual. It is also likely that if an individual's data are plotted, the shape of the distribution of data about the standard sample will differ for each subject. Thus, not only are there scaling problems to contend with, but there is also inconsistency in the distributional plot of the data. For these reasons, individual data cannot be assumed to come from a normal distribution, and further direct averaging of data would be misleading due to the scaling problems. Thus, data are transformed to insure that each individual has, in effect, used the same scale. Several methods can be used to rescale magnitude estimation data: modules equalization, modulus normalization, and external calibration.

Modules equalization requires that the ratings provided by each assessor are multiplied by a constant, with the aim of insuring that the geometric mean of each individual is the same as the geometric mean of the grouped data. Modulus normalization is used if many samples are evaluated over a number of sessions, and the experimenter has built in common samples that appear at each tasting session. The information from the common samples is then used to rescale the data based on the geometric mean.

Averaging magnitude estimation data is not as straightforward as interval data. However, these data usually have a log-normal distribution and hence, by taking the logarithms distribution of the data becomes symmetric and hence more like a normal distribution. It is often easier to analyze logarithmic data. Parametric statistics, as described above, can then be used to analyze transformed magnitude estimation data if it is certain that the transformed data are normally distributed; otherwise nonparametric methods must be used.

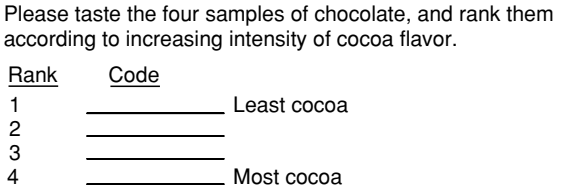

Figure 7 Flavor assessment by ranking, where the higher rank represents higher intensity of cocoa flavor.

Ranking

Ranking is neither a rating nor a scoring method, but as it is widely used in sensory analysis and provides ordinal data, it is included here for completeness. The method of ranking is used to order a number of samples according to increasing or decreasing perception of a specified attribute. Samples to be ranked need to be presented at the same time, and this limits the total number of samples that can be used in such a test, due to sensory fatigue. Ranking of five or six samples is often possible, although this number will depend largely on the nature of the samples; for example, chocolate has mouth-coating properties that make it difficult to rank many samples. An example of a ranking exercise is illustrated in Figure 7. Data are analyzed using nonparametric statistical methods, as described earlier in this article.

Descriptive Analysis

H Stone and J L Sidel, Tragon Corporation, Redwood City, CA, USA

Introduction

Descriptive analysis continues to attract interest and applications in more and more companies as the results from tests are discussed and used in support of product market decisions. At the same time research on new methods has been discussed, offering the sensory professional a variety of options. As a methodology, descriptive analysis is the most sophisticated source of product information available in the context of providing a complete and quantitative word description of a product's sensory characteristics. Such information can be considered in the same way as one considers chemical or biological information about products. Because it is quantitative, it provides a focus for development efforts; it provides a basis for measuring the effects of a process or of ingredients; i.e., establishing causal relationships between ingredients, technology, and perceptions; it provides a basis for linking consumer response behavior to specific product characteristics, and for business applications, identifying those product attributes that are most important to consumer preferences. Before discussing methodologies, it is necessary to define what we mean by descriptive analysis.

Descriptive analysis is a sensory methodology that provides quantitative word descriptions of products based on perceptions verbalized by a group of qualified subjects. It is a total sensory description, taking into account all the sensations that are perceived – visual, auditory, gustatory, olfactory, kinesthetic – when the product is evaluated. This evaluation could include product handling and use at home, for example, and in that sense, it is a more typical and total experience. The evaluation could focus on a single modality of a product, such as aroma or texture; however, there is considerable risk in such a narrow focus, a risk that will be discussed later in this article.

The earliest practitioners of descriptive analysis were the brewmasters, perfumers, flavorists, and other product specialists. Employers appreciated the value of their information because they not only described products and made recommendations about the purchase of specific raw materials, they also evaluated the effect of process variables on finished product quality (as they determined product quality). They also determined that a particular product met their criteria (and that of their company) for manufacture and sale to the consumer. These activities served as the basis for the foundation of sensory evaluation as a science, although at the time it was not considered within that context. It was possible for the expert to be reasonably successful as long as the marketplace was limited (i.e., less competitive and regional in character). However, this changed with the scientific and technical changes in consumer products industries and especially in the food and beverage industry. Use of more sophisticated raw materials and processes made it increasingly difficult for experts to be as effective as in the past. The increasingly competitive and international nature of the marketplace, the rapid introduction and proliferation of new products, and the sophistication of the consumer's palate further challenged the expert's ability to function as in the past. During this time, new sensory test methods and more sensitive scales were described along with improved statistical procedures for the analysis of responses. These developments enabled the sensory professional to provide more precise product information and participate more fully in product market

decisions. Formal descriptive analysis (and the separation of the expert from sensory evaluation) received its major impetus from 'flavor profile,' an approach which demonstrated that it was possible to select and train individuals to describe the sensory properties of a product in some agreed sequence, leading to actionable results without dependence on the individual expert. The method was distinctive in that no direct judgment was made concerning consumer acceptance of the product, although most investigators assumed consumer acceptance based on a result. The method attracted considerable interest as well as controversy; however, there was no question as to its importance to the development of the field. Since then, other methods have been developed, in part responding to its limitations as well as developments in measurement and human perception.

Background

We begin this discussion by first focusing on the most fundamental issues on which all descriptive methods are based, i.e., the subject selection process, the ability of the subjects to verbalize perceptions, and their ability to assign measures of strength (or intensity) to those perceptions in a reliable manner. Implicit in this statement is the recognition that each person is unique in terms of sensory skills; different individuals can be differentially sensitive to a sensation, more than a single subject (the expert n of 1) and more than a single judgment (from each person) is required for each product evaluated. People exhibit variation in their sensory skills and this variation reflects the state of those individuals at the time of that judgment – their physiology, attitudes, and motivation. Not only are people different from each other, but they also vary within themselves, from moment to moment, from day to day, and so forth. This individual variation is one of the most critical aspects of the descriptive process (and of all human response behavior) and it is often conveniently ignored. This issue will be discussed in more detail in subsequent sections; suffice to say that it must be accounted for in any descriptive test if results are to be believed, and to have any hope of external validity and credibility with the test requestor.

This discussion is particularly important because, in the course of organizing a descriptive panel, there are numerous decisions made by the sensory professional (the panel leader) that determine the usefulness of the results. These decision points and the actions taken derive from the panel leader's understanding of (1) the perceptual process in general and (2) the specific descriptive process used. Unlike discrimination and acceptance tests where subjects exhibit choice behavior in a global sense, i.e., all perceptions are taken into account to yield a single judgment, the descriptive test requires each subject to provide numerous judgments (one for each attribute) for each product. These judgments can be influenced by the instructions given to the subjects and the type and extent of the training. Too much information/instruction can yield a result that reflects the panel leader's knowledge of the products and not the subjects' perceptions. Alternatively, too little information will result in a lack of focus, as evidenced by greater than expected variability and loss of product differentiation.

Using the quantitative descriptive analysis (QDA) methodology as a reference, various methods, such as spectrum analysis, are described and contrasted. Other methods are also mentioned; however, most are modifications of the two previously mentioned. Free-choice profiling, the one different method requiring no subject selection and no training, has undergone many changes such that it more closely approximates the afore-mentioned methods and no longer warrants separate consideration.

All descriptive methods share some common characteristics as well as some differences and these will be compared and contrasted in the following sections. To understand better these similarities and differences, it is useful to think in terms of the steps involved in the development of a descriptive panel capability. These include four main activities: screening, training or language development, data collection, analysis and interpretation, and a fifth often overlooked activity, panel performance.

Screening

A descriptive test typically involves relatively few subjects (as few as 10 to as many as 20). Reliance on so few subjects is possible provided there is good evidence that the specific differences obtained are reliable and valid, and not the result of spurious responses from one or two insensitive or more variable subjects. An effective means of minimizing this latter problem is to screen the subjects for their sensory skills before training. One can show that in any population there is a wide range of sensory skills; some individuals will be very sensitive and some will be very insensitive (sometimes by as much as 100-fold or more), and this skill can be product- and attribute-specific. A goal of screening is to identify and excuse from further testing those individuals who cannot perceive product differences at better than chance – those that are insensitive or so variable as to raise doubt as to their participation in a test. Failure to carry out adequate screening raises serious questions

as to the quality of any sensory information obtained. Empirically, we observe that individuals whose sensory skills are not equal to or better than chance are usually less sensitive and more variable than the person who is sensitive and whose performance is better than chance. This enables one to use the fewest number of subjects without loss of information.

There are differences in the approaches used for the qualification of subjects, and panel leaders must decide what procedure(s) they are willing to use. For example, it has been recommended that screening for food or beverage tests be based on sensitivity to particular chemicals (e.g., sweet, sour, salt, and bitter stimuli or an identification of specific odorants) and/or on various personality tests. It is surprising that these types of sensitivity tests continue to be recommended (as used in flavor profile and related methods) in spite of earlier evidence that it had a low correlation with a subject's subsequent performance. The spectrum analysis method suggests using a combination of threshold testing followed by discrimination with actual products. Free-choice profiling claimed subject screening was not necessary and atypical responses would be dealt with by statistical means.

In QDA, the discrimination methodology is the screening method of choice. It is preceded by determining that the participant uses and likes the products that will be tested. Regular users of a product are more sensitive to differences in those products (e.g., compared to the infrequent user). The discrimination model is very effective for establishing the level of sensory skill among products that will be tested. It is also the most parsimonious in terms of time required to establish the level of skill. Based on results of 20–30 discrimination trials completed over 3 or 4 days (daily sessions last about 90 min), one can identify discriminators from amongst a group of totally naive individuals. The trials themselves encompass all the modalities that are expected to be involved, and the pairs of products are made progressively more difficult. Working with qualified subjects, extensive screening tests are not needed unless there is evidence that some subjects exhibited decreased sensitivity in a previous test, or one is using an entirely different product category, and again, there is reason to believe that such screening is warranted. Screening has several objectives: first, it identifies the less sensitive, more variable subject; second, it familiarizes the subjects with the sensory characteristics of the products; and third, it identifies any individuals who have difficulty following instructions. However, there are no guarantees, and it is only after data collection that one can empirically determine the effectiveness of the screening and subsequent training activities.

This screening procedure is intended to be product- or category-specific, as is the subsequent training effort. For example, if one were testing Cheddar cheeses, then screening would use samples of Cheddar cheeses, and preferably those that will be tested, and not other foods or unrelated ingredients or specific chemicals. This does not mean that subjects are product-specific, rather that screening should be of the products that will be tested or used during the language sessions. This should not be construed to mean that one must qualify subjects every time a different set of products is evaluated. Most subjects are capable of meeting the qualifying criteria for many different categories of products. Experienced subjects (e.g., those who have participated in at least one test within the past 1 or 2 months) will have learned how to use their senses and how to evaluate products within a category being evaluated without a significant loss of sensitivity, and are therefore very likely to be able to evaluate products beyond those for which they were screened. The panel leader makes this decision based on the existing subject performance data.

Screening subjects for more than one type of product makes sense provided the tests will follow one another with minimal delay. It will eliminate the need to initiate any additional screening before the next test. This does not guarantee that a subject will stay qualified, nor does it eliminate the need for the other stages of training. In addition, it does not excuse the panel leader from monitoring subject performance before the next test. Infrequent use of subjects, e.g., no testing for 3 or more weeks, may require that some screening is necessary, in which case much of the earlier effort will have been wasted. A potential problem with screening subjects on several products is the assumption that these individuals will be willing to participate in future tests. If used too frequently (e.g., daily) there is every likelihood that the subjects will lose interest and thus not perform satisfactorily. It may be better to develop a larger pool of qualified subjects and reduce reliance on a small subset of people for all testing, or qualify small groups for each category depending on the anticipated need for the product information. Panel leaders must develop guidelines for subject use based on their company experiences and not blindly follow an external practice.

In summary, it is necessary that subjects for a descriptive test demonstrate their ability to perceive differences at better than chance among the products that they will be testing. This will be insured if products used are representative of the products that will be tested. As a guide in selecting subjects we have used a minimum of 65% correct across all discrimination trials with greater emphasis placed on those

pairings that were more difficult. However, there have been situations in which the number of subjects meeting this criterion is not sufficient and it is necessary to lower this percent. In some instances an individual has been selected whose performance has been as low as 50%. This latter situation would be atypical, one which would be a decision of the panel leader. It is important to keep in mind that screening cannot guarantee subsequent performance; however, there is no doubt that individuals whose skill is less than chance do not perform well (in descriptive tests). Over many thousands of such tests we have observed that about 30% of those who volunteer will fail to meet these performance criteria. This particular point has implications that extend well beyond descriptive testing.

Training

Training is initiated directly after screening and it is here that one also encounters different approaches. While the training process is usually focused on the language (or attributes) used as a basis for scoring the products, there are other equally important activities. These include grouping attributes by modality, ordering them by occurrence within a modality, developing definitions for each attribute, familiarizing subjects with scoring the attributes, and identifying references that are helpful in training. Inexperienced subjects starting with a new set of products (and no list of attributes) will need about 7–10 h of training. For this same panel and an existing language, the time is reduced to about 6–7 h. Experienced subjects usually need about 5–6 h when presented with an entirely new product category. These training times are intended solely as a guide, as the products and the skill of the panel leader will also have an effect. Regardless of the situation, the subjects work, at times individually but mostly as a group, to insure that the attributes are sufficiently understood by one another, and that all of the product's characteristics have been fully accounted for. All of this is done under the direction of a panel leader who does not participate in developing the language. The QDA method was the first method and remains one of the few that excluded the panel leader from directly contributing attributes in language development. This is true whether one is working with an experienced panel or with a panel that has never participated before. The panel leader's primary responsibility is to facilitate communications among subjects and organize results of their discussion. Participating as a subject (as is allowed with the spectrum method) is not recommended because of bias related to one's awareness of product differences and the test objectives. Not only does this action communicate the wrong message to the subjects (subjects will tend to defer to the panel leader, whom they assume has the correct answer), but also the end result is more likely to be a group judgment rather than a group of judgments.

Developing a sensory language or using one that already exists is an interesting process and certainly one that is essential for the successful outcome of a test. For some, the language assumes almost mystical importance, such that a considerable body of literature has been developed in which lists of words (lexicons) are published for specific types of products. Implicit in use of an agreed list is the assumption of universality, i.e., panels in different parts of the world would yield the same result by using the same language. It appears that many of these lists were prepared by technologists and sensory professionals by consensus. Unfortunately, this is not very different from the efforts of product specialists or experts of 50 or more years ago when they developed quality scales and corresponding descriptions for products as part of an effort to establish food quality standards. Besides their interest in evaluation of their respective company's products, their technical and trade associations often formed committees for the express purpose of developing a common language for describing the flavor (or odor) of the particular category of products. For purposes of this discussion we chose the publication by Clapperton *et al.* (1975) on beer flavor terminology as an example of the efforts (of the association of brewers) to develop an internationally agreed terminology. These authors stated the purpose as follows: 'to allow flavor impressions to be described objectively and in precise terms.' Various literature and professional sources were screened for words (or descriptors) describing the flavor of beer, and, after reviews, the committee arrived at an agreed list. As the authors noted, the issue of chemical names compared with general descriptive terms was resolved by the inclusion of both.

From a technical viewpoint, the use of chemical names was appealing because it was believed that they could be related directly to specific chemicals in the beer. An example would be the term 'diacetyl,' which could be ascribed to a specific chemical, as compared with 'buttery,' a less precise term that might be ascribed to several chemicals. By including both types of terms it was stated that the terminology would be of value to the flavor specialist (the expert) and the layperson (the consumer). While the concept of an agreed terminology should have considerable appeal, careful consideration of this approach reveals significant limitations, especially in relation to its application beyond that technical panel. After all,

the words used to describe sensations are nothing more than labels to represent sensations – no causality is inferred. It is risky to decide *a priori* what word(s) subjects should use to describe a particular sensation, or still greater risk that naive consumers will understand them. Recall that about 30% of any population of consumers cannot differentiate products at least at chance. In addition, subjects will not be equally sensitive to all sensations. Some sensations are complex, and in all likelihood subjects will want to use more than a single word to represent that experience. The fact that product changes based on formulation, process, or both rarely yield a single sensation means that, for example, a flavor change would not be totally represented. To restrict subjects to specific words assumes that the language is unchanging, as are the meanings assigned to it, and that all subjects will associate a specific word to a specific sensation. The frame of reference for an attribute is unique to each subject, and attributes requiring a very different frame of reference are difficult for inexperienced and/or nontechnical subjects to understand. While chemical terminology is supposed to have specific meaning to an expert, it is unlikely to have the same meaning to a consumer, to a trained subject, or to another expert.

It should be noted that the use of technical terminology extends training time and this appears to be related to the complex nature of this terminology, especially for subjects with no technical training. The spectrum method provides the subjects with attributes, as well as references and designated intensity scores for those references, all of which are intended to enhance the testing process. The use of standard or previously specified attributes and references implies that product variables will not produce unique sensations, that references themselves are not variable, and forces subjects to limit the value of their perceptions relative to what has been perceived in the past by others. The training effort is extended over a period of 3 months; this raises questions as to its responsiveness and overlooks the inherent variability in the subjects (over time) and the references that are being used (that also change over time). Regardless of the source, a language that does not provide for subject input is unlikely to yield uncomplicated sensory responses. Subjects are influenced by the information given to them, and are much less likely to question it, because of its source. While it can be argued that such approaches are merely intended to help panel leaders and the subjects, the temptation is very strong to use this approach rather than allowing subjects to use their own terminology and, most important, to allow subjects to express what they perceive.

To the student of the history of psychology, descriptive analysis can be considered as a form of introspection, a methodology used by the school of psychology known as structuralism in its study of the human experience. Structuralism required the use of highly trained observers in a controlled situation verbalizing their conscious experience (the method of introspection). Of particular interest to us is the use of the method of introspection as an integral part of the descriptive analysis process and, specifically, the language development component.

However, the obvious difference is that products are included (in descriptive analysis) so that the subject's responses are perceptual and not conceptual. Subjects are encouraged to use any words, provided that they explain to the other members of the panel what they mean – they define the meaning of each word-sensation experience. The goal is for the panel, by consensus, to associate a particular sensation with a particular word or group of words. While each subject begins with his or her own set of words, they work as a group to come to agreement as to the meaning of those words, i.e., the definitions or explanations for each word-sensation experience, and also when they (the sensations) occur. In addition, they also develop a standard evaluation procedure. All of these activities require time; in the QDA methodology, there can be as many as five consecutive daily sessions, each lasting about 90 min. This amount of time is essential if the sensory language is to be developed and understood, and the subjects are capable of using it (and the scale) to differentiate the products. These sessions help to identify the word-attributes that could be misunderstood, and also enable the subjects to practice scoring products and discussing results, on an attribute-by-attribute basis. Of course, all this effort cannot make subjects equally sensitive to all attributes. In fact, subjects rarely, if ever, achieve complete agreement for all attributes, nor are subjects equally sensitive to all attributes, nor should it be expected (if this did occur, one could rely on the n of 1). The effectiveness of the training process can be determined only after a test, after each subject has scored products on a repeated trial basis and the data have been analyzed. The idea that there should be a specific number of attributes is, at best, questionable, as is the issue of whether or not one has the correct attributes. How does one know that all the attributes have been developed or that they are the right ones? The answer to the former is empirical (and in part answered in much the same way as one determines the number of angels that can occupy the head of a pin). The answer to the latter is also empirical, i.e., given a set of variables, do some attributes exhibit systematic changes as a function of those

variables? Other methods, including free-choice profiling, claim that no training is required; subjects can use any words they want and the results are collated for analysis. However, the 'no training' is not necessarily correct in the sense that researchers describe the time and effort required by the subjects to develop definitions for the words; in more recent publications on use of the method, as many as 10 training sessions are used. Clearly, there are wide differences in what is meant by training as concerns these different methods.

The words used to represent sensations are nothing more than labels. There is no reason to assume that these words represent anything beyond that – no causality is inferred. Without an appropriate design study any idea as to the external validity of a specific word is hypothetical, at best. Some researchers suggested that the words represent concepts, and that for a descriptive panel to be effective, concepts must be aligned, i.e., subjects must agree on all the sensations (or attributes that represent those sensations) to be included in a concept if the results are to be useful. Unfortunately this idea of concept alignment remains to be more clearly delineated before one can determine its relevance to the descriptive process. One could propose that the process by which subjects discuss their judgments for an attribute, and the definition for that attribute, represent concept alignment, which is an integral part of the QDA training process. Whether this, in fact, is concept alignment remains to be demonstrated; however, it is clear that most subjects can reach sufficient agreement on attributes and can reliably differentiate amongst products, after completion of training. How attributes are formulated in the brain and the true meaning of those attributes are issues that go well beyond descriptive analysis and sensory evaluation, in general.

One should remember that subjects are not likely to agree totally on all the sensations to be included, any more than there is agreement on all the attributes. The sensations are themselves complex and interactive, leading to multiple words to represent them. The individuality of each subject (sensitivity, motivation, and personality) further complicates or adds to the complexity of the process. As a result, a descriptive panel typically develops many more attributes (30 or 40 or more) than will be necessary to describe an array of products fully. The fact that there are many more attributes than are needed should not be unexpected or of concern. This reflects the uniqueness of the individual and the inherent imperfections of the perceptual process, or at least the ability to verbalize more precisely and/or capture those perceptions.

In addition to a descriptive language and definitions, it may be useful to have references available for training or retraining subjects. Here, too, one finds different opinions as to the types of references and how they are to be used. For example, a comprehensive list of references and how they are to be used may be presented, including their respective intensity scores for scale extremes. Unfortunately, these references are based on commercially available products, all of which are variable in the normal course of production, in addition to the intended changes based on changing technologies, ingredients, and/or market considerations. Over time, references will change which can influence subjects in unanticipated ways, further changing responses to product characteristics. What, then, is the value of such references? They have a role to play in helping subjects relate to a particular sensation that is not easily detected or not easily described. However, references should not introduce any additional sensory interaction or fatigue, or significantly increase training time. In most training (or retraining) situations, the most helpful references are usually a product's raw materials. Of course, there will be situations in which totally unrelated materials will prove helpful to some subjects, and it is the panel leader's responsibility to obtain such materials. There will also be situations in which no reference can be found within a reasonable time period. A panel leader should not delay training just because a reference cannot be found. While most professionals agree that references are helpful, there is no evidence that without them a panel cannot function or that results are unreliable and/or invalid. We have observed that so-called expert languages usually require numerous references, and subjects take considerably longer to learn (this language) than they do a language developed by themselves. This should not be surprising, if one thinks about it. After all, references are themselves a source of variability; they introduce other attributes unrelated to their purpose, they are out of context for the complete product, and increase the potential for sensory interactions. The panel leader must therefore consider their use with appreciation for their value as well as for their limitations, and must decide when and what references will be used. In our experience they are of limited value, for use in the language development and training or retraining activities. In retraining, or when adding new subjects to a panel, they are helpful in enabling these individuals to experience what the other subjects are talking about and possibly to add their comments to the language.

Some methods make great use of references, while others do so on an *ad hoc* basis, i.e., they use them only when they are helpful to the subjects.

Scoring

Most methods today are presented as quantitative, relying on various types of scales. The QDA methodology makes use of a line scale (a graphic rating scale) and the concept of functional measurement to obtain intensity judgments. The scale is a 15-cm line with two vertical lines, each placed 1.27 cm from the scale ends. Below each of the vertical lines are words that designate scale direction and intensity for that attribute. For the scale to be used effectively, the subjects must be provided with ample opportunity to practice scoring products and become comfortable with using the scale and with the range of product sensory characteristics. This latter point is especially important to the successful use of the scale. In the training no attempt is made to require subjects to use the same part of a scale, only that each subject be consistent with him- or herself. Because each product is scored on a repeated-trials basis by each subject, it makes little difference what part of the scale is used to differentiate the products. This use of a single scale is in contrast with those methods, in which more than one type of scale may be used. One type of scale is the difference from reference scale in which an identified product is provided with a designation as to its scale location, and products are scored relative to that standard. This type of scale is popular but is flawed as the reference itself will vary, requiring subjects to alter their perceptions (and responses) in relation to the variability associated with it. Most methods are now using some type of line scale but it is not clear as to whether a context is provided during training.

Design and Analysis

The design and analysis of a descriptive test are equally important for a successful outcome. A descriptive test yields a large sensory database (in comparison with a discrimination or an acceptance test), often yielding 10 000 or more data points. There are usually both univariate and multivariate components, and as such, it permits a wide range of statistical analyses. One of the main features of the QDA methodology was the use of a comprehensive statistical analysis of the data, which represented a significant development for sensory evaluation. With the availability of statistical packages and the power of personal computers, panel leaders have unlimited and low-cost resources, providing an online capability for obtaining means, variance measures, ranks and pairwise correlations, and for factor analysis, multiple regression, cluster analysis, discriminant analysis, etc.

All descriptive methods espouse the use of replication (repeated trials); but only the QDA method appears to use it for all test situations. The extent of replication is a decision that the panel leader makes based on the products, the expected degree of difficulty, and past experience of the panel. For QDA a maximum of four replicates is usually sufficient. With more replication, to six, eight, or more, there may be a decreasing return as the number of replicates increases versus the amount of time required for the subject to complete all the evaluations versus statistical power. Empirically we have not found decision changes as a result of increasing replication beyond four. As the number of products evaluated is increased beyond 10, one has the option of decreasing replication to three, taking advantage of the total number of evaluations. These are panel leader decisions; there are no rules as to how many replicates is necessary. The decision takes into account past test history with the product, expected product variation based on manufacturing experience, and so forth. Experience has shown that three to four replicates are usually sufficient.

The analysis of variance with replication model is a very powerful and robust system for descriptive data and is the core method with QDA; other parametric and nonparametric algorithms are also used. With repeated trials one is more likely to yield significant product differences. In addition, this design provides a basis for measuring and visually examining subject performance on an individual attribute basis. Other descriptive methods neither specify these kinds of analyses or make use of programs with defaults that remove some judgments without the researcher knowing what has happened. One such program, Procrustes Analysis, eliminates data based on a test for outliers; while mathematically correct, it takes no account of whether it is a true perception. Many consider its use as experimental and too risky for everyday use.

All sensory data need to be analyzed in some detail as a basis on which to reach conclusions about product differences. As noted before, the descriptive test uses a limited number of subjects and one must be very confident about their behavior before one initiates any extrapolations or investigations about the underlying structure of the data. Specifically, replication provides a basis for determining the skill of each subject and of the panel which increases the confidence of all product decisions. It is an essential cost that cannot be forfeited without serious compromises in any conclusions that are reached about results.

As noted previously, in QDA, there are parametric and nonparametric procedures to identify subjects and attributes for which sensitivity is reduced and/or

there is a significant interaction. This information has several applications. First it provides the panel leader with specific information about a subject's response behavior for each attribute relative to the panel's. Second, it identifies whether a subject is a significant source of interaction and the type of interaction. Crossover interaction is the more serious type (versus magnitude) and with the appropriate nonparametric procedure, one can easily determine a subject's rank order compared with the panel rank order. This process focuses the panel leader's attention on those subjects who exhibited this response behavior, as well as on that individual's scale use. This kind of information can be displayed numerically as well as graphically, along with other types of subject performance behavior, e.g., discriminant functions. For the panel leader, this information is very useful in determining the quality of the results. However, the value to the user rests with product differentiation, and the easiest way of demonstrating this is through the use of plots such as the one shown in Figure 1, a typical 'spider' plot for some of the mouth-feel attributes. Also included is the LSD (a black bar) for each attribute. The mean intensity score for each attribute is determined from measuring the distance from the center to that point at which the product bisects the line. With today's technology, these results can also be displayed in a variety of ways; for example, displaying only the most discriminating attributes based on a discriminant analysis, and so forth.

As with any readily available resource, statistics are often misunderstood and/or misused, particularly when responses are highly variable or when the panel leader confuses use of some of the multivariate procedures with evidence of the validity of results. In other instances, investigators use factor analysis and/or clustering techniques as a basis for excluding subjects who are not in agreement with the panel or to eliminate attributes that they believe are not being used to differentiate products or are used as

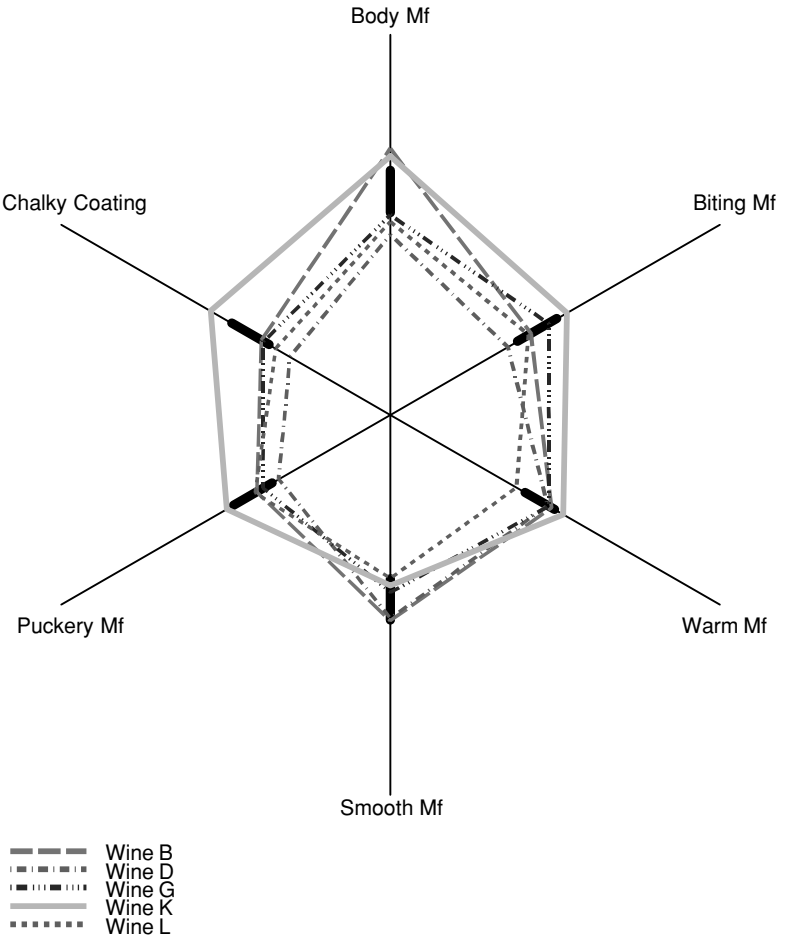

Figure 1 Typical 'spider' plot for selected mouth-feel attributes. Intensity scores are measured from the center out to that point where the product crosses. The attributes are spaced equally around the center point. Bars on the spokes represent the magnitude of difference for that attribute to be significant using the least significant difference (LSD Mf, mouth feel).

substitutes for the same sensation. These have been proposed for use during training to reduce the number of attributes on the score card (from 45 to 12) or the number of subjects. One must be careful about using procedures that, *a priori*, decide which subjects or attributes will be used. After all, the subjects are still in training and to have them score products and use the results as a basis for reducing either, or both, may be premature. This approach can lead to a group of subjects who are more likely to agree with each other, but how does one know that those who agree are correct? How does one differentiate subjects who are discriminators from nondiscriminators if, for example, the nondiscrimination is of 30% or 40% of the attributes? One of several objectives of training is to enable subjects to learn how to evaluate products using the attributes that they determined were helpful to them (at that stage of the training). To proceed from one session to another and substantially reduce the list of attributes is communicating a message that there is a correct list of words and, with a little patience, it will be provided. Using factor analysis to reduce the number of attributes during training is troublesome because it assumes that attributes highly correlated to a factor are measuring the same component of the product and, therefore, one or two attributes can represent the others. However, attributes correlated to a factor are only an indication of some common basis which assigns those attributes to that factor; it does not imply causality. It is interesting to note that one goes to considerable effort to encourage subjects to contribute words to use in a score card and then to devise procedures to eliminate about 75–80% of them before the actual test is performed, thus sending the message to subjects that there is a correct list. As mentioned previously, not all subjects will use all the attributes to the same extent in differentiating products, and eliminating too many of them substantially increases the likelihood of reducing sensitivity and overlooking product differences (an example of type 2 error).

After a test one should use univariate and multivariate procedures to help identify subjects who are experiencing difficulty with specific attributes and/or with use of the scale. This information is then used prior to the start of the next test so as to clarify further the testing process.

Conclusions

Descriptive methods are an established methodology recommended for all sensory programs. Results from a descriptive test provide precise quantitative descriptions of products, and this information has many applications that range from product development, to establishing relationships between ingredients and sensory characteristics, to advertising claims.

In the past decade much attention has been directed to the development of methods that provide the sensory professional with alternatives on how a test is organized and fielded, and how results are analyzed. There are currently two very different approaches described in the literature about the organization and operation of a trained panel. One takes an expert approach, relying primarily on thresholds, and identification of specific flavors and odors (flavor profile) while the other seeks to identify subjects based on their sensory skill with the products of interest. The former takes several weeks, while the latter takes 3–5 days.

For training, one method begins by focusing on single modalities with language obtained from a list and subjects must learn to respond to those attributes, while the QDA methodology requires that subjects develop the list of words, the order within a modality, the definitions, and the evaluation procedure. No standards are used in this training. While the former takes more than 8 weeks, the QDA completes these activities in about 7–10 h for a totally new panel and half or less this time for an experienced panel.

For data collection, QDA recommends a total of four replicates, while the spectrum method indicates that replication is appropriate without further discussion as to how much or in what way the data will be used. It is clear that those who have used these methodologies and those who will use them in the future will make their own modifications.

Data analysis is particularly important for determining the quality of the basic information. While current interest is very high in the use of clustering techniques and other multivariate procedures, such analyses should be considered only after the quality of the database has been assessed.

For the sensory professional there is much to choose from when considering a descriptive test. Whatever methodology is chosen, there are many aspects that require decisions from the professional. It is the authors' contention that these decisions should be influenced by the following considerations:

1. All subjects should be screened for their sensory skill using products from the category being tested.
2. About 30% of the people who volunteer to participate in these screening tests will not meet minimum requirements of at least 50% correct matches (in a discrimination test).
3. Subjects should use words that are derived from common, everyday language to describe products.

4. Subjects should practice scoring products using the afore-mentioned words as part of the training effort.
5. Subjects should develop definitions or, if using a previously developed score card, they should have the opportunity to modify the definitions.
6. Subjects should score each product on a repeated-trials basis with four replicates recommended.
7. Data analysis must provide measures of subject reliability on an attribute basis, means and variance measures for products, and tests for significance.
8. Multivariate procedures should be used where the data warrant the effort.

Sensory evaluation has achieved considerable recognition as a source of unique product information. Much of this derives from the use of descriptive analysis methods. This discussion is intended as a perspective of the development and use of descriptive analysis, as well as a review of the main features of methods currently in use.

Appearance

D B MacDougall, The University of Reading, Reading, UK

Introduction

Of the five human senses, vision has had probably the longest research into its mechanisms and is the best understood of the five. Human eyes have a vast ability

to detect and process external information for the brain to translate instantaneously into the perceptions of appearance and color. The appearance of any object or scene can be defined as the response of the observer to the totality of information that is perceived by the eyes. Because the mechanism of visual perception is complex, it can be divided into several interacting components, which, when taken together, are usually described as total appearance. Undoubtedly, the most important of these components is the perception of color. Most of this article will deal with the way human visual signals are perceived and how color is measured. However, a broader classification of the components that comprise total appearance would divide them into the physical and chemical nature of the object and the influences of the illumination and surroundings on the object's appearance. Additionally, for food, it must also include the social and psychological factors associated with the consumer such as culture, food habits and preference. The judgment of food appearance at the point of purchase is related to the potential satisfaction of the product coupled with its value. Such decisions are usually made quickly with the criterion that rejection may be more related to the presence of faults in the food's appearance than to what is regarded as normally acceptable. The success of the food industry in making consistent and attractive products depends on the consumer's continuing confidence that the appearance of the product is a true indicator of the subsequent acceptability of the eating quality of the product. That is, the appearance and color of the product are likely to be related in the consumer's mind with a value judgment of the other sensory attributes and their expected satisfaction.

The Visual Process

Vision is the property of the response of the eye to the stimulus of light, as interpreted by the brain. Human vision is binocular, i.e., objects are seen as solids in perspective space. The appearance of any object in a scene can be defined as the recognition of the properties of that object, i.e., size, geometry, solidity, surface characteristics, and subsurface optical properties, i.e., transmission, opacity, or degree of translucence and, most importantly, color. The visual process leading to the recognition of appearance, as with all sensory events, consists of a rapidly occurring sequence of steps such that the observer sees the response to the stimulus near instantaneously. Three factors are involved in vision: sufficient light to illuminate the object, human eyes with their complex detecting mechanism and the object itself with its interaction with the incident light and the background surroundings. Human eyes are virtually spherical, approximately 2 cm in diameter, with six muscles to control their mobility to give each eye a near circular field of view. Light is detected after entering the iris, which self-adjusts for light intensity. It is then focused through the eye's lens on to the retina with its two types of light-sensitive cells, the rods and cones. This results in a distinct image of the object being focused on to the retina. Most of the retina is sensitive to low levels of light, detected by the rods whose response is noncolored and is known as 'scotoptic vision.' The cones located in a small spot, approximately 2 mm in diameter, centrally located in the retina and known as the fovia, detect photoptic or color vision. In a person with normal color vision, i.e., one who is not color blind, there are three types of cones whose light-detecting ability is wavelength-dependent. The mechanism of light detection in the photoreceptor cells is by a conformational change in the photopigment molecule rhodopsin, producing an electrical potential for amplification and transmission via a nerve fiber to the brain. It is important to emphasize that the perception of an object's color and appearance exists in the observer's brain and not in the object itself.

The wavelengths of maximum sensitivity of the so-called blue (B) detecting cones is at 440 nm, that of the green cones (G) at 540 nm and for the red cones (R) it is at 600 nm. The G and R detecting bands overlap equally at 580 nm, producing that narrow band in the visible spectrum that appears bright yellow. The perception of any color is therefore due to the responses generated by three signals varying in absolute and relative intensity and is known as trichromatic or three-colored vision. Thus, because cone vision is trichromatic, a suitable mixture of monochromatic B, G, and R primary lights can match any colored light. Subsequent processing of the trichromatic signals by the brain gives rise to opponent red/green and blue/yellow color perception mechanisms and an achromatic lightness/darkness mechanism.

The human eye–brain relationship has the ability to adjust to changes in illumination without much of an apparent change in the color of the object. This process is called adaptation and is accompanied with the phenomena of color constancy, where colors remain essentially, but not truly identically, the same hue when the spectrum of the incident light changes. Hence, a colored product under a blue white light, such as occluded daylight with a high component of blue in the spectrum, will appear to possess a similar color as the same product under orange–yellow tungsten illumination. The reason for this is that, in most situations, white is normally a component of the

scene, and the eye adjusts to recognize white as white, whatever the light source might be.

Orderly Color Arrangement

Many attempts have been made to arrange colors in systematic order (Figure 1). Humans have the ability to remember between 1000 and 2000 colors, many of which can be identified by name, and most color atlases have more than 1000 distinctly different colors in them. The most obvious arrangement is that of hue, i.e., the difference between red, orange, and yellow, etc. to blue following the order of the colors in the spectrum. This is an insufficient separation, because colors can also be arranged in order of their lightness and saturation or intensity. This is the basis of two of the most commonly used color atlases, that of Munsell (Figure 2) and the more recent Natural Color System (NCS). They both have an achromatic lightness to darkness vertical axis around which the hues are visually separated and radiate from the central axis in increasing intensity

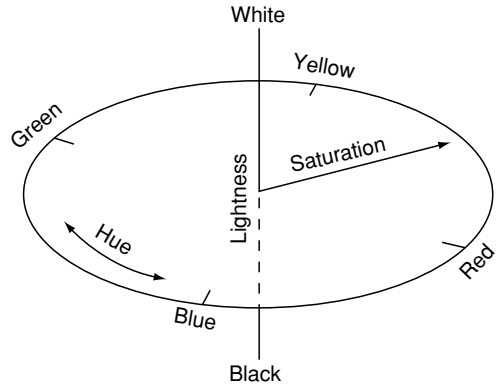

Figure 1 Three-dimensional color order system.

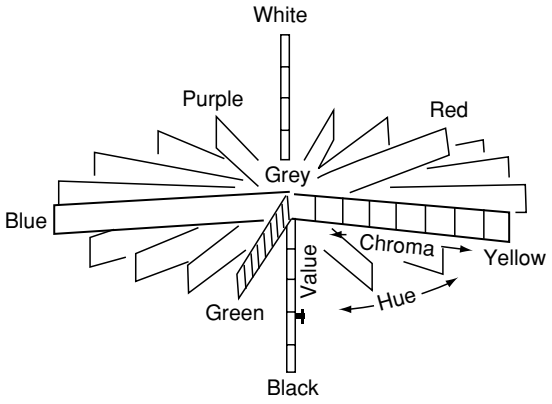

Figure 2 Munsell color system.

(saturation or chroma), but they are conceptually different. The NCS atlas is based on the fact that there are four uniquely distinct hue perceptions of red, yellow, green, and blue although derived from only the three tristimulus responses. Thus, the hue red is opposite green, yellow is opposite blue, and the four resulting quadrants of the space are divided, in the NCS atlas, into 10 steps. Thus, any color can be defined by its lightness, hue angle, and chroma values. The hue arrangement in the Munsell system was based on visual hue separation. Both atlases enjoy wide use as reference in the food industry.

CIE Color Spaces

Both the above atlases, and others like the Pantone Color Specifier, are based on visual matching of pigments on paper. For instrumental measurement, account must be taken of both the nature of the transmission or reflectance spectrum of the product and that of the incident light. The ability of an observer with normal color vision, under strictly controlled conditions, to match the color of any wavelength with a mixture of red, green, and blue wavelengths resulted in the construction of the 1931 CIE (Commission Internationale de l'Eclairage) color space. Color-matching functions of the responses to mixtures of three monochromatic wavelengths in the red, green, and blue regions were used to match the entire spectrum wavelength at a time. This resulted in what is known as the CIE 1931 2° visual field of view standard observer and is the basis of all instrumental color-measurement and color-match prediction. In 1964, a supplementary set of functions was defined for a wide field observer of 4°, because, for most practical purposes in real-life situations, samples are viewed at a wider visual angle than 2°. The functions used in the calculation of the tristimulus values X, Y, Z have the advantage that, unlike the original R, G, B matching, in which some of the matches are negative, they are all positive with Y equal to the luminance or lightness of the color. The relationship of X, Y, Z to R, G, B is:

$$X = 0.49R + 0.31G + 0.20B$$
$$Y = 0.17697R + 0.81240G + 0.0106B$$
$$Z = 0.00R + 0.01G + 0.99B.$$

Thus, the values of any set of CIE tristimulus values X, Y, and Z will define color in three-dimensional space. Although Y contains the entire lightness or luminance response, X and Z are more difficult to relate to color perception directly. The concept of chromaticity, correlating to the visual recognition of color perception of hue and color purity can be derived from the coordinates x and y where:

$$x = X/(X + Y + Z) \text{ and } y = Y/(X + Y + Z).$$

Therefore z, which equals $(1-(x + y))$, is not required in the construction of the space. The CIE Color Matching Functions and the 1931 chromaticity diagram are shown in Figures 3 and 4.

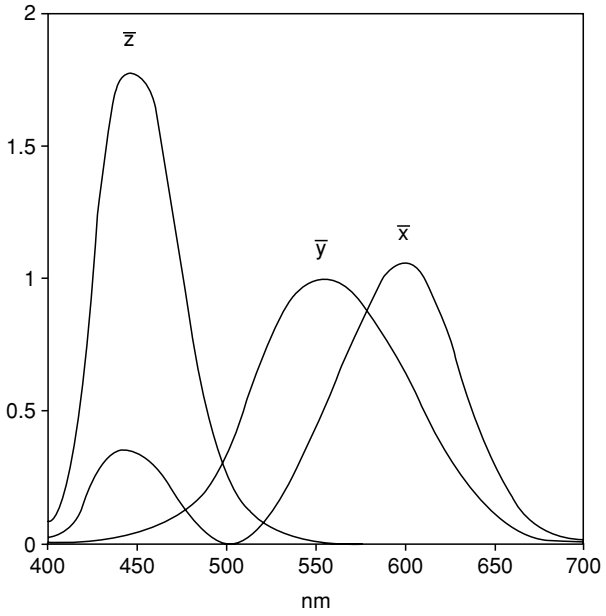

Figure 3 CIE color-matching functions for the 2° Standard Observer.

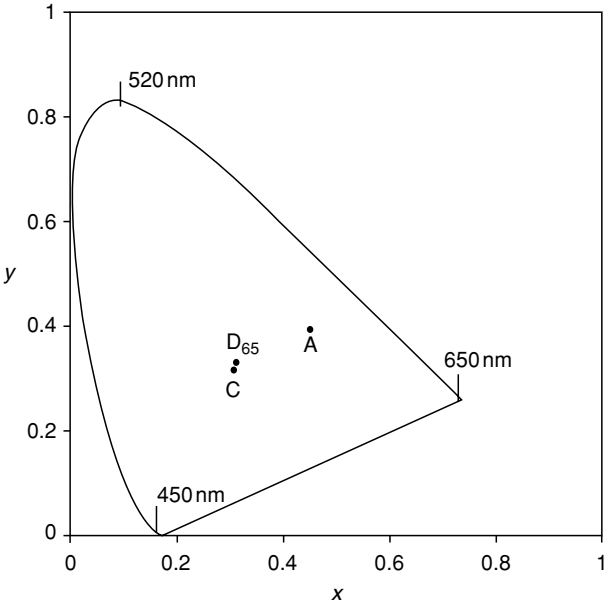

Figure 4 CIE x, y chromaticity diagram showing location of illuminants A, C, and D_{65}.

Uniform Color Spaces

Although the development of the 1931 CIE color space provided a means whereby any color could be defined unambiguously, it has the major disadvantage that the colors in the space are not equally separated from one another visually. For example, the chromaticity distance between just noticeable greens is several times greater than the equivalent distance between just noticeable blues. The objective of any color-measuring system is not only to provide an unambiguous definition of color but also to obtain a realistic relationship to visual perception of color differences. Two near-uniform color spaces that have importance to industry are the Hunter and CIELAB spaces. The Hunter L, a, b opponent color space (Figure 5) was a development of the earlier Adams chromatic value systems devised in the mid-1940s, where red is opposite to green, and yellow is opposite to blue, i.e., the concept of the four unique hues. The Hunter L, a, b was constructed in 1958 primarily for use in color-measuring instruments with analog devices. The formulae for transformation of the tristimulus values to L, a, b are:

$$L = 10Y^{1/2}$$
$$a = 17.5(1.02X - Y)/Y^{1/2}$$
$$b = 7.0(Y - 0.847Z)/Y^{1/2}.$$

The use of the square root of Y resulted in a color space that was readily interpretable and approached visual uniformity when compared with the spacing of the Munsell color atlas with its uniform and orderly arrangement of real colors. This space has had wide application in the food industry but is now being superseded by the 1976 CIELAB L^*, a^*, b^* color space, where L^*, the cube root of Y, is more uniformly spaced than L. The formulae are:

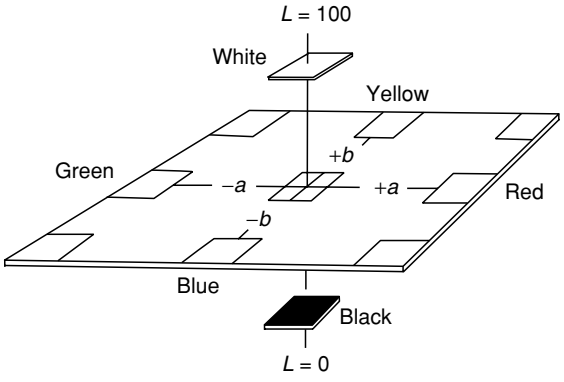

Figure 5 Hunter three-dimensional uniform L, a, b color system.

$$L^* = 116(Y/Y_n)^{1/3} - 16$$
$$a^* = 500[(X/X_n)^{1/3} - (Y/Y_n)^{1/3}]$$
$$b^* = 200[(Y/Y_n)^{1/3} - (Z/Z_n)^{1/3}],$$

where X_n, Y_n, and Z_n refer to the nominally white object color stimulus. Although this scale is similarly constructed to present lightness and opponent colors with distances that are more nearly inform, it has the additional advantage of being related to real illuminants rather than the L, a, b space, which used the theoretical light source C. The three most common illuminants used in the calculation of L^*, a^*, b^* are standards A, C and D_{65}. A is the spectrum of a tungsten filament lamp with a color temperature of 2856 K, and C is standard A with a blue filter to stimulate average daylight with a color temperature of 6774 K. Illuminant D_{65} is the spectrum of the color of daylight with a correlated color temperature of 6504 K. Currently, the tendency is to use the 10° standard observer and illuminant D_{65} rather than the 2° observer and C. Many modern color spectrophotometers also have the facility of additional illuminants in their programs, e.g., a series of typical fluorescent lamps of both wide and narrow emission spectra.

Food Appearance

The most important attribute of any food's appearance is its color, especially when it is directly associated with other food-quality attributes, for example the changes that take place during the ripening of fruit or the loss in color quality as food spoils or becomes stale. Every raw food and manufactured product has an acceptable range of color appearance that depends on factors associated with the consumer and the nature of the surroundings at time of judgment and the structure and pigmentation of the food itself. However, color specification alone is insufficient to define food appearance. The color quality of the illumination, in terms of intensity, color temperature and fidelity and the nature of the structure of the product all affect the appearance. The distribution of surface reflectance, the nature of internally scattered light, and the pigmentation of the product are all necessary for a complete specification of appearance. Most important is the interaction of the food's structure with its variable light scatter and pigmentation, which affect opacity and translucency as well as the color. Small changes in scatter can produce greater changes in visual color appearance than are attributable to the normal range in pigment concentration in some products. It is important to distinguish between these, but this is not always carried out during color measurement with the consequence that erroneous interpretation of the data commonly results.

A food's appearance therefore can be reduced to two principal factors, the physical and the psychological. The physical factors consist of the geometrical, the food's dimensions of size, shape and intrinsic characteristic variability in uniformity and mass, and the optical, surface gloss or dullness, the nature and degree of pigmentation, and the light-scattering power of the food's structure. The objective, therefore, is to convert the physical to the psychological by translating the object's reflectance or transmittance spectrum into the tristimulus values and then to a defined color space.

Food Color Measurement

As already discussed, foods have an infinite variety of appearance characteristics. Their surfaces may be diffuse, glossy, irregular, or flat. They may be transparent, hazy, translucent, or opaque, and their color may be uniform or patchy. Hence, color-measuring procedures for foods often have to be modified from the more standardized techniques used in the measurement of flat opaque surfaces such as paint and paper for which most color-measuring instruments are designed. Different instrument optical geometries will lead to difficulties in sample presentation, producing different color values for the same material. The inclusion or exclusion of surface specular reflection in the measurement depends not only on its importance as a characteristic of the food but also on the design of the detector-sensor unit in the instrument. Lateral transmittance of light through translucent materials affects their reflectance, and this should be allowed for in the assessment of such products as tomato paste and fruit juice, because the ratio of absorption to scatter varies with aperture area and the concentration of the components in the product. Colorimeters and spectrophotometers do not necessarily produce the same result, because of differences in their construction. Some spectrophotometers give the option of including or excluding the specular component of reflectance from the measurement. It has been the experience of this author to include the component unless the surface is flat when the difference between the two readings is likely to be related to the degree of gloss of the surface. Most colorimeters, unlike spectrophotometers which have measuring geometries of 8°/diffuse or diffuse/8°, exclude the specular by measuring at 45°/0°.

Measuring at a defined sample thickness is recommended for consistent data. Usually, this would be at a so-called infinite (∞) thickness, where an increase in thickness would not alter the reading. However, for

translucent samples, it is advisable to measure at more than one thickness on white and black background to distinguish between the light-scattering component of reflectance and pigment absorption. The technique of Kubelka and Munk, used by the paint and paper industry, is one method. This relates the ratio of an absorption coefficient (K) over a scatter coefficient (S) to reflectance at an infinite thickness thus:

$$K/S = (1 - R_\infty)^2/2R_\infty.$$

It is possible to calculate K and S separately and also the internal transmittance (T_i) from the differences in the readings of the white-backed and black-backed thin layers.

Measurement Procedures

Because foods are near infinitely variable in their appearance, it means that there is no consistent way of measuring them. With few exceptions, e.g., the measurement of tomato paste, there are no defined methods, although a variety of approaches have been found to be successful. For transparent liquids, there is no difficulty, but care has to be taken to define the concentration or series of concentrations that are measured. It can be advantageous to measure a series of dilutions and relate these to their change in the L^*, a^*, b^* diagram as well as the normal technique of absorbance measurement at fixed wavelengths. For solid materials, reflectance measurements are necessary, and the appearance variables encountered fall into three classes as follows:

1. The truly flat and opaque variables are easy to measure, and the procedure is to measure the sample at infinite thickness. Infinite thickness is defined as the thickness that, if it were increased, would not lead to a change in the data.
2. The translucent variables are less easy to measure, because the incident light falling on the material when viewed by the eye produces an image that is somewhat different to that presented to the instrument, because the effect of lateral light scatter may not be left out of the measurement. As well as measuring at infinite thickness, it is recommended that the sample be measured as thin sections on top of black and white from which K, S, and T_i can be calculated.
3. The particulate variables have the difficulty of holes and gaps in the material, e.g., the surface of many breakfast cereals is composed of both the cereal and spaces, which, when judged visually, are not included in the perception of color but are included when measured on an instrument. One way of alleviating the problem is to grind and filter the sample to a uniform particle size range and then measure the ground material packed into a cell.

Visual Assessment

Instrumental color measurement is only valid if it accurately describes the visual characteristics of the food. The quality of incident light alters the perception of the food's color. Light boxes used for color judgment are now equipped with several light sources fitted with color-matching lamps and also those typical of those used in industry. Foods are usually viewed in the supermarket under 'warm' appearing lighting, because the enhanced red in the spectrum aids attractiveness. In the home the most likely light source is the tungsten lamp with its yellow–orange illumination. However, most color data are reordered relative to D_{65} or C, and it should be appreciated that if accurate perceptual equivalence is required from the measured color data, it should also be measured to source A or to the requisite fluorescent lamp.

Realistic Limitations

In some industries, particularly the color-matching industries such as the paint, plastics and printing industries, the objective of color appearance measurements is to obtain data that are accurately related to existing colors, e.g., those in an atlas or some internal standard. This may not be required for specific foods. Control procedures for quality assurance may only demand that some critical aspect of appearance be measured. For some products, a single figure quality color scale might be appropriate, e.g., one of the CIE yellowness indexes. In recent years, miniaturization in instrument manufacture has led to a greater availability of hand-held colorimeters and spectrophotometers. The use of these instruments, even with their limitations, in the measurement of the color of food is likely to increase with commensurate improvements in assurance of consistent product quality to the consumer.

Texture

M C Bourne, New York State Agricultural Experiment Station, Cornell University, Geneva, USA
A S Szczesniak, New York, NY, USA

A Quality Factor

Texture is a sensory property of foods which, together with appearance, aroma, and basic taste, has a profound effect on consumer acceptance of foods. Each of these properties is composed of a number of notes. Texture lies between taste and aroma in this respect, several dozen different texture notes being detectable in foods, which is more than the four taste notes of sweet, sour, salt, bitter, and less than the hundreds of odor notes that can be recognized.

Textural perception occurs directly through the tactile (touch) and kinesthetic (movement) senses, and indirectly through the senses of vision and hearing. In contrast to color and flavor, there are no specific sensory receptors for texture. Texture is an important quality attribute in almost all foods and most important in foods that are bland in flavor, or have the characteristics of crispness or crunchiness. It contributes to the satisfaction of chewing and the pleasure of eating. Good textures are indicators of excellent food preparation. Highly valued is textural contrast, i.e., the presence of two or more contrasting, but compatible, characteristics that can occur within a meal, on the plate, or within a food product.

Texture may be defined as 'that group of physical characteristics that arise from the structural elements of the food, are sensed primarily by the feeling of touch, are related to the deformation, disintegration, and flow of the food under a force, and are measured objectively by functions of mass, time, and length.' This definition teaches that texture has its roots in structure (molecular, microscopic, macroscopic) and the manner in which this structure reacts to applied forces. It also emphasizes that texture is a multidimensional property comprising a number of sensory characteristics.

A large number of terms are popularly used to describe textural sensations. **Table 1** organizes many of these terms into a manageable system that facilitates understanding their interrelationships. It classifies textural properties into mechanical characteristics (reaction of the food to stress), geometrical characteristics (the feeling of the size, shape, and arrangements of particles in the food, sometimes called 'particulate properties'), and other characteristics (relating to the sensations of moisture, fat, and oil in the mouth). **Table 2** provides physical and sensory definitions of the mechanical characteristics.

Sensory Evaluation

Since, by definition, texture is a sensory property, the most logical approach to its description and quantification is by sensory evaluation. In the early days, panels with various degrees of training were used to score specific textural characteristics or 'texture' in general. The scoring methods used were either numerical intensity scales (frequently 0–7, with 0 denoting absence and 7 a very high intensity of a specific characteristic) or hedonic scales (ranging from 'dislike extremely' to 'like extremely'). The latter should not be used when the objective is to describe texture in terms of the characteristics present or to quantify their intensity.

The sensory perception of texture is a dynamic process which involves the rate and magnitude of the applied forces, and also the effects of temperature, saliva, and time. The time element includes the repeated application of destructive forces in the masticatory process, and the duration of the food's contact with saliva and mouth temperature.

The multiparameter nature of texture and the process dynamics of its sensory perception during mastication form the basis for the sensory texture profile,

Table 1 Classification of textural characteristics and their relationship to popular nomenclature

Characteristics	*Primary parameters*	*Secondary parameter*	*Popular terms*
Mechanical	Hardness		Soft, firm, hard
	Cohesiveness	Brittleness	Crumbly, crunchy, brittle
		Chewiness	Tender, chewy, tough
		Gumminess	Short, mealy, pasty, gummy
	Viscosity		Thin, thick
	Springiness		Plastic, elastic
	Adhesiveness		Sticky, tacky, gooey
Geometrical	**Class**		**Examples**
	Particle size and shape		Gritty, grainy, coarse, etc.
	Particle shape and orientation		Fibrous, cellular, crystalline, etc.
Other	Moisture content		Dry, moist, wet, juicy
	Fat content	Oiliness	Oily
		Greasiness	Greasy

Table 2 Definitions of the mechanical parameters of texture

	Physical	*Sensory*
Hardness	Force necessary to attain a given deformation	Force required to compress a substance between molar teeth (solids) or the tongue and palate (semisolids)
Cohesiveness	Strength of internal bonds	Amount of sample deformation before rupture when biting with molars
Fracturability	Forces necessary to fracture the material	Force with which the material crumbles, cracks, or shatters
Chewiness	Energy required to disintegrate a solid food to a state ready for swallowing	Number of chews required to masticate a sample at one chew per second and constant rate of force application to reduce it to a consistency suitable for swallowing
Gumminess	Energy required to disintegrate a semisolid food to a state ready for swallowing	Denseness that persists throughout mastication of a semisolid food
Viscosity	Rate of flow per unit force	Force required to draw a liquid from a spoon over the tongue
Springiness	Rate at which a deformed material goes back to its undeformed condition following removal of the deforming force	Degree and speed with which the material returns to its original height following partial compression with molar teeth
Adhesiveness	Work necessary to overcome the attractive forces between the surface of the food and other surfaces with which the food comes in contact	Force of the tongue required to remove the material that adheres to the mouth (generally the palate, but also lips, teeth. etc.) during the normal eating process

the schematic for which is shown in Figure 1. The method is used to define the texture characteristics present, the intensity of each, the order in which they appear, and all the changes that occur from the first bite through completion of mastication. Texture profile analysis is presently the preferred sensory method for texture characterization because it is the only method that provides a complete analysis of all the textural properties of a food. Using reference samples and standard scales for specific parameters, highly trained panels provide a descriptive and quantitative 'fingerprint' of the product's texture. The training and maintenance of the panel may be tedious and expensive, but the quality of the generated data usually compensates for it. The basic principles can be adapted to different products in different situations including untrained consumer panels. Two examples of sensory texture profiling are shown in Table 3.

Most other sensory methods can be regarded as partial texture profiles or modifications of the basic procedure. The two main methods are: Quantitative Descriptive Analysis (QDA) and Spectrum. QDA differs from texture profiling in that it uses unstructured line scales for quantifying the intensity of texture notes present, and the data are generated by averaging the ratings given by the individual panelists rather than through panel discussion and a consensus. Another difference is that the panelists generate their own sets of terms. In contrast, the Spectrum method uses an expanded set of terms within the standard lexicon of texture profiling. It employs 15-point intensity scales anchored by reference samples. The extensive panel training and the active role

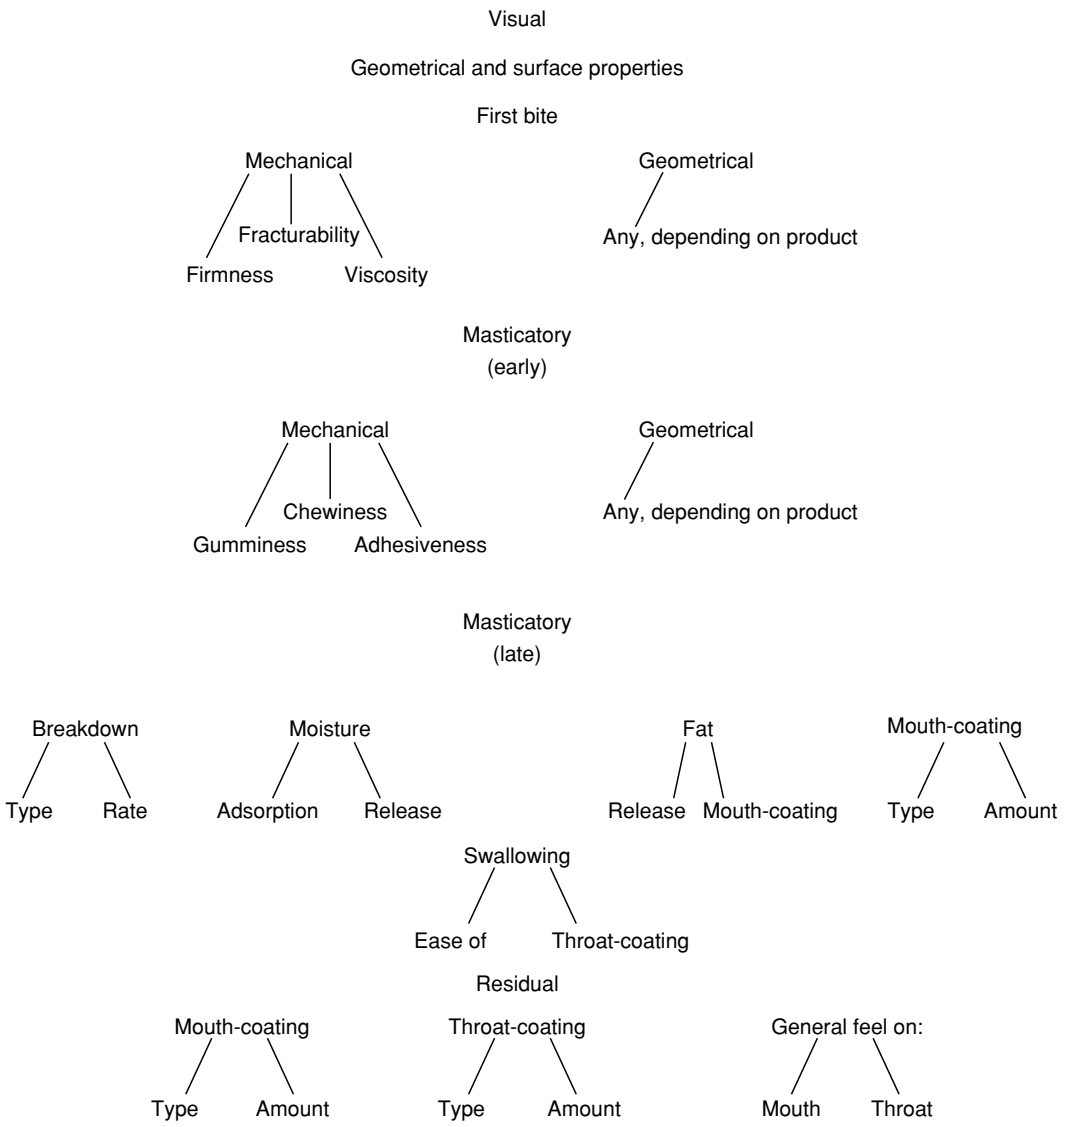

Figure 1 Sensory texture profiling technique. Reproduced from Sensory Evaluation: Texture, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press, with permission.

of the panel leader are similar to those of texture profiling.

Instrumental Evaluation

Although sensory methods are the final arbiter of textural quality, instrumental methods are the most frequently used for texture measurement because they are cheaper and less time-consuming. To be successful, any instrumental measurement must correlate highly with the sensory evaluation. It needs to be recognized that instrumental methods measure one or more textural properties of a food before it is placed in the mouth, but cannot follow the changes that occur during mastication. Most instrumental methods are 'one-point' measurements, i.e., they measure only one dimension of the texture, albeit usually a dominant textural property. Because there is a wide range of types of foods and textures, people use a wide variety of methods to assess texture sensorially. Before they put food into the mouth they use their fingers and hand to squeeze, stir, bend, or puncture the food. After the food is put into the mouth the chewing rate, the amount of lateral movement of the mandible (jaw), and the movements of the tongue are automatically adjusted to handle that particular food in the most convenient way. A large number of texture-testing instruments have been described in the literature and almost 100 are available commercially. Table 4 classifies objective methods of

Table 3 Basic sensory texture profile ballot for meatballs and soda crackers

Texture notes	*Meatballs*	*Soda crackers*
Initial		
Mechanical		
Hardness (9-point scale)	3.4	4.0
Fracturability (7-point scale)	0.7	2.5
Viscosity (8-point scale)	Not applicable	Not applicable
Geometrical	Lumps, with a grainy surface	Flaky and puffy
Other	Moist, uncut surface is slippery and cut surface is not slippery	Dry
Masticatory		
Mechanical		
Gumminess (6-point scale)	1.2	0
Chewiness	17.7 chews	16 chews
Adhesiveness (5-point scale)	1.2	0.7
Geometrical	Coarse, grainy; some fibrous particles are present	Flaky
Other	Moist	Dry
Residual		
Rate of breakdown	Large lumps break down fast; grains break down at a medium rate	High
Type of breakdown	Lumps turn into a nonhomogeneous, grainy paste, and grain size decreases. Some stringly fibrous grains are present; they become more noticeable towards the end and require more effort to chew	It breaks down into little rough sheets, then changes into a smooth dough
Moisture absorption	Initially moist. Saliva mixes easily with slurry and the bolus becomes progressively more moist. Residual grains feel dry	It absorbs a lot of saliva slowly and change into a moist dough
Mouth-coating	Slight residual oiliness. A few particles stick between the teeth and around the mouth	Little pieces stick to the mouth and gums

food texture measurement on the basis of the variable(s) measured and the principle of the test. Force-measuring instruments are the most common, but other principles, such as distance, time, and energy, are also used. There are a few examples where a chemical analysis correlates well with a textural prop-

erty. Finally, the sounds that are generated are an important dimension of the textural quality of crisp and crunchy foods. Characteristic sounds are generated when these foods are compressed. The sounds are of low frequency and come in a series of sharp bursts, that occur in rapid succession. Crunchy foods exhibit notes of a lower frequency than crisp foods.

The key element that differentiates force-measuring instruments is the geometry of the test cell which holds the sample and applies a force to it (cutting, puncture, compression, extrusion, etc.). Recognition of the above fact has led to the widespread use of strength-of-materials-testing machines that provide a sophisticated driving mechanism, force sensor, and recording of the force–time relationship. They are more expensive than the simple instruments that have been in use for many decades, and they came into use in the late 1960s. They are called universal testing machines (UTMs) because, with appropriate test cells attached, all test procedures that require rectilinear movement can be performed on the same machine. With the advent of computer retrieval and analysis of the force–time data their use is rapidly becoming routine for quality purposes also. One UTM, the TA.XT2 texture analyzer, has been expressly developed for measuring textural properties of foods. Its operation is so simple, yet precise, that it is now widely used for both research and quality control purposes.

The following criteria are recommended as a guide to selecting a texture-testing instrument or the type of test to program into an UTM.

- Purpose – research or quality assurance.
- Nature of product – rheological type, heterogeneity.
- Required accuracy – high variability inherent in unprocessed foods often necessitates many replications.
- Cost – including operation and maintenance.
- Time – routine use requires rapid testing.
- Location – ability to withstand adverse environmental conditions when placed in factory surroundings.
- Nature of sensory evaluation method used by people (squeeze in hand, cut with incisors, crush between molars, roll with the tongue against the hard palate, etc.)

This should narrow the field to the most promising two or three test principles. The final candidates should be tested over the full range of textures normally encountered with the food and correlated with sensory evaluation. A statistical analysis of the results should identify which principle and instrument are the best for each particular application. The final step is to establish the test conditions that give the strongest resolution between different samples and then standardize them. These include sample size, test cell dimensions, force range, speed of travel of moving parts, chart speed, temperature, and perhaps other factors.

Texture Profile Analysis

The methodology of texture profile analysis (TPA) brings instrumental texture evaluation a step closer to sensory testing. It involves compressing a bite-size piece of food two or more times in a reciprocating motion that simulates the action of the jaw, and quantifying from the resulting force–time curve a number of textural parameters that correlate well with sensory evaluation. The method, originally developed for the General Foods Texturometer, has been adapted to universal testing machines. Figure 2 shows a generalized TPA force–time curve. Hardness is defined as the peak force on the first compression cycle (first bite); fracturability is defined as the first significant break in the curve on the first bite. The areas under the curve during the first bite and the second bite are a measure of the work done in the compression. The ratio of these two areas (A2/A1) is defined as cohesiveness. The negative force peak in the first decompression is defined as adhesive force and the negative areas as adhesive work. The distance that the product extends in the decompression is defined as stringiness, and the distance that the product recovers its height between the first and second compressions is defined as springiness. Two other parameters are derived by calculation: gumminess is defined as the product of hardness $\times$ cohesiveness; chewiness is defined as the product of hardness $\times$ cohesiveness $\times$ springiness. Gumminess is the energy required to disintegrate a semisolid food while chewiness is the energy required to masticate a solid food. It is incorrect to report gumminess and chewiness for the same product.

In the early days, instrumental texture profile analysis was an academic curiosity because of the long time required to extract the information from the force–time curves. With computer retrieval and analysis of the data, the time requirement has been reduced to the point where it can become a simple routine test. The TA.XT2 texture analyzer is particularly well suited to do this, and as a result measuring TPA in the TA.XT2 is now a widely used procedure.

Rheological Measurements

Historically, rheology has been defined as the study of the deformation and flow of matter or the response

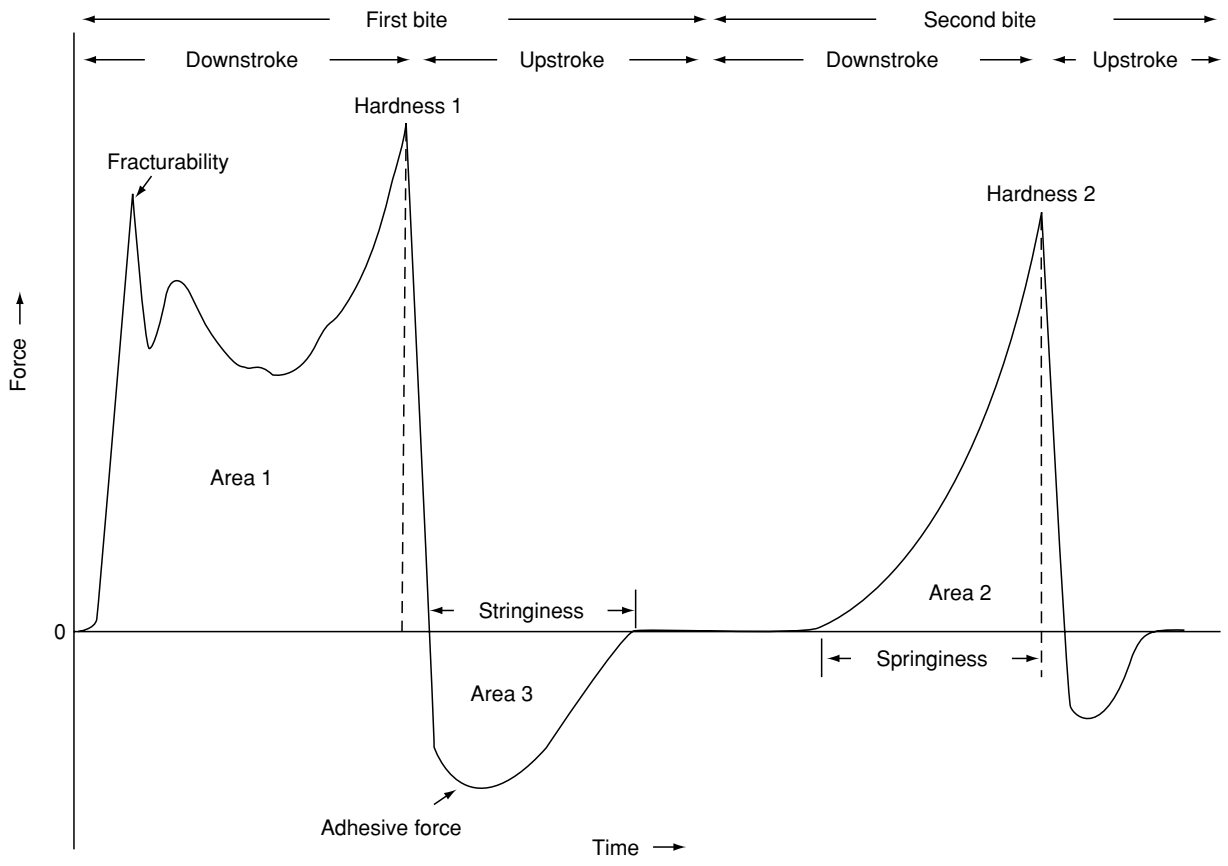

Figure 2 A generalized texture profile analysis curve. From Bourne MC (1978) Texture profile analysis. *Food Technology* 32: 63, with permission.

of materials to stress. The science of rheology, proven so useful in the field of high polymers, has many applications to food, including raw materials (e.g., grains, meats, fruits), intermediate products in the manufacturing process (e.g., bread dough, cheese curd, sausage emulsions), and finished products (all foods). However, rheology does not cover all aspects of texture. The size reduction that occurs during mastication is not rheology, neither are the sensations of oiliness, moistness, and particle size and shape.

Most people believe that there is a sharp distinction between solids (which do not flow) and liquids (which flow). In fact, the distinction between solids and liquids is far from clear because many liquids possess some of the properties of solids, and many solids possess some of the qualities of liquids. The science of rheology specializes in the study of these complex materials (of which there are many examples in foods) that are partly solid and partly liquid.

The flow of liquids may be divided into several broad classes:

1. Newtonian flow, in which the shear rate* is directly proportional to the shear stress†. Examples are edible oils, sugar syrups, milk, and honey. The measurement of the properties of these foods is straightforward, since viscosity‡ is independent of shear rate.
2. Plastic or Bingham flow, in which a minimum shear stress, known as the 'yield stress,' must be exceeded before flow begins. Examples are tomato ketchup, whipped egg white, mayonnaise, margarine, and butter.

*Shear rate (denoted by the symbol $\dot{\gamma}$ and expressed in s^{-1}) is the velocity gradient established in a fluid that results from the application of a shear stress.

†Shear stress (denoted by σ and expressed in Pa) is the force per unit area applied tangential to the plane on which the force acts.

‡Viscosity (denoted by η and expressed in Pa s) is the internal friction of a fluid or its tendency to resist flow ($\eta = \sigma/\dot{\gamma}$); it should only be used for Newtonian fluids. Apparent viscosity (denoted by η_a) is the viscosity of a non-Newtonian fluid expressed as the viscosity of a Newtonian fluid at a specified shear rate (e.g., $\eta_a = \sigma/\dot{\gamma}_{50}$ is the apparent viscosity of a non-Newtonian fluid at a shear rate of 50 s^{-1}).

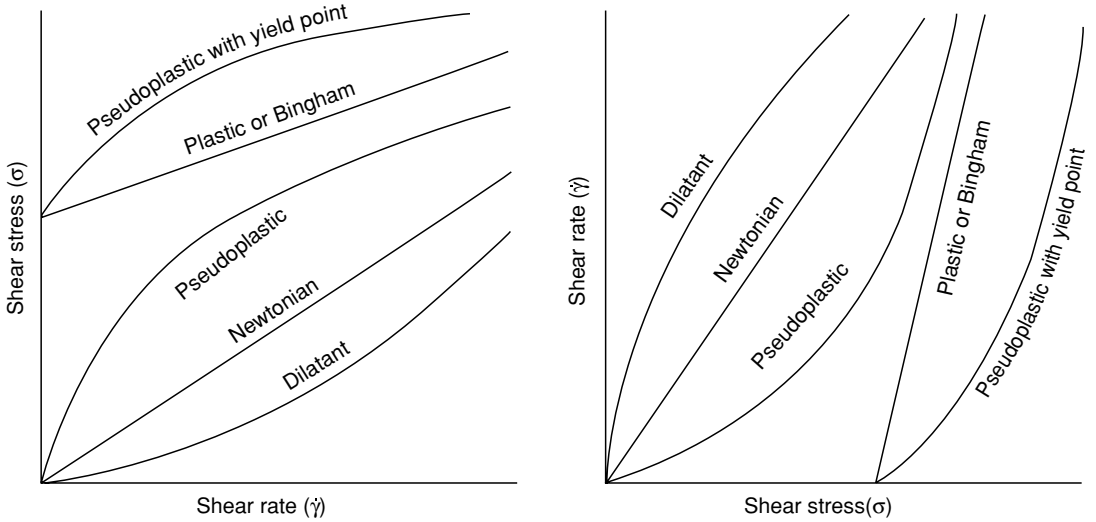

Figure 3 (a) Shear-stress versus shear-rate plots for various types of flow. (b) Shear-rate versus shear-stress plots for the same types of flow. From Bourne MC (1982), *Food Texture and Viscosity: Concept and Measurement*. New York: Academic Press, with permission.

3. Pseudoplastic flow, in which an increasing shear force gives a more than proportionate increase in shear rate, i.e., apparent viscosity decreases with increasing shear rate. Salad dressings exemplify this type of flow.
4. Dilatant flow, in which equal increments in shear stress give less than equal increments in shear rate, i.e., apparent viscosity increases with increasing shear rate. This type of flow is rare in foods but is found in high-solid suspensions of raw starch and some chocolate syrups. (Refer to individual foods.)

The differences between these types of flow are shown in Figure 3. The shear-stress versus shear-rate plot (Figure 3a) is the more common manner of presentation; another that is sometimes used is shown in Figure 3b, in which the axes are interchanged.

Time Dependency

For some fluids the shear stress is a function of both the shear rate and the time it is subjected to shear. For thixotropic products the apparent viscosity decreases with time of shearing. This condition is frequently found in food systems such as gum solutions and starch pastes. Rheopectic products increase in apparent viscosity with time of shearing. This type of behavior is rare in foods.

Viscoelasticity

As discussed above, most foods combine some of the properties of ideal liquids, which exhibit only viscosity (flow) and ideal solids which exhibit only elasticity (deformation). These are called viscoelastic foods. In characterizing these systems rheologically it is necessary to measure both the viscous component (loss modulus, G″) and the elastic component (storage modulus. G′). A food with high G′ and low G″ behaves more like a solid than a liquid, while a food with low G″ and high G′ behaves more like a liquid than a solid. An elastic solid such as rock candy will have a G″ value of zero, while a Newtonian liquid such as sucrose syrup will have a G′ value of zero.

Traditionally, viscoelasticity was measured by performing creep tests in which a weight was placed on the test material and the change in specimen height was monitored over a period of time. Presently, viscoelasticity is usually measured by an oscillation test in which a sample of known dimensions (if solid) or filled into the space between a cone and plate or parallel plates or a cup with standard dimensions (if liquid) is subjected to repeated small sinusoidal deformations that do not fracture the sample. Analysis of the resulting shear stress versus time curves yields the numerical values of G′ and G″. Modern instrumentation provides a computerized system for quantifying these moduli. The rate and degree of deformation may be varied to provide information on the internal structure and mechanical behavior of the material. (*See* **Food Acceptability**: Affective Methods.)

Aroma

D S Mottram and J S Elmore, The University of Reading, Whiteknights, Reading, UK

Aroma

The sense of smell (olfaction) is one of the two chemical senses in humans, the other being the sense of taste. The term 'odor' has been defined by the British Standards Institute as the quality of the sensation perceived, via the olfactory organ situated in the nasal cavity, from certain volatile compounds; aroma is an odor with a pleasant connotation. The olfactory organ is extremely sensitive, and hence the concentrations of volatile compounds in foods contributing to aroma (odorants) may be very low. These complex mixtures of volatile compounds may be analyzed by extraction, followed by separation and characterization.

Olfaction

The olfactory receptors are sited in the olfactory epithelia, two small patches of mucous membrane in the recesses of the nasal passages (**Figure 1**). The response of these receptors to airborne molecules determines the odor of a substance. Molecules entering the nose find their way to the olfactory epithelia where they come into contact with cilia (hairs) on the receptor cells. These produce a change in electrical potential and a signal travels along nerve fibers to the olfactory bulb, part of the brain. There are approximately 100 million olfactory receptor cells in the human nose.

Olfaction plays a primary role in the perception of flavor in foods and beverages. When food is eaten taste, smell and mouthfeel act in concert to produce the integrated sensation of flavor. The aroma of the food is not just perceived in inhaled air. When food is in the mouth, odorants can reach the olfactory receptors by the retronasal route, entering the nasal cavity by the same route as expired air.

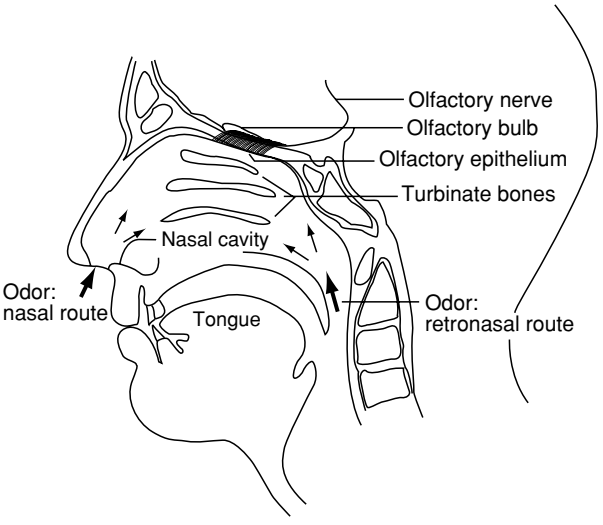

Figure 1 Representation of a section through the nasal and oral cavities showing the olfactory organ. From Thomson DMH (1986) The meaning of flavour. In: Birch GG and Lindley MG (eds.) *Developments in Food Flavours*, pp. 1–21. London: Elsevier Applied Science, with permission.

Odor Sensitivity

Odor perception is considerably more sensitive than the perception of taste, by factors of one million to one billion. As we are able to differentiate a large number of odorants, aroma plays the major role in delineating the characteristic flavor of a particular food. The inability to differentiate flavors is usually associated with anosmia (lack of a sense of smell) rather than ageusia (lack of a sense of taste).

It has been suggested that the triggering of one human olfactory neurone by a powerful odorant may require only eight molecules, and as few as 40 molecules can produce an identifiable sensation. The odor threshold of a compound is defined as the minimum concentration at which the odor of a compound can be detected. The range of thresholds exhibited by odorants extends over at least 10 orders of magnitude (Table 1). One compound with one of the lowest reported odor thresholds is bis-(2-methyl-3-furyl) disulfide, which has a meaty aroma and can be detected at concentrations of 2 parts in 10^{14} parts of water. This concentration is equivalent to about 20 μg in the water of a 50-m swimming pool of 1000 m^3 capacity! At the other end of the range, at least 1 mg of ethanol needs to be present in 10 ml of water before the smell of ethanol can be detected.

Chemical Nature of Aroma Compounds in Foods

The range of chemical classes that contribute to food aromas is diverse in both chemical composition and physical properties, and includes aliphatic, alicyclic, aromatic, and heterocyclic compounds. All aroma compounds have some volatility, but this ranges from permanent gases to compounds with very little vapor pressure and molecular weights up to 300. Approximately 10 000 different volatile compounds have been identified in foods and beverages; complex cooked foods such as coffee and meat contain in excess of 1000 aroma compounds. Many of these compounds are common to a number of different foods, and the contribution of any compound to the characteristic aroma of a particular food will depend on a number of factors, including:

- odor character;
- concentration in product;
- odor threshold;
- vapor pressure;
- adsorption on the food matrix;
- interaction with other components;
- synergism with other volatiles.

Some volatiles have little aroma and do not contribute to food flavor, whereas others define the aromas of specific foods (e.g., benzaldehyde – almonds; citral – lemons). However, for most foods, the aroma depends on contributions from a complex mixture of volatiles comprising different chemical classes. (*See* **Essential Oils**: Properties and Uses; **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Characterization of Aroma Volatiles

In attempting to identify those compounds that characterize different food aromas, flavor scientists have analyzed the volatile composition of many different foods. This usually involves the extraction of volatiles from the food matrix, their concentration, and the separation and identification of the individual components (Table 2). As far as possible, the extract should contain only the volatile components in the same relative proportions as the original food, without the introduction of artefacts. The wide range of odor thresholds can result in quantitatively minor

Table 1 Odor thresholds of some aroma compounds in aqueous solution

Compound	*Threshold (ppb, μg l^{-1})*
Ethanol	100 000
2,5-Dimethylpyrazine	1 800
Butyric acid	250
Limonene	10
Hexanal	5
Ethyl 2-methylbutyrate	1
Methanethiol	0.2
β-Ionone	0.007
2-Isobutyl-3-methoxypyrazine	0.002
Bis-(2-methyl-3-furyl)disulfide	0.00002
2,3,6-Trichloroanisole	0.0000003

components making a major contribution to the aroma, whereas some large components will have no sensory significance. Successful isolation and identification of minor components with aroma significance is one of the major challenges of aroma analysis.

Isolation and Concentration of Aroma Volatiles

The components of food that are responsible for aroma are present in extremely small quantities compared with the major constituents, of which water is usually the most abundant. A number of isolation techniques exist, all based on utilizing the volatile nature of the aroma compounds to separate them from the food matrix.

Headspace analysis The concentration of volatiles in the headspace vapor above a food or beverage will be very low. However, it will contain a representative mixture of those compounds that contribute to the aroma of the product, and therefore, analysis of that headspace will provide the best method of obtaining a sample representative of the food aroma. However, direct introduction of a given volume of the vapors above a food sample on to a gas chromatographic column is rarely used, because the volatiles are not present in sufficiently high concentrations and because water from the sample will often cause interference. Purging the headspace volatiles with a stream of inert gas (nitrogen or helium) and condensing the volatiles in a series of traps cooled by ice, solid carbon dioxide, or liquid nitrogen will result in a concentrated aroma condensate. Extraction of the condensate with a small amount of a suitable solvent provides an aroma extract suitable for chromatographic analysis. Instead of using cold traps, headspace volatiles can be collected on suitable adsorbents.

Adsorption The ability of certain solid surfaces to reversibly adsorb volatile organic molecules is widely used in the analysis of aroma compounds. Activated charcoal was the first to be used, but now, certain porous polymers, in particular Tenax TA, are frequently employed. Like charcoal, all of these materials readily adsorb volatiles while having little affinity for water, making them particularly useful in the analysis of samples with a high water content.

In a typical collection, a stream of a purified inert gas (helium or nitrogen) sweeps the volatiles from the sample flask into a small tube containing 10–200 mg of the adsorbent. Adsorbed volatiles can be heat desorbed directly on to a gas chromatographic column by placing the adsorbent trap in a specially modified injection port, thus avoiding any loss of components or unnecessary dilution. Cooling the front of the column ('cryofocusing') with solid carbon dioxide or liquid nitrogen during this desorption will avoid any loss in chromatographic resolution. Alternatively, volatiles may be removed from the trap by passing a small amount of a low-boiling-point solvent through the adsorbent. Concentration of the collected solution by careful evaporation of the solvent provides an aroma extract for gas chromatography (GC).

Solid-phase microextraction This is an adaptation of traditional adsorption methods in which a small fused silica fiber, coated in an adsorbent material, is mounted in a syringe-like device (Figure 2). The needle is pushed through a septum, and the fiber is exposed to the headspace above the food or beverage sample, which is sealed in a suitable container. Volatile compounds are adsorbed on to the fibre, and at the end of the extraction, the fiber can be removed from the sample vessel and directly desorbed into the split/splitless injector of a gas chromatograph. Again, cryofocusing of the aroma volatiles on the front of the gas chromatographic column is performed to insure no loss of resolution. Solid-phase microextraction (SPME) has evolved rapidly since its introduction in the early 1990s, and fibres coated with Carboxen™ are suitable for the analysis of a wide range of aroma compounds. SPME can be automated, and its ease of use, relatively low cost, and affinity for a large range of compounds would suggest that it will become a widely used technique for the isolation of aroma volatiles.

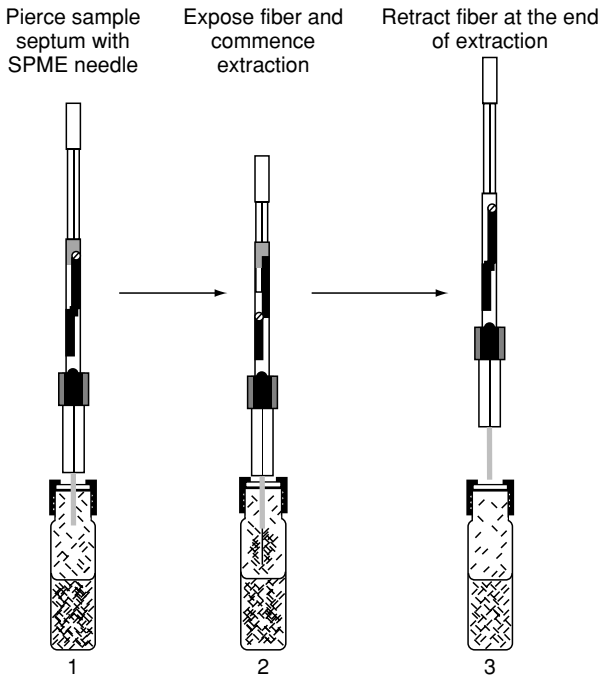

Figure 2 Principle of solid-phase microextraction.

Distillation Steam distillation finds application in the analyses of volatiles from beverages and high-water-content foods, although it is less applicable to fats and oils. It has the disadvantage that the large quantities of aqueous distillate require further extraction with a solvent, to separate the volatiles from the water. Concentration of the extract is then necessary. The formation of artefacts may also be a problem. Vacuum distillation finds wide application in the extraction of volatiles from fats and oils, and at low extraction temperatures artefact formation can be minimized. In molecular distillation, a high vacuum ($< 10^{-3}$ mmHg), is used, and the volatiles have a relatively short path to travel from the surface of a liquid oil sample to a cold surface where they condense. Efficient collection of high-boiling-point components is achieved because at high vacuum, the distance between the sample surface and the cold condenser (10–20 mm) is less than the mean free path of the molecules. All of these distillation processes incorporate cold traps for the collection of the distillate.

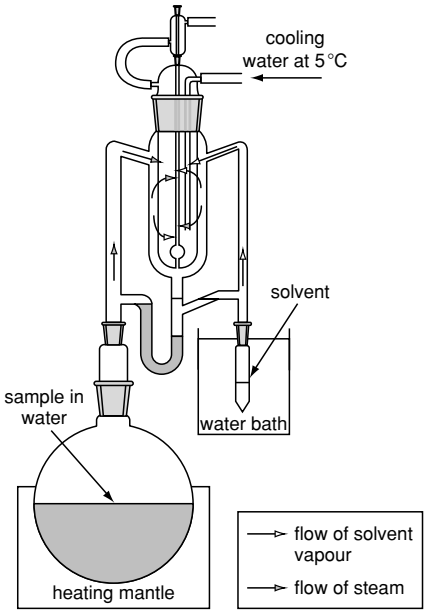

Figure 3 Likens–Nickerson apparatus for continuous steam distillation–solvent extraction.

Extraction Direct extraction of an aqueous food fraction with an organic solvent is of limited use, because the extract will contain a large amount of nonvolatile matter. However, supercritical carbon dioxide has been utilized as a solvent for the extraction of aromas on both a laboratory and a commercial scale, particularly the preparation of high-quality essential oils. Its solvating qualities can be altered by changing the pressure or temperature at which the extraction takes place, and under ideal conditions, supercritical carbon dioxide exhibits a strong affinity for most aroma compounds, whereas most nonvolatile constituents are insoluble. The ease of removal of the solvent, after extraction, to give a concentrated aroma extract is another attractive feature of supercritical carbon dioxide extraction.

One of the most widely used techniques in aroma analysis combines steam distillation with solvent extraction in a Likens–Nickerson apparatus (Figure 3), which was first reported in 1964 for the extraction of hop oil. The essential feature is the simultaneous condensation of the steam distillate with an immiscible extraction solvent. A simple U-tube, with appropriate side arms, allows the return of water to the steam distillation flask and the solvent, containing the extracted volatiles, to a reservoir flask where it redistils for further extraction. The technique provides a simple rapid method involving only small volumes of solvent. By carrying out the extraction under a reduced pressure, thermal degradation of labile components can be diminished.

The organic solvents used for extraction are chosen on the basis of their selectivity for the volatile compounds of interest and on boiling point. Commonly used solvents are diethyl ether, pentane, isopentane, dichloromethane, and some chlorofluorocarbons. After each type of solvent extraction, most of the solvent must be removed to provide an aroma concentrate suitable for GC. Removal of traces of water, using a drying agent (sodium or calcium sulfate) or by freezing out at $-20\,^{\circ}C$, is essential before careful removal of solvent by distillation. Final concentration to a volume of 0.1–1 ml is often achieved by purging with a gentle stream of nitrogen.

Separation of Aroma Components

To determine the sensorially important compounds in an aroma isolate, the complex mixture needs to be separated into its components. The amount of isolate is usually small, containing many compounds of diverse chemical structures, varying greatly in concentration, and important components are often present in extremely low amounts. The success of any aroma analysis depends mainly upon the efficiency of separation and the sensitivity of detection. GC using bonded-phase fused-silica capillary columns is almost universally used as the separation method in aroma analysis. Such columns can separate complex mixtures, and the most commonly used stationary phases are Carbowax 20M, a polar phase, and the two nonpolar phases, 100% poly(dimethylsiloxane) and poly(5% diphenylsiloxane/95% dimethylsiloxane). The stereochemistry of compounds can influence

aroma, e.g., (+)-carvone possesses a spearmint aroma, whereas (−)-carvone possesses a caraway-like aroma; capillary columns coated with chiral phases can be used to separate enantiomers. The retention times of an aroma compound on two columns with different stationary phases can be helpful in its identification, and databases containing retention data for volatile compounds are available.

Preparative liquid chromatography is sometimes performed on solvent extracts, as a first step, to simplify subsequent separations. The most widely used example of this is flash chromatography, where the extract is pipetted on to the surface of a stationary phase, such as silica gel, which is contained in a glass column. Fractions of the extract are obtained, as solvents of increasing polarity are passed through the column under positive air pressure. The fractions are analyzed subsequently by GC. (*See* **Chromatography**: Gas Chromatography.)

Detection of Components of Sensory Significance

An essential step in the analysis of aroma is to determine which volatile compounds contribute to the aroma of the food or beverage. Sensory profiling of the whole product can give some indication of the important aroma characters present in the product, and such information should be used when assessing the contribution of the individual components of an aroma isolate to the overall flavor quality. A widely used technique for determining components that contribute to aroma is GC olfactometry (GCO). The column effluent is split between a conventional GC detector and a vent to the outside of the oven, where the odors emerging can be smelled and described. Chromatogram peaks can thus be identified that correspond to specific aromas, and 'aromagrams' can be compiled to complement the chromatogram.

To estimate the relative contributions of volatile components towards the total aroma quality of a food, a set of serial dilutions of an aroma extract can be made up and analyzed by GCO. At a certain dilution, the aroma of a particular volatile compound will no longer be perceived. The flavor dilution factor for that compound is defined as the highest dilution at which that compound can be perceived by GCO. For example, if the concentration of the extract was halved at each dilution and the seventh dilution was the last at which the compound could be detected, its flavor dilution factor would be 2^7 (128). Hence, if the aroma extract is representative of the food from which it is derived, the most important contributors to the aroma of the food are those with the highest flavor dilution factors. It should be noted that components with high flavor dilution factors might not give GC peaks of any significant size.

Another way of estimating the contribution of a volatile compound to the aroma of a food is by calculating its odor unit number. The odor unit number of an aroma compound in a food is defined as the ratio between its concentration in the food and its odor threshold, as measured by sensory evaluation. Hence, the higher the odor unit number of the compound, the more likely it is to contribute to the overall aroma of the food. Several literature compilations of odor thresholds exist.

Identification of Components

Structure elucidation of the chromatographically separated components is the next step in the analysis of an aroma isolate. Coupled gas chromatography–mass spectrometry (GC–MS) allows direct analysis of the separated components and provides the most efficient means of volatile identification.

Gas chromatography–mass spectrometry The availability of coupled gas chromatograph–mass spectrometer systems in the late 1960s was one of the most important developments for flavor research, and this was followed a decade later by the introduction of efficient computerized data-handling systems. Today, sensitivity is usually such that a full spectrum can be readily obtained on 1 ng of a single component in a complex mixture injected on to the GC column, and in many cases, an identifiable spectrum can be obtained from as little as 10 pg. Quadrupole mass spectrometers, obtaining at least one spectrum per second, are ideal for low-resolution GC–MS of aroma extracts. However, double-focusing magnetic sector mass spectrometers can acquire accurate mass data, allowing the calculation of empirical formulae for ions in a spectrum, which can be a great asset in the identification of unknown compounds.

The characterization of unknown compounds is greatly facilitated by comparing their mass spectra with those of known compounds in compiled libraries incorporated into the GC–MS data system. Current databases contain the mass spectra of over 200 000 compounds, but special compilations containing only volatile compounds have also been prepared, and at least one is available in computer-readable format. Confirmation of the identity of compounds should always be carried out, preferably by comparing their mass spectra and retention times with those of authentic samples. (*See* **Mass Spectrometry**: Principles and Instrumentation.)

Spectroscopic methods Nuclear magnetic resonance and infrared (IR) spectroscopy are both extremely valuable techniques in the identification of organic compounds. However, they require larger sample

sizes than mass spectrometry and are not as widely used in aroma analysis. They are primarily used to aid structure elucidation of unknown compounds.

Fourier-transform IR instruments directly coupled to a gas chromatograph have been developed, giving adequate vapor-phase spectra on 10–100 ng of compound. IR offers functional group information and in general is complementary and supportive of MS. Because IR is nondestructive, it has been possible to develop tandem GC–IR–MS systems, providing a powerful tool for aroma analysis.

Quantification of Aroma Components

Often, quantitative information on aroma compounds in a food is needed, such as for the calculation of odor unit numbers. Quantification is rarely simple, because most extraction techniques only remove a proportion of the aroma from the food. Sometimes, the extraction technique may generate aroma compounds, and difficulties in quantification may arise when compounds are not resolved by GC. The most effective means of quantification is isotope dilution assay using GC–MS, where a known amount of a ^{13}C- or ^{2}H-labeled internal standard is added to a slurry of the food to be extracted, in order to quantify its nonlabeled equivalent. As the labeled and unlabeled aroma compounds possess similar physical properties, the proportion of each extracted will be the same. The relationship between the labeled standard and the compound of interest can be used to calculate accurately the amount of the compound of interest in the food.

Other quantification methods include the addition of an internal standard, not present in the food, of a similar chemical composition to the compound of interest, e.g., 2-methylpentanal could be used to quantify hexanal. Conversely, standards could be added to the extract, in order to calculate the amount of the compound of interest in the extract rather than the food itself. Standards can be injected into traps containing adsorbent and, in the case of SPME, injected on to the GC column immediately before desorption of the fiber.

The Electronic Nose

The electronic nose is an array of chemical sensors, connected to a pattern-recognition system that responds to odors passing over it. Different odors cause different responses in the sensors, and these responses provide a signal pattern characteristic of a particular aroma. The computer evaluates the signal pattern and can compare the aromas of different samples, using pattern recognition. For example, if a manufacturer uses coffees from around the world, the electronic nose can analyze them, and their aromas can be plotted on a multidimensional response map. The analysis of several samples of each coffee, under ideal conditions, can result in a group of points for each coffee, well resolved from any other group. As the number of samples increases, the resolution between the groups should also increase. Plotting the sensor responses of an unknown sample on the same map should permit its recognition, by its proximity to one of the known samples.

Sensors are usually made of metal oxides or organic polymers, although more recently, surface acoustic waves and piezoelectric crystals have been used. Problems may exist when samples with a high water content are analyzed, as many of the sensors respond strongly towards water, preventing any sample differences being observed.

Measurement of Aroma Release during Eating

Attempts have been made by several researchers to measure the release of aroma during the eating of food. At present, mass spectrometry using an atmospheric pressure chemical ionization (APCI) interface appears to be the most effective way of doing this. As a subject eats a food or beverage, a sampling tube draws the volatiles from the mouth or nose into the mass spectrometer interface. Released aroma compounds are ionized in air containing water vapor at atmospheric pressure in the APCI source; the ions are subsequently sampled into the high-vacuum area of the mass spectrometer. APCI does not normally induce fragmentation, and a strong protonated molecular ion is observed. By monitoring the molecular ions associated with the major aroma compounds in the sample, volatile release profiles can be measured. Pulsed release curves are usually obtained, due to respiration of the subject, and these can be smoothed to show how each of the volatiles of interest behaves during the eating process. This equipment has been used, for example, to examine how reducing the fat content of a food will affect its flavor or to study how the chewing patterns of different people affect flavor release.

Taste

H Valentová and Z Panovská, Institute of Chemical Technology, Prague, Czech Republic

Taste

Taste, according to the International Standard Sensory Analysis Vocabulary ISO 5492 (1992), is defined as sensations perceived by the taste organ when stimulated by certain soluble substances. Taste is closely related to smell. The perception of odor and taste, combined with trigeminal sensations, results in the overall flavor. Flavor influences food acceptance and selection of food intake, and helps us to distinguish potentially harmful compounds. The taste sensation is a very complex process starting at the sensory receptor level and finishing in the central nervous system, where it is combined with information coming from other senses. The earliest work concentrated on anatomical studies, and so we have a good deal of information about the structural taste system on the tongue.

Anatomy of the Tongue

Mouth

An important role in the perception of taste is played by our mouth cavity and especially by the tongue. Food is placed inside the mouth, where our teeth chew it, and the saliva makes it into a solution, and therefore, the food comes into contact with the surface of the tongue. The main role for perception of taste is played by taste papillae, taste buds, and taste cells.

Papillae

Taste papillae are located on the tongue, soft and hard palate, pharynx, and epiglottis. The papillae give the tongue its bumpy appearance and can be classified, according to their shape, into four types: fungiform, foliate, circumvallate, and filiform papillae. The first papillae appear when the human fetus is 6 weeks old, and at around 10 weeks, the first primitive taste pores are found. **Table 1** shows a description of the different types of papillae.

Taste Buds

In the epithelia of the papillae, there are taste buds, 40–80 μm in size. Children have about 10 000 taste buds, but the amount decreases with age. The average number for adults is 2000–3000 buds. The taste-bud density and placement of the taste buds among people vary. For example, the density on the tongue tip ranges from 3–512 taste buds per square centimeter, with an average of around 115 buds per square centimeter. People with a higher density of buds perceive taste stimuli more intensively. The specificity of individual taste bud cells is being studied. It is still not clear at the taste bud level whether there is modality specificity. Some studies have confirmed that some fungiform papillae contain only one taste bud, but this could not be proved. It has also been demonstrated that taste buds respond differently to different

Table 1 Description of papillae[a]

Types of papillae	*Number of papillae*[a]	*Taste buds per papilla*[a]	*Location*
Fungiform	100–400	0–22	Base and edges of the tongue

substances. It seems that all areas with taste buds respond to some degree to all tastes, but there is usually one taste to which the response is the best.

Taste Cells

The tip of the taste bud has a small opening about 2–5 μm in diameter, called a taste pore, where taste stimuli interact with taste receptors. Taste buds are aggregates of some 40–60 elongated epithelial cells. There are different types of cells in a taste bud: dark cells, light cells, cells with dark-cored and synaptic vesicles, basal cells, and perigemmal cells. It is not clear which of the cells serve as receptor cells or if the different cell types are specialized to detect different ranges of the gustatory spectrum. The taste cells continually regenerate; they live for only 7–10 days and, within this period, grow to maturity and die. The young taste receptor cells move from the periphery of the taste bud to its center, and the older taste cells in the central portion of the taste buds die away and are then pressed out from the taste bud into the mouth through taste pores. By replacing the cells in this way, the gustatory system is protected from losing its sensitivity. All taste cells from one taste bud are connected by basal synapses to about 50 afferent nerve fibers. The nerve fibers from taste buds converge into different cranial nerves.

Cranial Nerves

The sense of taste is mediated by three cranial nerves. The anterior (front) two-thirds of the tongue and palate is supplied by branches of facial nerves, namely chorda tympani branch (seventh cranial nerves), the back of the tongue by glossopharyngeal nerve (ninth cranial nerves), the base and central region, and the throat and larynx by certain branches of vagus nerve (tenth cranial). All nerves subserve not only taste but also touch, temperature, and pain sensitivity. The lingual nerve is the branch of the fifth cranial nerve and is responsible for the perception of pungency, heat, cooling, and others.

The taste fibers from all the sensory nerves from the mouth come together in the brainstem (medulla oblongata). From the brain's medulla, the gustatory fibers ascend by a pathway to a small cluster of cells in the thalamus and thence to a taste-receiving area in the anterior cerebral cortex.

Two main theories try to describe how taste information is coded in the brain. In the pattern theory, the main role is played by taste receptor cells that respond with different sensitivities to the different tastants. In the labeled line theory, the four tastes are sensed in four discrete type of receptor cells, and the information from receptors goes to the brain through independent channels. It seems that both types of mechanism are involved in taste perception.

Transmission of Taste Through Nerve Impulses

The transmission of electrochemical impulse through the nerves is called transduction. The understanding of this process has been the main focus of taste researchers.

Generally, the arrival of a chemical stimulant on the surface of a receptor changes the ionic conductance in the taste membrane and the electrochemical impulse is produced. The transduction pathway involves a number of different receptors and different cellular mechanisms.

Taste stimuli may interact:

- directly with the ion channel – this produces receptor cell depolarization either by direct permeation or by blockage of the ion channel;
- with receptors and alter the flux of ion through the ion channel (K^+, Na^+, Ca^+);
- may diffuse through lipid phase and affect G protein or the endoplasmatic reticulum.

Researchers believe that each basic taste has a particular transduction pathway (Table 2) that varies with the location of taste buds on the tongue. For

Table 2 Suggested pathways for individual tastes

Taste	*Possible pathways for transduction mechanism for different stimuli*
Bitter	Multiple mechanisms – depending on the structure of the compounds: (a) Inhibition of apical K^+ channel (mechanism for chinine, divalent salts) (b) Blockage of Na^+ amino transport system (c) G protein-mediated activity involving phospholipases
Sweet	Specific membrane receptors are required for transduction of sugars: (a) Multiple sweet receptors coupled to G protein (gastducin) and second messenger system (b) Stimulus-gated ion channel (c) Direct activation of G protein by sweet stimuli
Sour	Does not require specific taste receptor – several apically located ion channels may participate in sour transduction: (a) sodium ion channel – proton enters taste cells through amiloride-sensitive sodium channels; (b) channels are stimulated by protons that permit entry of cations into the cell
Salty	Does not require specific taste receptor – direct permeation of Na^+ ions through amiloride-sensitive sodium channel
Umami	Stimulus-gated ion channel: taste stimulus binds to a receptor site on a receptor–ion channel complex

sweet and bitter taste, there probably exist multiple pathways that can be common for substances with a similar structure. The transduction of the different taste stimuli has been studied on nonhuman species, and it is not still clear whether the same mechanism is involved in humans.

Basic Tastes

Over the centuries, the numbers of primary tastes have varied from two – sweet and bitter – to more then 10. Studies carried out to date have distinguished four taste categories: sweet, salty, bitter, and sour taste. Now, some of the scientists also include between basic tastes a less-established taste, 'umami.' International Standards ISO 5492 in paragraph 3.22, under basic taste, states: 'basic taste: any one of the distinctive tastes: acid, bitter, salty, sweet, alkaline, umami, metallic.'

Sweet Taste

Sweet taste is one of the favorite tastes and therefore the most studied. There is evidence that prenatal infants detect and like sweet *in utero* and that human infants are born with a preference for sweet taste.

Scientists tried to solve the problem of sweet taste through the chemical structure of sweet compounds, but substances that have a sweet taste are found in all chemical classes. They are usually associated with multiple hydroxyl groups, and α- but not β- or γ-amino acids. Salts such as beryllium or lead salts, simple organic compounds such as chloroform, and alcohols can have a sweet taste. The main groups are carbohydrates, with sweetness decreasing in a homologous series sugars > oligosaccharides > polysaccharides. Other sweet organic compounds include amino acids, peptides, proteins, compounds with NH_2 groups such as amides, ureas, and hydrazides. Benzene compounds with one single NO_2 group are often sweet, and those with more NO_2 groups are usually bitter. Small changes in the stereochemie of atoms within a molecule may affect its taste. The chemical structure of the sweet compound also plays an important role in the determination of the area of the tongue, where the sweet taste is perceived. For example, the taste of inorganic salts and nitrogen compounds is perceived on the front of the tongue, some dihydrochalcons on the back, and some sweet proteins such as thaumatine and nonelline on the sides.

From the time when, in 1914, the need for discrete functional groups of a sweet compound was recognized, several theories tried to explain the sweet taste. In Shallenberger's hypothesis sugar molecules must possess more hydrogen-bonded functional groups per carbon. The molecules interact with the sweet-taste receptor sites of a protein through hydrogen bonds. The question is if there is a receptor for sweet taste or if a different structural class has its own special receptor and how they interact with the sweet compound. It seems that this question will be answered soon. Recently, scientists discovered a sweet receptor gene, T1R3, thought to be the likely basis for the tongue's sweetness sensor. One of the newest theories is multipoint attachment theory. This theory assumes the presence, probably a seven-pass transmembrane receptor, of at least eight fundamental recognition sites. The multiple theory is supported also by other findings, such as synergy effects of sweeteners, the adaptation of the response to some sweeteners, but not to others, the sensitivity of different parts of the tongue to the different sweeteners, and human variability in sensitivity to different sweeteners.

Studies with a new approach to studying the mechanism of sweet taste also appeared during the last decade. Schallenberger in 1993 described the role of symmetry. Sweetness is elicited through a bilaterally symmetrical and concentrated dipolar interaction between glycophore and the receptor. Also, the role of partial molar and specific volumes has been explored in sweet taste chemoreception. Some scientists focused on the role of water that could be the vehicle by which stimulus molecules are transported to the receptor environment and oriented towards it. Recent studies suggest that there is a different transduction mechanism for natural sugars and synthetic sweeteners that could be activated by different G proteins from those activated by sucrose. Although the sweet taste may be present in hundreds of compounds, fewer than 30 are permitted for use. The sensory reference standard for sweet taste is sucrose. No other sweetener is perceived to be identical; for example, glucose produces moderate burning and a bitter taste. Humans are more sensitive to synthetic sweeteners. A comparison of the sweet taste of synthetic sweeteners with that of sucrose is given in Table 3. Some synthetic sweeteners have a bitter and metallic taste, so they are used in mixtures.

Bitter Taste

Bitter taste is closely linked to sweet taste. Some compounds can have both a sweet and bitter taste, and slight structural modifications can alter their intensities. Bitter compounds require polar (electrophilic or nucleophilic) and hydrophobic groups and must be at least slightly soluble in water. Among the best-known bitter substances are alkaloids (often toxic) such as quinine, caffeine, and strychnine.

Table 3 Relative sweetnesses for several artificial sweeteners compared with 3% sucrose solution

Sweetener	*Date of discovery*	*Relative sweetness (sucrose = 1)*
Saccharin	1879	300–500
Dulcin	1883	70–350
Cyclamate	1937	30–60
Aspartame	1965	100–200
Acesulfame-K	1967	130–200
Sucralose	1974	600
Alitame	1979	2900

Alkaloids are often found in many plants, and so bitter taste is thought to be a mechanism for poison avoidance by animals. Also, salts that contain the cesium or rubidium cation or the iodide anion are bitter. Other bitter-tasting compounds include peptides, amino acids, ureas, thioureas, terpenoids, and polyphenols. The ability to perceive bitter substances has been related to their lipid solubility, which can be altered by pH. Bitterness is perceived towards the back of the tongue, but some compounds are perceived also on the tip. Transduction of bitter tastants can involve multiple mechanisms, depending on the structure of the bitter compound. One group of bitter compounds may be detected by several different mechanisms. The existence of more bitter receptors is confirmed by a single Mendelian gene, which affects the ability to taste one particular class of bitter compounds. Recently, remarkable progress has been made in establishing the nature of bitter taste. Two groups of scientists have confirmed the existence of bitter taste receptors. They identified a large family of G-protein-linked receptors (40–80 members). These receptors are organized in clusters.

One of the most interesting bitter compounds that has been studied in the past decade is 6-n-propyl-2-thiouracil (PROP). Individuals detect this compound with very different sensitivities that could be inherited.

Salty Taste

Salty taste is the last of the basic tastes that a newborn child perceives (at approximately 4 months). It is mainly associated with the taste of NaCl. At first, it was thought that the saltiness of NaCl is caused by Cl^- anions, but later, scientists preferred the theory that saltiness is produced by Na^+ cations and that anions modulate the intensity of the saltiness (larger anions reducing saltiness more than smaller anions). The molecular weight of the cation does not influence the saltiness, but anions with a low molecular weight are predominantly salty, whereas those of a higher molecular weight tend to be bitter. The salts of heavy metals such as mercury have a metallic taste. The degree of saltiness decreases in the following order: ammonium (most salty), potassium, calcium, sodium, lithium, and magnesium salts (least salty). This order can vary for different animals. Some salts in low concentration can taste sweet, NaCl tastes sweet in concentrations below 0.04 M, KCl below 0.02 M, and in some salts, especially lead acetate and beryllium chloride, the sweet taste dominates. It was found that people are more sensitive to NaCl at the tip than on the more posterior region of the tongue and that NaCl taste thresholds are systematically related to the size and region of tongue stimulated.

Although sodium chloride is essential for life and is the second most-used additive, it is believed to contribute to hypertension and some cardiovascular diseases. Therefore, scientists are looking for possible substitutes. Other chlorides have a salty taste but cannot be used as a good substitute because of their bitter and sour taste or toxic effects. Recently, peptides with a salty taste (L-ornithyltaurine, glycine methyl, or ethylester hydrochloride) and also different dipeptides were examined. The food industry tries to avoid using salt by replacing it with herbs, spices, and organic acids.

Sour Taste

Sour taste is acceptable when mild but becomes unpleasant when strong. It helps us to avoid unripe fruit and damage our tissue with acids. In humans, acids induce salivation, which increases bicarbonate secretions, the major buffering agent in saliva.

From a chemical point of view, acids can be distinguished by their pH index (describes the activity of protons in a solution) as a weak pH 3–7 and strong pH 1–3. We cannot use this distinction when we look at sour taste. Weak organic acids (e.g., the acetic acid in vinegar) taste more sour than mineral acid at the same pH.

The perception of sour taste is influenced not only by the activity of the proton, but also by the quality and character of the anion. The role of anion has not been studied in detail at receptor level. Sour taste in food is mainly connected with citric, malic, oxalic, and tartaric acids in fruits and lactic acid in yogurt and other dairy and meat products. Propionic acid is found in Emmental cheese, and acetic acid is used in the canning industry.

Umami

In 1909, the Japanese scientist Ikeda described a special delicious or savory taste and used the Japanese word 'umami.' This taste is familiar in the East, where seaweed and mushroom are used as ingredients,

because they have a high content of glutamate. This taste is sometimes called a savory or meat-like taste, because meat also has a high content of glutamate. Extensive scientific tests carried out in the twentieth century indicated that the umami taste is different from the four classical tastes and that it is connected with the L form of monosodium glutamate (MSG). Later, nucleotides such as guanosine-5′-monophosphate (GMP) and inosine-5′-monophosphate (IMP) were also considered to have umami flavor.

The occurrence of peptides (around 30), usually dipeptides and tripeptides, with a possible umami taste has also been reported, but this has not been confirmed by other scientists. Some dipeptides have a salty or bitter taste, or their taste is described as a salty/umami or sour/umami taste.

Faurion in 1991 found that the MSG taste is recognized by more than one type of glutamate receptor. Recently, the genes for proteins that serve as the molecular receptors for umami taste were identified.

Other Tastes

Other tastes such as metallic, soapy, alkaline, and astringent are described for the use of sensory evaluation but have not been studied at the receptors level.

Astringency taste Astringency is a tactile taste felt as a dry, rough feeling in the mouth and contraction of the tongue tissue. It usually involves the formation of aggregated precipitates between tannins or polyphenols and proteins in the saliva. Tannins positively influence the taste of tea, coffee, cocoa, wine, and beer but have a negative effect in immature fruit (bananas). Lawless and co-workers developed a vocabulary for astringency taste to describe its multiple perception characteristics. They defined astringency as a combination of three tastes: drying (the lack of lubrication or moistness), roughing (the rough texture in the mouth) and puckery (the drawing or tightening sensation). There are also specific terms such as sappy, harsh, woody, powdery, and gritty that are used for describing astringency taste in wine and beer.

Metallic taste Metallic taste is elicited by some metal salts, as a standard is used iron (II) sulfate heptahydrate in concentration $0.00475\,g\,l^{-1}$. The taste threshold for copper (using copper sulfate and copper chloride) in different types of drinking water is $2.4–3.8\,mg\,l^{-1}$, depending on the type of water.

Alkaline taste An alkaline, soapy taste is associated with potassium carbonate (potash), a substance that was used for the production of soap.

Pungency The trigeminal nerve is stimulated by chemical-induced sensations such as pungency. A pungent taste is characterized by spices such as hot pepper (in which the pungency substance is the alkaloid piperine), ginger, Spanish red pepper (capsaicine), and clove (eugenol). Vegetables from the *Brassicaceae* family such as horse-radish, black and white mustard, and cabbage have a pungent taste owing to their isothiocyanates content. Pungency is also the main sensory attribute of benzoic acid (3–36 mM). Sometimes, other sensations are described, such as the bite of carbon dioxide, the sting of horseradish, and other sensations derived from spices.

Factors Influencing Perception of Taste

Color

Several studies have examined the effect of color on taste perception. The results depend on conditions, concentration of taste substances, and intensity of color. Generally, red and orange increase the threshold for bitter, sour, and sweet taste, and green and yellow increase the threshold for sour. The effect of color on salty taste has not been studied.

Viscosity

The influence of viscosity has been studied mainly for sweet compounds, but it is clear that it depends on the taste substances and thickening agents. Viscous solutions can suppress taste because of a lower diffusion rate and poorer access to the receptors, but they can enhance the taste because the time during which the compounds bind to the receptors is longer. For example, in a chocolate drink, sweetness increases with increasing concentrations of lecithin. Usually, the sweetness of sucrose is lower in liquid than in aqueous solutions. The threshold of pure substances in aqueous solutions is different from the threshold values in other liquids.

Temperature

Temperature effects must be studied separately for every taste and in a wide range of temperatures. Sweet and bitter tastes are more affected by temperature than salty or sour tastes. Increasing the temperature usually increases the sweetness of the solution. For some compounds, a V-shaped function has been described, meaning that the minimum is near the center of the temperature range. For example, the sensitivity for NaCl was greatest in the range of 22–37 °C and lower at 0 and 55 °C. The optimum temperature for the perception of bitter taste is 10 °C, and the bitter aftertaste is longer than for

other tastes. The sweetness of sugars is reduced in cool solutions and the optimum is 35–50 °C.

Odors

Smell and taste are closely related. Therefore, several studies have concentrated on the relationship between perception of an odor and the taste of the solution to which the odor is added. It has been confirmed that flavorings added to a solution of sucrose increase or suppress the perception of sweet taste. For example, the flavor of caramel, marajuca, and strawberry enhance sweetness, whereas angelica oil and damascone suppress sweetness. Also, caramel odor suppresses the sourness of citric acid.

Interactions Between Basic Compounds

Food is a complex of chemical substances, and therefore, it is important to study not only the individual responses of the basic taste but also the responses and interactions in a mixture. Although this problem has been studied extensively and in a previous review, it is difficult to summarize general conclusions. Usually, only binary mixtures in aqueous solutions are studied, and their results cannot be extrapolated directly to food.

Moreover, the interaction between specific chemicals in a binary mixture must be studied also, because compounds from one taste group, such as bitter compounds, do not behave in the same way. Also, all interactions must be studied over different concentration ranges. An important role is played not only by the type of mixture, but also by the type of experimental work and differences in human sensitivities. The interactions in mixtures can be linear – suppression (perceived as less intensive), enhancement (perceived as more intensive) – and non-linear – masking and synergism.

The results can be summarized as follows:

- salts and acids enhance each other at moderate concentrations but suppress each other at higher concentrations;
- some salts enhance the sweet taste (potassium acetate, potassium chloride, sodium chloride);
- sour substances inhibit sweetness and vice versa;
- bitter compounds and acids can either enhance or suppress each other, depending on the concentration;
- bitter taste is generally suppressed by sodium salts, and saltiness is unaffected;
- bitter and sour tastes are suppressed by nucleotides, and salty and sweet tastes are enhanced by nucleotides;
- umami substances in water solution do not influence basic taste: there is only synergism between umami substances.

Examples of Some Interesting Compounds

Caffeine and other methylxanthines can enhance some sweeteners with a bitter component (acesulfam-K, thaumatin, steviosid, sodium saccharin), but not compounds such as aspartame, sucrose, fructose, and calcium cyclamate.

Certain amino acids, including D-phenylalanine, L- and D-histidine, and L-arginine are also enhanced by caffeine. Sweetness is inhibited, for example, by sodium (+)-2-(methylphenoxy)phenoxy propionate, triterpene saponins (gymnemic acid, holodulcin, ziziphens), cyclohexyl acetic acid, indole acetic acid, and α-naphthol sulfate.

Molecules that inhibit more than one taste are called multisaphoric molecules. The glycoproteins miraculin (without taste) and curculin (sweet taste) have a special property, because they convert the taste of acids from sour to sweet.

Cause of the Differences in Feeling Taste

There are more reasons why people differ in their perception of taste. Some can be explained by differences in anatomy and psychology among people, others by some illnesses or by the process of aging. The most-studied factor that influences taste perception is aging. Among older people at about the age of 60, there is normally a decline in the sense of taste, especially sour and bitter.

Disorders associated with taste are less common than with smell, because taste is innervated by three cranial nerves compared with a single cranial nerve for olfaction. Ninety per cent of patients complaining of a reduction or loss of taste had a reduction or loss of smell. This was confirmed by findings that people who had lost their sense of smell (anosmic) can distinguish between four basic tastes. Changes in the sense of taste can be either temporary or permanent.

Decreased perception of taste is called hypogeneusia. This loss was initially thought to be due to a reduced number of taste buds, but recent data indicate that a decline in the number of receptors may be responsible. A persistent taste in the mouth in the absence of stimulation is called dysgeusia, and complete loss of the sense of taste is called ageusia (gustatory anesthesia).

Loss of the sense of taste can be due to acute and subacute diseases: seasonal allergies, head injury, acute viral illness, idiopathic causes, and also the case of hormonal disorder, tumors in the brain, cancer, disease of the gums or teeth, nerve damage,

Table 4 Values of detection thresholds for individual tastes

Sweet	*Threshold (mol dm^{-3})*	*Salt*	*Threshold (mol dm^{-3})*	*Sour*	*Threshold (mol dm^{-3})*	*Bitter*[a]	*Threshold (mol dm^{-3})*
Saccharose	0.011–0.017	Sodium chloride	0.03	Citric acid	0.00078	Caffeine	0.00002–0.002
Lactose	0.065–0.072	Calcium chloride	0.017	Acetic acid	0.00183	Quinine	0.0000001–0.00001
Maltose	0.038	Ammonium chloride	0.004	Tartaric acid	0.00053	(+)-Catechin	0.002
D-glucose	0.065–0.08	Sodium fluoride	0.005	Malic acid	0.00082	L-Leucine	0.015
Saccharin	0.000000023	Magnesium chloride	0.015	Hydrochloric acid	0.0078	Magnesium sulfate	0.005

[a]A range is given because the values for bitter taste differ between authors.

and so on. Burning mouth syndrome is an oral pain disorder occurring primarily in women who have difficulties with identifying salty and sour tastes. The intake of certain drugs (for example anesthetics such as pantocaine and novocaine) and exposure to chemical substances can also influence our perception of taste. For example, chlorhexidine, an antiseptic, can decrease the bitterness of quinine, and it is the only known blocker of the human salty taste.

Some people cannot taste the bitter substance phenyl thiocarbamide (taste blindness), and people with congenital idiopathic hypoparathyroidism cannot recognize sweetness.

Methods of Sensory Analysis

The basis of sensory analysis is the perception of food attributes through the direct use of human senses. The main tool, therefore, is an assessor, who must be selected and trained. There are standardizing methods for training, but it is necessary to check, refresh and update the performance of assessors. Sensory methods must be standardized on international, regional, or national scales. Of all the sensory methods, the most useful for studying taste are detailed below.

Methods for Investigating Sensitivity of Taste

Taste is studied by different methods of sensory analysis that require good methodological and experimental control. The International Standard ISO 3972 describes the method of investigating sensitivity of taste. First, the assessors identify the taste of reference substances (for example, the concentration for reference sucrose is 5.76 g l^{-1}, and for caffeine 0.195 g l^{-1}). It has been proven by practical tests that these concentrations are detected by 50% of novice assessors. Another approach is to determine the threshold. We recognize three types: detection threshold (stimulus threshold) is the minimum value of a sensory stimulus needed to bring about a sensation. In a recognition threshold, accessors must identify this sensation, and the difference threshold is a value of the smallest perceptible difference in the physical intensity of a stimulus. The threshold values from different studies differ between authors, but the results also vary between individuals and the results from one individual can vary, depending on their health condition and mood, and so on. Among all tastes, bitter generally has the lowest detection threshold for naturally occurring compounds (see Table 4). The threshold is usually measured by using pure substances in aqueous solutions. The temperature of solutions and aqua used must be specified, because there are differences between values obtained from distilled water, tap water, and deionized water.

Time–intensity Technique (TI)

The time–intensity technique is the only technique to measure changes in perceptual characteristics with time. The idea of measuring sensation intensity originated in the 1960s but now has become widely used with the development of computerized systems for data collection.

The concept of TI is founded on the assumption that intensity and time are two independent dimensions of sensory space. During measurement, curves are produced, with time on the horizontal axis and sensation on the vertical axis, and these curves can indicate how long it takes to reach the maximum intensity for that taste, the overall maximum intensity, the total duration of sensation, the rate of extinction, and the rate of appearance.

New Analytical Methods for Determination of the Taste

Sensory analysis is a time-consuming and expensive method that requires trained assessors or experts. Attempts have been made to replace this method by various chemical and instrumental methods. An 'electronic tongue' has recently been developed to measure taste (based on pulsed voltametry). The Japanese electric tongue is composed of several lipid/polymer membranes that transform the information of taste substances into an electric signal.

Analytical methods can be useful but still are less objective than sensory analyses, because the former measure only stimuli and not sensations.

SEPARATION AND CLARIFICATION

J E Lozano, Plapiqui (Uns-Conicet), Bahía Blanca, Argentina

Background

Every year thousands of different processed food products are introduced in supermarkets. Food processing has three major aims: (1) to make food toxically and microbiologically safe; (2) to provide products of the highest nutritional and organoleptic quality; and (3) to make foods with ease of use.

Most food-processing comprise a series of physical processes, or unit processes, that can be separated into a number of basic operations, or unit operations, which depend upon coherent physical principles.

The main unit operations usually present in a typical food-processing line, including:

1. Flow of fluid – when a fluid is moved from one point to another by pumping, gravity, etc.
2. Heat transfer – in which heat is either removed or added (heating; cooling; refrigeration and freezing).
3. Mass transfer – whether or not this requires a change in state. Processes that use mass transfer include drying, distillation, evaporation, crystallization, and membrane processes.
4. Other operations requiring energy, such as mechanical separation (filtration, centrifugation, sedimentation, and sieving); size adjustment by size reductions (slicing, dicing, cutting, grinding) or size increase (aggregation, agglomeration, gelation); and mixing, which may include solubilizing solids, preparing emulsions or foams, and dry blending of dry powders (flour, sugar, etc.).

For example, the manufacture of concentrated clarified apple juice includes several unit operations

such as size reduction, pressing, heating, pumping, and evaporating, in sequence.

Separation Processes

Separation technologies, including extraction and sedimentation, are widely used in the food industry and basic knowledge on separation science is required to design a process properly. Separation in food usually implies pumpable suspension of solids in a liquid (water solution of true solutes, like sugars) or wet solid (e.g., fruit pulp). Separations can be achieved on the basis of density or size and shape, and may be classified into settling (or flotation), filtration, and expression methods (Figure 1). Washing, a typical food process, may also be considered a separation process in which soil or some other undesirable component is eliminated by the combined use of water and mechanical methods.

Washing

Washing of foods includes soaking, brushing, and the application of chlorine or water spraying. Heavy spray and rotary brush wash applications may also be required to remove any rot. Many products such as mechanically harvested berries are air-cleaned on mesh conveyors or vibrator passing over an air jet. Washers are conveyor belts or roller conveyors with water sprays, reel (cylinder) type with internal spray (Figure 2), brushes, and/or rubber rolls with or without studs. Vibratory-type washers are very effective for berries and small fruits. Brushes are effective to eliminate rotten portions of fruits, thus preventing problems with yeast toxins.

Settling

Settling is the use of the force of gravity to cause particles to settle down the liquid food. Although settling does not give a complete separation, it is often the best way to process very large volumes of a food suspension and remove most of the liquid. The concentrated suspension can then be filtered with smaller equipment and the cloudy liquid can be clarified if necessary. Settlers can also be used for classifying particles by size or density, which is not usually possible with filtration.

Gravitational separation Separation by the action of gravity, or sedimentation, can be represented by Stoke's law:

$$V_p = \frac{g(\rho_p - \rho_1)D_p}{18\mu} \qquad (1)$$

where V_p = the velocity of particles ($m\,s^{-1}$); ρ_1 = specific gravity of liquid media ($kg\,m^{-3}$); ρ_p = specific gravity of particles ($kg\,m^{-3}$); D_p = mean diameter of particle (m); μ = viscosity of liquid media ($Pa\,s^{-1}$); and g = gravitational constant ($m\,s^{-2}$). Solid–liquid separation by screening is also possible for some food suspensions, including coarse particles (fruit juice from belt presses), but it is not widely applicable.

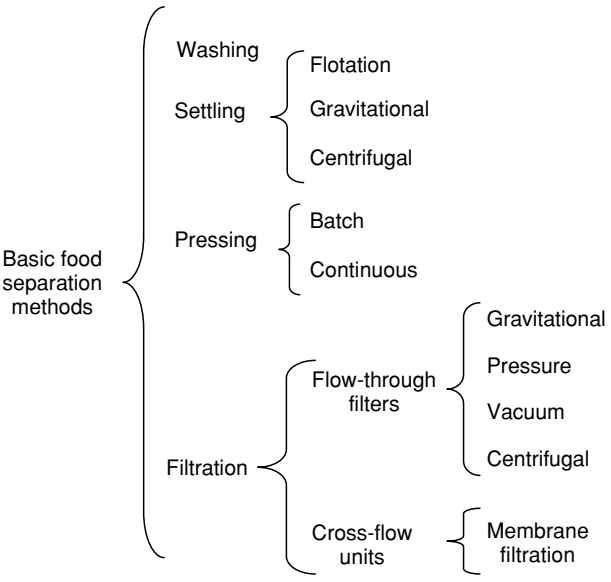

Figure 1 Separation methods commonly used in the food industry.

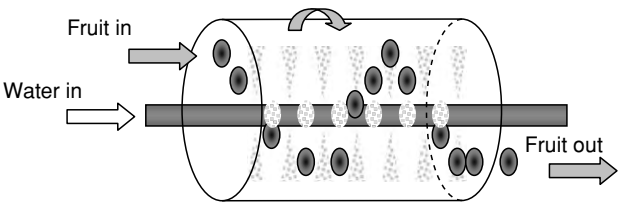

Figure 2 Reel washer with internal spray.

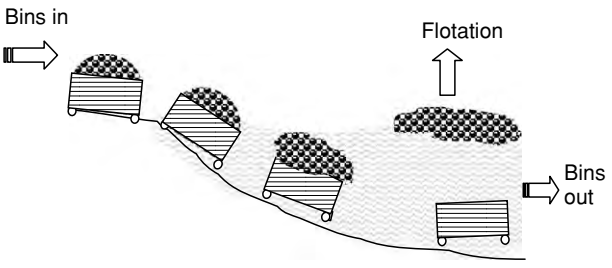

Figure 3 Example of the use of flotation for separation of fruits from container (bins).

Flotation A typical example of flotation as a separation process is unloading fruits into a silo system. Harvesting containers, known as bins, are commonly used to transport fruit from the orchard to the processing plant. Once in the plant, bin dumping unloading and soil and foreign material separation can be performed by flotation (this is good for fruits with density < 1, like apples), as Figure 3 shows.

Centrifugation Centrifugal separation is a process which is quite often used in the food industry. In the dairy industry, for example, uses of centrifugal force include butter oil purification (separation of serum phase from anhydrous milk fat); clarification (removal of solid impurities from milk); separation of fat from whey; skimming and standardizing.

Centrifugation is based on the same Stoke's law presented in eqn (**1**) by changing the force of gravity g by $(r\omega^2)$, where r = radius of axis of rotation; and ω = angular velocity. Stoke's equation (eqn (**1**)) indicates that a fat globule with a diameter of 2 μm will rise four times faster than a fat globule with a diameter of 1 μm.

Modern centrifuges are self-cleaning, allowing a continuous separation/clarification process. Centrifuges have also been used in preparing fruit juice from which sediment and microorganisms can be removed centrifugally in a clarifier, which are disk-type centrifuges that employ forces of 5000–10 000 times gravity.

Pressing

Solid–liquid separation is concerned in this article with mechanical processes for the separation in foods of water (including soluble solids) and finely divided insoluble particles. Expression is the removal of relatively small content of liquid from compressible milled food, by mechanical means. The way to separate most water and soluble solids depends on the food.

For citrus fruits there are three main types of extractors: (1) The FMC-type (FMC Corporation, Lakeland, USA) citrus juice extractor which basically consists of a pair of cups that cut two holes in the fruit, separate the peel, and move the peeled fruit into a strainer tube where the juice is separated from the seeds and the rest of the fruit; (2) the Brown-type extractor (Automatic Machinery & Electronic, Los Angeles, USA); in which fruit is cut in half, the halves placed in rubber cups and the juice removed by rotating plastic reamers; and (3) the rotary press, in which fruit is cut in halves and juice extracted in rotary cylinders.

Most systems for extracting juices from apple and similar fruit and vegetable pulps use some method of pressing juice through cloth of various thickness, in which pomace is retained. These systems are called filter presses and usually come in three main types: (1) rack-and-cloth press; (2) horizontal pack press; and (3) continuous belt press.

1. In a rack-and-cloth press the milled fruit pulp is placed in a nylon, Dacron or polypropylene cloth to form a 'cheese' with the help of a cheese framework. Layers of pulp cheeses, separated by racks made of hardwood or plastic, are stacked up to 1 m or more in height depending on the maturity of the fruit and the size of the racks (Figure 4). Rack-and-cloth presses are efficient but very labor-intensive in operation, cleaning and repairing.
2. Cage presses are horizontal presses with enclosed cages of several cubic meters in which pressing takes place. The cage is filled with a complex filter system consisting of grooved flexible rods filled with sleeves of press cloth material (Figure 5a). Juice passes from the pulp, through press cloth sleeves, along grooves in the flexible rods, and out to collecting channels in the ends of the cage

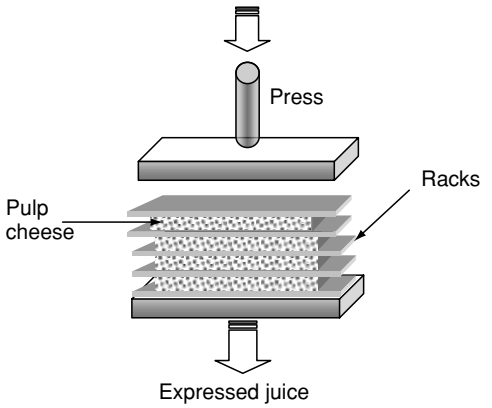

Figure 4 Rack-and-cloth press.

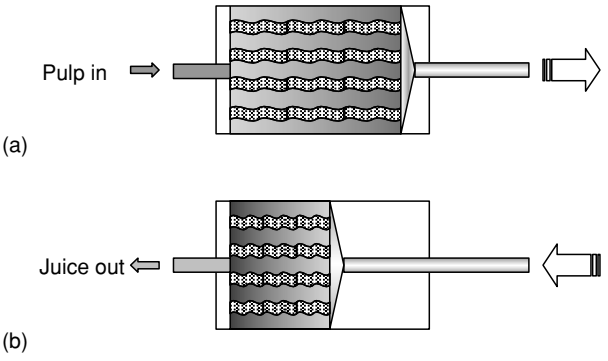

Figure 5 Hydraulic press: (a) loading; (b) pressing/extraction.

and in the piston (Figure 5b). The drum may be rotated, breaking up the pulp, and adding more water, permitting a second pressing with more juice extraction. The whole process may be automated. Although some cleaning labor is saved, rods and sleeves require a considerable amount of maintenance.

3. Continuous belt presses are based in the Ensink design for paper pulp pressing. This type of press offers a truly continuous operation (Figure 6). In belt presses, a layer of mash (pulp) is pumped on to the belt entering the machine. Press aid may be added for improved yield.
4. Screw presses. A typical screw press consists of a stainless-steel cylinder screen enclosing a large-bore screw with narrow clearance between screw and cylinder. Adjustable backpressure is usually provided at the end of the chamber. Breaker bars must be incorporated to disrupt the compressing mash.
5. Diffusion extraction. Typically used for the extraction of sugar from sugar beets (Figure 7), diffusion extraction is a typical countercurrent-type process. It is desirable to retain the same driving force, ΔC (concentration of soluble components in solids vs concentration of soluble components in liquid). In order to maintain a constant ΔC throughout the extraction process, it is necessary to carry out a continuous weighing of feed and to control the water flow to the counterflow extractor by means of a control loop. The diffusion extraction process is influenced by a number of variables (temperature, raw product size, water, etc.) Extracted products are usually passed through a conventional press system and the very dilute juice may be returned to the extractor.

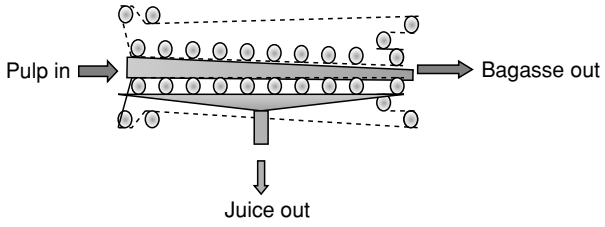

Figure 6 Typical fruit belt press.

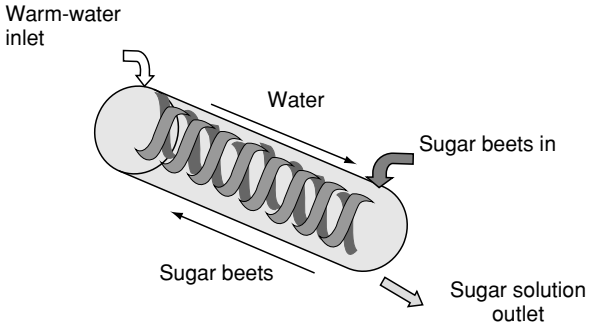

Figure 7 Diffusion extraction process.

Hydraulic pressing does not usually requires the addition of press aids, unless exceptionally overmature fruit is used. For continuous screw presses, however, it is usually necessary to add 1% (w/w) or more of cellulose. Mixing off cellulose and fruit occurs in the mill and subsequent pumping to press.

Filtration

Filtration is also a mechanical process designed for clarification by removing insoluble solids from a valuable liquid food, by the passage of most of the fluid through a porous barrier which retains most of the solid particulates contained in the food. The piece of equipment by which filtration is performed is named the filter. The filter medium, which may be a screen, cloth, paper, or bed of solids, is the barrier that lets the liquid pass while most of the solids are retained. The liquid that passes through the filter medium is called the filtrate. Filtration and filters can be classified in several ways, including:

1. Driving force: The filtrate is induced to flow through the filter medium by:
   c. Hydrostatic head (gravity)
   d. Pressure (upstream filter medium)
   e. Vacuum (downstream filter medium)
   f. Centrifugal force across the medium
2. Filtration mechanism:
   a. Cake filtration (solids are retained at the surface of a filter medium and pile upon one another)
   b. Depth or clarifying filtration (solids are trapped within the pores or body of the filter medium)
3. Operating cycle:
   a. Intermittent (batch)
   b. Continuous rate.

These methods of classification are not mutually exclusive. Thus filters are usually divided first into the two groups of cake and clarifying equipment, then into groups of machines using the same kind of driving force, then further into batch and continuous classes. Some filtering devices usually employed in the food industry are described below.

Pressure filters The main advantages of pressure filtration compared to other filtering methods are

that cakes are obtained with very low moisture content; clean filtrates may be produced by recirculating the filtrate or by precoating; and solutions may be polished (finished) to a high degree of clarity. Among the disadvantages it must be noted that cloth washing is difficult and precoat is required; the operator cannot see the forming cake and is unable to carry out an inspection while the filter is in operation; the internals are difficult to clean, and this may be a problem with food-grade applications.

With the exception of the rotary drum pressure filter, these types of filters are semicontinuous machines in which wash and cake discharge are performed at the end of the filtration cycle. Since the operation is in batches, intermediary tanks are required. The collection of filtrate depends on the operating mode of the filter, which can be constant flow rate, constant pressure, or both, with the pressure rising and flow rate reducing during filtration. The filtration rate is mainly influenced by the properties of food (particle size and distribution, presence of gelatinous solids like pectin, liquid viscosity, etc.) Although continuous-pressure filters are available, they are mechanically complex and expensive, so they are uncommon in the food industry.

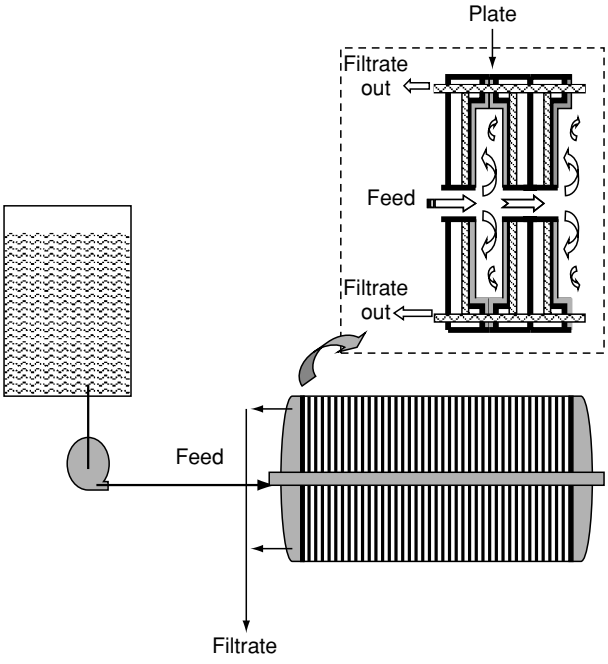

Figure 8 Filterpress operation sketch and details of filtering plate.

Filter Aid and Precoating Filter aid and precoating are often mentioned as in the case of pressing, in connection with pressure filtration. Filter aid is used when the pulp or turbid liquid food is low in solids content, with fine and muddy particles that are difficult to filter. To enhance filtration, coarse solids are used with large surface area that capture and trap in their interstices the slow-filtering particles from the suspension, producing a porous cake matrix.

On the other hand, precoating is the formation on the filter plates of a defined thick medium of a known permeability. Precoating prior to filtration serves when the particles to separate are gelatinous and sticky, forming a barrier that avoids cloth blinding. The filter aids and precoating materials most commonly employed in the food industry are: diatomaceous earth (silicaceous skeletal remains of aquatic unicellular plants); perlite (glassy crushed and heat-expanded volcanic rock); cellulose (fibrous, lightweight, and ashless paper); and special groundwood.

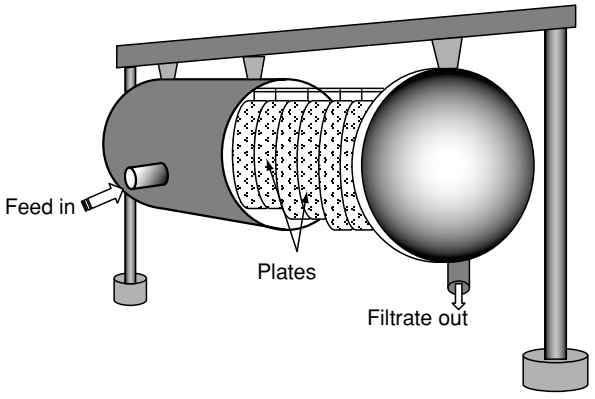

Figure 9 Horizontal plate filter.

Types of pressure filters Pressure filters usually found in the food industry are:

1. Filterpress, also named plate-and-frame, consists of a head and follower contained between a pack of vertical rectangular plates supported by side or overhead beams (Figure 8). The head serves as a fixed end to which the feed and filtrate pipes are connected and the follower moves along the beams and presses the plates together during the filtration cycle by a hydraulic or mechanical mechanism. Each plate is dressed with filter cloth on both sides and, once pressed together, they form a series of chambers that depend on the number of plates. The plates generally have a centered feed port that passes through the entire length of the filterpress, so that all the chambers of the plate pack are connected together.
2. Vertical and horizontal pressure leaf filters consist of a vessel that is fitted with a stack of vertical

(Figure 9) or horizontal leaves that serve as filter elements. The leaf is constructed with ribs on both sides to allow free flow of filtrate towards the neck and is covered with coarse mesh screens that support the finer-woven metal screens or filter cloth that retain the cake. The space between the leaves may vary from 30 to 100 mm depending on the cake formation properties and the ability of the vacuum to hold a thick and heavy cake to the leaf surface. They may be applied to polishing liquid foods with very low solids or for cake filtration with a solids concentration < 20–25%. In contrast to filterpress, pressure leaf filters may be readily jacketed for applications whenever hot or cold temperatures are to be preserved. The cloth mesh screens that cover the leaves may be accessed more easily on horizontal than on vertical tanks.

3. Candle filters may be used in applications that require efficient low-moisture cake filtration or a high degree of polishing (finishing). Candle filters are available in many sizes, containing up to 250 or more filtering elements (Figure 10). The candle filter consists of three major components: the vessel, the filtering elements (candles), and the cake discharge mechanism. Vessel configuration may be with a conical bottom for cake filtration and polishing, or with a dished bottom for slurry thickening. This last vessel is scarcely or never used in the food industry.

The filtering element generally consists of the filtrate core and the filtering medium. The core serves for filtrate passage and to support the filter medium. In the food industry the core is a bundle of perforated stainless-steel tubes. The types of filter medium available are diverse, such as porous ceramics, woven mesh screens, sintered metal tubes, or synthetic filter cloths. Finally, there are two methods of discharging the cake at the end of the cycle: snap blow or vibrating mechanism. The advantages of a candle filter are the excellent cake discharge capacity and its mechanical simplicity.

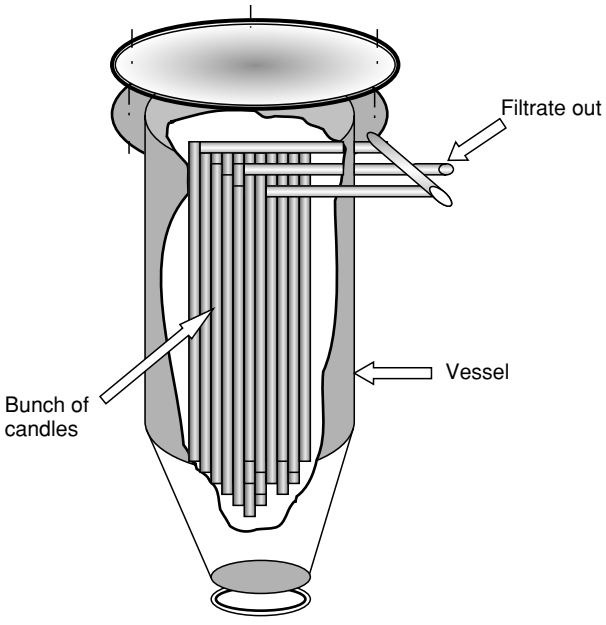

Figure 10 Candle-type filter.

Vacuum filters Vacuum filters are simple and reliable machines and therefore have gained wide acceptance in the food industries. Among the different types and sizes for standard vacuum filters, the following are included: drum; disk; horizontal belt; tilting pan; and table filters.

Drum filters are usually utilized in the food industry. Advantages and disadvantages of vacuum filtration as compared to other separation methods are as follows:

- Advantages: continuous operation; very effective polishing (finishing) of solutions (on a precoat filter); and easy control of operating parameters such as cake thickness.
- Disadvantages: higher residual moisture in the cake and difficult to clean (mainly as required for food-grade applications).

Precoat filters are used when liquid foods (e.g., clarified apple juice) require a very high degree of clarity. To polish the solution the drum deck is precoated with an appropriate medium. A scraper blade, also called the doctor blade, moves slowly towards the drum and shaves off a thin layer of the separated solids and precoating material. This movement continuously exposes a fresh layer of the precoat surface so that when the drum submerges into the tank it is ready to polish the solution. On precoat filters the entire drum deck is subjected to vacuum (Figure 11).

Membrane processes The membrane is an interface between two bulk phases. In the food industry, membrane processes include a wide range of unit operations, from sieving to reverse osmosis. However, during conventional filtration, only the separation of coarse particles to micron range was considered. This operation requires frequent cleaning due to a build-up of a cake layer which results in increased resistance to filtration. For separation of fine solids from liquids, cake filtration or cross-flow filtration should be considered. In this section only cross-flow membrane filtration will be considered. In cross-flow filtration (Figure 12) the bulk phase under pressure flows along

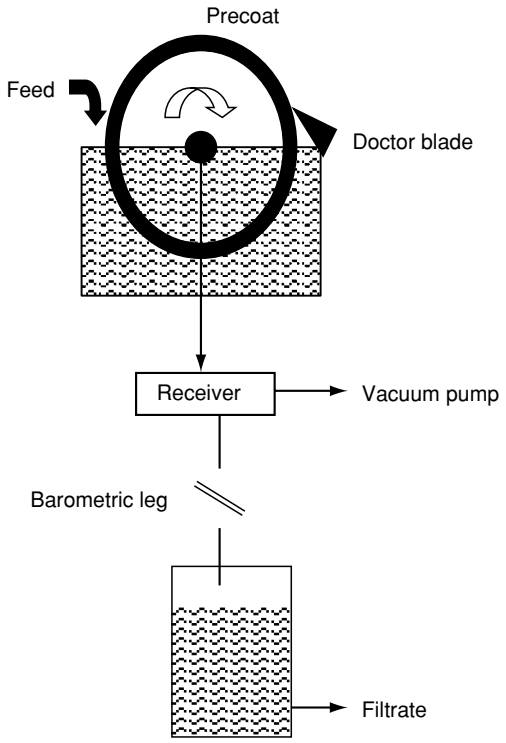

Figure 11 Vacuum drum precoat filter.

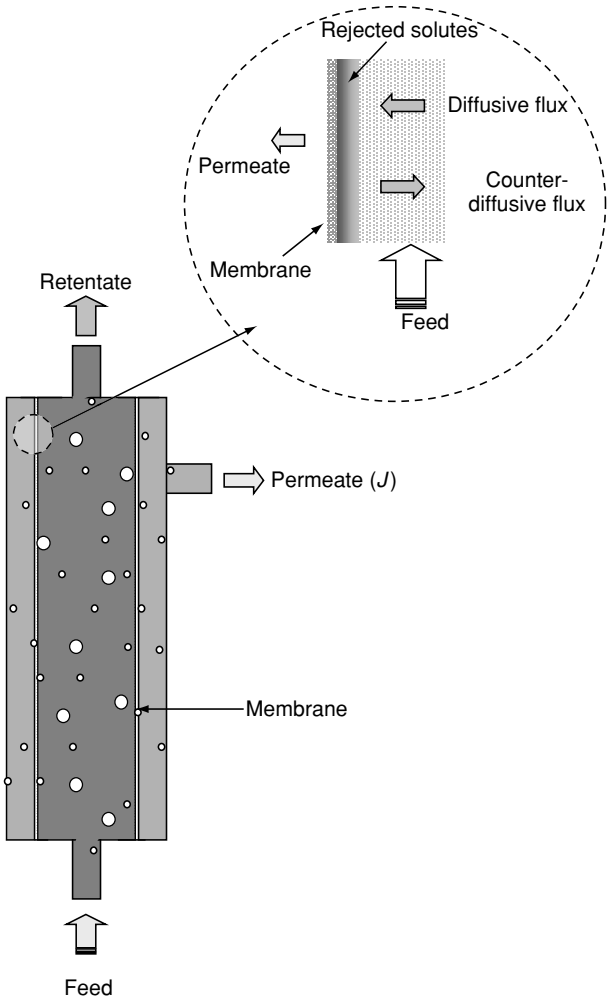

Figure 12 Typical cross-flow membrane process and details of acting fluxes.

the surface of the membrane, sweeping and at least partially removing the cake layer. This allows relatively high permeate fluxes over long periods. Reverse osmosis (RO), ultrafiltration (UF), and microfiltration (MF) are typical cross-flow filtration methods that use membranes with varying pore sizes to effect separation on the basis of size and shape. RO has membranes with the smallest pore and is used to separate water from other solutes.

High pressures (up to 10 000 kPa) are required to overcome the high osmotic pressure of solutes (sugars and salts). UF has membranes with larger pores and will retain proteins, lipids, and colloidal salts, while allowing smaller molecules to pass through to the permeate phase. Required working pressures during UF are in the range 130–1400 kPa. MF, with pores $> 0.1\,\mu m$, is used to separate fat from proteins and to reduce microorganisms from fluid food systems. This process requires the lowest operating pressure (< 350 kPa).

Table 1 lists examples of commercial uses of membrane processes in different food industries. However, there are still a number of technical obstacles that still need to be resolved, including inadequate processing rates (flux) and separation capabilities (rejection and selectivity), insufficient membrane or module life, and incompatible materials.

Clarification

Many liquid foods are colloidal suspensions which must be unstabilized to give a completely transparent liquid. This process is known as clarification (Table 2). Usually, colloidal state is only defined in terms of particle size; the lower limit is generally taken as 1–5 nm (10–50 Å) and the upper size limit as 1–5 µm. When the dispersed phase is a solid and the continuous phase is a liquid, the system is defined as a sol. A typical example of a food sol is a cloudy fruit juice, which is a colloidal system where the continuous medium is a solution of pectin and sugars, and the dispersed (colloidal) matter is mainly formed by cellular tissue comminuted during fruit processing. Pectin is basically a biopolymer made by D-galacturonic acid units.

Particles in a cloudy juice adhere together and form aggregates of increasing size (flocculation) which may

	Clarification of dextrose	Recovery of sugar from rinse water

Table 2 Fruit juice clarification agents

Name	*Description*
Sparkolloid	A natural albuminous protein extracted from kelp and very finely powdered
Gelatin	Mixture of gelatins and silicon dioxide, with the active ingredient being animal collagen
Kieselsol	Suspension of small silica particles usually used in combination with gelatins. This fining aids in pulling proteins out of suspension
Bentonite	Refined clay (montmorillonite) presented as powder or coarse granules. Bentonite must be added to hot water: stir well and let it stand for 36–48 h before use, so that it swells and becomes almost gelatin-like
Isinglass	Protein produced from sturgeon swim bladders. It is presented either as a fine powder or as dry hard fragments

settle due to gravity. If flocs change to a much denser form, it is said to undergo coagulation which is an irreversible process. For a clear juice, these suspended particles have to be removed. It may seem simple merely to filter them out, but unfortunately some soluble pectin remains in the juice, making it too viscous to filter quickly. A dose of commercial enzyme is the accepted way of removing unwanted pectin. Enzyme depectinization has two effects: it degrades the viscous soluble pectin and it also causes the aggregation of cloud particles. Figure 13 shows how this may happen: pectin forms a protective coat around proteins in suspension. In an acidic environment (apple juice typically has a pH of 3.5), pectin molecules carry a negative charge. This causes them to repel one another. Pectinase degrades this pectin and exposes part of the positively charged protein beneath. The electrostatic repulsion between cloud particles is thereby reduced, so that they clump together.

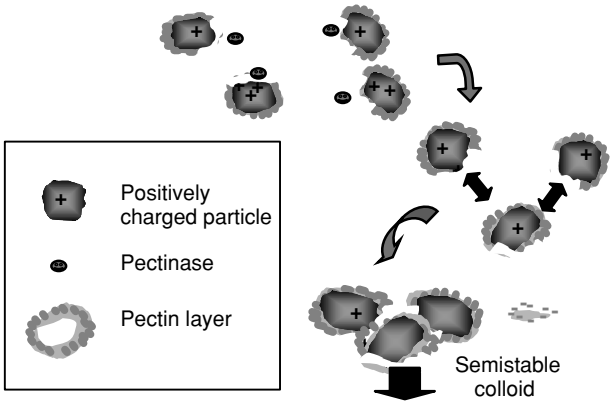

Figure 13 How the breakdown of pectin leads to the formation of aggregated cloud particles during fruit juice clarification.

These larger particles will eventually settle out, but to improve the process, flocculating, also named fining, agents (Table 1) can be added. Fining agents work either by sticking to particles, making them heavy enough to sink, or by using charged ions to cause particles to stick to each other, making them settle to the bottom. What is left is a transparent but by no means clear juice. A second centrifugation and subsequent filtration (fining) are needed to give the clear juice that many consumers prefer.

Another potential contributor to the haziness of juice is starch. Unripe apples, for example, may contain up to 15% starch. Although the first centrifugation (before the juice reaches the clarification tank) removes most of the starch, about 5% usually remains. This can be broken down using a specific enzyme (amyloglucosidase) added at the same time as

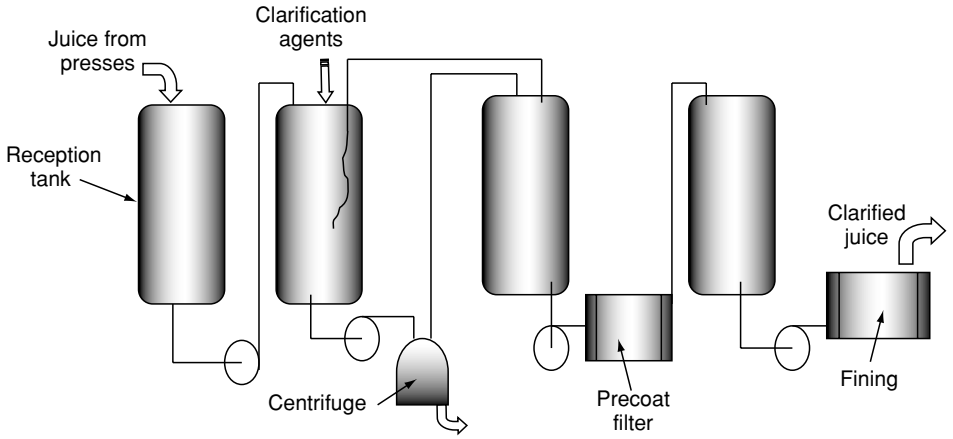

Figure 14 Fruit juice conventional clarification line.

the pectinase. Optimization of fining and ultrafiltration steps can help retard or prevent postbottling haze development. Figure 14 shows a typical fruit juice clarification process.

Prepress treatment with pectinase takes anything from 15 min to 2 h depending upon the enzyme, the reaction temperature, and the fruit chosen. Enzyme treatment is considered to be complete once the viscosity of the juice has returned to its original level or less. It is important that the pulp is not broken down too much. Other polysaccharides (like araban, a polymer of the pentose arabinose) may appear as a haze in fruit juices and other beverages a few weeks after it has been concentrated. Although commercial pectinase preparations often contain arabanase, certain fruits (like pears) are rich in araban and may require the addition of extra arabanase to the clarification tank.

Clarification by Ultrafiltration

The application of UF as an alternative to conventional processes for the clarification of fruit and vegetable juices has been demonstrated. However, the acceptance of UF in the food-processing industry is not yet complete, because there are problems with the operation and fouling of membranes. During UF, two fluid streams are generated: the ultrafiltered solids free juice (permeate), and the retentate with variable content of insoluble solids and macromolecules.

Permeate flux (J) results from the difference between a convective flux from the bulk of the retentate to the membrane and a counterdiffusive flux or outflow by which solute is transferred back into the bulk of the fluid (Figure 12). The value of J is strongly dependent on hydrodynamic conditions, membrane properties, and operating parameters. The main driving force of UF is the transmembrane pressure (ΔPTM), which, for example, in the case of hollow fiber ultrafiltration systems, can be defined as:

$$\Delta PTM = (P_i + P_o)/2 - P_{\text{ext}} \qquad (2)$$

where P_i = pressure at the inlet of the fiber, P_o = outlet pressure, and P_{ext} = pressure on the permeate side. In practice, the J-values obtained with apple juice are much less than those obtained with water only. This phenomenon is attributable to various causes, including the concentration polarization boundary layer (defined as a localized increase in concentration of rejected solutes at the membrane surface due to convective transport of solutes) and plugging of pores due to fouling. Where some of these phenomena are reversible and disappear after cleaning of the UF membranes, others are definitively irreversible.

Flux decline due to this phenomenon can be reduced by increasing flow velocity on the membrane. Traditionally, correlations of J with ΔPTM have been determined by parameter fitting of the experimental data.

As a summary, membrane processes are limited by the following factors:

1. They must be combined with other processes or steps.
2. The process is practically limited to low-viscosity liquids and foods.
3. Ceramic membranes are versatile, but expensive to install.
4. Although the membrane process is easy to understand, very careful design and trained and skilled operators are needed to insure long-term filtering capacity.

A generalized application of membrane technology in the food industry may require improvements in thermal stability and chemical resistance; a more

controlled pore structure and narrow pore size distribution; a higher permeate flux; an improved microbiological resistance; and more controlled fouling.

Meat

A J Kempster, Formerly of Meat and Livestock Commission, Snowdon Drive, Milton Keynes, UK

Background

Lamb is the meat from young sheep. It should be distinguished from mutton, which is from adult animals. The two categories together are referred to as sheep meat.

Sheep, raised for both meat and wool production, form a significant part of the economy of many countries. The current world production of mutton and lamb is 6.5 million tonnes (FAO, 1990). Sheep are farmed in all the main regions of the world, but it is notable that 17% occur in Australia and New Zealand and that exports from these countries are the core of world trade.

Sheep farming is possibly the most diverse branch of animal production. There are hundreds of breeds, each with its particular environmental niche and economic function. There is a large variation between the major sheep-producing countries in climatic

conditions, in management procedures and in the breed types available. At one end of the climatic scale, there are the fat-tailed desert sheep, which survive and thrive where other sheep would perish; at the other extreme are mountain breeds like the Scottish Blackface of the UK, which can stand harsh conditions, high rainfall, snow, and indifferent herbage. Most sheep feed outside continuously with only limited supplementation of available pasture, whereas a few, mainly in Europe and North America, are housed from birth and fed carefully formulated diets. There is little mechanization or intensification.

In some countries, sheep-farming systems can cover wide ranges of climatic condition, as in the UK, where there is a stratification system involving the crossing of breeds adapted to particular environments: crosses from hill and upland areas are the female breeding stock for lowland areas where they are mated with sire breeds selected specifically for meat production.

Genetic improvement in the world's sheep population has been very uneven. There are pioneering examples of application of genetics, particularly in Norway, Australasia, and the UK. Published information on sheep breeding is much more a review of the technology about to be applied, rather than a record of achievement.

Progress is slow because environmental, technical, and economic conditions prevailing in areas where sheep are kept are frequently difficult. Breeding objectives are often not clear: indeed, there may be direct conflicts between adaptation for survival and for productivity. Relatively low reproduction rates and long generation intervals do not help. The multipurpose use of sheep for meat, wool, and milk also reduces the selection pressure for meat characteristics under some circumstances.

Sheep meat production is dominated by two factors: first, there are the biological and agricultural considerations of resource use; second, there are the marketing considerations, in particular the ability of farmers to adapt output to conform more closely with changing market demand. In developed countries, this demand is for an increasingly lean product.

Carcass Quality

The value of sheep carcasses depends on several factors, namely weight, conformation (carcass shape), proportion of the main tissues (muscle, fat, and bone), distribution of these tissues through the carcass, muscle thickness, and meat quality. (*See* **Meat**: Structure.)

The weight and size of the carcass have a major influence not only on the quantity of the various tissues but also on the size of the muscles exposed on cutting and of the individual joints prepared from it. This is of importance particularly in relation to a retailer's ability to provide cuts of a suitable size to meet customer requirements. Over generations, wholesalers and retailers from different regions of countries and different parts of the world have become accustomed to handle certain weight ranges of carcasses; abattoir practices and cutting methods have been developed accordingly. Most wholesalers state the desired weight ranges in buying schedules and apply discounts to carcasses outside these ranges. In some cases, these discounts are severe and are a constraint on the use of improved breeds and production systems. There has, for example, historically been a demand in the UK for small legs suitable for the Sunday roast, which has slowed the movement to heavier carcasses that are likely to be more efficient to produce and process. This demand has also had a major effect on the type of carcass produced in New Zealand for the British market. (*See* **Meat**: Slaughter.)

Although conformation (the shape of the carcass) provides a poor indication of carcass composition, it is still regarded by many in the meat industry as valuable in this respect. Carcasses with good conformation normally command higher prices, and most national classification and grading schemes include conformation as a factor. It is particularly important in some European markets.

Among carcasses of similar weight, the percentage formed by each tissue varies considerably depending on the breed type and level of feeding. The proportion of lean meat in the carcass is of major importance, since this is the principal determinant of yield and commercial value in many countries. Taken as a generalized ideal, the best carcasses should have an optimum level of fatness, sufficient to ensure that carcasses do not dry out and to ensure good eating quality, and minimum bone.

The general trend is now towards the production of leaner carcasses because of consumers' increasing demand for meat with a low fat content. Table 1 lists the typical composition for carcasses in different fat classes of the National Carcass Classification Scheme operated in the UK (this can be linked directly to the developing EC scheme). (*See* **Meat**: Nutritional Value.)

Definition of Retail Cuts

Traditionally, lamb is sold by butchers largely bone-in, so about 90% of the carcass is 'saleable meat' and goes across the counter.

The lamb carcass is typically separated into the sides by cutting it lengthwise through the spine. The main cuts (using British terminology) are as follows.

Table 1 Composition of carcasses in different fat classes of the British classification scheme

	Fat class[a]					
	1	*2*	*3L*	*3H*	*4*	*5*
Lean meat in carcass (%)	62.4	58.7	56.1	54.3	51.7	48.1
Separable fat in carcass (%)	16.5	21.7	25.6	28.2	32.1	37.3
Total protein in carcass (%)	14.2	13.3	12.7	12.2	11.4	10.2
Lipid in lean (%)[b]	3.6	5.1	6.2	6.9	8.1	9.6

[a]Most carcasses fall into fat class 3L. Fat classes 4 and 5 would be too fat for most requirements.
[b]Intramuscular fat.
Data from Kempster AJ, Cook GL and Grantley-Smith M (1986) National estimates of body composition of British cattle, sheep and pigs with special reference to trends in fatness. A review. *Meat Science* 17: 107–138.

The *forequarter* is a large cut which includes the neck, shoulder, and part of the breast. It makes an economical family roast but is more difficult to carve than a leg. Boned and rolled or stuffed, it is easier to carve.

The *shoulder* is smaller than the leg and is easier to carve after boning. Shoulder chops or cubed shoulder meat should be well trimmed to remove excess fat before grilling or stewing.

Neck chops may be stewed, braised, or casseroled.

Breast is an economy cut. The ends of the rib bones can be cut out to simplify carving or rolling.

The *best end of neck* or *rack* is made up of six or seven rib chops. When it is to be cooked whole, it may be boned and rolled, or chined (backbone removed) for easy carving. The rib chops are trimmed to make cutlets.

The *loin* can be cut into about seven or eight meaty chops, each with a short T bone; alternatively, it can be left in one piece and rolled or trimmed, boned, rolled, and cut into noisettes before cooking.

Chump chops (or *leg chops*) are lean, meaty chops cut from the end of the leg nearest the loin.

The *leg* is a large, lean roast which may be cooked with the bone in, or boned and stuffed. Meaty steaks can be cut from the thick part of the leg.

Consumer attitudes indicate that lamb is often regarded as fatty, not versatile, and difficult to carve. Major developments have, therefore, taken place in new cutting methods. This work produces boneless cuts which are convenient in size, easy to carve, and lead to minimal waste on the plate.

The new techniques only work satisfactorily on lambs which are quite lean at the outset, since it is difficult to trim the intermuscular fat without adopting a complete muscle seaming technique. If there is increasing use of these boneless techniques, it will create further pressure towards the production of heavier and leaner lambs.

Lamb and mutton are used less in processed form than other meats. One of the main reasons is the high bone-to-meat content of the carcass and the small size of the carcass. These two factors make it more labor-intensive for boning-out and processing and therefore more costly relative to other meats. Lamb fat is also more saturated and less suitable for processing.

The main area of development in the UK at the moment is in kitchen-ready products which offer variety, convenience, and novelty to consumers. The range of products now being introduced in the UK, particularly by independent butchers, includes lamb burgers, marinated chops and steaks, and more exotic dishes such as lamb bengali, lamb pasanda, and lamb italliene. Lamb is the basis for many spiced dishes on a worldwide basis, and quite a number of these are being introduced into Europe by the major supermarket chains.

Recently, there has been renewed interest in the curing of lamb because of its cheapness in some countries relative to pigmeat. (*See* **Meat:** Preservation.)

Milk

M Juarez, Instituto del Frio (CSIC), Madrid, Spain
M Ramos, Instituto de Fermentacinos Industriales (CSIC), Madrid, Spain

Background

Although the production of sheeps' milk (approximately 8 million tonnes) is of marginal importance

compared to cows' milk in quantitative terms (2% of the total), it is of major economic relevance in a numbers of areas such as the Mediterranean and Middle East, where the climatic conditions are not favorable for raising cattle. The number of sheep does not fully reflect the amount of milk produced, since sheep are often used for other purposes, such as meat and wool. In general, sheeps' milk is used essentially for cheesemaking, but in some countries, some is made into yogurt or whey cheeses.

Chemical Composition

Milk is a characteristic secretion of mammals designed to meet the complete nutritional requirements of the neonate of the species. It is a mixture, in equilibrium, of proteins, fat, lactose, and minerals in different states of dispersion in water, such as emulsions, colloidal suspensions, and true solutions.

Sheeps' milk is more viscous than cows' milk and is more resistant to the proliferation of bacteria during the first hours after milking, owing to its greater immunological activity. It has a unique smell, characteristic of the animal that produces it, and is an opaque white in color.

The variability in the composition of sheeps' milk is due to genetic, physiological, and environmental factors. The principal factor is breed; breeds selected for a high milk yield produce milk with a lower total solids content. Fat shows more variation between breeds than proteins. Another factor to consider is the stage of lactation. Colostrum contains high levels of fat (10.7–17.2%), proteins, mainly as immunoglobulins (7.1–19.5%), and low levels of lactose (1.6–4.0%). The fat levels of protein in the milk decline during the first weeks postpartum and then increase gradually after the first month until lactation ends, and the yield falls off. At the end of 7 months' lactation, fat values may be as high as 8.1–10% and protein as high as 6.8–8.9%. The lactose content falls slightly throughout lactation and more sharply at the end (3.4–4.1%). Another factor having a notable influence on milk composition, especially the fat content, is the feeding of the livestock. Other influencing factors include the age and health of the animal, season, and milking times and procedures. Table 1 shows the gross composition of sheeps' milk. Sheeps' milk contains higher concentration of fat, proteins, mineral salts, and total solids than cows' milk. The lactose content is comparable in the two species. Fat and protein are the principal components of the, total solids, constituting 69% in sheeps' milk, compared to 56% in cows' milk. The fat-to-protein ratio is higher in sheeps' than in cows' milk, and the cheese yield expressed as kilograms of cheese per 100 l of milk is approximately 18–20 kg, compared to 10 kg for cows' milk.

Nitrogen Compounds

Sheeps' milk contains 0.7–1% nitrogen. This is distributed in fractions the importance of which varies in terms of dairy technology and nutrition. Proteins account for approximately 95% of total nitrogen, while 5% is nonprotein nitrogen. Milk proteins occur in two distinct phases. One is an unstable micellar phase composed of caseins, which is suspended as micelles averaging about 190 nm in diameter, interlinked by calcium phosphate and small amounts of magnesium, sodium, potassium, and citrate, which diffuse light and give the milk its opaque white appearance. The other is a soluble phase composed of whey proteins. The caseins precipitate at pH 4.6 at room temperature, whereas under the same conditions, the whey proteins (β-lactoglobulin, α-lactoalbumin, and serumalbumin) remain soluble.

Caseins Caseins are the principal proteins in sheep's milk (76–83% of total proteins) and are present in most types of cheese. The caseins are of four types of polypeptide chain, αs1-CN, αs2-CN, β-CN, and

Table 1 Composition of ewes' milk

Component	*Average content (%)*	*Range (%)*	*Average of dry matter (%)*

Average values have been calculated from the results given by different authors.

κ-caseins. The heterogeneity of caseins is due either to the presence of genetic variants or other factors such as a discrete phosphorylation level, variation in the extent of glycosylation of the κ-casein fraction, and the coexistence of protein forms having different chain lengths. It has been demonstrated that four ovine casein genes, αs1-CN, αs2-CN, β-CN, and κ-casein, are polymorphic and are linked on the both the ovine and the bovine genome. In recent years, five variants of αs1-CN have been described, designated A, B, C, D, and E, in line with the nomenclature proposed for cow or goat caseins. αs1-CN D was called the Welsh variant in view of its discovery in the milk of Welsh mountain sheep by King in 1966. This is the least phosphorylated variant. The lower number of phosphate groups explains the higher migration time of this variant by capillary electrophoresis at acid pH and the slow migration by alkaline polyacrylamide gel. Variant αs1-CN C differs from the A variant by the substitution of Ser for Pro at position 13, which explains the loss of the phosphate group on site 12 of the protein chain. Two variants of αs2-CN, A and B, have been described, differing in that Asn_{49} and Lys_{200} are replaced by Asp_{49} and Asn_{200}. In addition, a variant with a high electrophoretic mobility and a low molecular weight has been found in the milk of the Manchega breed. Ovine β-CN consists of 209 amino acid residues. There is nongenetic polymorphism due to varying degrees of phosphorylation, with six and five phosphate groups in β1 and β2, respectively. In addition, three genetic variants, designated A, B, and C, have been described recently. The only sequence difference found between A and C is the substitution of Glu at position 2 in variant A for Gln in variant C; no sequence data for the B variant are yet available. Both the stability of the casein micelle and the availability and distribution of Ca are affected by the extent of phosphorylation of the caseins. Sequencing of ovine κ-casein has shown that it consists of 171 amino acid residues. No genetic variants of κ-casein have been found, but it shows nongenetic polymorphism due to varying degrees of glycosylation at three Thr residue sites (positions 135, 137, and 138) and two phosphorylation sites (Ser P_{151} and Ser P_{168}). The casein fraction also contains γ-caseins, the products of the breakdown of β-caseins by plasmin.

Whey proteins Sheeps' milk whey proteins represent 17–22% of total protein. The principal proteins are β-lactoglobulin and α-lactalbumin. Immunoglobulins, serum albumin, and proteose peptones are present at lower concentrations. The latter are products of the breakdown of β-casein by plasmin. Another soluble protein found in small amounts and possessing antibacterial properties is lactoferrin. In the case of rennet whey, caseinomacropeptide is present also, produced by the chymosin action on the bond 105–106 of κ-casein. Serum albumin is not specific to milk, and it is considered to be the same as that found in the blood. The IgA in milk is synthesized in the mammary gland, i.e., it is milk-specific.

β-Lactoglobulin, the principal protein in the whey, consists of a polypeptide chain of 162 amino acids. Three genetic variants have been described in sheep's milk: β-Lg A, β-Lg B, and β-Lg C. Ovine β-Lg B and A differ only by a single amino acid exchange, His for Tyr at position 20. β-Lg C is a subtype of ovine β-Lg A with a single exchange, Arg for Gln at position 148. α-Lactalbumin is closely homologous to bovine α-lactalbumin. It is a metalloprotein, containing one atom of Ca per molecule and is important from a biological standpoint in that it is involved in lactose synthesis. Two genetic variants, A and B, have been described, although the B variant is very uncommon.

Nonprotein nitrogen Nonprotein nitrogen accounts for between 5 and 6.8% of total nitrogen. Nonprotein nitrogen compounds are: urea (45%), amino acids (16%), creatine (2.4%), creatinine (1.7%), ammonium (1%), uric acid (2.1%), and other unidentified compounds (32.3%). Sheeps' milk contains more urea and uric acid than cows' milk.

Lipid Fraction

Lipids are one of the most important components of milk in terms of cost, nutrition, and the physical and sensory characteristics they impart to dairy products. They are present in the form of globules and are characteristically abundant in sizes of less than 4.5 μm. No appreciable differences have been found in the mechanism of fat-globule secretion in sheep and cows; the structure and composition of the membrane are similar in both species. The phospholipid profile in both species is similar to that of the plasma membrane, which would tend to confirm their common origin. Along with triglycerides, the lipid fraction of sheeps' milk contains other simple lipids (diglycerides, monoglycerides, and cholesterol esters), complex lipids (phospholipds) and liposoluble compounds (sterols, alcohols, and hydrocarbons). Triglycerides constitute the largest group (nearly 98%), including a large number of esterified fatty acids, and so the composition is complex.

Fatty acids Fatty acids may be saturated or unsaturated (having from one to four double bonds). Most acids, from acetic to arachic acid, contain an even number of carbon atoms, of while approximately 2% are saturated with an odd number of atoms, and

roughly the same percentage of saturated fatty acids with branched methyl chains with an odd or even number of carbon atoms. Sheeps' milk contains more caproic, caprylic, and capric acid than cows' milk. These fatty acids are associated with the characteristic flavor of sheeps' milk cheeses and can also be used to detect mixtures of milk from different species (Table 2).

The most important of the factors that affect fatty acid composition is the feed. The addition of animal fats to the diet produces a decrease of C4–C14 acids and an increase of C16, C18, and C18:1 acids. If the intake of forage is reduced, the proportion of C4 to C16 fatty acids decreases accordingly.

Triglycerides The triglyceride structure of the milk fat is responsible for its rheological properties and its behavior during melting and crystallization. The triglyceride composition is useful to verify the authenticity of milk fat.

Triglycerides are almost invariably accompanied by small amounts of di- and monoglycerides, mainly at positions 1 and 2, which are therefore probably intermediates in the biosynthesis of triglycerides. The distribution of fatty acids in the triglyceride molecule, as determined by stereospecific analysis, differs slightly from cows' milk fat, but the distribution of acids in the molecule is not random. However, in both sheeps' and cows' milk, butyric acid and other short-chain fatty acids (C6–C8) are esterified mainly at position 3 of the glycerol molecule; the distribution of the other fatty acids (C10 or greater) exhibits no such marked specificity for positions 1 or 2.

Table 3 shows the average triglyceride composition of sheeps' milk fat compared with cows' milk fat. The triglycerides in sheeps' milk show a wide range of molecular weights when distributed according to the number of carbon atoms (taking into account the carbon atoms of the three acyl radicals), with two peaks at C38–C40 and C50–C52 and a minimum at C44–C46. Sheeps' milk fat has a higher percentage of short-chain triglycerides (C26–C36) than cows' milk fat (18% versus 11%). Percentages of medium-chain triglycerides (C38–C44) are also higher in sheeps' milk fat (33% versus 25%), and the percentages of unsaturated trglycerides are lower than in cows' milk fat (51% versus 55%). These differences relate to the need for a triglyceride composition with the appropriate melting point to allow the fat to be secreted. It has been established that the principal triglycerides in sheeps' milk fat are composed largely of three fatty acids (C14, C16, and C18:1), combined with the short-chain fatty acids C4 and C6.

Unsaponifiable lipids The unsaponifiable fraction of the milk fat is composed largely of sterols, with a smaller proportion of hydrocarbons, mainly squalene, and trace amounts of a number of normal- and branched-chain hydrocarbons in the range C17–C48 with odd and even numbers of carbon atoms, liposoluble vitamins and aliphatic alcohols. Ovine milk contains virtually no tocopherol or β-carotene.

Sterols are a minor fraction of total milk fat, the main component being cholesterol (270–350 mg per 100 g of fat, equivalent to approx. 20 mg per 100 ml of sheeps' milk), but small amounts of other sterols

[a]Triglycerides are identified by the number of acyl carbon atoms per glyceride molecule.
Ranges have been calculated from the results given by different authors.

implicated in cholesterol biosynthesis have also been found in ovine milk: lanosterol (5–15 mg per 100 g of fat) and, in even smaller proportions, dihydrolanosterol, desmosterol, and lathosterol.

Phospholipids The major phospholipids in both sheeps' and cows' milk are: phosphatidylethanolamine, phosphatidylcholine, phosphatidylserine, phosphatidylinositol, and sphingomyeline. These account for roughly 0.8% of the total lipid fraction.

Lactose

Lactose is the principal carbohydrate in milk. Chemically, it is a disaccharide consisting of a residue of D-glucose and D-galactose joined in a β-1, 4-glycosidic linkage. Sheeps' milk contains between 45 and 50 g of lactose per kilogram of milk, and lactose accounts for 22–27% of dry matter versus 33–40% in cows' milk. The lower lactose content does not present a problem in cheesemaking, since a sufficient amount of lactose is available to ensure lactic fermentation.

Enzymes

Enzymes are constituents of the mammary gland which pass into the milk during the secretion process. The enzymes found in milk are highly specific and are chiefly oxidoreductases, transferases, and hydrolases. Particularly important for technological purposes are proteases and lipase. Lipase, lysozyme, ribonuclease, and xanthineoxidase are less active in sheeps' milk, whereas alkaline phosphatase, despite having the same molecular weight and the same properties, is more active than in cows' milk. The most abundant enzyme is lactoperoxidase, which has proved impossible to distinguish from the bovine enzyme but appears to be more thermolabile. The indigenous proteases include aminopeptidases, thermolabile neutral acid proteinases, and serine proteinases, which are heat-resistant. The serine proteinase, plasmin, is heat-stable and hydrolyzes Lys—X and Arg—X bonds, becoming more active after thermal treatment.

Renneting Properties

The renneting properties of sheeps' milk are affected by a number of factors such as pH, physicochemical composition, micellar system, salts equilibrium, calcium concentration, and the temperature and time of heating. Sheeps' milk coagulates well and is indeed very suitable for making high-quality cheeses. It coagulates faster than cows' milk, and less rennet is needed to coagulate it in the same time as cows' milk. Curd formation is also faster than in cows' milk, but syneresis takes longer. The reason for this difference may be that sheeps' milk contains more casein, ionic calcium, and colloidal calcium than cows' milk. The renneting time and rate of firming are practically unaffected by the addition of calcium.

Physical Properties

The differences in the composition of sheeps' and cows' milk affect their physical properties. Sheeps' milk has a higher density, viscosity, refractive index, freezing point, and titrable acidity than cows' milk. Sheeps' milk is slightly more acid (lowest pH) than cows' milk, possibly due to its higher protein content.

Nutritive Value

The nutritional importance of sheeps' milk is due to its composition. Although sheeps' milk is richer in nutrients than cows' milk, it is rarely used as milk for drinking. In general, it is used for cheesemaking, but in certain countries, some is made into yogurt or other fermented milks. Sheeps' milk is an excellent source of high-quality protein, calcium, phosphorus, magnesium, zinc, and several vitamins. Only iron is in short supply, but its bioavailability is good because it is bound by lactoferrin, which is involved in the transport of iron in the body.

There is a good balance between the protein, fat, and carbohydrate components, each being present in similar amounts. The supply of nutrients is high in relation to the calorie content of the food. Sheeps' milk has a higher calorific value (500 kJ per 100 g) than cows' milk. Table 4 shows the range of concentrations of minerals and vitamins in ewes' milk.

Sheeps' milk contains mineral salts (around 0.9%). The most abundant elements are Ca, P, K, Na, and Mg. Ca and P are the most important of the macroelements in nutritional terms and for their role in the stability of casein micelles, and hence in the behavior of the caseins during milk processing. The most abundant of the trace elements are Zn, Fe, Cu, and Mn. With the exception of sodium, the concentrations of these elements are higher than those found in cows' milk. Sheeps' milk contains an average of 2 g of citrate per kilogram, which is slightly higher than that in cows' milk.

Concerning the distribution between the soluble and colloidal phases, the percentages of Ca and P in the soluble phase are, respectively, 20–25% and 35–40% of the total. These proportions are lower than in cows' milk, but the absolute concentrations in the soluble phase are comparable for the two species. Therefore, the concentrations of both elements in the colloidal phase are much higher than in cows'

Table 4 Vitamin and mineral content of sheeps' milk (per 100 g)

Cu ($mg\,l^{-1}$)	0.07	0.04–0.14

[a]Values have been given by different authors.

milk, given the higher levels of casein found in sheeps' milk. Na and K are the major elements in the soluble phase. Of the trace elements Zn, Mn, Fe, and Cu, the first two are present mainly (around 90%) with the colloidal fraction of the milk, while Fe and Cu are present to a lesser extent (70 and 65%, respectively).

The vitamin content is generally higher in sheeps' milk than in cows' milk. The level of retinol activity of ewes' milk is approximately twice that of goats' and cows' milk.

Cheeses

Practically all sheeps' milk is used to make cheeses, most of which are craft products. Some have an Appellation of Origin, so that production is confined to specific regions, and only a minority are made on an industrial basis. There are six categories of sheeps' milk cheese based on the technology used: fresh, white brined (pickled), blue-veined, semihard, hard, and whey cheeses.

Roquefort cheese, is a blue-veined cheese made in France from raw sheeps' milk inoculated with *Penicillium roqueforti* spores. It undergoes extensive proteolysis, 50% water-soluble nitrogen in total nitrogen (WSN/TN) and lipolysis, 8–10% of total fatty acids after 5 months of ripening. Spain produces a blue-veined variety, Cabrales cheese, with similar characteristics. This cheese is highly appreciated, although the raw material is a mixture of cows', sheeps', and goats' milk.

Feta cheese is a white-brined cheese originally from Greece, and is one of the most popular cheeses internationally. Traditionally, it is made from raw sheeps' milk and is ripened in barrels with brine (6–8% NaCl) for around 1 month at 8–10 °C; it is then kept chilled for at least 2 months prior to consumption. Nowadays, it is made mainly from pasteurized sheeps' milk. There is a variety similar to feta called teleme, originally from Romania, which is generally made from a mixture of milk of all three species. The white-brined category also includes halloumi, a cheese produced chiefly in Cyprus from raw sheeps' milk.

Pecorino is an Italian semihard or hard cheese. There are several varieties with Appellations of Origin, including Romano, Siciliano, and Fiore Sardo. The Romano variety accounts for 50% of total production. This cheese is made with raw or pasteurized sheeps' milk, in most cases coagulated with lamb or kid rennet paste. Proteolysis is moderate (≈20% WSN/TN), but there is intense lipolysis due to the presence of pregastric esterases in the traditional rennet pastes used. Kefaloteri is a variety similar to pecorino produced in Greece, although rennet pastes is not normally used for coagulation.

Kachkaval has been produced in various European countries, particularly in the Balkans, at least since the eleventh century. This is a stretched-curd cheese which undergoes moderate proteolysis even after 3 months of ripening (≈13% WSN/TN).

The most characteristic Spanish semihard/hard sheeps' milk cheeses are Manchego, Zamorano, Roncal, and Idiazabal, traditionally made from raw milk. These are generally ripened for 3–6 months, although Manchego may be matured in olive oil for a longer period. Proteolysis is medium/high, 20–45%WSN/TN, while lipolysis is low. Idiazabal cheese is ripened for 1–2 months and then smoked.

Some sheeps' milk cheeses are made in Portugal and Spain using vegetable rennet extracted from the flower of the thistle, *Cynara cardunculus*. Examples include Serra da Estrela in Portugal and La Serena, Los Pedroches, and Torta del Casar in Spain. These are commercialized after relatively short ripening (30–60 days), but the proteolysis levels are high (40–50% WSN/TN) due to the strong proteolytic activity in the curd. Spain produces two highly popular fresh cheeses, Burgos and Villalón. These are now made from pasteurized milk using animal rennet, but without a starter culture. They must be kept in chilled storage and consumed in less than 6 days.

Finally, in various countries, the whey from sheeps' milk in cheesemaking is used on its own or mixed with milk to manufacture products of high nutritional value. The whey contains mainly water-soluble

Table 5 Average content of fat, protein, calcium, and phosphorus in cheeses made from ewes' milk

Country	*Name*	*Type of cheese*	*Fat content (percentage total solids)*	*Protein (%)*	*Ca (%)*	*P (%)*
France	Roquefort	Blue-veined	50.00	21.00	0.62	0.42
Greece	Feta	Brined	40.00	18.00	0.65	0.40
Italy	Pecorino	Hard	42.00	29.00	0.40	0.32
Portugal	Serra da Estrela	Semihard	56.00	20.00	0.65	0.53
Romania	Teleme	Brined	50.00	18.00	0.53	0.40
Spain	Manchego	Semihard	50.55	23.00	0.68	0.54

Average values have been calculated from the results given by different authors.

proteins ($\approx 1\%$), fat ($< 1\%$), lactose, minerals, nonnitrogen substances, and vitamins. These whey cheeses are the result of heat-induced coagulation of the whey protein (which occludes fat). The best-known whey cheeses are ricotta from Italy, Manouri and Myzithra from Greece, and Requesón from Spain.

Besides the cheeses mentioned here, many countries produce cheeses, generally semihard varieties, in which the raw material is a mixture of sheeps', cows', and goats' milk.

Nutritional Aspects of Cheese

Cheese, in its concentrated form, contains much of the same nutrients as milk, caseins, fat, minerales, vitamins, colloidal salts, and some whey constituents. Some (up to 90%) of the hydrosoluble vitamins may be lost in the whey, but the levels of vitamins in cheeses depend on the balance on the consumption and production of the vitamins by microorganisms. The important nutrients in cheese come mainly from the high content of biologically valuable proteins which supply essential amino acids, and the levels of minerals, mainly calcium and phosphorus. Table 5 shows the average content of fat, protein, calcium, and phosphorus of some of the principal sheeps' milk cheeses produced in different countries, indicating the type of consistency.

The transformation of lactose to lactic acid occurs during the first stage of processing, this means that people who are lactose-intolerant can consume cheese with impunity.

The protein content of different varieties of ewes' milk cheese varies between 20 and 30%. In cheese manufacture, the casein is incorporated into the curd. The more biologically valuable whey proteins are lost in the whey, but the biological value of the proteins in cheese is higher than that of casein alone. The biological value of proteins is improved when the whey proteins are incorporated into the cheese by membrane processes such as ultrafiltration. During ripening, caseins are hydrolyzed to peptides and amino acids by the action of rennet and microbial proteases. The nutritional value of the proteins in cheese is not affected by the above-mentioned processes, and the bioavailability of lysine is comparable to that of casein in milk.

The fat is hydrolyzed during ripening by microbial lypases, which produce free fatty acids. These components contribute to the development of the aroma of the cheeses. The level of fat in sheeps' milk cheeses varies from 12 to 30%, depending on the length of time and degree of ripening. The digestibility of the fat of different varieties is between 88 and 94%. The content of Ca and P in cheese is higher than that in milk, four to five times higher in fresh cheeses, seven to eight times higher in semihard cheese, and 10 times higher in hard cheeses. Only in acid-coagulated cheeses is the content of Ca and P lower than in milk. The bioavailability of calcium cheese is comparable to that from milk and is not affected by the ripening process.

Characteristics of Crustacea

D A Jones, University of Wales Bangor, Gwynedd, Wales, UK

Introduction

As shellfish or shelled aquatic invertebrates, the Crustacea share important features, such as bilateral symmetry, body segmentation, and the possession of a well developed exoskeleton, with the other groups within the phylum Arthropoda. However, they may be separated at the subphylum level from the Cheliceriformes (scorpions, spiders, etc.), Trilobitomorpha (fossil trilobites) and Uniramia (insects and myriapods) by the features listed below:

1. Appendages are uniramous or biramous.
2. Brain is tripartite (with deutocerebrum).
3. Body is divided into cephalon and trunk, or latter subdivided into thorax and abdomen.

4. There are five pairs of cephalic appendages: preoral first antennae and four pairs of postoral appendages – second antennae (which migrate to preoral position in adults), mandibles, maxillules, and maxillae.
5. Mandible is gnathobasic (mandible arises from limb base); endopod and exopod are reduced in adults.

There are at least 39 000 species of crustaceans, ranging in size from less than 1 mm in length to spider crabs with leg spans of over 4 m, and these are subdivided into six classes and 38 orders. Although most of these are marine, small groups have exploited the fresh-water and terrestrial environments, so that crustaceans can be found from mountain tops and deserts to abyssal depths. Despite the large number of species, many are either too small or too dispersed to be exploited by humans. The forms most commonly exploited commercially are crabs, lobsters, and shrimps. Planktonic copepods (10 000 species), Cladocera (450 species), planktonic and benthic Ostracoda (5000 species), and mainly benthic Amphipoda and Isopoda (10 000 species) often form an essential link in food webs which support fisheries, but such forms are only rarely themselves the subject of fisheries. However, a key problem in the management of crustacean fisheries concerns euphausiids (krill) which play a central role in the Antarctic ocean food web as food for many whales, seals, and birds, yet are also increasingly being fished directly as food for humans and domestic animals.

Taxonomy

A brief outline classification of crustaceans utilized directly by humans is given in Table 1; for more detailed descriptions, refer to the Further Reading section. It is clear that, apart from larger planktonic species such as euphausiids, mysids, and sergestids, which swarm in sufficient concentration to be harvested economically, and gourmet species such as stalked barnacles (*Pollicipes*) and stomatopods, the majority of edible crustaceans are found in order Decapoda, which comprises some 10 000 species. The possession of branched or dendrobranch gills, external fertilization, and release of eggs into the sea separates the penaeid and sergestid shrimp from the rest of the Decapoda.

The Pleocyemeta have unbranched gill filaments and brood their eggs, which hatch at a later stage than the nauplius produced on hatching by the Dendrobranchiata. This group contains the majority of the familiar shrimps or prawns (the terms are now synonymous), crayfish, lobsters, squat lobsters, and crabs. Caridean shrimps (*Palaemon, Macrobrachium*) possess phyllobranchiate or flattened, plate-like gills, separating them from the larger and more robust Astacidea (which possess trichobranchiate or unbranched, tubular gill filaments). All the fresh-water crayfish (Astacidea) and marine lobsters (*Homarus* and *Nephrops*) have greatly enlarged chelae or claws on the first pair of walking legs, distinguishing them from the Palinura (spiny and slipper lobsters), which have similar gill structures, but lack the enlarged claws. This marine group tends to be more mobile and possesses a flattened abdomen and large tail fan used in swimming.

The Anomura contain forms in which the abdomen is either soft and twisted asymmetrically to fit into gastropod shells, or flexed beneath the cephalothorax as in galatheid lobsters. The coconut crabs (*Birgus*) and lithodids represent extreme groups in which the asymmetrical abdomen is closely applied to the underside of the thorax, giving the appearance of true crabs or Brachyura. This final group is distinguished by the lateral expansion of the cephalothorax, and reduction of the abdomen to form a symmetrical flap, lacking uropods, which is flexed under the thorax.

Crustacean Structure and Function

As a predominantly aquatic group, crustaceans have been able to exploit the arthropod chitinized exoskeleton fully without the weight restrictions imposed by such a system on land. In the classes under consideration (Table 1), fusion of the head and one to three thoracic segments has occurred to produce a carapace, or protective shield, which often extends forwards in the form of a rostrum and posteriorly to protect the cephalothorax (Figure 1). The abdomen usually retains flexibility by means of soft cuticular joints between each segment. Even barnacles (Figure 1) retain most of these features, although much modified for their sedentary existence.

Each segment typically bears a pair of jointed appendages, anteriorly. The two pairs of antennae are often elongated and mobile, and carry esthetascs which are chemosensory hairs. Other head appendages usually form mouthparts concerned with feeding and include the mandibles or jaws, maxillules, and maxillae, and, in malacostracans, additional maxillipeds.

The rest of the thoracic appendages are modified into pereopods (Figure 1) specialized for walking, swimming, respiration, feeding, or defense. The abdominal segments (pleonites) typically bear biramous pleopods, paddle-like appendages, used for

Table 1 Pennant (1771) classification of phylum, subphylum or superclass Crustacea utilized directly for human nutrition

Class Maxillopoda	
Subclass Cirripedia	
Order Thoracica	Stalked barnacles, e.g., *Pollicipes*
Subclass Copepoda	
Order Calanoida	Copepods, e.g., *Calanus plumchrus*
Class Malacostraca	
Subclass Hoplocarida	
Order Stomatopoda	Mantis shrimp (*Squilla mantis*)
Subclass Eumalacostraca	
Superorder Peracarida	
Order Mysidacea	Possum shrimp (*Neomysis intermedia*)
Superorder Eucarida	
Order Euphausiacea	Krill, e.g., *Euphausia superba*
Order Decapoda	
Suborder Dendrobranchiata	Penaeid and sergestid shrimps, e.g., *Penaeus, Sergestes*
Suborder Pleocyemata	
Infraorder Caridea	Caridean and procaridean shrimps, e.g., *Macrobrachium, Palaemon*
Infraorder Astacidea	Crayfish and chelate lobsters, e.g., *Astacus, Homarus, Nephrops*
Infraorder Palinura	Palinurid, spiny, and slipper lobsters, e.g., *Panulirus, Palinurus, Thenus, Scyllarides*
Infraorder Anomura	Galatheid crabs, king crabs, e.g., *Paralithodes, Pleuroncodes*
Infraorder Brachyura	Crabs, e.g., *Cancer, Scylla, Callinectes, Maia*

swimming in malacostracans. In this group the terminal somite bearing the anus forms a flattened telson, and the last pair of abdominal segments are modified to form uropods; together with the telson; these form a tail fan used in swimming.

The gut is divided into a chitin-lined fore- and hindgut and a midgut lined with endoderm. The foregut esophagus leads to a stomach which is often subdivided into cardiac and pyloric regions in malacostracans. The midgut forms an intestine of variable length and bears the digestive cecae or hepatopancreas, emptying into the pyloric chamber of the stomach. The hindgut is usually short, absorptive in function, and leads to the anus. In crabs and lobsters, mechanical breakdown of food in the gastric chambers of the stomach is performed by heavily sclerotized teeth which form a grinding gastric mill; in shrimps this structure may be absent and breakdown is solely by enzymes secreted from the hepatopancreas. The products of digestion are absorbed by cells in the fine tubules of the hepatopancreas, or cells lining the midgut trunk, where further intracellular digestion occurs. In some groups, expelled fecal material is sheathed in a peritrophic membrane.

The circulatory system is comprised of a dorsal muscular heart with ostia or pores to draw in blood from the pericardial cavity. In advanced malacostracans the heart has a series of blood vessels insuring that blood flows to body organs and to the gills (Figure 1). Return to the heart is via pools or the hemocoel, although active crustaceans may have a primitive venous system to return the blood to the pericardial cavity. Gaseous exchange in large, advanced crustaceans is via gills, which arise as branches from the base of the thoracic limbs. The gills are modified in various ways to provide a large surface area of thin, permeable cuticle, and in decapods are protected under the carapace in branchial chambers through which ventilating currents of water are drawn.

Excretion is in the form of ammonia, which is released across gill surfaces and via nephridia in maxillary or, in most malacostracans, antennal glands (Figure 1). These glands are also active in osmoregulation, as are the gill surfaces. The crustacean cuticle, unlike the waxy insect cuticle, is largely permeable, and imposes severe constraints upon ionic regulation; hence few crustaceans are found away from water.

The crustacean brain is composed of three fused ganglia – two anterior dorsal supraesophageal ganglia and a third which forms a pair of circumenteric connectives extending round the esophagus to a subesophageal ganglion linked to the ventral nerve cord. This cord bears paired segmental body ganglia. The optic and antennulary nerves run to the supraesophageal ganglia, and the subesophageal ganglia often become a large, fused mass serving the nerves to the mandibles, maxillules, maxillae, and maxillipeds. In crabs all the thoracic ganglia fuse to form a large ventral nerve plate. Sensory systems are well developed, despite the exoskeleton, and take the form of innervated setae responding to touch or currents, whilst others, such as esthetascs, detect chemicals or gradients in attractants emanating from food.

Crustaceans are well adapted to detect light, and photoreceptors range from the simple larval naupliar eye, responding to light direction and intensity, to the

Table 3 Habitats and global distribution of crustaceans utilized for human nutrition

Group	*Habitat*	*Distribution (commercial fisheries)*
	Marine	
Copepods	Pelagic	Norway, Canada, Japan
Cirripedes	Rocky, coastal	Portugal
Mysids	Pelagic, coastal, estuarine	Japan, South-east Asia, China, Korea
Euphausiids	Pelagic, offshore	Antarctica, Canada, Norway, Mediterranean
Sergestids	Pelagic, coastal, estuarine	China, South-east Asia, Japan, East Africa, India, Brazil, Surinam, Philippines
Penaeid shrimp (60 species)	Benthic, soft-substrate, nutrient-rich, estuarine, coastal	Worldwide between 40 °N and 40 °S
Plesiopenaeus	Benthic, soft-substrate, deep-water	Atlantic, Australia, South Africa
Pleoticus	Soft-substrate, deep-water	South-west Atlantic
Caridean shrimp		
Crangon	Benthic, soft-substrate, coastal	Europe, former Soviet Union, Algeria
Pandalus	Benthic, coastal to 1500 m	North Pacific, Atlantic
Palaemon	Benthic, rocky, coastal	Europe, Algeria
Stomatopoda	Benthic, rocky, coastal	Tropical to Mediterranean
Lobsters		
Homarus	Benthic, rocky-soft, coastal to 700 m	North Atlantic, Mediterranean
Nephrops	Benthic, soft substrate, 15–800 m	North-west Atlantic, Mediterranean
Panulirids	Benthic, rocky, coastal, 700 m	30 °N–50 °S worldwide
Syllaridae	Benthic, soft-rocky, coastal	Mediterranean, Japan, Indian Ocean
Anomurans		
Galatheids	Benthic, rocky, coastal	Mediterranean, Japan, western USA
Lithodes	Benthic, rocky-soft, coastal	South-west Atlantic
Paralithodes	Benthic, rocky-soft, coastal	North-west Pacific
Crabs		
Chionecetes	Benthic, rocky, coastal	North-west Atlantic, north-west Pacific, east central Atlantic
Maia	Benthic, rocky, seaweeds, coastal	Mediterranean
Cancer	Benthic, rocky-soft, coastal	Africa, north-east and central Atlantic, Mediterranean, north-east and -west Pacific, east central Pacific
Portunids	Benthic, rocky-soft, coastal	North-east Atlantic, Asia, west Pacific
Callinectes	Benthic, rocky-soft, coastal, shelf edge	West and north-west Atlantic
Scylla serratus	Benthic, mangal, coastal	Asia, India, west central Pacific
Geryon	Benthic, soft, 300–1500 m	North-west Atlantic
	Fresh water	
Caridean shrimp		
Macrobrachium	Estuaries, rivers, benthic, soft-substrate	Tropical, introduced worldwide
Palaemonids	Estuaries, rivers, lakes, soft, benthic	Tropical
Astacidea		
Crayfish	Rivers, lakes, streams, rocky-soft, vegetated	Temperate to tropical, worldwide

stalked, multifaceted compound eye found in decapods. This is capable of discerning shapes, patterns, and movement and at least some have color vision. Molting, chromatophore activity, tidal and daily locomotor rhythms, and aspects of reproduction are under hormonal and neurosecretory control, but an understanding of the mechanisms of this control is still at an early stage.

Sexes are separate in most crustaceans, but even some advanced malacostracans such as *Pandalus* may be protandrous hermaphrodites (maturing first as males, then later changing sex). Gonads are paired structures which are found in various regions of the trunk and empty via genital pores, usually on a trunk sternite. In male decapods an anterior pair of pleopods is modified for sperm transfer. Sperm is deposited directly into the oviduct or into a seminal receptacle, where it may be stored for some time. Crustaceans may brood fertilized eggs, usually in an external pouch (mysids) or attached to pleopods (most decapods), but exceptionally (penaeids) may release their eggs freely into the sea.

Typically crustacean eggs hatch into planktonic larval forms, although these are suppressed, for example, in the Mysidacea, Amphipoda, Isopoda and fresh-water Astacidea, where direct development occurs. The most primitive larva is the nauplius, with a single median simple eye and three pairs of biramous limbs; this is followed by the zoea and megalopa, gaining additional limbs and segments at each molt. A wide variation in numbers of larval stages and duration is seen; penaeids have 12 stages extending over 13 days, homarid lobsters four stages over 15 days, whilst the planktonic life of palinurids may extend up to 12 months.

Table 2 gives the composition of crustaceans commonly consumed by humans and reveals that all are low in saturated fats, high in polyunsaturates, particularly the highly unsaturated *n*-3 series, and contain medium levels of cholesterol. (*See* **Carbohydrates**: Requirements and Dietary Importance; **Energy**: Measurement of Food Energy; **Fats**: Requirements; **Protein**: Requirements.)

Several crustacean groups (copepods, branchiurans, cirripedes, and isopods) have given rise to parasites which may cause serious infestations in edible fish and shellfish.

Habitats and Distribution

Apart from the pelagic zooplanktonic copepods, mysids, euphausiids, and sergestids, which are mainly fished commercially in colder productive waters (Table 3), most other crustaceans only occur in commercial densities in shallow coastal seas. The fast-growing, high-value penaeid shrimp are restricted to warmer waters, as many have life cycles associated with estuarine mangals, and many burrow in sands and muds. In contrast, the slower-growing caridean shrimps are centered in the northern boreal region, where the shallow-sea pandalids make up the bulk of the fisheries.

The slow-growing homarid lobsters also have a cold-to-warm temperate distribution and are replaced in warmer seas by the panulirid and scyllarid lobsters. The most productive crab fisheries used to be those for king crabs (*Paralithodes*) and snow crabs (*Chionecetes*) from the North Pacific and Alaska, but blue crabs (*Callinectes*) from the western Atlantic have recently produced the highest landings. Although most lobsters and crabs show a preference for rocky habitats, both *Cancer* and *Homarus* will construct burrows in soft substrates.

Many crustacean groups have invaded fresh-water habitats, but only caridean shrimp, notably *Macrobrachium* and crayfish, attain commercial fishery sizes. The former are restricted to tropical waters, whilst the latter occur worldwide. European crayfish populations declined as a result of disease, but recent introduction of expatriate species has led to these becoming pests, particularly in Africa and southern Europe.

Commercially Important Crustacea

B D Paterson, Bribie Island Aquaculture Research Centre, Bribie Island, Australia

Background

Visit a fish market, supermarket, or restaurant anywhere in the world, and a variety of crustaceans are likely to be presented for sale. The particular species found will depend greatly upon the country and the region concerned. However, as crustaceans and other kinds of seafood move further afield with the

increasing international trade in food products, this means both an increasing variety in the product displayed in the major markets of Asia, USA, and Europe, and more intense competition within broad product categories. As a consequence, the names of imported product can be a hot 'branding' issue amongst local producers. But rather than perpetuating arbitrary distinctions, for example about what constitutes a 'true' lobster, in order to objectively come to grips with the varieties of crustaceans produced in significant quantities throughout the world, it is easier to consider the three broad product groups; shrimp, lobsters, and crabs. These commodity divisions nevertheless mirror broad taxonomic differences, largely because the morphology of crustaceans has a large impact on their processing and marketability.

Most of the commercially important crustaceans are decapods, the group containing the largest and most familiar crustaceans (Table 1). The sheer diversity and global distribution of fished and cultured crustacea seemingly count against any attempt at a detailed statistical compilation. But it is possible, within the limits of the data available, to find major patterns in the production figures and identify outstanding species. Of course, species that do not rate highly in terms of global production can still be commercially important. They may be high in value and on display, such as crustaceans marketed alive, or they may be less valuable but still contribute locally to nutrition, employment, and prosperity. Commercial exploitation itself is enough to warrant local regulation and management of stocks or farming operations, though, now, the viability of 'local' industries and the quality of their products have reached new horizons of concern, now that quality and sustainability are the concern of world consumers and trade regulators.

Table 1 Taxonomic relationships amongst commercially important crustacea

- Crustacea (Class)
  - Decapoda (Order)
    - Natantia (Suborder)
      - Caridea (Infraorder)
        - Crangonidae (Family) *Crangon crangon*
        - Palaemonidae (Family) *Macrobrachium rosenbergii*
        - Pandalidae (Family), e.g., *Pandalus borealis*
      - Penaeoidea (Infraorder)
        - Penaeidae (Family), e.g., *Penaeus* spp.
        - Sergestidae (Family), paste shrimp, *Acetes japonicus*
    - Reptantia (Suborder)
      - Anomura (Infraorder)
        - Galatheidae (Family), Squat lobsters, *Pleuroncodes monodon*
        - Lithodidae (Family), Stone crabs, *Paralithodes camtschaticus*
      - Astacura (Infraorder)
        - Cambaridae (Family), Freshwater crayfish, e.g., *Procambarus clarkii*
        - Nephropidae (Family), Lobsters, e.g., *Homarus americanus*, *Nephrops norvegicus*
        - Parastacidae (Family) Freshwater crayfish, e.g., *Cherax quadricarinatus*
      - Brachyura (Infraorder)
        - Cancridae (Family), Edible crabs, e.g., *Cancer* spp.
        - Majidae (Family), Spider crabs, *Chionoecetes* spp.
        - Portunidae (Family), Swimming crabs *Portunus trituberculatus*, *Callinectes sapidus*
      - Palinura (Infraorder)
        - Palinuridae (Family), Spiny lobsters, e.g., *Panulirus argus*
  - Euphausiacea (Order)
    - Euphausiidae (Family), Krill, *Euphausia superba*

The total global production of crustaceans from fisheries and aquaculture was 7.8 million tonnes in 1999, and crustaceans represented about 20.1% of global aquaculture production in that year. Shrimps and shrimp-like crustaceans account for about half the global crustacean trade, largely due to the large output of shrimp fisheries and an increasing component of farmed tropical marine shrimp. About 81% (6.3 million tonnes) of harvested crustaceans came from capture fisheries, so the taxonomic/market breakdown of this group (Figure 1) still has a significant effect on global totals. Marine shrimp currently dominate the crustacean farming sector (Figure 2), with much of the remaining farm production based in freshwater.

Beyond the level of the total contribution by various taxa, it is not always possible to categorically identify the most important species by isolating these data from the production figures. Sometimes, the compiled global statistics for particular groups include large percentages of production that cannot be assigned to anything but the broadest taxonomic categories. Nevertheless, the species that emerge from the data contain no surprises, even where relatively large proportions of production remain unspecified.

While the better known crustaceans originate from the world's oceans, it would be wrong to discount altogether the 10% of global production of crustaceans that originates from freshwater sources. While these of course are also shrimp, crabs, or indeed 'lobsters', they deserve separate treatment, because they do not necessarily compete in the same market segments as their marine relatives.

Marine Shrimp

The suborder Natantia (shrimps and prawns) are decapod crustaceans adapted for swimming, with a light cuticle and a well-developed abdomen with a

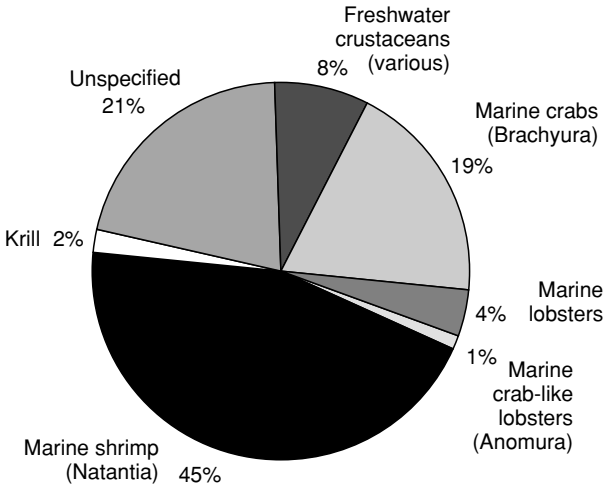

Figure 1 Global fisheries production of major product/taxonomic groups of crustaceans in 1999. From Anon (1999) *FAO Fishery Statistics: Capture Production; Aquaculture Production; Commodities*, vol. 88(1–3). Rome: FAO.

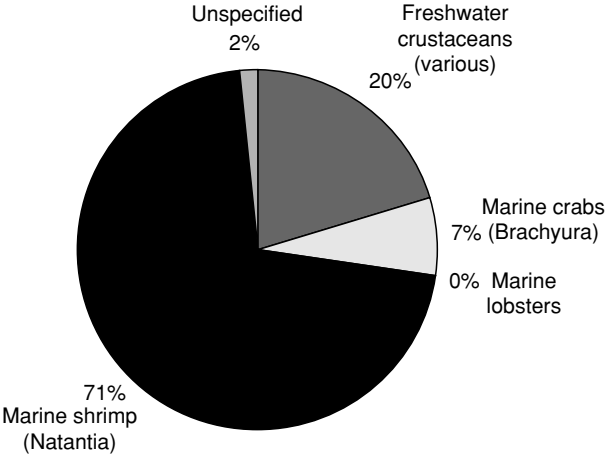

Figure 2 Global farmed production of major product/taxonomic groups of crustaceans in 1999. From Anon (1999) *FAO Fishery Statistics: Capture Production; Aquaculture Production; Commodities*, vol. 88(1–3). Rome: FAO.

full complement of swimmerets. The abdomen is also used for the powerful tail-flicks that the shrimp uses to flee danger, so it is ironic that it is this very adaptation that makes shrimps so commercially attractive.

Production of shrimp in 1999 was about 4 million tonnes. There is sufficient detail in the global statistics to be sure of the general spread of taxonomic groups, as only about 13% of recorded production is unassigned. The diversity in this group is such that a number of major taxonomic groups of shrimp and shrimp-like organisms are involved. Three quarters of the total shrimp production is represented by shrimps of the Infraorder Penaeoidea, most of that accounted for by several species of the diverse and widespread Family Penaeidae (2.4 million tonnes). The Sergestidae, a group common in deeper water, make up a major slice of the remaining penaeoids harvested, and most of that is the akiami paste shrimp *Acetes japonicus*, a species used for manufacture of paste, salted, and fermented products. While another major superfamily, the Caridea accounts for only 10% of the global production of shrimp (or 430 000 tonnes), the bulk of that (91%) is represented by a single North Atlantic species of pandalid shrimp, the Northern shrimp, *Pandalus borealis*. The remaining data for the caridean shrimp are mostly taken up by landings of common shrimp *Crangon crangon* (around 37 000 tonnes).

The diversity of the shrimp group is such that it is not possible to discuss all in detail. If we arbitrarily consider species to which landings represent individually more than 10% of total shrimp landings, four species stand out. The paste shrimp and the Northern shrimp (*Acetes japonicus* and *Pandalus borealis*) have already been mentioned, but to this group should be added the giant tiger shrimp, *Penaeus monodon* (on the basis of farmed production!), and the southern rough shrimp, *Trachypenaeus curvirostris*. But this summary perhaps unfairly overlooks the diversity of other species of the Penaeidae such as the banana shrimp *Farfantepenaeus merguiensis*, *P. chinensis*, and *P. aztecus*.

By 1999, aquaculture accounted for over a third of of global shrimp production (1.1 million tonnes). As a market segment, farmed shrimp has been floating around 20–25% of global shrimp landings since the mid-1990s, the upward trend being checked or reversed by outbreaks of shrimp viral diseases at various times around the world, with consequences for supply and pricing felt throughout the market. The farmed shrimp are also penaeids and about half of the total is represented by farmed production of giant tiger shrimp *Penaeus monodon*. The three most notable farmed shrimp in the FAO statistics (in order of decreasing quantities) are the giant tiger shrimp (*Penaeus mondon*), the Pacific white shrimp *Litopenaeus vannamei*, and the Chinese white shrimp *Penaeus chinensis*. *L. vannamei* is farmed in the Americas, while the other two species are produced in South-east Asia. These species also figure highly in wild production statistics, though the farmed production for these species now exceeds the corresponding fisheries production.

Shrimp, which probably owes its dominance to sheer biological abundance as well as simple peeling and high meat recovery (50–60% of fresh weight), lends itself to a diversity of processed fresh/frozen and

packaged, value-added forms. Live marketing of the kuruma shrimp (*Marsupenaeus japonicus*) involves relatively small quantities but is noteworthy for the high prices achieved. Chilled, raw shrimp have a limited shelf-life, so much of the product is processed at sea or on farm in various ways to allow for marketing. This might involve simply packaging and freezing the raw or cooked shrimp in a manner suitable for sea-freight, but more sophisticated processing is increasingly being practiced (Figure 3).

One concern with minimal processing is 'black spot', a form of enzymatic spoilage common to commercial crustacea. This melanosis is mediated by polyphenoloxidases in the shell or hemolymph (blood). (*See* **Browning**: Enzymatic – Biochemical Aspects.) 'Black spot' can be avoided to some extent by removing the shell or by thorough cooking (to deactivate the enzymes), or treating the product to inhibit the formation of melanin. A widespread 'black-spot' treatment is to dip the raw or cooked shrimp in a solution of sodium metabisulfite or related chemicals (which scavenge oxygen, a requirement for melanosis). However, concerns over introducing undesirable sulfite residues into the product has recently led to adoption of other methods. One of these involves an enzyme inhibitor (4-hexylresorcinol), which interrupts the enzyme cascade leading to melanin.

Given the diversity of species, it would be wrong to say that there is one homogeneous global market for these 'commodity' shrimp, though few sectors seem immune from the ups and downs of supply and demand. The meat of different species varies in appearance, flavor, and texture, and this still explains some market segmentation in countries or regions where historically consumers ate particular types or shrimp or prawns. Marine penaeid shrimp have already made inroads into the European market, where *Pandalus borealis* once held sway, but even these penaeids vary. Consider the contrast, in terms of both raw and cooked meat between the highly pigmented giant tiger shrimp and various species of 'white' shrimp marketed.

However, ultimately, national tastes may come to mean little when products are highly processed, breaded, and packaged. Raw shrimp can be headed and the tail split (or 'butterflied'), breaded, and stored frozen in a form ready for cooking. Similarly, raw or cooked shrimp can be shelled and the peeled meat frozen and once again marketed as a convenience product. The processing, freezing, and cooking equipment used varies, with the cost of labor in the country concerned having a major role. The packaging used can range from bulk packs to prepackaged individual serves.

The shrimp sector has not been without troubles. Sporadic disease episodes in the farming sector have impacted upon supply and in recent years have raised concerns about the transfer of shrimp diseases by the global trade in shrimp. In addition, major seafood importing markets such as the USA, the European Union (EU), and Japan have emphasized the quality and safety of food imports by insisting on the adoption of Hazard Analysis Critical Control Point (HACCP) and related schemes. The trade in 'commodity' shrimp has had to fall in line with this, since imports from noncompliant countries have been banned. Various segments of the shrimp industry have also found themselves squarely in the sights of environmental activists concerned with reducing trawl by-catch and stemming the impact of the farming sector. For example, the fate of turtles drowned in trawls prompted calls in the USA for shrimp imports to be banned from countries using gear considered harmful to turtles. This has seen an increased emphasis on 'turtle excluders' and other kinds of by-catch reduction devices amongst world shrimp capture fisheries. The environmental impact

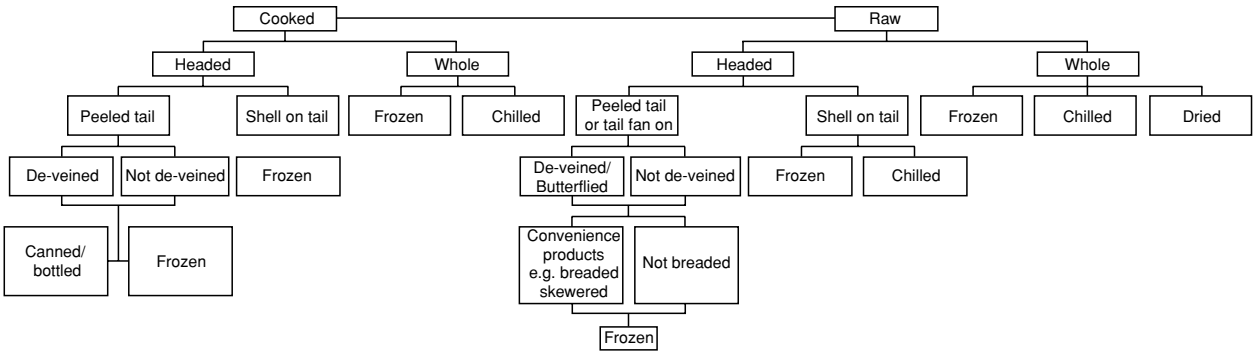

Figure 3 Summary of processing and storage methods applied to raw and cooked shrimp. Based on Lee DO and Wickins JF (1992) *Crustacean Farming*. Oxford: Blackwell Scientific.

of shrimp aquaculture is another area of controversy. All agriculture has some environmental impact, and it would be surprising if any global industry producing around a million tonnes of product annually had no local impact on the environment. Nevertheless, the recurrent problems with disease outbreaks certainly point to areas where farm management has needed to become more sustainable. Producers now appreciate the power that can be wielded by consumer campaigns, and development of more environmentally friendly farming methods is already a major priority.

Marine Crabs

The so-called 'true' crabs and, to some extent, certain 'crab-like' lobsters are the pinnacle of the tendency amongst decapod crustaceans to abandon the pelagic, swimming lifestyle. Their commercial importance no longer relies on tail meat, owing to their rudimentary, indeed vestigial, abdomen. Crabs hide from attack in burrows, buried in sand or beneath rocks, or perhaps rely for protection upon sheer size, a heavy cuticle, and threatening, sometimes well-muscled claws.

The marine production of true crabs in 1999 was about 1.3 million tonnes, or about 16.4% of global crustacean production. It is hard to be definitive as to the contribution of individual species to this total. As much as 26% of the total is represented by statistics that are only assigned to the broadest categories. Still, the available detail reveals a number of significant fisheries for swimming crabs of the Family Portunidae, particular centered in Asia. This group of crabs swim using a pair of modified, paddle-like legs. This, if anything, reiterates the capacity of evolution to reinvent a trait since lost in other crabs. About a third of estimated true crab production is represented by the swimming crabs *Portunus trituberculatus* (22%) and *P. pelagicus* (10%). Another important swimming portunid, the blue crab *Callinectes sapidus* from the east coast of the USA represents just 8% of the crab total. To contrast this approximately 40% share for portunids, the spider crabs (queen, snow, or tanner crabs, *Chionoecetes* spp.) together account for 16% of the total for true crabs. A diversity of other species of crab are harvested, and perhaps a discussion of the true crabs should not omit mention of the edible crabs, Cancridae, represented by various species of *Cancer*.

A small number of crab-like lobsters are not included in this total for true crabs. Marine crab-like lobsters such as stone crabs (Lithodidae, 57 500 tonnes) and squat lobsters (Galatheidae, around 26 500 tonnes) together account for only about 1% of global crustacean production. Taxonomically, these crustaceans belong to the diverse Infraorder Anomura. This assemblage of crustaceans has a diversity of body forms, though again with a trend for the abdomen to shrink. The major species of stone crabs and squat lobsters are, respectively, the Alaskan king crab *Paralithodes camtschaticus* and the red squat lobster *Pleuroncodes monodon*.

Crabs are harvested in a variety of ways, ranging from trawls to pots. Some farm production of portunid crabs has been achieved using *Scylla* spp. and *Portunus pelagicus* in South-east Asia, but it has some way to go before it reaches levels of production typical of shrimp farming. Probably the most unusual method of harvesting a crab or indeed any crustacean is one that takes advantage of the ability of crustaceans to regrow missing limbs. In the fishery for the stone crab *Menippe mercenaria*, only the claws are harvested, and the crab is returned to the sea, to grow new claws! The processing and marketing of newly molted blue crabs *C. sapidus* as 'soft-shell' crabs is another case where crustacean physiology is exploited commercially.

Processing options for crabs are broadly similar to those applied to shrimp, though in contrast to shrimp, many 'minor' species of crabs are often sold, transported, and marketed while alive, giving them a high level of consumer recognition. The live trade is preferred over that for raw chilled or frozen product, because the digestive gland (hepatopancreas) breaks down soon after death, discoloring the meat and releasing digestive proteases that readily soften the meat.

Unlike shrimp and lobsters, crabs cannot be conveniently 'headed' to remove the digestive gland. Instead of 'peeling' cooked crabs, more ingenuity is required to cut or saw through the thicker exoskeleton. The catch from the big tonnage fisheries is processed in large quantities and may reach the consumer in a highly refined form. Crabs taken live to a processor can be cooked (to inactivate the enzymes) and sold either whole/frozen or in a progressively broken apart form, to give packaged/frozen or canned meat. Processing the cooked product involves breaking open the shell and extracting the meat associated with the leg muscles and the claws. Though the details differ between species, picked meat production is probably as close as the crab sector comes to achieving the 'commodity' status as a source of convenience food. Conditions of strict hygiene must be employed during picking, because physically breaking the shell to extract meat presents an opportunity for the introduction of microbial contamination (e.g. *Listeria* and other pathogens), unless the product is further pasteurized. These risks can be addressed using the principles of HACCP.

Significant quantities of crabs are processed by individual factories, which translates into a considerable amount of waste. As companies in some countries are increasingly finding that waste costs money to dispose of, attention continues to be paid to economically recovering saleable material or products (e.g., chitin, astaxanthin, and other biological material) from the waste.

Marine Lobsters

While armored and strictly designed for walking, marine lobsters (and crayfish and indeed some 'shrimp' from freshwater) retain the basic body plan of pelagic crustaceans. The cephalothorax or head of lobsters is more prominent than is generally the case for shrimp, but the abdomen or 'tail' is only slightly diminished and, when danger threatens, can still generate powerful tail-flicks.

Marine lobsters account for only about 3% of total global landings, or nearly 229 000 tonnes. At least three-quarters of this is in the form of clawed Homarid and Nephropid lobsters from the North Atlantic (from the Infraorder Astacura). The American lobster *Homarus americanus*, from the USA and Canada, accounts for almost 40% of the lobster landings, followed by the Norway lobster *Nephrops norvegicus* at about 27%. Lesser quantities of European lobster *Homarus gammarus*, and a few species of other minor Nephropids (e.g., *Metanephrops* spp.) are caught elsewhere. The other major group of lobsters, the Infraorder Panulira – the spiny and rock lobsters – has a more widespread distribution. These lobsters lack claws as such, and instead have prominent spiny antennae. The Caribbean spiny lobster *Panuilrus argus* accounts for 16% of global lobster landings, but there are several other *Panulirus*, *Palinurus*, and *Jasus* species harvested commercially throughout the tropical to temperate seas of the world.

Harvesting methods for lobsters vary from species to species, but potting and trawling are practiced. Clawed lobsters can be produced in hatcheries, but currently, this is for reseeding programs rather than aquaculture *per se*. The numerous long-lived planktonic larval stages of typical panulirids is a major practical obstacle to the aquaculture of panulirids, with aquaculture ventures mostly concentrating on the collection of wild seed. Commercial production of farmed shovel-nosed lobsters *Thenus orientalis* from the hatchery is currently under development, while research continues on aquaculture of other panulirids. Like crabs, lobsters tend to be marketed whole and alive, though frozen product is also distributed cooked whole or tailed. Again, the major objective is to deal with quality loss associated with breakdown of the hepatopancreas. There is also some cutting, chopping, and meat picking from cooked lobsters, to produce both canned and frozen product. Where live transport of lobsters is logistically difficult (e.g., Pacific Islands), there is a preference for marketing frozen raw tails rather than freezing whole animals with the hepatopancreas intact.

Others

Global production of crustaceans from freshwater is estimated at about 817 000 tonnes (about 10% of the total). About half of that is fisheries data from Asia and particularly China, and is not identified to species level. To the extent that the data allow, two cultured species, the Chinese river crab *Eriocheir sinensis* and the giant river prawn *Macrobrachium rosenbergii*, together account for at least 33% of the global production of freshwater crustaceans. Another recognized aquaculture species in the USA, *Procambarus clarkii*, accounts for only 2% of the total landings, and beyond this, the landings are divided amongst numerous species that may of course be relevant in a geographical context. Freshwater crustaceans include numerous freshwater crayfish of the Astacidae, Cambaridae in Europe and the Americas, and a small representation from the Parastacidae (originally from Australia).

Product from freshwater tends to have a milder flavor, largely due to the different demands for osmotic regulation faced by freshwater-adapted crustaceans. Anatomically, commercial freshwater shrimp and crayfish also tend to have relatively smaller abdomens leading to less favorable meat recoveries than from their marine counterparts, though the variety of raw, cooked, and processed products can come close to rivalling that of marine shrimp in variety, if not in quantity. Translocation and release of Cambarid species into Europe have seen the spread of an introduced crayfish disease that has decimated native crayfish populations in some areas. Freshwater shrimp or prawns such as *M. rosenbergii* belong to the Caridea (Palaemonidae).

Another notable group, the krill are small shrimp-like crustaceans that swarm in the plankton of the world's oceans and form an importance food source for marine foods chains (and particularly many whales). These small shrimp are a different order of Crustacea altogether, the Order Euphausiacea. Global landings have varied between 80 000 and 100 000 tonnes for the past few years. One important use of dried krill meal is for aquaculture feed ingredients (*see* **Fish Meal**). Excitement about using krill as a human food source has been tempered in recent

years by a more realistic understanding of the resource and its limitations.

If imitation is considered to be the most sincerest form of flattery, then the very existence of surimi is further evidence of the commercial importance of crustaceans. Surimi is the deboned, washed, and gelled protein manufactured from white fleshed fish. Formed into sticks, flakes and chunks, the edges are coloured red to resemble picked crab meat.

Characteristics of Molluscs

K J Boss, The Agassiz Museum Harvard University, Cambridge, MA, USA

Background

Molluscs constitute a unique phylum of animals, the Mollusca, which are characterized by a combination of morphological and anatomical features separating them from all other invertebrate organisms. Many common names, such as snails, clams, and squids, apply to representatives of these animals, which number fewer than 50 000 living species. Molluscs are known to have diversified early in the fossil record, namely the Cambrian of the Paleozoic over half a billion years ago; the antecedent or ancestral mollusc is presumed to have evolved in the Precambrian and many different lineages have radiated into the vast array of ecological niches of the world's biotopes.

Molluscs are widespread in marine environments, living from the shore to the greatest abyssal depths and occurring in pelagic or oceanic realms as well as benthically, both on and in all kinds of substrates. In some parts of the world, they dominate the intertidal zone, and in the recently discovered aphotic deep-water vents and seeps as well as other oxygen-depleted environments, molluscs, especially mussels and certain clams, are particularly conspicuous, frequently utilizing endosymbiotic chemoautotrophic bacteria. Groups of representative snails and bivalves have also successfully adapted to terrestrial and freshwater habitats. Finally, some species have become specialized endoparasites.

In adult size, molluscs range from tiny gastropods and bivalves less than 1 mm in diameter or length to the giant squid which may be over 15 m long and upwards of 1000 kg in weight.

Typical Morphological and Anatomical Features

Molluscs are protostomous coelomates, exhibiting spiral, determinate cleavage and schizocoely as well as having trochophore larvae and the blastopore forming the mouth of the adult. They usually possess all or a combination of the following features: (1) a reduced coelom and vestiges of metamerism; (2) a mantle or fleshy epidermis of the dorsal body wall which has glands capable of secreting calcium carbonate to form an exoskeletal shell or shelly parts, such as plates, spines, and spicules; (3) a mantle cavity or an invagination of the mantle which contains a pair or more of specialized respiratory structures, the ctenidia or gills, and into which the digestive, metanephridial excretory, and reproductive systems debouch their products; (4) the ventral body surface modified into a pedal groove or muscularized foot for progression or locomotion; (5) a special chitinized, rasp-like tongue or radula; (6) an open hemocelic circulatory system with a chambered heart having auricles and ventricles. Additionally, the nervous system has variously paired ganglionic portions, particularly cerebral, pedal, and visceral ones, as well as ventral anteroposterior cord-like connective elements; specialized sensory structures were evolved for olfaction, vision, balance, and tactile stimulation.

Primitively, these animals were gonochoristic, that is, having the male and female sexes in separate individuals; fertilization was external and the eggs developed into pelagic larvae; hermaphroditism with both sexes in the same individual, brooding of eggs, and ovoviviparity are a few among many of the modifications in the reproductive strategies of these animals.

Taxonomy of the Group

Currently seven classes of living molluscs are recognized. The entirely marine, shell-less Aplacophora,

with at least 250 species, are vermiform animals which have calcareous spicules, scales, or plates embedded in the mantle and which are separable into two principal groups, sometimes considered as independent classes. The more or less cylindrical, gonochoristic Caudofoveata (Figure 1a), having the body somewhat separated into anterior, medial, and posterior sections and possessing an anteroventral pedal shield, attain lengths of 140 mm and live mostly as infaunal burrowers. Fewer than 100 species are known, and they feed mainly on microorganisms and detritus. The free-living, more or less uniformly worm-like, elongate and laterally compressed Solenogastres (Figure 1b, c), with over 200 recognized species, are 1–300 mm in length. Hermaphroditic and predacious, they have a distinct pedal groove, posterior gill folds and live either epibiotically on sediments or epizoically on cnidarians, which usually constitute their principal food.

The Monoplacophora (Figure 1d, e), with fewer than 20 living species, have a controversial fossil history dating from the Early Cambrian; they are benthic, mainly deep-sea animals having a single cap-shaped or limpet-like shell and variously paired organ systems such as the pedal retractor muscles, gills or ctenidia, nephridia or kidneys and gonads, reflecting a primitive metamerism. In monoplacophorans, the foot is large with a flattened, creeping sole, and the pallial mantle cavity is peripheral along the sides of the animal.

The chitons or so-called coat-of-mail shells, separated as the class Polyplacophora (Figure 1f, g), also have a broadened, flat muscular foot and a mantle cavity containing numerous pairs of ctenidia. Consisting of about 600 species of marine benthic epifaunal animals with dorsoventrally depressed bodies, they are unique in having eight calcareous shell plates held together by a strong, peripheral girdle. The body outline is elongate to ovate, and adult individuals range in size from 3 to almost 400 mm in length. Although some chitons are known to occur at depths beyond 7000 m, most live in shallower waters and are mainly grazing herbivores, with a radula having 17 teeth in transverse rows and cusps reinforced with magnetite. The anterior portions of the alimentary canal have pairs of glands for the digestion of carbohydrates, and the broad, large foot is used to creep over, or to attach by suction to, the substrate. Special photosensory structures, the esthetes, are found on the dorsal surface of the valves and may, along with the iron-containing radula, facilitate homing behavior.

The Gastropoda or snails (Figure 2a–c), the largest and most diverse class with as many as 40 000 species, have representatives in most of the world's biotopes and are known from the Early Cambrian. Although most species live in the marine environment, many kinds occur both on land and in fresh water; a few taxa have become specialized internal parasites. Principally, gastropods are univalves, usually with a coiled, apically closed calcareous shell, which also exhibits a great many different shapes and forms, being sometimes merely cap-shaped, greatly reduced, or even altogether lost. The very largest of living snails has a shell over 500 mm in length, the smallest less than 1 mm.

Anatomically, snails and their relatives are basically divisible into head, foot, and visceral mass; they are all characterized by a unique process called torsion which occurs during ontogeny. Primitively, the mantle cavity, into which the alimentary canal, excretory structures, and gonads of the visceral mass empty, contains a pair of laterally disposed respiratory ctenidia or gills and is located posteriorly in the early larval gastropod (Figure 2a). During development, the entire mantle cavity and its contents are twisted or torted through an arc of 180 ° to the right, bringing the cavity itself into an anterior position above and behind the neck and head of the snail (Figure 2b). Internally, torsion causes a peculiar crossing (or streptoneury) of the laterally disposed, paired nervous connections between the anteriorly placed cerebral ganglia and the posteriorly located visceral ganglia.

The head of a gastropod usually has at least one pair of cephalic tentacles, and eyes are often associated with them; however, both structures can be lost. The foot has a creeping sole, and primitively, there are lateral grooves between it and the mantle, forming a so-called epipodium with sensory tentaculate and integumentary organs. The sole of the foot may be subdivided and variously modified for swimming and, in the case of internal parasites, it is entirely lost. The distinctive visceral mass, a dorsal hump, is covered by the mantle which secretes the shell, and contains the internal organs or viscera, including the heart, kidneys, gonads, and alimentary canal. Generally speaking, the jaws and radula assist the mouth in bringing food into the digestive tract; one or more pairs of salivary glands or specialized pouches may contribute enzymes to the buccal cavity or esophagus; the stomach leads through the intestine to the terminal anus and may have a crystalline style, style pouch, typhlosole, digestive diverticula, and a triturating gizzard associated with it. All these structures – the head, foot, visceral mass, mantle and shell – are different and variously altered in the major subdivisions of the Gastropoda.

Traditionally, the snails are subdivided into three major subclasses: the Prosobranchia, Opisthobranchia, and Pulmonata. Recently, with the advent of

cladistic analysis and the discovery of unusual forms in the deep sea, authorities have begun to dismantle the more conservative classification system long in use by elaborating complex split taxonomic systems incorporating numerous new higher-level taxa; but at least 350 families constitute the diversity of gastropods, about 150 in the prosobranchs and 100 each in pulmonates and opisthobranchs, and if one

includes the fossil taxa, there are about 8000 different genera though many more than this have been named.

Prosobranchs (Figure 2c), with the gills anterior to the heart, form the most primitive and most numerous of gastropods with more than 20 000 species; the shell is almost always present and usually spirally coiled, although it may sometimes be patelliform, tubular, or lost in the adult; usually the foot with its creeping plantar sole bears a calcareous or corneous operculum, a structure capable of covering the aperture of the shell when the animal is retracted. As a rule, the mantle cavity is anteriorly directed and it contains, in the most primitive prosobranchs, a pair of respiratory structures (the ctenidia), a pair of chemosensory organs (the osphradia), and a pair of mucus-secreting structures (the hypobranchial glands – sometimes also a source of purple pigments that are a problem in commercially important species); the alimentary canal as well as the excretory and reproductive tracts empty into the mantle cavity. The ventricle of the heart is, in the most primitive forms, traversed by the rectum; there are also paired lateral auricles. In more advanced prosobranchs, for example, the so-called neogastropods, the mantle cavity becomes somewhat detorted and shifted toward the right; the paired structures, e.g., the gills, osphradia, hypobranchial glands, auricles, and kidneys, are reduced to single ones; siphonal structures, elaborated by folds of the mantle, direct the flow of water into and out of the mantle cavity and thus facilitate respiration as well as the removal of excretory and alimentary waste products. The nervous system is streptoneurous, with the cerebrovisceral connectives crossed, and the animals are usually gonochoristic. Prosobranchs primitively are herbivorous grazers or detritus feeders, using the radula to scrape edible material off the substrate, but different evolutionary lines have culminated in many highly specialized carnivores, frequently accompanied by changes in, or even loss of, the radula. According to the kind of preferred diet, great differences obtain in the nature of the alimentary canal with its radula and various associated digestive glands.

On more than one occasion, prosobranchs have given rise to lineages which have invaded fresh-water and terrestrial habitats, and, of course, concomitant alterations, especially in the respiratory and reproductive structures have resulted. Land prosobranchs tend to be more tropical or subtropical in their distribution while the fresh-water groups are widely successful in both the tropics and temperate zones. In the marine realm, prosobranchs are the predominant snails from the intertidal areas over the continental shelf and slope down to the greatest depths.

The opisthobranchs, with the gills, if present, usually behind the heart, are a numerically much smaller group than either prosobranchs or pulmonates, with fewer than 2000 species; their hallmarks include the progressive loss of the shell and operculum in adults, further detorsion and loss of streptoneury, wherein the cerebrovisceral connectives are not crossed (euthyneury), and finally, hermaphroditism.

With only a few fresh-water representatives, this subclass of snails is virtually entirely marine and includes herbivores, vigorous, rapacious carnivores, and floating mucus-net suspension feeders. Probably their most spectacular representatives are the nudibranches, which, as adults, lack the shell and mantle cavity with its ctenidium; instead, they have sometimes elaborated separate respiratory structures, such as cerata and anal or lateral gills, which, along with the mantle, may be brilliantly colored.

The third subdivision of gastropods, the Pulmonata, with about 15 000 species, are, with a few exceptions, entirely fresh-water and terrestrial; these animals are hermaphroditic and detorted, euthyneurous, lack an operculum, ctenidium, or osphradium, and have transformed the pallial cavity into a special, highly vascularized pulmonary or lung-like cavity which facilitates gaseous respiration and opens to the exterior by means of a pneumostome, a narrowed, contractile aperture. Generally, a shell is present, spirally coiled, and variously shaped or reduced to a patelliform or flattened disk; sometimes, the shell is wholly enveloped by the mantle or totally lost, an evolutionary phenomenon adopted by several different lines of descent and leading to a slug-like condition as an adult. In contrast to the prosobranchs, the pulmonate radula shows a remarkable degree of uniformity, mostly being adaptations for herbivory, although some lineages of these snails have become carnivores.

Fresh-water pulmonates, though occurring in tropical and subtropical waters, are particularly successful in exploiting marginal, sometimes ephemeral habitats; they are widespread but more dominating in the cool and temperate regions of the Paleoarctic. Terrestrial lunged snails are cosmopolitan in distribution, with some taxa found on the most remote islands or in the most rigorous deserts. Although largely living on the ground or in leaf-litter, some representatives of these snails have become arboreal, adapting to conditions on the bark, branches, or leafy canopy of trees. In these taxa, often the shells are brilliantly colored and exhibit great polymorphism.

A sister-group of the Gastropods, the Cephalopoda, including squids and octopuses, with some 600 living species are also entirely marine organisms

which have almost exclusively reduced, lost, or internalized the shell, reorganized the body, and adopted a predatory mode of feeding either in the open ocean or along the bottom of the sea; these animals are discussed elsewhere. (*See* **Marine Foods**: Edible Animals Found in the Sea.)

The Bivalvia (Figure 2d, e), comprising familiar organisms such as clams and mussels, with fewer than 8000 species and over 100 families, are aquatic, marine and fresh-water, epifaunal or infaunal, predominantly deposit or filter-feeding animals characterized by having bilaterally disposed shells or valves which can be tightly closed by adductor muscles. In size, living bivalves are known to range from 1–2 mm up to over 1000 mm such as the giant clams of the reefs of the Pacific Ocean. Formed by specialized distal portions of the flap-like mantle, the valves are connected dorsally by a hinge which may consist of a ligament and so-called dental elements. The body is generally laterally compressed; the spatulate or lanceolate foot is variously developed, adapted for creeping, burrowing, or cleansing, and, in attached or cemented forms such as oysters, it may be greatly reduced or lost. A pedally secreted byssus normally occurs in bivalves, though sometimes only in the young embryonic stages. In the reduction of a distinct cephalic region, these animals lost the radula and evolved specialized palps on either side of the mouth which assist in sorting the filtered, particulate food. Their nervous system is decentralized and more specialized posteriorly in conjunction with the posterior development of mantle openings or siphons.

In bivalves, the mantle cavity shows marked expansion and deepening, occupying much of the space between the shells, and the ctenidia exhibit a significant elaboration in most taxa. These form greatly enlarged structures consisting of lateral pairs of plates or sheets of filaments, in which there are blood vessels for respiration and on the surfaces of which are elaborated a complex ciliation, facilitating the filtering of edible materials from plankton suspended in the water column or microorganisms from the detritus or bottom sediments. Mainly gonochoristic with external fertilization, bivalves may also be hermaphroditic and sometimes protandrous, with free-swimming or parasitic larva; retention of the young in the mantle cavity or in special incubatory marsupia in the gills occurs in many species.

Living benthically both in fresh and saline waters, clams and their relatives have exploited many of the biomes of aquatic habitats; they occur from shallow intertidal waters to the greatest abyssal depths of the oceans; they utilize both soft sediments and hard substrates, attaching, burrowing, and even boring into limestones, other shells, or wood. Fresh-water bivalves include the tiny so-called fingernail clams which almost become terrestrial, sometimes living in moist litter, and the pearly mussels, widely distributed on continental areas and even oceanic islands. One group of small marine epizoic and commensal clams has evolved as internal parasites in echinoderms.

Closely related to the bivalves, the Scaphopoda (Figure 2f), commonly known as tusk or tooth shells, with about 350 species, first occur in the Middle Ordovician over 450 million years ago. With a bilaterally symmetrical body occupying an elongate, gently curved, tubular shell which is open at both ends, scaphopods have fused their lateral mantle flaps, reduced their cephalic region, and lost their ctenidia, replacing these respiratory structures with crenulations or folds in the mantle cavity. Calcareous and composed of three layers, the shell is attenuated into a narrow posterior opening; the external shell surface is variously smooth or sculpted, and in size the animals range from 2 to 150 mm in length in adults, though one fossil species at the end of the Paleozic attained nearly 300 mm. Located on a protrusive proboscis, the mouth is surrounded by long filiform, tentacular organs called captacula which probe the sediment and collect, by adhesive glands and ciliary tracts, tiny interstitial microorganisms such as benthic foraminiferans, which constitute their food.

Entirely marine and relatively conservative in their radiation, scaphopods are shallow infaunal burrowers found throughout the world's oceans from the sublittoral to deep abyssal zones below 6000 m. Preferring soft substrates, they flourish mainly in muddy, sand bottoms with the posterior portion of the shell with its aperture projecting from the substrate.

Background

The commercially important molluscs belong to the classes Bivalvia, Gastropoda, and Cephalopoda, with this article covering the first two groups (for cephalopods, *see* **Marine Foods:** Edible Animals Found in the Sea). Bivalves and gastropods constitute a huge fishery resource, amounting to over 12 million tonnes from marine harvest fisheries and aquaculture in 1999, and over 550 000 tonnes from freshwater. The production methods are as diverse as the species, and products range from high value, such as abalone, to low value, such as periwinkles. This article provides details on the size and diversity of the commercially important species and includes information on major production methods and countries, product types, and current issues.

Vernacular terms to describe edible molluscs vary around the world and may cause confusion, e.g., 'clam' may refer to at least three distinct taxonomic groupings. Vernacular names will be used only for important species, with scientific taxonomy used generally.

Bivalves

There are approximately 20 000 bivalve species worldwide, with the principal commercial species belonging to three taxonomic orders: Mytiloida (including mussels, scallops, and oysters), Veneroida (true clams and cockles), and Myoida (soft-shell clams and geoducks).

Bivalves are generally characterized by paired shell valves joined at a dorsal hinge and a sessile, filter-feeding way of life. Their internal body form consists of adductor muscles (usually paired) for shell closure, the mantle for shell secretion, gills for feeding and respiration, a digestive gland, and seasonally variable gonad tissue.

These features influence their commercial importance and use as food products. Generally, bivalves are consumed whole, e.g., oysters and mussels, or processed to adductor muscles (meat) and/or gonad (roe), e.g., scallops. Muscle tissue is rich in carbohydrate (glycogen) and protein, and mature gonad tissue is high in lipid.

Mussels

Production Commercially important mussels belong to the family Mytilidae and are predominantly marine (see Table 1). Freshwater mussels involved in pearl production belong to the Order Unionida. Commercial *Mytilid* species come from wild harvest fisheries (global production of 237 823 tonnes in 1999) and a greater proportion from aquaculture (1 451 032 tonnes in 1999). Global mussel aquaculture at first sale was worth US$0.52 billion in 1999.

Harvest fisheries Harvest fisheries target three main species, *Mytilus edulis* (Blue) (121 964 tonnes in 1999), *M. galloprovincialis* (Mediterranean) (55 819 tonnes) and *Perna viridis* (Green) (21 520 tonnes). The main countries harvesting *M. edulis* were Denmark (96 215 tonnes), Canada (11 565 tonnes), UK (7972 tonnes), USA (4086 tonnes), and France (2098 tonnes). Production of *M. galloprovincialis* comes from Italy (37 876 tonnes), Greece (15 860 tonnes), and Turkey (1800 tonnes). Thailand dominates production of *P. viridis* (21 500 tonnes). Mytilid mussels are principally caught by dredging flat seabed areas where the animals occur in dense aggregations, connected by byssus, which are proteinaceous threads used for attachment in many bivalves.

Aquaculture Aquaculture production is also dominated by *M. edulis* at 498 461 tonnes, worth US$0.27 billion, and ranked as the 15th species by quantity under cultivation. The principal producing countries are Spain (261 969 tonnes), The

Table 1 Principal commercial mussels, including main production sources and methods

Species	*Common name*	*Main production sources and method*
Mytilus edulis	Blue	Europe/North America/China (F/A)
Mytilus galloprovincialis	Mediterranean	Europe, South Africa (F/A)
Mytilus chilensis	Chilean	Chile (F/A)
Aulacomya ater	Cholga	Chile, Peru (F)
Perna viridis	Green	South-east Asia (F/A)
P. perna	South American rock mussel	Brazil, Venezuela (A)
P. canaliculus	New Zealand or green lipped	New Zealand (A)

A, aquaculture; F, fisheries.

Netherlands (100 800 tonnes), France (51 600 tonnes) and Germany (37 912 tonnes).

Also important is *M. galloprovincialis* at 162 179 tonnes, valued at US$100 million. Italy (130 000 tonnes), Greece (16 912 tonnes), and France (10 900 tonnes) dominate production. The green-lipped mussel (*Perna canaliculus*) (not to be confused with the green mussel, *P. viridis*) is also a significant aquaculture species at 71 000 tonnes, worth US$21.3 million, with production dominated by New Zealand. The other main species, *P. viridis*, provides 68 509 tonnes, is worth US$8.3 m, and is cultivated in Thailand (40 300 tonnes) and the Philippines (15 478 tonnes).

It should be noted that China is the dominant aquaculture producer of mussels at 608 115 tonnes, worth US$90 million. International statistics do not recognize individual species composition in Chinese production, but other sources indicate that *M. edulis* dominates, with additional supply from *M. coruscus, Musculus senhousei*, and *P. viridis*. All are local species. Mussel aquaculture is principally based on suspended longline or raft culture, although other methods exist. (*See* **Shellfish**: Aquaculture of Commercially Important Molluscs and Crustaceans.)

Product types Mussels are traditionally a chilled, live product, particularly in Europe, where a post-harvest shelf-life of around 5 days is expected. Recently, new packaging and processing methods, greater acceptance of convenience foods, and value adding have led to new products. Mussels are now frequently sold as individually quick frozen (IQF) cooked in the whole or half shell, precooked ready-to-eat meals and high value, luxury products such as smoked mussels. Traditional pickled or brined preserved products are common.

Issues As coastal filter feeders, where the whole animal is consumed, food safety is important for mussels and other bivalves. Accumulation of bacteria, viruses, toxic chemicals, elements, and biotoxins is associated with bivalves. Most edible bivalves, including mussels, are generally subject to purification, or depuration, which places the shellfish in a clean water flow for 12 h or more. This enables expulsion of many potentially harmful contaminants. Health certification of live mussels is now common, as are monitoring and certification of growout waters.

However, depuration does not remove biotoxins, produced by microalgae (more accurately phycotoxins), and their control and impact on mussel production are generally managed by long-term monitoring programs. These toxins may result in illnesses such as paralytic, diarrhoetic and amnesic shellfish poisoning. In severe biotoxin outbreaks, area closures may be necessary, and these have been well reported in recent years. The protozoan parasites *Marteilia* spp. affect *Mytilus* spp., although generally, mussels appear to little affected by disease in culture systems.

Scallops

Production Commercial scallops belong to the family Pectinidae, and the principal species are listed in Table 2. Global harvest fishery production in 1999 was 567 507 tonnes and from aquaculture 951 866 tonnes. Aquaculture production has increased from 340 807 tonnes in 1990, with an equivalent increase in value from US$0.55 billion in 1990 to US$1.35 billion in 1999.

Harvest fisheries Fisheries are dominated by *Patinopecten yessoensis* (305 510 tonnes), *Placopecten magellanicus* (131 962 tonnes), *Pecten maximus* (35 411 tonnes), and *Argopecten purpuratus* (30 141 tonnes). Japan (299 628 tonnes, 98%) is the main

Table 2 Principal commercial scallops, including main production sources and methods

Species	*Common name*	*Main production sources and method*
Pecten maximus	Great/king scallop	Europe (F/A)
Pecten novaezelandiae	New Zealand scallop	New Zealand (F)
Pecten fumatus/meridionalis	Commercial scallop	South-eastern Australia (F)
Placopecten magellanicus	Sea scallop	USA, Canada (F)
Chlamys islandica	Iceland scallop	Iceland, Canada, USA (F)
Chlamys farreri	Zhikong scallop	China (A)
Patinopecten yessoensis	Yesso scallop	Japan, Russia, China (F/A)
Patinopecten caurinus	Weathervane scallop	Canada, USA (F)
Argopecten irradians	Bay scallop	China, USA (F/A)
Argopecten purpuratus	Peruvian Calico scallop	Chile, Peru (F/A)
Argopecten ventricosus	Pacific Calico scallop	Mexico (F/A)
Aequipecten opercularis	Queen scallop	Europe (F/A)
Amusium balloti	Saucer scallop	Western and eastern Australia, Japan (F)

A, aquaculture; F, fisheries.

producer of *P. yessoensis*, with the Russian Federation (5764 tonnes, < 2%), providing the remainder. *P. magellanicus* production is from the USA (77 179 tonnes, 59%) and Canada (54 756, 41%), and *P. maximus* fishery production derives mainly from the UK (19 108 tonnes, 54%) and France (12 745 tonnes, 36%). Peru provided all production of *A. purpuratus* in 1999.

Wild harvest of all the main commercial scallop species usually involves a toothed (e.g., *Pecten* spp.) or smooth-framed dredge (e.g., *Placopecten* spp.), or occasionally conventional trawl gear (e.g., *Amusium* spp., *Argopecten gibbus*). There are several large-scale diver fisheries for some species, e.g., Chile, China, and Mexico, and some small fisheries that supply high-value, live product markets, e.g., Scotland.

Scallop fisheries are noted for catch fluctuations, as a result of exploitation and recruitment variability. Several fisheries have consequently declined or closed, although notably, the successful application of stock enhancement and management programs helped to revive Japanese and New Zealand production during the 1970s and 1990s.

Aquaculture Three countries and two species dominate scallop aquaculture production. In 1999, China was the largest producer of *P. yessoensis* at 712 330 tonnes, followed by Japan at 216 017 tonnes. Chile produced 20 668 tonnes of *A. purpuratus*, with the remainder from Peru (1585 tonnes). On a much smaller scale, and using various species, other countries are developing pectinid aquaculture. For example, in 1999, the UK produced 114 tonnes of *Aequipecten opercularis*, whereas France, Spain, Ireland and the UK produced over 700 tonnes of *P. maximus*.

Scallop production from aquaculture is based on suspended longline culture or on some form of seabed culture.

Product types Scallops are sold in processed form; fresh or frozen, meat (muscle) only or meat with gonad (roe) attached, although there is a small, valuable market for live scallops, particularly in Western Europe. Processing removes the meat (and gonad) from the remaining viscera and shell, a procedure known as shucking. This is usually a manual operation, although machines are available. Usable product may be block frozen in multi-kilogram amounts or IQF if the product is of a higher value and quality.

In scallop marketing, the term *Coquille St Jacques*, refers to the Genus *Pecten* and is specified under French law. This category is important because of France's position as one of the principal scallop markets. True *Pecten* species are sold as adductor muscle and gonad together (roe-on) and command higher prices. This premium relates partly to selling gonad also, providing a greater return per scallop.

China is unique in predominantly producing a dried scallop meat product, although small quantities are locally sold live.

Issues Because of the type of product (meat and/or gonad only), scallops are less affected by contamination and biotoxin problems, as the contaminated portions (mainly mantle and digestive gland) are discarded during processing. However, microalgae biotoxins can concentrate in meat and gonad, and have resulted in production closures in some countries (e.g., UK) and the widespread establishment of precautionary monitoring programs (e.g., New Zealand, UK, various states in the USA).

Diseases affecting scallops appear to be rare compared with other bivalves, with *Rickettsia*-like and *Chlamydia*-like organisms occasionally associated with mass mortalities of wild scallops and hatchery mortalities. Outbreaks may be associated with scallop density. The protozoan *Marteilia* spp. has been implicated in mass mortalities of wild scallops in the USA, although such events are rare.

Oysters

Production Commercial oysters belong to the family Ostreidae, and principally to the genera *Ostrea* and *Crassostrea* (see **Table 3**). The global wild harvest in 1999 was 157 538 tonnes, and aquaculture production 3 711 606 tonnes, valued at US$3.4 billion. Aquaculture production has increased from 1 251 660 tonnes since 1990 (value US$1.57 billion).

Harvest fisheries The dominant fishery species in 1999 was the American oyster, *Crassostrea virginica* (132 207 tonnes, 84% of total), followed by the Pacific (cupped) oyster, *C. gigas*, at 12 271 tonnes (8%). The genus *Ostrea* contributed an additional 5951 tonnes, the majority (2456 tonnes, 41%) from *O. edulis*, the European flat oyster, the remainder from *O. lutaria* and other minor species.

Fishery production of *C. virginica* in 1999 was from three countries: the USA (89 714 tonnes), Mexico (39 268 tonnes), and Canada (3225 tonnes). Almost all (11 609 tonnes) of *C. gigas* production comes from China, Taiwan, and South Korea. Fishery production of *O. edulis* derives from Turkey (840 tonnes), Ireland (680 tonnes), Spain (443 tonnes), and the UK (407 tonnes). New Zealand produced 994 tonnes of the dredge oyster, *O. lutaria*, and Mexico 2489 tonnes of unnamed *Ostrea* spp. European *Ostrea* fisheries were

Table 3 Principal commercial oysters, including main production sources and methods

Species	*Common name*	*Main production sources and method*
Crassostrea gigas	Pacific (cupped) oyster	China, Japan, Korea, France, USA, New Zealand (F/A)
Crassostrea virginica	American oyster	USA, Canada (F/A)
Crassostrea iredalei	Slipper oyster	Philippines (F/A)
Ostrea edulis	European flat oyster	Europe (F/A)
Ostrea lutaria	Dredge oyster	New Zealand (F)
Ostrea chilensis	Chilean flat oyster	Chile (F/A)
Saccostrea glomerata	Sydney rock oyster	Australia (A)

A, aquaculture; F, fisheries.

formerly more significant, but the protozoan, *Bonamia ostreae*, introduced from the USA, devastated production in the 1980s. Commercial fishery methods for oysters are predominantly dredge-based, although hand picking occurs in some countries, e.g., USA, Australia.

Aquaculture The dominant aquaculture oyster is the Pacific (cupped) oyster, *Crassostrea gigas*, providing the greatest quantity of any aquaculture species in 1999 at 3 600 459 tonnes. This species accounted for 97% of all oyster aquaculture production with a value of US$3.3 billion in 1999. China accounted for 2 988 613 tonnes, with other major producers including Japan 205 345 tonnes, Korea 177 259 tonnes, France 134 800 tonnes, and the USA 33 259 tonnes. Other aquaculture species are *C. virginica* 57 522 tonnes (54 037 tonnes, USA), *C. iredalei* 13 698 tonnes (Philippines), *Ostrea edulis* 6496 tonnes (Spain 3348 tonnes, France 2300 tonnes), and *Saccostrea glomerata (commercialis)* 5104 tonnes (Australia). Production methods vary, although most are based on the oyster's natural attachment to artificial structures, or seabed sowing.

Product types Oysters are best known as live seafood, and most production is live, in-shell, or fresh chilled in half-shell. Traditionally, oyster culture has produced a bottled product, with the whole shucked animal, washed and preserved in salt water. They survive low-temperature storage for several weeks, but half-shell and bottled oysters have a limited shelf-life. Maintenance of quality and rapid transport and sale are essential components of the industry. Oysters are now sold as a frozen product, either in whole or half shell. This maintains the traditional appearance while limiting spoilage and health risk. Other value-added products such as smoked oysters and pre-cooked meals are becoming common.

Issues Oysters are subject to many significant diseases affecting fishery and culture operations. These include the protozoans *Bonamia* spp. (particularly affecting *Ostrea* spp.), *Marteilia* spp. (affecting *Ostrea* and *Saccostrea* spp. (causing QX (Queensland unknown) disease in the latter), *Mikrocytos* spp. (affecting several *Crassostrea*, *Saccostrea*, and *Ostrea* spp.), *Haplosporidium* spp. (affecting *Crassostrea* spp.), and *Perkinsus* spp. (affecting *Crassostrea* and *Haliotis* spp. (abalone)). An iridovirus, causing gill necrosis, is also associated with hatchery-reared *C. gigas*.

From a human health perspective, oysters are often associated with food poisoning events, because of their intake of bacteria and viruses and subsequent consumption as a whole, raw product. Such events focus attention on the production environment and require management of local sources of pathogenic effluent. Consequently, water-quality monitoring and health certification of production areas are common, along with a certification requirement from importing countries.

Other Bivalves

Production International fisheries statistics combine true clams and cockles (order Veneroida) with arks (order Arcoida, *Anadara* spp.) and indicate total world production from fisheries at 812 501 tonnes, with a further 2 744 846 tonnes from aquaculture, alone worth US$3.15 billion. This constitutes a commercially significant group, despite including numerous species. They are treated under broad groupings, with taxonomic relationships indicated where appropriate.

Order Veneroida This includes, amongst many others, the families Veneridae (venus clams), Cardiidae, (cockles), and Tridacnidae (giant clams). Several *Ruditapes* spp. (carpet shells), support a modest harvest fishery, mainly Japanese, producing around 58 874 tonnes in 1999. The most important carpet shell is *Ruditapes philippinarum* (Manila clam), which also provided 1 820 413 tonnes (worth US$2.19b) from aquaculture, mainly from China. Other cultivated *Ruditapes* spp. added 54 421 tonnes and US$0.13 billion. The fishery for *Chamelea*

gallina (striped venus) was 45 012 tonnes in 1999, and mainly from Italy (36 462 tonnes).

Meretrix spp., known as hard clams, are fished in South-east Asia, and provided 22 100 tonnes in 1999. Indonesia is the largest supplier with 17 990 tonnes. This genus is also cultivated in South Korea (*Meretrix lusoria*, 17 tonnes), but more widely in Vietnam, where 80 000 tonnes of *M. meretrix* and *M. lyrata* are produced per annum. This product is sold into South-east Asia, Japan, and Europe, although EU regulations regarding biotoxin monitoring have limited the European market.

Arctica islandica (Ocean or black Quahog) is an important fishery species in North America, with the USA producing 147 933 tonnes in 1999. Iceland also produces a small quantity (3501 tonnes) through harvest fisheries, most of which is exported to the USA.

Mercenaria mercenaria (also known as the northern Quahog or hard-shell clam) is also principally a North American species, with Canada and the USA traditional producers. In recent years, only Canada has provided a harvest fishery product of 2536 tonnes (1999), with a further 53 050 tonnes, worth US$63.4 million, from aquaculture, equally from China and the USA. As with most clam culture, spat are sown on to preselected sand/mud bottoms at densities appropriate for good growth and survival and with well-exchanged phytoplankton rich water. Harvesting is by dredge. To reduce growout periods, some clams are cultured on trays, either suspended or stacked off the bottom. This improves growth through increased exposure to nutrients and higher temperatures.

Fishery production of *Paphia* spp. (short-necked clams) was 42 282 tonnes in 1999, from Thailand and the Philippines. The North Atlantic surf clams, *Spisula solidissima* and *S. polynyma*, are produced from harvest fisheries in the USA (142 370 tonnes in 1999) and Canada (26 722 tonnes), respectively. Razor clam (*Solen* spp.) aquaculture in China is significant with 479 252 tonnes, worth US$383 million, produced in 1999. Additional sources indicate that this species may also be reported as *Sinonovacula constricta*.

The European edible cockle, *Cerastoderma edule*, is dredge-fished in The Netherlands (50 888 tonnes) and the UK (14 123 tonnes), for a total production of 70 401 tonnes in 1999. Recent aquaculture, based in Spain (3713 tonnes) and France (1300 tonnes), also contributed 5169 tonnes to production, valued at US$8.9 million. Aquaculture produced very small quantities (2 tonnes, in 1998) of cockles (Family Cardiidae) in the USA.

Order: Myoida The soft-shell clam, *Mya arenaria*, and Geoducks, *Panopea abrupta* are produced and consumed in North America. In 1999, the USA and Canada produced 5113 and 2643 tonnes of *M. arenaria*, and 2451 and 1800 tonnes of *P. abrupta*, respectively.

Order: Arcoida There are three main genera of Ark 'clams' of commercial importance, *Arca* spp., *Scapharca* spp., and *Anadara* spp. Fishery production of *Arca* spp. and *Scapharca subcrenata* totalled 52 972 tonnes in 1999. Aquaculture of *S. broughtonii* in South Korea produced 8550 tonnes, worth US$49.8 million.

Dredge fisheries also produced 42 627 tonnes of *Anadara* spp. in 1999, with *A. granosa* (misleadingly called the blood cockle) the main species. Aquaculture of *A. granosa* was 315 811 tonnes, worth US$277.4 million, mainly from China (188 355 tonnes) and Malaysia (79 912 tonnes).

Gastropods

The class Gastropoda is commercially less important, although the marine abalone, periwinkles, conchs and whelks, and terrestrial snails are significant as food products. Other species of gastropod are valued as shell products, such as mother of pearl and specimen shells. Gastropods are generally characterized by a single spiral shell and large muscular foot, enabling greater motility than bivalves and forming the principal edible portion. Fishery production of gastropods, as abalone, winkles, and conchs was 105 047 tonnes in 1999. Equivalent aquaculture production was 2694 tonnes, worth US$32.4 million.

Abalone

Production Abalone (family Haliotidae) is mainly a temperate marine group, although they extend into tropical areas. Approximately 50 species are recognized, associated with rocky habitats off Australia, New Zealand, Japan, Pacific North America, and South Africa. The main commercial species are shown in Table 4. Abalone production is from divercollected harvest fishery or aquaculture.

Harvest fisheries The total fishery production was 10 453 tonnes in 1999, the majority from Australia (5593 tonnes of *Haliotis rubra*), followed by Japan (2109 tonnes of *H. gigantea*). The value of combined fisheries production has not been estimated, but, as an indicator, the Australian fisheries production in 1999–2000 was worth approximately US$118 million (A$235.6 million) (Australian Bureau of Agricultural Resource Economics).

Commercial harvest is by diver using hookah or scuba equipment. Abalone attach to rocky substrates

Table 4 Principal commercial abalone, including main production sources and methods

Species	*Common name*	*Main production sources and method*
Haliotis gigantea	Giant	Japan (F)
Haliotis tuberculata	Tuberculate or Ormer	Channel Islands, France (F/A)
Haliotis midae	Perlemoen	South Africa (F/A)
Haliotis rubra	Black lip	Australia, Solomon Islands (F/A)
Haliotis laevigata	Green lip	Australia (F/A)
Haliotis roei	Roe's	Australia (F)
Haliotis conicopora	Brown lip	Australia (F)
Haliotis iris	Paua	New Zealand (F)
Haliotis rufescens	Red	Pacific North America (F/A)

A, aquaculture; F, fisheries.

with a muscular foot, and they are manually removed with a blunt knife or similar implement. Owing to the slow growth rates and high value, most countries regulate harvesting. Size and catch limits and closed seasons apply in Australia, New Zealand, South Africa and the USA, although with variable management success.

Aquaculture World aquaculture production in 1999 was estimated at 1885 tonnes, valued at US$30.6 million. China dominated with 1799 tonnes (*H. discus hannai* and *H. diversicolor*) and Chile with 48 tonnes (*H. discus hannai*). Variable production since 1990 has originated from South Africa, the USA, Australia, and New Zealand. The principal culture methods include suspended net culture, raceway culture, or tidal pond culture. (*See* **Shellfish**: Aquaculture of Commercially Important Molluscs and Crustaceans.)

Product types Most Australian abalone production is canned, with 2340 tonnes (US$60 million) exported to Hong Kong (40%), Japan (27%), and Taiwan (20%) in 1999–2000. Other product types for fished and cultivated abalone include; parboiled and frozen on shell, frozen on shell, chilled, frozen, or salted meat, and vacuum packing. Live abalone are common as a value-added market product or mail order.

Issues The long growout period of most abalone, up to 5 years, may affect aquaculture viability, although their final value is significant and may offset cash flow issues. Abalone are affected by potentially significant diseases, notably the protozoan, *Perkinsus olseni*, *Rickettsia*-like infections, and the bacterial pathogen *Vibrio*.

Other Gastropod species The following gastropod molluscs are of minor commercial importance in terms of volume, but may be regionally or traditionally important.

Periwinkles Periwinkles of the family Littorinidae are small, intertidal algal grazers, associated with rocky shores. They are a traditional source of food throughout their almost-worldwide distribution, particularly in Europe, where commercial production is greatest.

Production of wild-harvested Littorinids was 4828 tonnes in 1999. The principal species is *Littorina littorea*, with 3144 tonnes, mainly derived from Ireland (3018 tonnes) and Spain (126 tonnes). Other Littorinids, without species designation, contributed 1714 tonnes, 78% from the UK, with the remainder from the USA and Canada. European production is by hand harvesting from intertidal areas and represents a source of income for both local and transient workers. Periwinkles are bagged and sold as a live product, or processed as brined or pickled meat only. There is interest in cultivation, principally in France and Scotland. French aquaculture production of *Littorina* spp. in 1999 was 800 tonnes, worth US$2.08 million.

Conchs The family Strombidae includes algal or detrital feeders, mainly associated with inshore sandy or muddy areas throughout tropical and subtropical seas. Conchs are an important marine resource in the Caribbean, where the Queen conch (*Strombus gigas*) is particularly well known. Conch fishery production was 15 487 tonnes in 1999. The largest producer was Mexico (8591 tonnes), followed by Jamaica (1366 tonnes) and the Dominican Republic (1257 tonnes). Aquaculture of *Strombus* spp. is developing with 9 tonnes, valued at US$61 000, produced by Netherlands Antilles and Turks and Caicos Islands in 1999.

Whelks Whelks are predatory or scavenging molluscs, of boreal, temperate, and tropical seas. The term 'whelk' is associated with several families, with Buccinidae and Melongenidae being commercially important. The common whelk, *Buccinum undatum*, and *Busycon* spp. are the principal species with 17 988 and 6181 tonnes, respectively, in 1999. The *B. undatum* fishery is dominated by France (7885 tonnes), the UK (4925 tonnes), and Ireland (4561 tonnes). The USA and Canada produce all *Busycon* spp., with 4624 and 1557 tonnes, respectively.

Nutritional features of commercially important molluscs Table 5 provides information on the

Table 5 Proximate nutritional composition (per 100 g fresh weight) of principal commercial molluscs (sources: Nettleton (1985), Ulieg (1988))

Contamination and Spoilage of Molluscs and Crustaceans

D R Livingstone, Plymouth Marine Laboratory, Plymouth, Devon, UK
S Gallacher, Fisheries Research Services, Aberdeen, UK

Introduction

Seafood is of worldwide economic and nutritional importance, providing about 16% of the total animal protein consumed globally. Of this, approximately 25% is shellfish, corresponding to an annual 17 million tons taken from sea, coastal, and estuarine waters, with a total value on landing of about £10 billion. Included in the shellfish are crustaceans (e.g., crab, lobster, shrimp), and bivalve (e.g., mussel, oyster, clam, scallop), gastropod (e.g., whelk,

periwinkle), and cephalopod (octopus, squid, cuttlefish) molluscs. The nutritional value of shellfish and other seafood resides in their high-quality protein, essential amino acids, vitamins, and minerals. They are also the only natural dietary source of *n*-3 polyunsaturated fatty acids (or PUFAs), necessary for normal development of human neural, cerebral, and visual functions. The health benefits of this food source are reflected in the lower risk of coronary heart disease, hypertension, and cancer indicated in human populations eating seafood. However, spoilage of shellfish can occur through two major and distinct processes, namely the uptake of chemical pollutants, such as metals and organic compounds, and the accumulation of biological agents, principally bacteria, viruses, and specific toxins produced by phytoplankton (Table 1). In both cases, there are usually no visible signs of contamination. Chemical pollutants may take from days to years to show adverse effects towards human consumers, whereas the impact of biological agents is generally more immediate and obvious, with illness occurring within hours to weeks. (*See* **Fatty Acids**: Properties.)

The section on chemical contaminants covers the variety and levels of chemicals found in tissues from near pristine through to highly polluted environments; the processes of uptake, metabolism, accumulation, elimination, and persistence, including food chain aspects; the toxic threat to consumers; and monitoring and regulatory considerations. The section on biological agents is divided into two. The first covers the types and characteristics of shellfish toxins and the second deals with microbial infectious agents, particularly viruses and bacteria. Some information is given on monitoring procedures and the methods applied to biological contaminants of shellfish. In addition, the effectiveness of depuration and processing on these agents is discussed.

The terms 'contaminant' and 'pollutant' are often used interchangeably and arbitrarily in both the scientific and lay literature in referring to chemicals which are generally regarded as not normal to the environment and potentially harmful. The term 'pollutant' will be used in this article to describe chemicals that are potentially toxic to the consumer that may be synthetic, or natural but present at levels significantly above what is considered to be in the normal biological range. 'Contamination' in this article is taken to describe the presence of pollutants, algal toxins, bacteria, or viruses in the molluscs or crustaceans leading to the condition of spoilage, i.e., rendering them unsuitable for human consumption. The term 'xenobiotic' also appears widely in the scientific literature in relation to the metabolism of pollutants, drugs, and other organic chemicals by organisms, and refers to a chemical that is foreign to an animal, i.e., not part of its normal metabolism.

Pollutants

Types of Pollutants, Routes of Entry, and Tissue Levels

The amount, variety and number of industrial, agricultural, and other chemicals produced by humans are continually increasing. In the early 1990s, the Organization for Economic Cooperation and Development (OECD) estimated that approximately 1000–1500 new substances entered daily use each year, adding to the already existing 60 000 substances. Of these chemicals, it was estimated that about 11 000 were being manufactured in sufficient quantities to merit environmental attention and assessment. Additionally, more pollutants are produced by the process used to treat industrial and domestic waste such as chlorination. The major classes of chemical pollutant are given in Table 1, most of which are synthetic, but also include natural chemicals whose presence in the environment has been increased by human activities, e.g., metals and polycyclic aromatic hydrocarbons (PAHs). A part of

Table 1 Sources of contamination of molluscs and crustaceans

Nature of contamination	*Type of contamination*	*Major sources*
Pollutant	Metals	Industrial
	Organic compounds	Industrial, agricultural, combustion, domestic
	Organometallic compounds	Industrial, agricultural, boating
Shellfish toxins	Paralytic, diarrhetic, amnesic, and neurotoxic shellfish poisons	Phytoplankton
Bacteria	*Campylobacter* spp., *Escherichia coli*	Fecal sources
	Salmonella spp.	
	Vibrio spp.	Natural sources
	Shigella spp., *Staphylococcus aureus*	Food handling
Viruses	Norwalk-like viruses, hepatitis A	Fecal sources

this potentially toxic material enters the aquatic environment where it comprises a diverse range of chemicals of both long-standing and more recent concern. The former includes PAHs, organochlorine pesticides and industrial compounds, and metals (sometimes called heavy metals) such as arsenic (As), cadmium (Cd), copper (Cu), iron (Fe), lead (Pb), mercury (Hg), silver (Ag), and zinc (Zn). Pollutants of more recent concern include polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs), organophosphorous insecticides, organotin antifouling agents such as tributyltin (TBT), and estrogenic compounds such as alkylphenol ethoxylate surfactants. Whereas some of the metals, such as Cd and Hg, have as yet no discernible biological function, most are essential to animals and pose a toxic threat only at concentrations considerably in excess of the normal levels. (*See* **Arsenic**: Requirements and Toxicology; **Cadmium**: Toxicology; **Copper**: Properties and Determination; **Iron**: Properties and Determination; **Mercury**: Toxicology; **Zinc**: Properties and Determination.)

Pollutants enter and are dispersed in aquatic ecosystems by various routes, including direct discharge,direct use, land run-off, atmospheric deposition, *in situ* production, abiotic and biotic movement, and food chain transfer. Pollutants are generally readily taken up into the tissues of molluscs, crustaceans, and other resident animals. The uptake into the individual organism can occur via several routes, including from bottom sediments, suspended particulate material, the water column and food sources. The major routes of input depend on the particular dietary and ecological lifestyle of the species, e.g., via algae, particulates, and water column for filter-feeding bivalves; detritus and mixed diet for scavenging crabs; and the food chain for carnivorous cephalopods. All species of molluscs and crustaceans will therefore likely take up pollutants from the environment into their tissues, and any pollutant present in the environment is likely to be present in the tissues of resident organisms. Exceptions to the latter are those pollutants that are not bioavailable to the animal, e.g., those that for physicochemical reasons are tightly bound and 'locked up,' such as PAHs in sediment particles and metals in biological granules.

The extent to which pollutants taken up by shellfish remain in their tissues depends on a number of factors, including continuing input from the environment, duration of exposure, biotransformation and depuration, which are discussed in a later section. Pollutants have been measured in the tissues of many different commercial and noncommercial crustacean and molluscan species, and many different types of pollutants have been detected. The crustaceans include crabs, crayfish, lobsters, prawns, shrimps, copepods, amphipods, and barnacles. The molluscs include clams, cockles, mussels, oysters, scallops, snails, whelks, winkles, squids, chitons, and limpets. Examples of the range of pollutants detected in shellfish tissues are given in Table 2. Also, taken up into the tissues of shellfish are radionuclides associated with the nuclear fuel cycle, such as uranium and the transuranium elements plutonium (Pu) and americium (Am), i.e., ^{239,240}Pu, ^{238}Pu, and ^{241}Am.

The major factor determining the levels of pollutants in the tissues of shellfish is the levels in the immediate environment and their food sources. Thus, the more polluted the environment, the greater the chemical contamination of the tissues. This is particularly evident in pollution incidents, such as oil spills, and in comparisons of urban or industrial

Table 2 Examples of pollutants detected in crustaceans and/or molluscs in the field

Type	*Chemicals*
Metals	Cadmium, chromium, cobalt, copper, iron, lead, mercury, manganese, nickel, silver, zinc
Organic compounds	
Aliphatic hydrocarbons	Acyclic isoprenoids, *n*-alkanes (C_{15}-C_{35}), UCM
PAHs and related compounds	Many two-through to six-ring PAHs, including naphthalene, phenanthrene, anthracene, fluorene, fluoranthene, pyrene, benzo[*a*]anthracene, chrysene, benzo[*b*]fluoranthene, benzo[*k*]fluoranthene, benzo[*a*]pyrene, benzo[*e*]pyrene, dibenz[*ah*]anthracene, benzo[*ghi*]perylene indeno[1,2,3-*cd*]pyrene, dibenzothiophenes, methylated PAHs
PCBs	Many of the possible 209 congeners, including tri-, tetra, penta-, hexa-, hepta-, octa-, nona-, and decachlorobiphenyls
PCDDs, PCDFs	2,3,7,8-Tetrachlorodibenzodioxin, others
Other organochlorine compounds	Chlordanes, chlorinated cyclodienes (e.g., aldrin, dieldrin), DDTs, DDDs, DDEs, hexachlorobenzene, hexachlorocyclohexanes (e.g., lindane), polychlorinated phenols (e.g., pentachlorophenol)
Organometallic Compounds	Tributyltin, triphenyltin, methylmercury

UCM, unresolved complex mixture of alkanes; PAH, polycyclic aromatic hydrocarbon; PCB, polychlorobiphenyl; PCDD, polychlorinated dibenzo-*p*-dioxin; PCDF, polychlorinated dibenzofuran; DDT, 1,1-bis(4-chlorophenyl)-2,2,2-trichloroethane; DDD, 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane; DDE, 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethylene.

locations with remote pristine environments. The pollutants are generally not distributed evenly through the different tissue types, but are often highest in tissues concerned with the processing of food, such as the hepatopancreas and digestive gland, and in the case of organic pollutants are highest in tissues high in fat, such as digestive tissues (hepatopancreas/digestive gland) and ripe reproductive tissues, e.g., mantle of mussels. Some pollutants, such as organophosphorous pesticides, are short-lived and readily broken down in the environment, and therefore their concentrations are often low in the tissues of animals. Examples of levels of pollutants found in different tissues of crustaceans and molluscs from different types of environment are given in Tables 3 and 4 respectively.

Because of the marked accumulation of pollutants by shellfish, the analysis of their tissues has for many years been used in pollution monitoring as a measure of environmental contamination. Mussel and oyster species in particular have been extensively used in so-called 'mussel watch' monitoring programs because of their bioaccumulating properties, sessile nature, wide geographical distribution, and resistance to general stress. Such programs have been carried out on the coasts and inland waters of North and South America, Europe, Asia, and Australia, including the North and South Atlantic, Pacific, Indian, and Mediterranean regions. Common species of marine and fresh-water mussel used include the blue mussel (*Mytilus edulis*), Mediterranean mussel (*Mytilus galloprovincialis*), American mussel (*Mytilus californianus*), horse mussel (*Modiolus modiolus*), swan mussel (*Anodonta cyngea*), and green-lipped mussel (*Perna viridis*). Commonly used oyster species include *Crassostrea virginica* and *Crassostrea gigas*.

Processes of Uptake, Depuration, Biotransformation, Bioaccumulation, and Persistence

Organic pollutants The accumulation of organic pollutants in shellfish (i.e., bioaccumulation) depends principally upon the processes of uptake and depuration, with probably lesser roles for active excretion, 'storage' and biotransformation. The uptake and depuration of pollutants by shellfish depend on a number of physicochemical and biological variables, but mainly on the environmental concentration of the chemical and its fat-solubility. Other environmental and biological factors that may affect uptake and depuration to varying degrees include temperature, tidal cycle, dissolved organic material, algae, nutritional state, feeding habits, and reproductive condition and/or seasonality.

Uptake and depuration are thought to be largely passive processes, involving movement and equilibrium of the chemical between aqueous (external environment) and biotic (animal) compartments. Rates of uptake are usually greater from the water column than from sediments and abiotic particles. Distribution of the pollutant within the animal depends on route of intake and tissue fat levels, e.g., gills are an initial site of bioaccumulation where uptake is from the water, whereas digestive tissues are important for pollutant input from food sources. If the external exposure concentration of the pollutant is constant, then the uptake usually involves an initial linear rate, followed by the eventual reaching of a maximal tissue equilibrium concentration. Uptake of the pollutant into the shellfish will thus continue for as long as pollutant is present in the environment and/or food source, and until the tissue equilibrium concentration is reached. Multiphasic patterns of uptake have also

Table 3 Examples of pollutant levels in different tissues of crustaceans from different environments[a]

Animal	*Chemical*	*Location*	*Tissue*	*Level ($\mu g\, g^{-1}$ wet wt)*

been seen, which have been interpreted in terms of equilibration of the pollutant into multiple compartments (tissue, cellular, subcellular, or molecular) within the animal. The initial rate of uptake and final tissue equilibrium concentration of the pollutant increase with increasing concentration of the chemical in the environment.

The tendency of organic pollutants to bioaccumulate increases with increasing fat-solubility of the chemical and with increasing levels of fats (lipids) in the shellfish tissue. For many organic pollutants taken up by molluscs and crustaceans, a linear relationship exists between the equilibrium bioconcentration factor (BCF; ratio of pollutant concentration in the animal to that in the environment) and fat-solubility, i.e., chemical hydrophobicity, the latter being measured in terms of either octanol/water coefficient (K_{ow}) or water-solubility. Positive linearity of BCF with K_{ow} in shellfish is seen over a log K_{ow} range of about 2–6 which encompasses most of the organic pollutants of environmental importance, i.e., aliphatic hydrocarbons, many polycyclic aromatic hydrocarbons (PAHs) and polychlorobiphenyls (PCBs), dioxins, and other organochlorine compounds. Thus, pollutants of high hydrophobicity, such as PCBs and 1,1-bis(4-chlorophenyl)-2,2,2-trichloroethanes (DDTs), show high BCF values of up to $\times$ 100 000. Deviations from these relationships also occur, particularly for very hydrophobic compounds ($K_{ow} > 6$), such as the five-ringed PAH benzo[a]pyrene and high hexachloropolybiphenyls, which show BCFs less than expected. In other cases, higher BCFs than predicted from K_{ow} have been seen, e.g., > 100-fold higher bioaccumulation of the antifouling paint TBT by mussel (*Mytilus edulis*). These enhanced BCF are probably due to strong interactions between pollutant and the biological system, particularly proteins. The time required for the uptake of the pollutant to reach the tissue equilibrium concentration is relatively quick for water-soluble compounds, e.g., hours for toluene ($\log K_{ow} < 3$), but may take weeks or even months for very fat-soluble compounds, e.g., hexachlorobiphenyl ($\log K_{ow} > 7$).

Partial or complete decrease in pollutant levels in the environment, either by cessation of input, or transfer of the shellfish to clean water, will result in depuration, i.e., loss of pollutant from the tissues back into the water. This depuration will continue

as long as the environmental pollutant level remains very low by dilution into a large body of water, replacement with fresh clean water, or removal of the pollutant. Depuration is normally exponential, with the pattern of loss being resolved into an initial faster phase followed by a longer-term slower phase. The rate of loss during the phases can be described in terms of the depuration half-life ($t_{1/2}$), i.e., the time required for the tissue concentration of contaminant to be reduced by 50%. Single-phase depuration has also been seen in some instances. Depuration can also be markedly affected by the length of time of the exposure period. Short-term exposure results in rapid and complete, or almost complete, elimination of the pollutant during subsequent depuration, whereas longer-term exposure is followed by slower and often incomplete elimination. This is particularly evident for the depuration of petroleum hydrocarbons by bivalve molluscs where the $t_{1/2}$ of depuration is seen to increase with increasing time period of previous exposure (Table 5). Therefore it may be very difficult, if not impossible, to remove all organic pollutants by depuration in clean water from shellfish that have had a long history of exposure to pollution in the field. For pollutants of similar fat-solubilities, the chemical structure of the chemical may also affect uptake and depuration, e.g., PAHs were bioaccumulated less from sediments than were PCBs of similar log K_{ow} by mussel (*M. edulis*), but PCBs were depurated more slowly than equivalent PAHs. (*See* **Polycyclic Aromatic Hydrocarbons.**)

The bioaccumulation of organic pollutants in shellfish can also be affected by active excretion processes, 'storage,' and biotransformation. Although knowledge of these processes is relatively limited, their quantitative impact is indicated not to be great, at least in the long term, because the bioaccumulation of most types of organic pollutant occurs according to a simple water/octanol partitioning model, where water is the environment and octanol represents the animal, i.e., BCF is directly related to K_{ow}. Active excretion has been indicated in some studies; e.g., naphthalene lost from gills and kidney of mussel (*M. edulis*), but not others; e.g., the anus and kidney played little or no role in the clearance of naphthalene from crab (*Hemigrapsus nudus*). Active energy-driven pumps that function to pump xenobiotics out of cells, variously known as *P*-glycoproteins, multidrug resistance (MDR) transporters or multixenobiotc (MXR) transporters, have recently been identified in a wide range of aquatic organisms, including molluscs and crustaceans. However, relatively little is yet known about their ability to pump out organic pollutants, although hydrocarbons, pentachlorophenol, DDTs, and PCBs have been indicated as potential substrates for some shellfish species, but not others.

Fecal material and urine can also make a contribution to elimination, e.g., in the loss of sulfadimethoxine from lobster (*Homarus americanus*). The term 'storage' is probably a misnomer, but organic pollutants are known to accumulate in specific subcellular organelles, namely lysosomes that are present in high

Table 5 Increase in duration of exposure period results in increased length of time for subsequent depuration of a range of hydrocarbons by various bivalve shellfish

Shellfish	*Pollutant*	*Exposure period*	*Depuration half-life*
Mussel (*Mytilus edulis*)	Naphthalene	4 h	2 h
	Heptadecane	24 h	< 24 h
	n-alkanes	2 days	0.5 days

numbers in tissues such as the hepatopancreas and digestive gland. They can also become chemically bound to macromolecules, including in particular proteins and DNA, to form macromolecular adducts. Such adducts are likely eventually removed and the macromolecules repaired or replaced, but nevertheless will contribute to the persistence of a pollutant in an animal. Examples of pollutants indicated, or demonstrated, to give rise to adducts in shellfish include chlorinated paraffins, vinyl chloride, PAHs, nitroaromatics, fenitrothion (organophosphate pesticide), picric acid, and phthalate ester plasticizers. In common with all other animals, shellfish also possess a suite of biotransformation enzymes, present in several tissues but highest in the hepatopancreas or digestive gland, the major function of which is to convert fat-soluble organic xenobiotics such as pollutants to water-soluble excretable products (metabolites). Modeling of biotransformation in shellfish shows that: (1) biotransformation is significantly slower than uptake, such that bioaccumulation of the original pollutant inevitably occurs; and (2) generally crustaceans have slightly higher biotransformation rates than molluscs for both hydrocarbons and other types of organic pollutants. Paradoxically, biotransformation, which is meant to speed up elimination, can contribute to persistence if the rate of loss of metabolite to clean water is slower than the rate of depuration of the original unchanged pollutant. This has been seen for mussel (*M. edulis*) for 1-naphthol and for several crustaceans for phenoxyacetic and phenylacetic acid herbicides, hydrocarbons, and sulfadimethoxine.

Because pollutant uptake from the environment is largely a passive process determined by physicochemical principles, the rates of uptake are therefore somewhat similar for different animal groups, including shellfish and vertebrates such as fish. In contrast, rates of biotransformation of pollutants and excretion of the water-soluble metabolites are intrinsic to the particular animal or group of animals, and depend on the level of biotransformation enzymes in the organism and the effectiveness of its excretory mechanisms. These are generally significantly greater in vertebrates such as finfish than in invertebrates such as shellfish. Rates of biotransformation approach more rates of uptake in finfish than shellfish, and can therefore reduce the long-term bioaccumulation of readily metabolizable pollutants in the former compared to the latter. In food chains, the differences between uptake and biotransformation therefore result in different patterns of bioaccumulation in different animal groups, with readily metabolized pollutants, such as PAHs, reaching highest tissue concentrations near the bottom of food chains in shellfish, and poorly metabolized or recalcitrant pollutants, such as many PCBs, accumulating to highest tissue concentrations in vertebrates at the top of food chains.

Metals and radionuclides The uptake and depuration of metals have some, but not all, similarities with the situation for organic pollutants. Bioaccumulation depends on chemical speciation of the metal, routes and mechanisms of uptake, intracellular compartmentation, cellular control of metal levels, excretion, and depuration. All of these processes may be strongly affected by the species' particular biology, including morphology, physiology, feeding mode, and environmental adaptations. Overall, there is probably more variability in bioaccumulation trends with respect to species and individual pollutant for metals compared to organic compounds, particularly for crustaceans. For example, below a certain threshold metal tissue level, a range of bioaccumulating properties for essential metals such as Zn and Cu may be seen in crustaceans, ranging from regulation (i.e., no accumulation where rate of uptake equals rate of excretion) to accumulation, e.g., at an exposure concentration of 100 p.p.b., Cu was bioaccumulated from sea water by the barnacle *Elminius modestus* but not by the decapod *Palaemon elegans*.

Direct uptake of metals and radionuclides from the water column is a quantitatively important process because most metals occur in highly water-soluble forms, e.g., Am, Cd, Hg, Pb, Pu, and vanadium. Rates of uptake are generally proportional to the metal concentration in the water column. Uptake is thought to occur mainly by passive transport processes, involving both diffusion of polar metal ions/complexes and partitioning of hydrophobic metal organic complexes into lipid membranes. The influence of dissolved organic matter, particulates, and food on uptake is complex. Depending on the nature of these substances and the metal, either increased or decreased bioaccumulation can occur, e.g., in one study, food contributed significantly to the uptake of Am, Pu, and Pb, but not Cd, by mussel (*M. edulis*). The gills are an important site for soluble metal uptake, whereas digestive gland is a major site for particulate-bound metal uptake. The latter occurs via an active transport process, endocytosis, which results in the fusion of the endocytotic vesicles, containing the metal, with the lysosomes. The kidney is another major site of metal accumulation, and metals can also be incorporated into the shells of, for example, bivalves. Major sites of localization of radionuclides in bivalves include byssal threads and the periostracum covering the shell. The metals are retained within the tissues by binding to various

specific and nonspecific sites. The former includes specialized proteins called metallothioneins, specialized sulfur- or phosphate-containing insoluble inorganic granules, and lysosomal residual bodies, all of which have high affinities for metals. The inorganic granules in particular can result in very high levels of metals in certain shellfish, e.g., metal/phosphate granules in scallops, winkles, and crabs.

Exposure of the shellfish to clean water will result in depuration and loss of part or all of the previously accumulated metal. Like the situation for organic pollutants, the depuration is biphasic with a fast initial loss followed a slower subsequent loss, describable in terms of $t_{1/2}$ values. Overall $t_{1/2}$ values can vary from days to several months. The observations on depuration profiles for both metals and organic pollutants indicate at least a two-compartment model (often called the 'fast' and slow' compartments) of pollutant uptake and release. The slow compartment likely includes fat stores, lysosomes, and macromolecular adducts for organic pollutants, and metallothioneins, lysosomes, and granules for metals. The phenomenon of induction, i.e., increased synthesis of metallothionein, in response to metal exposure could also contribute to the slow compartment. Active excretion of metals in molluscs can occur through elimination of residual bodies by the process of exocytosis. Such processes appear to be more important for some metals than others, resulting in very different $t_{1/2}$ for certain metals and species, e.g., in mussels (*Mytilus* spp.), the $t_{1/2}$ for Cu was 9 days compared to 7 months for Cd. Metal that is nonbioavailable in metal/phosphate granules can also be eliminated when prey are eaten by predators, e.g., the metal/phosphate granules contained in barnacles eaten by whelks are lost from the latter in its feces. The consequence of such nonbioavailability is that generally metals, like readily metabolizable organic pollutants such as PAHs, are present in highest tissue concentrations at the bottom of food chains, i.e., in shellfish, and do not bioaccumulate to higher concentrations in top predators, such as fish and other vertebrates. The exception is Hg that is bioaccumulated along food chains, but principally in the form of fat-soluble methylmercury.

Toxic Threat and Regulatory Standards

The vast range and diversity of pollutants that are produced by human activities permeate to varying degrees every part of the earth's ecosystem, from urban and industrial centers through to remote areas such as deep oceans and the Arctic and Antarctic circles. For example, polychlorinated aromatic compounds such as PCBs, PCDDs, and PCDFs appear ubiquitous, having been found in air, soot particles, sediments, water column, and all types of animal tissue from shellfish to fish and other vertebrate wildlife, to human fat, milk, and blood serum. Therefore, unlike the biological agents described later, and excepting localized pollution incidents such as the Minamata disease tragedy, the main potential health threat to humans of pollutants in shellfish is probably their contribution to the general body-burden of such chemicals. The latter can receive a wide range of inputs of pollutants from various sources, including other foodstuffs, cooking procedures, smoking, and atmospheric pollution. Depending on the fat content and which part is eaten, shellfish may make a particular contribution in the case of very fat-soluble organic pollutants, such as PAHs, PCBs, dioxins, and other chlorinated hydrocarbons. Because there are so many pollutants that may be present in shellfish, the potential deleterious effects that they may cause in the short, medium, and long term are many and diverse and encompass most known mechanisms of chemical-mediated toxicity. Examples of some of these are given in Table 6. The extent to which such illness and effects will be manifested or not will depend on the dosage of pollutant to which the consumer is exposed, of which the shellfish may contribute only a part. Some routes of exposure may be much more important for some pollutants than others, e.g., atmospheric pollution can be a major route for Pb.

Localized poisoning incidents involving shellfish have happened in the past, but largely due to major ignorance at the time. In the infamous Minamata disease incident in the 1950s, industrial waste that included mercuric chloride was discharged into Minamata Bay in Japan. The water-soluble Hg was methylated by bacteria to fat-soluble methylmercury that was then bioaccumulated and passed along the food chain. The combination of the high toxicity of Hg, and the seafood forming a major part of the diet, resulted in illness appearing within a year and eventually over 70 deaths and 700 cases of poisoning in the local population.

Chemical analysis of processed commercial seafood in the 1970s through to the 1990s revealed highest levels of PAHs in molluscs, lower levels in crustaceans, and lowest in fish, consistent with their general capacity for biotransformation. In one study, the carcinogenic PAH benzo[a]pyrene was detectable in commercial molluscan seafood from nine countries. Levels of benzo[a]pyrene were 0–36 $ng\,g^{-1}$ wet weight in molluscs compared to 0–8 $ng\,g^{-1}$ wet weight in crustaceans, and were higher in smoked seafood and in animals collected or kept near obvious environmental sources of PAHs, e.g., lobsters held in a commercial tidal pound constructed of creosoted timber had levels of benzo[a]pyrene of 2300 and

Table 6 Examples of possible deleterious effects and mechanisms of toxicity of pollutants found in shellfish to human consumers[a]

Pollutant	*Toxic effect*	*Biochemical effects*
PCBs, PCDDs, PCDFs	Cancer, developmental effects, immune dysfunction, liver damage, reproductive effects, thymic atrophy, weight loss	Induction of CYP1A, UDPGT
Certain PAHs, e.g., benzo[a]pyrene	Cancer	Induction of CYP1A, DNA adduct formation
Aromatic amines	Bladder cancer	
Organophosphorous pesticides	Neuromuscular and neurotoxic effects	Inhibition of acetyl cholinesterase
Cadmium	Kidney damage, bone damage	Induction of metallothionein
Lead	Neurotoxic effects, bone and kidney damage	Interference of heme and porphyrin synthesis
Mercury and methyl mercury	Neurotoxic effects, memory loss, loss of muscle coordination, cerebral palsy	Binds to protein sulfhydryl groups

[a]Data are for humans and/or mammalian studies.
PCB, polychlorobiphenyl; PCDD, polychlorinated dibenzo-*p*-dioxin; PCDF, polychlorinated dibenzofuran; CYP1A1, cytochrome P4501A1; UDPGT, UDP-glucuronyl transferase; PAH, polycyclic aromatic hydrocarbon.

$281\,ng\,g^{-1}$ wet weight in the hepatopancreas and edible tail meat respectively.

Various national and international bodies issue regulations and/or advise on matters relating to the health quality, production, and marketing of fishery products, including shellfish, e.g., the European Union (EU) issues directives which pertain both to member countries and to exports received within the EU. In the UK, environmental quality standards (EQS) exist for some pollutants, whereas guidelines only are identified for others. Examples of these for shellfish from UK waters are given in Table 7. In the USA, the Food and Drug Administration (FDA) issues action levels and guidelines for shellfish; guidelines are also issued by the US Environmental Protection Agency (EPA). Depending on the country, contravention of statutory EQS, action levels, or guidelines can form the basis for closure of a shellfish fishery and/or removal of products from outlets. Guidelines may also be used in conjunction with risk assessment to provide health advice on minimizing chronic effects of pollutants such as PCBs, dioxins, and Hg through limiting shellfish consumption. This advice may be targeted at particularly vulnerable groups such as pregnant and nursing women, children and women of child-bearing age. On the other hand, in the case of certain metals, higher levels may be permitted in some shellfish species if environmental or tissue levels are considered to be high naturally, e.g., Cu and Zn. Chemical analytical techniques exist for many thousands of pollutants, but routine measurement is generally limited to a select few which are of particular concern (Table 7). The bodies responsible for the measurement, and the conditions of measurement (e.g., sampling frequency), vary with the national or international organization. The depuration procedures required for treatment of shellfish prior to marketing (i.e., to remove bacteria and other biological agents) will also remove most or many of the pollutants.

Table 7 Outline of standards/guidelines for maximum acceptable pollutant levels in shellfish from UK waters[a]

Pollutant	*England and Wales*[b] *(mg kg^{-1} wet wt)*	*Scotland and Northern Ireland*[c] *(mg kg^{-1} wet wt)*
PCBs	Molluscs 0.02–0.1 Crustaceans 0.01–0.05	Mussel 0.3–1.0
DDT	Fish liver 0.5	Mussel 0.03–0.1
Dieldrin	Fish liver 0.2–0.3	Mussel 0.015–0.05
Hexachlorobenzene	Fish liver 0.1	Mussel 0.03–0.1
Mercury	Molluscs 0.12–0.2 Crustaceans 0.1–0.3	Mussel 0.2–0.6
Cadmium	Mussel 0.4–1.0	Mussel 1.0–3.0
Copper	Some molluscs 5.0 Crustaceans 20–30	Mussel 3.0–6.0
Lead	Some molluscs 4.0 Crustaceans 1.0	Mussel 3.0–10
Zinc	Some molluscs 100 Crustaceans 100	Mussel 50–100

Dry wt converted to wet wt using a conversion factor of × 0.2.
PCBs, polychlorobiphenyls; DDT, 1,1, bis(4-chlorophenyl)-2,2, 2-trichloroethane.

Shellfish Toxins

Shellfish, particularly marine bivalve molluscs, can be contaminated with naturally occurring poisons, also known as toxins, phycotoxins, or marine biotoxins. It is common to refer to the toxins under generic headings (Tables 1 and 8), with each grouping

consisting of a number of compounds. Consumption of shellfish containing the toxins may lead to illness and/or death in humans. Details of the toxin groups, their origin, and associated toxic syndrome are summarized in Table 8.

The source of toxins in bivalve molluscs is microscopic planktonic algae, termed phytoplankton, which are concentrated in bivalves by their filter feeding mechanism and which form part of the animal's natural diet. Other types of shellfish (e.g., crabs, lobsters), finfish, marine mammals, and seabirds may also be contaminated with the toxins, generally through the food chain. With the exception of shellfish, the other animals have not been associated with human food poisoning, and may themselves become ill or die due to the toxins. The toxins may also cause physiological changes in some shellfish. However, generally the changes are not obvious and contaminated shellfish cannot be differentiated from their nontoxic counterparts by their physical appearance.

Table 8 Details of shellfish toxins, their origin, and toxic syndromes

		Toxin group		
	Paralytic shellfish toxins	*Amnesic shellfish toxins*	*Diarrhetic shellfish toxins*	*Neurotoxic shellfish toxins*
Principal toxin (molecular weight)	Saxitoxin (carbamate toxin); (299.3)	Domoic acid (311.14)	Okadaic acid (OA) (804.5)	Brevetoxin PbTx 1 (867.07)
Associated toxins	Carbamate toxin (neo-STX); gonyatoxins (GTX 1–4); *N*-sulfocarbamoyl toxins (B1, B2, C1–C4); decarbamoyl toxins (dc-GTX 1–4, dc-Neo, dc-STX, do-STX, doGTX2, doGTX3)	C5' diastereomer; Isodomoic acid, mainly D, E, and F in shellfish	OA compounds: dinophysistoxins (DTXs), OA; OA-diol esters; others: YTXs; PTXs; AZTs	PbTx 1–10
Chemical type	Water-soluble tertrahydropurine	Water-soluble tricarboxylic acid	Polyethers	Polyethers
Origin in relation to shellfish	*Alexandrium* spp. *Gymnodinium catenatum* *Pyrodinium bahamense*	*Pseudo-nitzchia* spp.	OA compounds: *Prorocentrum* spp. and *Dinophysis* spp. PTXs, *Dinophysis fortii* YTXs, *Protoceratium reticulatum* AZTs, unknown	*Gymnodinium breve*
Type of phytoplankton	Dinoflagellates	Diatoms	Dinoflagellates; AZPs unknown	Dinoflagellates
Food-poisoning syndrome	Paralytic shellfish poisoning	Amnesic shellfish poisoning (ASP)	Diarrhetic shellfish poisoning (DSP)	Neurotoxic shellfish poisoning (NSP)
Mode of action	Block influx of sodium ions in neuronal and muscular voltage gated sodium channels	Glutamate agonist, binds to kainate-type glutamate receptors	OA/DTXs inhibit serine/threonine protein phosphatases; YTX hepatic and cardiac damage; PTXs hepatotoxic; AZTs necrosis of pancreas cells, liver, lymphocytes, and myocardium	Influx of sodium ions into voltage gated sodium channels
Examples of symptoms	Tingling of lips and tongue, numbness, mild headache, incoherent speech, nausea, vomiting, respiratory difficulties, paralysis, death	Nausea, vomiting, diarrhea, headache, memory loss, seizures, coma, death	Diarrhea, nausea, vomiting, abdominal pain and chills (OA, DTXs and AZTs); PTX and YTX not defined	Abdominal pain, nausea, diarrhea, chills, reversal hot/cold, headache, muscle/joint pain
Time to onset	30 min–4 h	24–48 h	30 min–12 h (OA + DTXs)	3–6 h
Life-threatening	Yes	Yes	No	No
Concentration reported to cause symptoms	144–12 400 μg 100 g^{-1}	60–295 mg	OA 25–36 μg 100 g^{-1}; AZP not defined	1600 μg 100 g^{-1}
Regulatory limit	80 μg 100 g^{-1}	20 μg g^{-1}	Not detected by mouse bioassay	20 MU 100 g^{-1}

STX, saxitoxin; YTXs, yessotoxins; PTX, pectenotoxins; AZT, azaspiracid toxins; PbTx, brevetoxin; MU, mouse units.

Approximately 40 of the estimated 5000 phytoplankton species produce toxins. These occasionally occur in large numbers causing discoloration of the water column that has led to descriptions such as 'red' and 'brown tides.' However, large numbers of algal cells need not be present for toxins to accumulate in shellfish. The toxic algae and hence shellfish containing toxins occur worldwide, and it has been suggested that they are increasing in distribution, frequency, and intensity. Reasons postulated include climate change, increased utilization of coastal waters, and transport of toxic species via ships' ballast water. The toxins are generally described as secondary metabolites and their functional significance to the algal cell is unknown. Inter- and intraspecies differences in the quantity of toxin produced and the toxin profile exist, as do nontoxic variants of toxic species. The pathways for toxin biosynthesis have not been fully elucidated for most of the toxin groups, although some steps have been characterized. The genes involved are currently not identified.

The occurrence of specific algal species in some areas, in some seasons, is fairly predictable (e.g., *Alexandrium* species, associated with paralytic shellfish toxins (PSTs), tends to occur in the summer months in parts of the UK). Although, some field data are available on environmental factors that trigger the emergence of these toxic phytoplankton and production of their toxins, it is currently not possible to predict accurately the number of toxic cells and the length of time for which these cells will remain in the water column, nor their cellular toxin concentration. All of these factors influence the total toxin burden in exposed shellfish. Other factors which may influence shellfish toxicity are rate of ingestion, degradation to nontoxic compounds, biotransformation from one toxin in a group to a less toxic compound in the same group, and excretion.

Toxin Groups

Paralytic shellfish toxins PSTs are a group of approximately 20 closely related tetrahydropurine compounds of varying potency (Table 8). The dinoflagellates involved in production of these toxins are listed in Table 8. Saxitoxin (STX) was the first of these compounds to be identified and is also considered the most potent. Some steps in the biosynthesis of STX have been determined. These involve a high-energy methyl group donor (*S*-adenosylmethionine), a two-carbon unit (acetate), and an amino acid precursor (arginine). However, the sequence of reactions and exact number of biosynthetic steps have not been fully defined. Additionally, controversy surrounds suggestions that the dinoflagellate's bacterial flora are involved in the production/biotransformation of PSTs.

Shellfish contaminated with PSTs can contain different combinations of the compounds that can differ from that of the dinoflagellate ingested. This is more pronounced in some shellfish species (e.g., *Spisula solidissima*) than others (e.g., *M. edulis*). PSTs are also produced by some species of fresh-water cyanobacteria, e.g., *Aphanizomenon flos-aquae*, although to date there are no reports of human food poisoning from fresh-water shellfish due to these toxins. The mode of action of PSTs is listed on Table 8, along with details of the toxic syndrome, i.e., paralytic shellfish poisoning (PSP) that they cause. PSP has been known for centuries and the concentration of PSTs reported to cause illness varies (Table 8). Out of all the shellfish toxins, some consider PSTs to be the most dangerous. This is due to the high concentrations of PSTs that may occur in shellfish (Table 9) and the fact that death can result within an hour.

Amnesic shellfish toxins Details of the amnesic shellfish toxins (ASTs) are summarized in Table 8. In this group, domoic acid (DA) is considered the

Table 9 Example of peak toxin concentration and depuration rates for some shellfish species contaminated with paralytic shellfish toxins

Species	*Peak toxicity (μg STX equiv. 100 g^{-1})*	*Time to regulatory limit (weeks)*	*Detoxification rate (% per day)*
Crassostrea gigas	209–710	0.6–2.0	NA
Ostrea edulis	1000	6.4	4.0
Mytilus edulis	100–19259	0.6–15.6	4.8–15.4
Mytilus californianus	240–5300	2.8–9.0	5.1–8.9
Pecten maximus	2700	6.4	7.4
Placopecten magellanicus	809–6179[a]	> 52	0.2–0.6
Patinopecten yessoensis	6000–340000[b]	> 12–30	1.2–11.7

Regulatory limit, 80 μg saxitoxin (STX) equiv. 100 g^{-1}; NA, not available.

Modified from Bricelj MV and Shumway SE (1998) Paralytic shellfish toxins in bivalve molluscs: occurrence, transfer kinetics and biotransformation. *Reviews in Fisheries Science* 6: 315–383.

main compound of concern. Little detailed toxicological information exists on the other ASTs, although it has been suggested that the isomers are less toxic than DA, and the diastereomer is of equivalent toxicity. DA has been detected in a range of marine macroalgae and in some species of the diatom genus *Pseudo-nitzschia*. Biosynthesis of DA is thought to involve two different precursor units. One is formed from the direct incorporation of acetate into oxaloacetate during the Krebs cycle, forming an activated derivative, e.g., 3-hydroxyglutamic acid. The other unit is thought to be an isoprenoid unit, geranyl-pyrophosphate.

Accumulation of DA-producing *Pseudo-nitzschia multiseries* in *M. edulis* led to the first recorded incidence of amnesic shellfish poisoning (ASP; Table 8) in shellfish consumers in Canada in 1987. Gastroenteritis was the milder form of the illness and tended to occur in those under 40 years of age. Severe neurological symptoms, such as short-term memory loss, were experienced by older people, reportedly lasting in some cases for a number of years. Those who died suffered from other preexisting illnesses, e.g., diabetes. Although DA has subsequently been detected in shellfish in countries other than Canada, no further confirmed outbreaks of ASP have been reported.

Diarrhetic shellfish toxins Diarrhetic shellfish toxins (DSTs) were originally defined as okadaic acid (OA) and related toxins called dinophysis toxins (DTXs; Table 8) They were first suspected of causing shellfish-related illness (Table 8) in the Netherlands in 1961, and confirmed as being responsible for food poisoning in Japan in the 1970s. The principal toxin of this group, OA, has also been detected in the sponges *Halichondria okadai* and *H. melanodocia*. The method of detecting DSTs is a mouse bioassay using a solvent extract. The nonspecific nature of this technique has led to the inclusion of other compounds in the DST group. These include fused polyether compounds named yessotoxins (YTXs) and a group of macrocyclic polyether lactones called pectenotoxins (PTXs). Some effects of these compounds in rodents are summarized in Table 8. However, little detailed toxicological and epidemiological information is available and international debate is ongoing on their inclusion in the DST group, their threat to human health, and values, if any, for regulatory limits. The biosynthesis of OA and the related YTXs and PTXs is thought to occur by the successive additions of acetate units to a growing polyketide chain, mediated by the enzyme polyketide synthase (PKS). Modification of PKS, involving for example oxidative modification, methylation, and cyclization, results in different structural types of the enzyme.

A further group of toxins, named azaspiracid toxins (AZTs), is also currently included within the DSTs. These are lipophilic, highly oxygenated polyethers containing an unusual azaspiro-ring structure. Although dinoflagellates are suspected as the source of the toxin, undisputed evidence does not yet exist. AZTs were first reported as causing food poisoning in the 1990s with symptoms similar to those for OA (Table 8). Effects of AZTs on rodents are summarized in Table 8. There is strong support to separate this group from the other DSTs and to name the illness azaspiracid shellfish poisoning. Discussions are currently ongoing on what regulatory limits should be set, given the limited extent of epidemiological data available.

Neurotoxic shellfish toxins Neurotoxic shellfish toxins (NSTs; Table 8) cause shellfish-related food poisoning. However, they are more noted for finfish and seabird kills than human illness. Produced by the dinoflagellate *Gymnodinium breve*, they are infamously known as the cause of the Florida red tides that have been recorded for centuries. *G. breve* is typically found in Florida waters, but similar forms have been detected in waters elsewhere, particularly New Zealand.

Monitoring and Methodology for Shellfish Toxins

A large number of countries worldwide monitor their waters for toxic algae, the shellfish for toxins, or a combination of both. Internationally accepted standards are recognized for PSTs and ASTs (Table 8). Regulations for DSTs are less clear, with some countries using detection by mouse bioassay as criteria for implementing harvesting closures and others suggesting a limit of 8–16 μg $100\,g^{-1}$ (Table 8). Within the EU, limits are incorporated into directives with which member states and countries exporting to the EU must comply.

Some suggest that these regulatory limits can be deemed effective as judged by the lack of shellfish toxin-related food poisoning in countries with comprehensive monitoring programs. However, detailed toxicological and epidemiological data supporting these limits are lacking for many of the toxins, hindered in some cases by lack of toxin standards and appropriate methodology for toxin detection. Additionally, questions relating to sampling procedures for collection of an appropriate representative sample from shellfish populations remain, e.g., sample size, frequency, definition of sampling area, and number of samples per area.

Most countries use a mouse bioassay for the detection of PSTs, DSTs, and NSTs in shellfish-monitoring programs. Ethical considerations are the driving force

behind the development of alternative methods, such as immunoassays, cell assays, and analytical instrumental techniques, e.g., liquid chromatography–mass spectrometry. In some cases progress is hampered by the complexity of the toxins and the lack of toxin standards, and to date, with one exception, no alternative method has been fully accepted for use in routine monitoring. The exception is ASTs where a high-performance liquid chromatographic technique was developed at the time of the Canadian ASP outbreak and is now used routinely in many countries.

Depuration and Processing of Shellfish Contaminated with Toxins

Once shellfish are contaminated with toxins, options for detoxifying or depurating the animals are limited. They mainly involve commercial canning of some shellfish species e.g., *Mya arenaria* and *Mytilus edulis* contaminated with PSTs. However, the effectiveness of these processes is dependent upon initial low levels of toxin and caution is recommended in their use.

Currently, commercial depuration systems are ineffective at cleansing shellfish of toxins, which leaves the option of allowing shellfish to depurate naturally in the environment. This can be problematic as rates of detoxification vary considerably between species, with some shellfish remaining toxic for a year or more (Table 9). Depuration in some shellfish species seems to be biphasic. It has been suggested that the initial detoxification phase represents gut evacuation of unassimilated toxin, whereas the second phase represents the release of toxins assimilated and incorporated in the tissue. The situation is made more complex by changes in toxin profile observed during depuration, particularly for PSTs. A role for biotransformation enzymes in this process has been suggested and recent work has demonstrated the induction of glutathione *S*-transferase in *M. edulis* exposed to PSTs. Nevertheless, mechanisms involved in the depuration of shellfish toxins are poorly understood and hinder the development of commercial depuration processes.

Infectious Microbes

A number of bacteria and human viruses responsible for food poisoning are transmitted via the fecal–oral route (Table 1). Infected individuals can shed large numbers of these microbes in their feces. The link between shellfish-transmitted disease and sewage pollution in the marine environment has been known since the late nineteenth century, with early documented evidence associated with the bacterial infection typhoid fever (Table 10). Of the different shellfish species, bivalve molluscs are the main source of microbial contamination that poses a health risk to human consumers. This is exacerbated by traditional consumption of some species raw or only lightly cooked. As with shellfish toxins, there are no obvious visible indications of contamination.

Ineffectively processed or untreated sewage, faulty septic tanks, and feces from farm animals and seagulls are a principal source of bacterial food-poisoning agents in the marine environment. However, human sewage is currently thought to be the only source of human enteric viruses in marine waters. Sewage treatment processes are only partially effective at removing viruses, and therefore coastal discharges are a major source of these infectious agents in some areas. Additionally, contamination of the marine environment by both bacteria and viruses is exacerbated after heavy rainfall due to increased land run-off and storm water discharges. However, not all infectious agents concentrated in shellfish are from fecal sources. Naturally occurring bacteria from the genus *Vibrio* are also responsible for shellfish-transmitted infection, particularly from raw oysters.

In recent years there have been fewer incidences of infection due to shellfish consumption and this is generally attributed to the success of the controls now implemented in many countries for reducing bacterial contamination of shellfish. When shellfish-related food poisoning does occur, evidence from the UK and USA suggests that the causative agent is not identified in the majority of cases. However, enteric viruses are often suspected because the clinical symptoms are frequently consistent with the epidemiological criteria for viral gastroenteritis.

Bacterial Contaminants

Table 10 lists bacterial contaminants reported to cause shellfish-related food poisoning. These can be split into two main groups – bacteria where the principal source of contamination is from animal or human feces, and those which occur naturally in the marine environment.

Salmonella spp. are commonly found in intestinal tracts of animals and human carriers. Over 2000 different serotypes have been reported, most of which are pathogenic to humans to varying degrees. The most serious illness is typhoid fever resulting from infection from *Salmonella typhi* (Table 10). A number of cases of this acute systemic disease occurred in the early 1900s, due to contaminated oysters from grossly polluted waters. Nowadays, modern sanitation practices, improved control systems, and a reduced number of human carriers mean this disease has not been reported in relation to shellfish from developed counties for a number of years. Gastroenteritis is a more common *Salmonella*-related illness, although again as a consequence of modern practices

Table 10 Microbes reported to cause shellfish-related food poisoning and a summary of the symptoms

Type	*Name*	*Description*	*Type of illness*	*Incubation period*	*Symptoms*	*Length of illness*
Bacteria	*Salmonella typhi*	Gram-negative	Typhoid fever	1–2 weeks	Fever, chills, headache, constipation, diarrhea (20%), muscle pain	1–2 weeks; can be fatal
Bacteria	*Salmonella* spp.	Gram-negative	Gastroenteritis	12–36 h	Diarrhea, nausea, occasionally vomiting, abdominal pain, chills, moderate fever, drowsiness	2–7 days; low number of fatalities
Bacteria	*Campylobacter* spp.	Gram-negative	Gastroenteritis	2–5 days	Bloody diarrhea, nausea, malaise, fever, and severe abdominal pain	3–5 days; low number of fatalities[a]
Bacteria	*Escherichia coli*	Gram-negative	Gastroenteritis	12–72 h	Diarrhea, abdominal cramps, nausea, and chills	2–3 days
Bacteria	*Vibrio parahaemolyticus*	Gram-negative	Gastroenteritis	4–48 h	Profuse diarrhea, abdominal pain, nausea, sometimes fever, and occasional vomiting	2–5 days
Bacteria	*Vibrio vulnificus*	Gram-negative	Primary septicemia	< 24 h	Fever, abdominal pain, vomiting, diarrhea, sepsis	50% mortality[a]
Bacteria	*Vibrio cholerae* non-O1	Gram-negative	Gastroenteritis		Diarrhea, abdominal cramps, occasionally vomiting and fever	
Virus	Norwalk-like viruses	Single-stranded RNA; 30–35 nm diameter	Gastroenteritis	1–4 days	Nausea, vomiting, abdominal pain, occasional diarrhea and low-grade fever	12–48 h
Virus	Hepatitis A	Single-stranded, RNA *c.* 27 nm diameter	Hepatitis	2–6 weeks	Fever, headache, nausea, vomiting, diarrhea, abdominal pain, jaundice	Up to several months

[a]Mortality rate highest in people with other predisposing illnesses, e.g., diabetes.
Data source: Eley AR (1992) *Microbial Food Poisoning*. Hackney CR and Pierson MD (eds) (1994) *Environmental Indicators and Shellfish Safety*. London: Chapman and Hall.

is not often caused by shellfish (Table 10). Gastroenteritis has also been reported from consumption of shellfish contaminated with species of *Campylobacter* and enterotoxigenic strains of *Escherichia coli* (ETEC: Table 10). (*See* ***Salmonella***: Salmonellosis; ***Campylobacter***: Properties and Occurrence; ***Escherichia coli***: Food Poisoning by Species other than *Escherichia coli*.)

Hemorrhagic strains of *E. coli*, particularly strain 0157, causes hemorrhagic colitis bloody diarrhea, with 10% of cases developing serious complications, such as hemolytic uremic syndrome. This may lead to death, particularly in children and the elderly. Although to date there are no reports of infection via shellfish from this pathogen, they remain of concern given their prevalence in the environment, association with cattle, and their low infective dose. Research is required to assess their survival in the marine environment, their potential to accumulate in shellfish exposed to farm run-off, and the risk to the consumer of shellfish. However, it must be borne in mind that other bacterial pathogens, including *Yersinia enterolitica* and *Clostridium perfringens*, may be isolated from molluscan shellfish, although no cases of shellfish-borne illness due to these species have been reported. Bacteria such as *Shigella* spp. and *Staphylococcus aureus* have also been associated with shellfish-borne infection, but generally by contamination from infected food handlers. (*See* ***Clostridium***: Occurrence of *Clostridium Perfringens*; ***Shigella***; ***Staphylococcus***: Properties and Occurrence.)

Vibrios, particularly species of *Vibrio parahaemolyticus* and *V. vulnificus*, are also causative agents of illness due to the consumption of raw shellfish. However, unlike the bacteria described above, these species are prevalent naturally in warm estuarine waters throughout the world. Attempts to recover these bacteria can be complicated by their reported ability to form a viable but nonculturable state. *V. parahaemolyticus* tends to cause gastroenteritis,

whereas *V. vulnificus* is a particularly invasive pathogen which may cause primarily septicemia within 24 h of exposure (Table 10). Raw oysters containing large numbers of the latter bacterial species tend to be the main source of infection, which is characterized by a mortality rate of 50% in susceptible individuals. *V. cholerae* is separated into two groups on the basis of the O1 somatic antigen. Strains possessing the O1 antigen were previously believed to derive only from human feces, but are now known to exist in low numbers in some estuarine waters. These strains are responsible for cholera, and shellfish have been implicated as a vector for the disease. *V. cholerae* non-O1 are ubiquitous in some coastal waters and are frequently identified as a cause of gastroenteritis from raw shellfish (Table 10). (*See* **Vibrios**: *Vibrio cholerae*; *Vibrio parahaemolyticus*; *Vibrio vulnificus*.)

Viruses

Viral pathogens may also cause food poisoning due to consumption of contaminated bivalve molluscs (Table 10). Epidemiological evidence suggests that the Norwalk-like viruses (NLV), also known as small round structured viruses, are the most common cause of infection. This group of viruses consists of a genetically diverse virus strain, separated into genogroups I (including the prototype Norwalk virus) and II. With an infectious dose thought to be as low as 10–100 virions, an US FDA risk assessment estimated that 100 000 cases of seafood-related NLV gastroenteritis occur per year. The immunological response to NLV infection is not well understood and appears to be short-term, with individuals becoming susceptible to reinfection within 6 months to 1 year. Patients may also suffer from a mixed infection due to viruses of both genogroups.

The most serious virus infection linked to shellfish consumption is hepatitis A. This virus is extremely stable and is currently thought to replicate in the liver. Unlike the other enteric viruses, hepatitis A has a long incubation period of about 2–6 weeks and causes a serious debilitating disease (Table 10). It is a self-limiting infection and, although it rarely causes death, infected people may be incapacitated for several months. Young children frequently experience only mild illness, whereas full symptoms develop in the majority of infected adults. Recovery is complete and leads to long-term immunity from reinfection. Occasionally, epidemics due to hepatitis A in shellfish occur. In Shanghai, China, during 1988, approximately 300 000 cases of hepatitis A were traced to clams from a sewage-polluted area. It is also interesting to note that incidences of gastroenteritis, followed by hepatitis A infection, have been reported from contaminated shellfish.

Astroviruses have also been implicated in outbreaks relating to oysters. However, detailed epidemiological data are lacking and the importance of these organisms in shellfish-related food poisoning is not clear. Other viruses, such as rotaviruses, adenoviruses, and enteroviruses, have been detected in shellfish, but to date they have not been linked with infectious disease following seafood consumption. Despite their name, enteroviruses (e.g., polioviruses) do not commonly cause gastroenteric symptoms, e.g., diarrhea and vomiting, although they do replicate in the intestinal tract and are passed via the fecal–oral routes. These viruses are often found in shellfish but have not been reported to cause infection.

Parasites

Helminth parasites have been implicated in human infection, primarily from consumption of raw or under cooked finfish and, more rarely, from crabs and bivalves. Protozoan parasites of the genera *Giardia* and *Cryptosporidium* cause human disease and are generally associated with contaminated fresh water. Both occur in detectable numbers in raw and treated sewage. There is a dearth of information regarding the survival of these organisms in sea water and their potential to contaminate shellfish.

Monitoring, Methodology, and Use of Indicators for Infectious Microbes

Bacteria Most countries have implemented sanitary controls for the production of bivalve shellfish. In the EU, these are applied via the European Directive 91/492/EEC (Table 11) and in the USA by interstate trading agreements set out in the FDA National Shellfish Sanitation Program Manual of Operations. Third-country imports into the EU and the USA have to comply with these standards. These regulations include assessment of fecal pollution in shellfish (determined by measuring bacterial indicators), processing requirements for shellfish from contaminated areas, conditions for processing and dispatch establishments, and marketing documentation.

The bacterial indicators generally involve measurement of fecal coliforms or *E. coli* in shellfish (EU) or shellfish-growing waters (USA). The concept is that if indicators are present in sufficiently high numbers, there is a high probability that specific pathogens are also present. The appropriateness of these indicators has been intensely debated over the years. Nevertheless, fecal coliform/*E. coli* indicators are used routinely worldwide and their implementation, along with specific processing methods, has resulted in a decrease in shellfish-related bacterial food poisoning.

Table 11 Regulatory limits implemented on biological contaminants of shellfish using EU regulations as an example

	Harvesting limits for bacteria		*Harvesting limits for toxins*		*End-product standard*[a]
Classification	*Microbial standard (per 100 g shellfish)*	*Treatment required*	*Toxin*	*Limit*	
A	< 230 *Escherichia coli* or < 300 FC	None	PSTs	80 μg 100 g^{-1}	Negative for *Salmonella* in 25 g of bivalve flesh
B	< 4600 *E. coli* or < 6000 FC in 90% of samples	Depuration or relayed	DSTs	Not detected in bioassay[b]	< 230 *E. coli* (or < 300 FC) 100 g^{-1}
C	< 60 000 FC 100 g^{-1}	Relayed for at least 2 months	ASTs	20 μg g^{-1}	Below harvesting limits for toxins
Ns	> 60 000 FC 100 g^{-1}	Prohibited			

[a]Microbes and toxins only.
[b]Mouse bioassay methodology not defined.
FC, fecal coliforms; PSTs, paralytic shellfish toxins; DSTs, diarrhetic shellfish toxins; ASTs, amnesic shellfish toxins; Ns, not stated but often called class D. Data source: Council Directive 91/492/EEC and 97/61/EC.

One of the main advantages of these bacterial indicators is the relative ease by which they can be detected and quantified utilizing traditional bacteria culture techniques. For example, in the UK, a five-tube, three-dilution, most probable number, two-stage technique with minerals-modified glutamate broth and chromogenic medium for detecting β-glucuronidase activity, is used for the detection of *E. coli* in shellfish.

Viruses People in a number of countries have contracted viral infections after consuming shellfish that comply with bacterial indicator regulations. This suggests bacterial standards are inappropriate controls for a viral hazard in shellfish; yet virus standards for bivalve molluscs do not currently exist. Developments of such regulatory limits are hampered largely by lack of appropriate, reliable, robust, and easy-to-use methods.

The most common methods for the detection of viruses is electron microscopy and cell culture, neither of which has proved very successful in the detection and quantification of enteric viruses, such as NLVs and hepatitis A, in shellfish. Electron microscopy is not sufficiently sensitive and many of these viruses are considered nonculturable (NLV) or difficult to culture (hepatitis A). In recent years, immunoassays have become available, although the success of application to shellfish has been limited. Molecular techniques, such as polymerase chain reaction (PCR), combined in some instances with sequencing of the amplified product or hybridization of the product with probes, seem to be the most promising approach to date. Such methods have been developed for hepatitis A and NLV detection in shellfish. Their use, however, is not straightforward because shellfish extracts contain substances inhibitory to PCR that may cause false negatives. This has resulted in the use of time-consuming, laborious extraction procedures that are problematic to apply in a routine monitoring scenario. Additionally, it is uncertain that PCR results indicate the presence of viable infectious viruses. However, some workers argue that this is not an issue because viral RNA is unlikely to survive for any length of time in shellfish without a complete protein coat. Others suggest use of antibody-capture techniques aimed at recovering the whole virion, prior to PCR. This also has the potential advantage of reducing complex extraction techniques. However, for NLVs, application of immunocapture techniques is hindered by the lack of suitable immunological agents. Although PCR-based methods have advanced research on viruses in shellfish, further work is required to simplify, improve, and standardize the methodology. It has been suggested that their routine use is a number of years in the future and that consideration should be given to utilizing viral indicators.

Bacteriophages are the most frequently suggested viral indicators because of their physical and genomic similarity to human enteric viruses, their abundance in sewage effluents, and the relative ease in which they are quantified. Methodology generally utilizes plaque assays, although it should be noted that these are not always robust. Use of general somatic bacteriophage of coliforms has also been proposed. However, standardization and reproducibility of methods utilizing this diverse group are problematic. Male specific (F+) bacteriophages are another contender as viral indicators and have been used by some researchers to study shellfish depuration. Studies have shown that F+ elimination kinetics reflects that of enteric viruses and that it is a more effective indicator of viral presence in depurated shellfish than *E. coli*. However, one criticism of F+ bacteriophage is that their distribution is not restricted to human effluents,

thereby causing doubt as to their suitability as human virus indicators in rural areas primarily impacted with animal fecal contamination. Currently, researchers are attempting to optimize systems to differentiate between animal and human F+ bacteriophage. As an alternative, the bacteriophage of the obligate anaerobe *Bacteroides fragilis* has been proposed as an indicator of human specific pollution.

An alternative to bacteriophage is the detection of other human viruses that are either widely prevalent in polluted waters and/or easier to detect than viral pathogens. Human enteroviruses have been used in this context, particularly for water. However, methods of detection are currently complex. Human adenoviruses have also recently been suggested but further work is required to determine their prevalence in relation to NLVs and hepatatis A. Overall, more work is needed to assess further prevalence of potential indicators compared to the viral pathogens, to improve methods, and to develop standards to apply before the most appropriate viral indicator approach can be developed.

Depuration and Processing of Shellfish Containing Infectious Microbes

Shellfish may be harvested and marketed directly without any further processing providing they meet specific standards, including limits on the numbers of bacterial indicators. However, if they exceed these limits, depuration and/or relaying are permissible up to certain concentrations of the indicators. To provide an example of the type of regulations imposed, the criteria set within the EU are summarized in Table 11.

Depuration procedures for treatment of microbial contaminants of shellfish were first developed during the 1920s. These involve placing bivalves in clean sea water in tanks away from the source of microbial contaminants and allowing their natural excrement process to remove contaminants within the mollusc. The tanks contain static, flow-through, or recycled sea water sterilized with ultraviolet irradiation, ozone, or chlorination. Depuration is implemented for 1–7 days, although 2 days is more common. The effectiveness is assessed generally by a reduction in fecal coliform or *E. coli* numbers to specific concentrations (e.g., to class A in the EU). However, shellfish from depuration plants meeting these limits may still contain human enteric viruses at concentrations sufficient to cause infection. Recent work suggests that during depuration viruses are eliminated at much lower rates than bacteria and sea-water temperature is critical.

Relaying requires that shellfish are removed from their original contaminated harvesting site and placed in an area with reduced microbial contaminants for at least 2 months to allow natural depuration to occur. Practical difficulties associated with this process include problems in finding suitable waters and obtaining ownership rights to these waters. One additional issue that is rarely addressed is the possibility that shellfish may be contaminated with the resting stage of toxin-producing dinoflagellates. Moving such shellfish to a 'clean' site risks seeding that site with toxic dinoflagellates. Shellfish may also be sold as a processed product which have been commercially heat-treated. These modern, regulated methods (e.g., raising internal shellfish meat temperature to 90 °C for 1.5 min) are effective at reducing both the bacterial and virus loading in contaminated shellfish.

Future Perspectives

The impact of contaminants on shellfish as a resource can be severe in terms of both the viability of the associated industries and the health of the human consumers. The highly nutritious and economic value of shellfish argues for the continuing improvement of its husbandry and the monitoring of contamination by pollutants, toxins, and microbes in order to prevent spoilage, waste, and ill health. Vigilance and awareness of existing and changing contamination threats are imperative. The selection of statutory tissue levels and contaminants to be monitored must be responsive to changing and improving information on toxicity, toxic mechanisms, production of new chemicals, occurrence of 'new' toxins, and increasing hazards from viruses. Automation, new analytical/biological techniques and the production of appropriate standards will increase the number and efficiency by which contaminants can be routinely measured. These may include biological measurements (i.e., biomarkers) of chemical exposure, such as inhibition of the shellfish cholinesterase (EC 3.1.1.8) activity as an indicator of contamination by organophosphate pesticides, and induction of 7-ethoxyresorufin *O*-deethylase (EROD) activity in cell systems as an indicator of PAHs. The development of new technology based on immunorecognition and molecular biological techniques is also likely to become increasingly important in the future. Efforts must be made to prevent contamination of this valuable resource from occurring and, in the case of toxins and pollutants, models should be produced to assist regulatory authorities to predict their accumulation and depuration in shellfish. A greater understanding of the biological processes in shellfish, once contaminated, is also required in order to develop efficient and safe treatment processes. Additionally, the standardization of statutory contaminant levels and analytical procedures between national and international bodies

will facilitate regulation and monitoring of the shellfish industry to the consumer's benefit.

Aquaculture of Commercially Important Molluscs and Crustaceans

P F Duncan, The University of the Sunshine Coast, Maroochydore DC, Queensland, Australia

Background

Aquaculture is the managed cultivation of aquatic organisms for food or profit and now contributes approximately 36% of total global fishery production. As capture fisheries have declined or plateaued over the last decade, aquaculture is the alternative supply for increasing aquatic product demand and has been growing at a rate of 10% per annum since 1990. Aquaculture products are diverse, with molluscs, crustaceans, finfish, and algae predominating. This section deals with molluscs and crustaceans whose global production volumes are considerable, for example, the pacific oyster (*Crassostrea gigas*) 3.6 million tonnes, carpet clams (*Ruditapes philippinarum*) 1.8 million tonnes and various penaeid prawn species (*Penaeus* spp.) 0.9 million tonnes. Production methods for mollusc and crustacean aquaculture vary from subsistence level, artisinal scale to high intensity managed systems. This article covers the key species, production quantities, methods and sources, and current and future issues.

General Characteristics of Aquaculture Species

The basic requirement for all aquaculture species include market acceptability, established production methods, availability of appropriate and economically viable feeds, and biological characteristics suitable for culture. These include high growth rates, captive reproduction or seed stock availability, tolerance to environmental variation (e.g., temperature), disease resistance, and behavioral characteristics amenable to high-density culture.

Molluscs

Molluscs, and particularly bivalves, are well suited to aquaculture. The principal groups include oysters (Family Ostreidae), mussels (Family Mytilidae), scallops (Family Pectinidae) and clams (various taxonomic groups), which constitute 87% of the 10.1 million tonnes (**Table 1** and *see* **Shellfish**: Commercially Important Molluscs). All of these bivalves have a high market demand and feature in the traditional diets of most human cultures. Recently, increasing affluence and health benefits associated with seafood

consumption have increased the demand for these products.

Mollusc Nutrition

Almost all cultivated molluscs are bivalves and therefore herbivorous or omnivorous filter feeders, consuming planktonic microalgae and organic detritus. Tridacnid (giant) clams are filter feeders with additional nutrition from symbiotic photosynthetic algae contained within their tissues. The main cultivated Gastropod group, abalone (Family Haliotidae) consists of herbivorous micro- or macroalgae grazers. All are therefore low trophic-level feeders and either obtain nutrients from their surrounding environment or have it supplied during hatchery-based culture periods. Although production of microalgae requires equipment and expertise, it is not technically difficult or expensive relative to the provision of the more complex crustacean and finfish diets. Abalone differ owing to their grazing habit. After the larval phase, juvenile abalone are provided with plates covered with bacterial and algal films. In growout systems, fresh macroalgae (e.g., *Laminaria japonica*) or recently developed artificial diets are supplied.

Production Methods (Bivalves)

Owing to the shared biological characteristics of bivalves, the basic principals of culture are similar.

Hatchery Egg production (fecundity) is high, typically several to tens of millions of eggs per spawning, e.g.,scallops and oysters, respectively. Spawning of mature adults occurs in the wild or under controlled hatchery conditions. Spawning may be induced by temperature change, emersion, exposure to UV-treated water or chemical inducers, e.g., serotonin. A planktonic larval phase follows hatching, which, in the wild, acts to disperse the juveniles from the parent stock. The larval phase, which may last from days to weeks, depending on the species, consists of several developmental stages. A ciliated trochophore larva occurs after hatching, and as shell secretion continues, the swimming larva becomes a veliger and finally, near metamorphosis to a non-swimming form, a pediveliger, which has an active foot for crawling. Under hatchery conditions, the larval phase occurs in large-volume tanks, typically between 5 and 40 m^3. For balanced nutrition, larvae are fed on mixed microalgal cultures, e.g., *Chaetoceros* spp., *Pavlova* spp., *Isochrysis* spp., and *Tetraselmis* spp.

Settlement At metamorphosis, larvae settle on to either natural or artificial substrates, and at this stage, collection of spat, or settled bivalves, occurs. In the wild, spat are collected on suspended or fixed material substrates, such as ropes (e.g., mussels), shell, stones, wooden structures (e.g., oysters), or mesh-filled suspended bags (e.g., scallops). Similar materials can be introduced into larval rearing tanks to collect spat in hatcheries.

Bivalve spat attach via proteinaceous byssal threads (e.g., mussels, scallops) or by direct cementation of the lower valve (oysters). Byssally attached spat may be easily removed manually or by mechanical stripping. Many scallop species stop byssal attachment around 15 mm and may be collected directly from settlement bags. Mussels attach throughout life. Oysters may be removed manually or retained on settlement material for further growout. All bivalves are size-graded and thinned before transfer to growout systems, producing a more consistent-sized product and a culture density to maximize growth and survival.

Growout Growout to commercial size typically takes from 12 months to 4 or 5 years (in the case of some temperate scallops and abalone). However, most cultured bivalves are an annual or 2-year crop, e.g., blue mussels (*Mytilus edulis*) 12–18 months, greenlip mussels (*Perna canaliculus*) 18 months, Manila clam (*Tapes philippinarum*) and the Australian rock oyster (*Saccostrea glomerata*) approximately 24 months.

As filter feeders, bivalves grow optimally in suspended culture system, which maximizes access to food. Consequently, most bivalves are grown in this way, although some exceptions, such as clams and some oysters, are grown on, or in, the bottom substrate.

Suspended culture systems are generally based on hanging a form of enclosure from a surface, or

subsurface floating structure. Alternatively, oysters may be held just off the bottom on a series of trays and frames. The most common systems employ a longline, a rope, up to 250 m or longer, supported by floats and anchored to the seabed at several points to ensure stability. From this main rope are hung vertical droppers that hold animals directly, e.g., byssally attached mussels, or, for ear-hung scallops, the shell is pierced and attached via nylon line.

More commonly, a cage or net holds animals. Lantern nets are a collapsible net stocking with multiple horizontal platforms holding shells, individual pearl nets have a rigid frame, and vertical panel nets contain numerous pockets in which individuals are placed. For lower-intensity operations, or for some particular species, such as the South-East Asian *Ruditapes* and *Meretrix* clam species, and the American hard clam (*Mercenaria mercenaria*), growout is based on seeding of suitable sandy/mud nearshore areas. The juveniles may be produced in the hatchery or collected in the wild.

Production Methods (Gastropods)

The main gastropods under cultivation are abalone, and, although production systems are still under development, their high value and declining wild harvest give them significant potential. Production now comes from China, Chile, South Africa, Australia, New Zealand, and the USA. The principal culture methods include a suspended lantern net system, using larger and more structurally complex cages than for bivalves, and raceway culture in long, narrow glass fiber or concrete tanks, within which flat plates are inclined to provide shelter and a surface for growth of algal feed. Tidal pond culture is also practiced in China, though less frequently than other methods.

Abalone culture relies on hatchery-produced juveniles, and broodstock are spawned using similar methods to bivalves. The larval development of abalone is similar, though shorter at 7 days or less, and nonfeeding, so provision of algae is not necessary. At settlement, the larvae metamorphose into the bottom-living form. This transitional phase from larvae to settled juveniles remains the period of highest mortality. At settlement, larvae are induced to attach to corrugated plastic or tiles, which have a surface growth of algal and bacterial cells. The juveniles feed on these films and, as growth continues, are transferred to nursery and growout systems. The options of open-water ranching or restocking depleted areas have also been attempted and have the advantage of no management input, but the disadvantage of little control over stock.

Current Issues and Future Prospects

As with most aquaculture, there is a tendency away from wild seed collection, for sustainability and supply reasons, but also for benefits from hatchery production. These include genetic selection (e.g., faster growth rates, disease resistance) and genetic manipulation to develop polyploid animals, i.e., three or four copies of genes, compared with two. Polyploid animals may be reproductively inactive, essential for translocation of non-native species to open-water systems, and often show increased somatic growth rates owing to reduced gonadal development. Continued vigilance in the control and detection of toxic algal blooms and monitoring for product safety will remain significant issues if public confidence in mollusc consumption is to be maintained.

Crustaceans

Most aquacultured crustaceans belong to the Class Malocostraca, Order decapoda, e.g. prawns/shrimps, crabs, lobsters, although brine and mysid shrimp (Classes Branchiopoda and Mysidacea) and copepods (Class Copepoda) are also produced in small quantities as live feeds for other aquaculture species, such as finfish. Decapod production is dominated by the marine penaeid prawns, with the black tiger prawn (*Penaeus monodon*) being the most widely cultivated crustacean worldwide. In 1999, production was 575 842 tonnes, predominantly from Asia, with an estimated value of US$3.65 billion. *P. vannemei* and *P. chinensis* are the aquacultured penaeids in the Americas and China, respectively, contributing 359 196 tonnes. Penaeids are grown worldwide (Table 2).

The giant river prawn (*Macrobrachium rosenbergii*), is the most widely cultured freshwater decapod crustacean, with production in 1999 of 102 124 tonnes, worth US$416 million. It has been introduced into many countries, including North and South America, Africa, Asia, and the Pacific Islands. China, Bangladesh, and Taiwan account for over 90% of production. Freshwater crayfish culture is widespread and based on six main species (in order of quantity): *Procambarus clarkii*, *Pacifastacus leniusculus*, *Astacus leptodactylus*, *Cherax destructor*, and *C. quadricarinatus*. Total production amounted to 21 171 tonnes in 1999, with US production of *P. clarkii* over 19 000 tonnes alone. Other minor species are produced locally (Table 3).

Crab aquaculture production is relatively small and dominated by the freshwater Chinese river crab (*Eriocheir sinensis*) at 171 955 tonnes in 1999.

Table 2 Principal aquacultured penaeids and main production sources

Species	*Sources*
Penaeus monodon Giant tiger prawn	Thailand, India, Vietnam, Indonesia, Philippines
Penaeus vannamei Whiteleg shrimp	Ecuador, Mexico, Brazil, Colombia
Penaeus merguiensis Banana prawn	Vietnam, Indonesia
Penaeus stylirostris Blue shrimp	Ecuador
Penaeus chinensis Fleshy prawn	China, Korea
Penaeus japonicus Kuruma prawn	Japan, China, Australia
Penaeus indicus Indian white prawn	India, South Africa

Table 3 Principal aquacultured freshwater crayfish and main production sources

Species	*Source*
Procambarus clarkii Red swamp crawfish	USA, Mexico, France (I)
Pacifastacus leniusculus Signal crayfish	France (I), Spain (I)
Astacus leptodactylus Danube crayfish	France
Astacus astacus Noble crayfish	France
Cherax destructor Yabby	Australia
Cherax quadricarinatus Redclaw crayfish	Australia, Argentina (I), Mexico (I)
Cherax tenuimanus Marron	Australia, South Africa (I)

I, introduced.

Additional species under small-scale culture, but with potential, include the mud crab (*Scylla serrata*) and various portunid swimming crabs.

Lobster culture worldwide is extremely small, 58 tonnes from four different *Panulirus* spp., a tropical/subtropical genus. The slow development of lobster culture is due to a relatively long larval cycle that is technically difficult to replicate in hatcheries.

Crustacean Nutrition

The larval stages of crustaceans vary in their nutritional requirements. Typically, under hatchery conditions, early stages feed on stored yolk, before moving to phytoplankton then zooplankton, e.g., *Artemia* (brine shrimp) larvae or rotifers. Crabs and lobsters may be carnivorous from hatching.

Penaeid prawns are fed a processed pelleted diet, consisting principally of marine fish meal, and additionally balanced for nutritional requirements. The food conversion ratio, i.e., the quantity of feed (kg) required to produce 1 kg of product is typically around 1.5–2.5:1, in semi-intensive/intensive penaeid production systems.

Feed is a major cost and may constitute around 30% of production costs. Uneaten feed is a major contributor to poor water quality, and nutrient-rich waste water contributes to external environmental impacts. Feed management is vital for successful aquaculture.

Freshwater crayfish are omnivores and obtain much of their nutritional requirements from the culture environment in the form of organic detritus. Grain-based pellets, or hay, are often added to ponds to provide additional feed and promote pond productivity by enhancing nutrient levels.

Crabs, such as *Scylla* spp., are also omnivores but with a tendency towards animal protein. Crab aquaculture is still relatively undeveloped, to the extent that no standard feed is produced or used. Most production is from South-east Asia, and much use is made of local feed sources such as trash fish and shrimp, squid, and plant meals such as soy. Pen culture in mangrove areas also provides additional nutrition in the form of fallen mangrove leaves.

A feeding behavioral characteristic of many crustaceans, and one that heavily influences production management, is cannibalism. Crustaceans are most vulnerable immediately after molting, a regular process essential for growth. When the old, hard exoskeleton is shed, the animal is soft until the new shell hardens and is vulnerable to predation, especially if stocking densities are high. Cannibalism is less common in penaeids and crayfish, where it is managed by appropriate stocking, size grading and feeding regimes, but more common in crabs and lobsters. Similar management strategies are again employed but are not wholly effective. As a consequence, crab production densities tend to be low, and separation into individual culture vessels has been employed for cultivated soft-shell crab and Hommarid lobsters. The associated cost of this makes it viable only for high-value products, or short-term culture of juveniles for restocking purposes.

Production Methods

Decapod crustaceans are characterized by complex and diverse larval cycles, which, as previously noted, have contributed to their relative ease and development of aquaculture. Differences in larval cycles also contribute to differences in production methodologies.

Hatchery The most commonly cultured crustaceans, the penaeid prawns, are unusual in having no maternal

care, and fertilized eggs are shed directly into the water. Most decapods retain the developing larvae, within the egg, on modified appendages beneath the abdomen, e.g., freshwater crayfish and crabs, and release larvae at a later developmental stage.

For aquaculture operations, mature broodstock are typically sourced from wild populations, although farm-reared broodstock are becoming more common as they enable reliable supply and the opportunity for genetic selection. Broodstock are maintained in specialized spawning tanks, under conditions of reduced density and high-quality nutrition favoring gonad development. Environmental variables such as temperature and light intensity are also controlled to reduce stress and promote gonad maturation. Mating involves transfer of a sperm package that the female retains until required, and fertilization typically occurs as the eggs are released. Spawning occurs under relatively predictable circumstances following ovary maturation, enabling hatcheries to harvest eggs as they are produced.

Penaeid eggs hatch within about 12 h into the nauplius phase, which persists through several stages, before progressing through major metamorphoses into protozoeal, mysis, and postlarval phases. The duration of the whole larval cycle, up to saleable postlarva (PL) is typically around 20–25 days. The larval phase, whether in open water or in the hatchery, is a free swimming period, becoming the more familiar bottom-living form after the postlarvae phase.

Growout Typically, the postlarval stage is transferred from the hatchery to grow out ponds, although some operations also have intermediate nursery growout or conduct growout in indoor, tank-based systems under high-density conditions. However, growout is generally earthen pond-based, ranging in size from less than 0.5 ha to over 10 ha, although larger ponds are typically harder to manage effectively. Ponds are generally 1–2 m in depth and are stocked with PL at between 1 (or less) to more than 100 PL m^{-2}, depending on the production type. For example, Australian stocking rates for *P. monodon* under relatively intensive 1-ha pond production is 30–40 PL m^{-2}.

During the production cycle of 3–4 months, water quality is managed through aeration, water exchange, and a phytoplankton bloom, which tends to stabilize physicochemical water parameters, e.g., oxygen, carbon dioxide, pH. Feed is provided three or four times per day, with consumption closely monitored and adjusted as necessary. Production from such intensive penaeid culture is typically 5–10 tonnes per hectare per crop but varies with species and management.

For other crustaceans, the principal differences in larval development and production methods are as follows.

Freshwater Crayfish Females hold 500–800 eggs under the abdomen that hatch as miniature crayfish after 2–10 weeks, depending on the temperature and species. Juveniles are collected and graded for size and gender, and stocked at around 5–15 m^{-2} (e.g.*C. quadricarinatus*), typically into earthen ponds. Production of this species seldom exceeds 1–1.5 tonnes per hectare per crop, owing to lower densities and lower intensity management.

Crabs The crab larval phase begins as a zoea, of which there are five, followed by megalopa then crab. Although still developmental, pond-based culture for *Scylla* spp. crabs appears feasible. Small-scale commercial trials have indicated that monosex cultures, low–medium stocking densities, and provision of shelters, to protect newly moulted individuals from cannibalism, provide improvements on current low-intensity culture systems. Polyculture with penaeids, as a secondary crop, also occurs.

Perhaps the greatest opportunity for value adding to crab culture is a soft-shell product. Soft-shell crabs have been a valuable secondary product of the eastern US blue crab (*Callinectes sapidus*) fishery for more than 100 years. The development of culture techniques, and the ability to control aspects of molting, should enable commercial scale production within a few years. Presently, it remains labor-intensive and confined largely to South-east Asia.

Macrobrachium spp. have even fewer distinct larval stages, with several zoea, followed by a pl, then adult. Unusually, the larvae require brackish water for development, although culture is in fresh water. This finding was critical in enabling the development of *Macrobrachium* aquaculture.

Harvest, Handling, and Marketing Harvesting is dependent, to some extent, on the market requirements. Fresh, frozen, or processed crustaceans are drain-harvested, with the complete crop being removed immediately. This applies to most penaeids, e.g., *P. monodon*, crabs (except soft-shell, which are harvested at molt), and *Macrobrachium* spp. Most live products, e.g., freshwater crayfish and some penaeids (*P. japonicus*), are harvested in small batches, typically using baited traps. Harvesting of crayfish may make use of their rheotactic behavior, in which the animals self-harvest, by following a water flow up a ramp into a collection chamber.

Crustaceans generally, and prawns in particular, are typically processed and sold as either frozen

(cooked, green, whole or tails and as block or individually quick frozen), fresh chilled, or as a prepared or preserved product, e.g., canned. Aquaculture tends to concentrate on the higher value fresh or frozen product, to offset production costs. Some species, notably, *Penaeus japonicus*, freshwater crayfish, and some crabs, e.g., *Scylla* spp., are marketed live for value-adding or spoilage reasons. Live kuruma prawn can attract prices of US$75 kg^{-1} during Japanese holiday periods, justifying the significant extra harvest, processing and packaging procedures necessary to ensure survival. By contrast, freshwater crayfish tend to be marketed live to ensure product quality at market.

Current Issues and Future Prospects

The principal issues affecting penaeid prawn culture worldwide are disease and environmental impacts. The possibility of rapid disease spread in high-intensity production systems is high, and mortality can be significant. At the individual farm level, and outwith epidemic-type outbreaks, producers manage disease risk through quarantine, exclusion of disease vectors, health testing of stock, and management of water quality and animal density.

On a larger scale, where entire regions are affected, disease impacts, particularly viruses, have been catastrophic. These outbreaks are harder to manage and appear to be due to overall pathogen levels in stock, both broodstock and pl, and the general status of the culture or external aquatic environment. For example, the passage of whitespot syndrome virus (WSSV) and yellowhead disease through Asia can be traced from the early and mid-1990s. Whitespot alone was considered to have resulted in losses of US$600 million in Thailand and in excess of US$2 billion throughout Asia in 1997.

Similarly, taura syndrome virus and WSSV affected central and South American production from around 1992.

These diseases occur naturally in the environment, but significant outbreaks occur when animals are produced under high-density, sub-optimal conditions. However, introductions of diseases, for example from Asia to the Americas, have occurred.

Disease is also a major concern for freshwater crayfish production given the impact that the fungus *Aphanomyces astaci*, or crayfish plague, had on wild and captive populations in Europe. As a result, several resistant species have been introduced from North America, now forming the basis of European production. The high susceptibility of native Australian crayfish to the fungus has ensured that strict quarantine procedures apply to importations of potential vectors.

The environmental impacts of aquaculture, and particularly prawn farming, have attracted significant debate in recent years. Largely as a result of unregulated development in Asia and South America, prawn aquaculture has been linked with coastal ecosystem destruction, disease outbreaks and introductions, and unsustainable practices. Consequently, significant environmental and planning regulations are now enforced in many countries new to aquaculture, such as Australia and the USA, and increasingly so in established aquaculture countries. Regulatory measures have included limiting farm sizes and number, control of discharge water quantity and quality, and the introduction of disease-management and health-monitoring strategies.

The reliance on fish meal and oil for the production of animal feeds is an issue facing aquaculture. Estimates suggest that fish meal use by aquaculture will increase from the 35% of total production (6.5 m tonnes in 2000) to 55% by 2010. In addition, fish-oil use by aquaculture was 55% of total production in 2000 and is expected to rise to 75% over the same period. Although mostly used in finfish diets, crustacean feeds also contain significant quantities, and usage should be reduced because of supply-reliability issues and energy-conversion inefficiency. Substitution with plant proteins, such as soy, may represent viable alternatives.

Crustacean aquaculture offers significant advantages over traditional wild-capture fisheries, which are generally in decline or static. The ability to manage most aspects of aquaculture means that, theoretically, the environmental impact can be minimized, which will be essential for public acceptance of aquaculture product and practices. Waste-nutrient management programs, including the use of plants and animals to lower nutrient concentrations (bioremediation), multiple water use for irrigation, and polyculture will reduce off-farm impacts and improve production efficiency. Improved feed management, reduced fish meal usage, and the application of biotechnology, in the form of genetic selection and management, should contribute further to cost reduction and efficiency improvement, enabling aquaculture to continue its growth.

Nutritional Features of Commercially Important Shellfish

Shellfish are high in protein and unsaturated oils, and low in cholesterol. They are particularly high in ω-3 and ω-6 polyunsaturated fatty acids, which are considered beneficial in reducing high blood pressure, coronary heart disease, arthritis, and some cancers. Consequently, nutritionists and medical authorities have promoted their consumption recently. Table 4

SHERRY

Contents

The Product and its Manufacture

J Bakker, Old Town, Swindon, UK

Introduction

Sherry is the name given to a number of related fortified wines made from grapes grown in Jérez de la Frontera, in the province Cádiz in the south of Spain. The hot climate of the region would be expected to produce white grapes which would turn into rather bland white table wines. However, as a result of a unique method of maturation, the wines have individuality and style. White wine made from Palomino fino, the main grape variety, is fairly neutral, lacking in acidity and without distinct varietal character. This neutral base forms an excellent background for the delicate flavors produced as a result of the maturation and blending procedures. There are three main types of sherry, made from the base wine by three different aging techniques. Sherry can be matured under flor (a layer of yeasts growing on top of the wine), developing into fino, or matured without flor yeasts, developing into oloroso. A combination of flor maturation followed by a period of aging without flor results in amontillado. The type of wine making has also been adopted by other wine-making regions, but the discussion below will focus on sherry as made in the demarcated area around Jérez de la Frontera. The quality and style of the product depends on many aspects, such as grapes, viticulture, soil, and climate. The combination of factors is unique for this region, making sherry stand apart from these wine styles made elsewhere. The factors affecting the production of grapes, the wine making, the maturation, and final blending of sherry are described.

Grape Production

Climate

The climate in Jérez de la Frontera is generally warm, with maximum temperatures in the summer of about 40 °C. Rainfall is moderate and can be variable, but is generally about 60 cm $year^{-1}$. Most rain falls between November and February, but rain during the vintage in September is not uncommon. It causes inconvenience in the harvesting of the grapes, but has no effect on the quality of the grapes. Winters are cool, and occasionally there is light frost, which tends to occur when the wines are dormant, and therefore it does not usually cause any damage. The predominant winds are southwesterly, and come from the sea and have a cooling effect while increasing the humidity. The southeasterly winds are unpopular and are believed to dry the crop due to a drop in humidity.

Soil

The best vineyards consist of rather chalky soils, known as Albariza, and are situated in the low hills west of Jérez de la Frontera. The main merit of the soil seems to be its associated physical properties: this soil has good water-absorbing properties and is able to retain water throughout the very dry summer. However, the soil goes to a paste-like consistency when wet, making vineyard access difficult. The soil dries to a powdery structure, without cracks. The light color of the soil reflects the heat, and also helps to prevent the soil from drying out. Irrigation of the soil is not allowed, but water availability has been improved by cutting square basins in vineyard slopes after the harvest. This reduces soil erosion by diminishing the water flow during the rains.

Vineyards

All vines are grafted on rootstocks to avoid infection by the root aphid *Phylloxera*. The rootstocks are hybrids between American and European vines; the American influence is to confer resistance to the root aphid *Phylloxera*. The rootstock should not influence the flavor of the grapes, but can affect the vigor of the vine. The very high calcium carbonate in the soil requires special selection of rootstock, since not all are able to grow in this type of soil. Young vines start to produce small quantities of grapes about 2 years after grafting. A good commercial yield is obtained after 6 years, and after 25 years the vineyard gives its maximum production of fine wines. After 30–40 years the yield drops, and when the vineyard is no

longer economically viable, the vines are pulled up, and replanted once the soil has recovered. Currently only four varieties are allowed to be planted (Palomino fino, Palomino de Jérez, Muscatel and Pedro Ximénez). Palomino Fino is the main variety grown; this variety yields a much higher crop than Palomino de Jérez, which is currently not planted. Only about 2% of the planting consists of Muscatel, grown on sandy soil, and a little can be used to flavor the wines. Pedro Ximénez is used to sweeten wines, and producers are allowed to buy this outside the demarcated area. Rows of vines are now planted well apart (2.3 m), so access with machinery for mechanical harvesting is possible, but these are not yet in commercial use. Vines are generally supported by stakes with two wires 50 cm and 100 cm above the ground respectively. The vines are pruned low with two short spurs 30–40 cm above the ground. However, low pruning systems cannot be harvested mechanically. Concerns exist regarding the possible damage to grapes due to mechanical harvesting, with negative effects on wine quality due to expected oxidation problems.

Harvest

The grapes must have a potential alcohol content of at least 10.5% by volume before they are allowed to be picked. Generally, 11.5% potential alcohol by volume and a fairly low acidity (2.75 g l^{-1} total titratable acidity as tartaric acid) are considered satisfactory. Optimum ripeness is defined as maximum juice and sugar yield, when the stems start to darken and the seeds separate easily from the pulp. Since only one grape variety is grown in a small area, the grapes tend to ripen all at the same time, and harvesting needs to take place over a short period. Generally the harvest starts in the first week of September, and takes no more than 3 weeks. Since damage to the grapes leads to the release of polyphenol oxidase, which will cause browning, care is taken to cause minimal damage to the grapes. Grape bunches are picked by hand, put in small containers, and transported to the winery. Crushing within 4 h of picking will help to prevent tissue damage and the resulting negative effect on wine quality. The style of wines depends on the growing season. In hot years, with drying easterly winds, the vintage is early, and more oloroso is produced, while in cooler, more humid years the vintage is late, and more fino is produced.

Wine Making

Pressing

A number of crushing and pressing methods are used. Whole bunches are conveyed from the hopper into a roller crusher by screw conveyor. The stalks help with the draining of the juice, and are not removed. Pressing takes place immediately after crushing, to avoid juice contact with the skins and the stems. Both batch and continuous presses are used, and although both produce good-quality juices, the latter is more economical to use due to the lower cost of labor. It is at this stage that the juice is separated for the intended wine style to be produced. The free-run juice and the early pressings containing no more than 200 mg l^{-1} total phenols (expressed as gallic acid equivalent) are separated from pressed fractions which contain up to 500 mg l^{-1} total phenols, while heavily pressed juices containing more than 850 mg l^{-1} total phenols are not suitable to make quality sherry. The solids in the must are reduced to about 1% before fermentation. Therefore the juices are usually cooled (12–15 °C) and allowed to settle for 8–18 h to allow the excess solids to deposit, before being centrifuged. Since the acidity of the grapes is often low due to the warm growing conditions, traditionally calcium sulfate was added to the grapes at crushing, precipitating calcium tartrate, and apparently liberating free tartaric acid. Nowadays, an addition of tartaric acid is made to juices with low acidity to reduce the pH to about 3.45. An addition of about 100 mg l^{-1} sulfur dioxide is made to the juice; the amount is varied according to the condition of the grapes. Sulfur dioxide has a number of functions and will be more effective at a lower pH value. It inhibits browning of the juice, thus protecting its pale yellow color. It also inhibits some of the undesirable microflora and favors the growth of fermenting yeasts.

Fermentation

Sherry used to be made by fermentation in oak casks, with a capacity of 500–600 l. Due to the small volume of fermentations, temperature control was not essential. Some wines are still made in small casks, to produce blending wines with a characteristic flavor, or to season new vats before being used for the maturation of sherry, or to satisfy the demand from the Scottish whisky industry for vats seasoned by sherry. Currently most wine is fermented in large open cylindrical fermentation tanks, normally with a capacity between 500 and 1000 hl. Temperature control in these large tanks is essential, and most wine is fermented at about 25 °C. Commercial yeast inocula are not normally used, but yeast starters are often prepared by harvesting some grapes just before the vintage and allowing the naturally present fermenting yeasts to develop. This will help to ensure that the fermentation vats will start to ferment after a short time. The initial fermentation is dominated by apiculate yeasts, such as *Kloeckera* and/or

Hanseniaspora, but at the later stage *Saccharomyces cerevisiae* (the main fermenting yeast) predominates. Most of the fermentation will have completed in about a fortnight, but the fermentation continues slowly until all the sugar has been depleted. (*See* **Beers**: Biochemistry of Fermentation; **Yeasts**.)

Classification

By November the fermentation is finished, and the dry wines have an alcoholic strength of 11–12% by volume. By that time, lactic acid bacteria naturally present in the wine have completed the malolactic fermentation, which converts the fairly sharp-tasting malic acid into the softer-tasting lactic acid and carbon dioxide. The wines are initially classified on the basis of their quality, and fortified accordingly. However, at this stage it cannot always be predicted which wines will spontaneously produce flor, which is a layer of yeasts on the top of the wine and allows the wine to develop the typical characteristics of fino sherry. Generally, wines from grapes grown on soils with high calcium carbonate content in vineyards with a cool westerly exposure are likely to develop flor. Therefore in cooler years more fino-style wines are produced. Fino is usually made from the lighter dry wines, made from mainly free run juice and some light pressings. This wine has a pale yellow color, low total phenols (200 mg l^{-1}), a good pungent aroma, a volatile acidity between 0.3 and 0.5 g l^{-1} (expressed as acetic acid), and is free of any bacterial spoilage. These wines usually develop flor spontaneously. Oloroso is usually made from slightly darker wines, with higher concentrations of total phenols (up to 475 mg l^{-1}), which are less likely to develop and support flor. These base wines have a more vinous and full-bodied nose and a higher volatile acidity (0.7–0.9 g l^{-1}). Wines made from the higher pressings and subsequently with higher total phenols (over 550 mg l^{-1}) are classed as raya wines, but also belong to the oloroso style.

Fortification

After fermentation the wines usually clarify spontaneously, and just after their classification they are racked of their lees (the deposit of yeast cells, and lactic acid bacteria from the malolactic fermentation). At that time the wines are fortified with fortifying spirit, which is almost neutral in character. The fortifying spirit makes little direct contribution to the sensory characteristics of the wine, but it will affect the maturation of the wine. It is prepared by distillation of wine and wine byproducts such as lees and pomace (the left-over solids after pressing the grapes). It has a strength of at least 95% by volume. The fortifying spirit is also produced outside the sherry region and is usually produced in the La Mancha area in central Spain. Fino and oloroso wines are fortified 15.5% alcohol by volume, while raya wines are fortified to 18.5% alcohol by volume. Before adding the fortifying spirit it is mixed with an equal quantity of wine, and allowed to settle for about 3 days. The half-strength spirit is used to fortify the wines, and causes much less clouding of the wine than the undiluted spirit would have done.

Maturation

Wines are stored in bodegas, which are tall, well-ventilated buildings, designed to stay relatively cool, especially from the ground level to about 2 m above the ground. The wines are matured in seasoned oak casks, with a capacity of 500–600 l, and organized to simplify fractional blending. The wine can either be matured under flor, and develop the typical fino character, or matured without flor to develop oloroso wines. The wines will be allowed to mature unblended for about a year, and a collection of wines all from one year is referred to as añada. Young fino wines are kept in vats only 80% full, providing a relatively large wine–air interface on which flor can develop, and may need frequent topping up to maintain the wine level. They are kept at a uniform temperature in the cooler part of the bodega, and the alcohol is maintained between 14.5 and 15.5% by volume. The casks are disturbed as little as possible, to prevent any damage to the layer of flor. Young oloroso wines, which did not develop much or any flor, are fortified to 18.5%, which inactivates any flor yeast and prevents flor from being formed. The casks are kept 95% full and their storage temperature is less critical than for the fino wines. Raya wines will be matured at higher temperature, often by storing them outside in the sun, and the losses in wine as a direct result of evaporation can be substantial. They will develop into dark wines and can be blended with olorosos, or develop into oloroso-style wine themselves. In order to obtain large quantities of wines with a consistent quality, an elaborate fractional blending system is used, referred to as a solera system. The sherries from the añada will gradually be fed into a solera system.

Flor

The wines with low total phenol contents suitable to become fino-style wines will spontaneously develop a wrinkly film of yeast on the surface of the wine. The composition of the wine determines whether a vigorous flor is able to develop. There is still a debate regarding the origin of the flor yeasts and their taxonomy, although a number of the flor yeasts belong to

the *Saccharomyces* species. However, the yeasts are physiologically different from the fermenting yeasts dominating during the fermentation. The fortification of the wines to 15.5% alcohol (by volume) inhibits film-forming acetic acid bacteria, which would spoil the wine. Development of flor depends on the temperature, and wines should be stored between 15 and 20 °C. The activity of the flor depends on the season; the flor is most active between February and June, and then declines until October time, when activity increases again. The flor protects the wine from the uptake of oxygen, and prevents oxidative browning, to which the wine is very susceptible. The growing flor will consume any dissolved oxygen and protects the wine from absorbing oxygen from the head space in the cask. This lack of oxygen in the wine prevents the oxidation of phenols, hence fino maintains a pale yellow color. The flor also results in numerous biochemical changes, which greatly influence the character of the wine. There is a slow decrease in volatile acidity, a reduction in glycerol, and a reduction in alcohol, which is used as a carbon source for flor yeast growth. There is a significant increase in acetaldehyde, normally to 260–360 mg l^{-1}. Acetaldehyde contributes to the typical, somewhat apple-like nose of fino wines. Possibly autolysis (spontaneous rupture of old yeast cells, thus releasing their contents) of the yeast cells which form part of the sediment on the bottom of the cask may well contribute to the typical flavor. The film should not be disturbed; however, the blending system is crucial to maintain the flor. Small volumes of wine have to be taken out frequently, and replaced with fresh wine from the añada to renew the oxygen supply and renew nutrients for flor maintenance. Specific wine transfer techniques have been established to transfer the wine with minimal disturbance of the flor in order to maintain the flor and to achieve the blending.

Maturation without Flor

In order to produce a good oloroso, the neutral base wine needs to contain sufficient oxidizable phenols, and is therefore not suitable for fino wines. Fortification to 18.5% alcohol by volume avoids the growth of any flor. Wines are stored in warmer parts of the bodega and under oxidative conditions. The dark golden color of the oloroso can be attributed to oxidation of phenols. Although the wines are fermented to dryness, the glycerol formed during alcoholic fermentation (7–9 g l^{-1}) gives a hint of sweetness on taste. A considerable loss in volume during maturation and usually an increase in alcoholic strength have been reported in oloroso wines, resulting in a higher concentration of nonvolatiles. The volatile acidity and the concentration of ethyl acetate increase also, in part as a concentration effect and in part formed by oxidation and esterification. The higher alcohol concentration, often combined with a higher storage temperature, may lead to increased extraction of phenols from the wood during maturation of olorosos, explaining the higher concentrations of phenols. Oloroso takes a long time to develop and requires about 7–8 years of maturation.

Maturation With and Without Flor

Some wines mature initially under flor, and develop all the characteristics of a fino. However, when the wines are not refreshed with additions of younger wines in the solera system, or when the wine has reached a considerable age, the wine may start to lose the flor. Further fortification to about 17.5% alcohol by volume is usual, to protect the wine against spoilage by acetic acid bacteria and prevent any further development of flor. The wine is matured in a second solera system in casks which are 95% full, and the aging processes change, with oxidation of the wine changing the pale yellow color to amber and dark gold, together with the development of a nutty, complex flavor typical for this wine, called amontillado. It takes at least 8 years to transform a fino into an amontillado, and genuine amontillados may have gone through three fino solera systems (which may be between 18 and 21 criaderas) and an amontillado solera system (5–8 criaderas).

Solera System

The solera system contains blends of wines of different ages and vintages, and aims to mature wines to achieve a steady supply of wine of comparable and consistent quality. The blending procedure to which the solera system is subjected is very complex. Some of the oldest wine is frequently taken out, and prepared for shipping. Wine from the previous stage is used to replace the oldest wine taken out, and the topping-up of older wines with younger wines continues throughout the solera system, until the youngest stage is reached; this is then replenished with a suitable añada wine. Wine in the last stage of the solera system is usually called solera, while the other wines at various stages of blending and maturity are referred to as criaderas. Since the fino wines are most variable in composition, they tend to need the largest number of blending stages or criaderas. Careful management of the system is needed to ensure that a continuous flow of wine with the required quality characteristics is obtained. The añada wine, with which the solera system is topped up, is carefully selected based on analysis and tasting, but there will be some differences in composition from year to year. A typical solera system with flor

maturation may consist of five criaderas and a solera, each stage comprising 100 casks. The maturity of the wine in the casks increases progressively, with wines in the fifth criadera being the youngest. Typically upto 25% of the wine in a fino solera is moved every 3 months. Less frequent withdrawals of larger volumes tends to hinder the development of the flor. However, in order to meet seasonal demand, the withdrawals need to be made at somewhat irregular intervals.

Coloring Wines

Special coloring wines are prepared, which also impart flavor to the blend. Grape must is concentrated by boiling down, which heavily caramelizes the must. This concentrate is added to fermenting must made of the last pressing of Palomino fino grapes, in a sufficient quantity to stop the fermentation at about 8% alcohol by volume. After about 3 months the wine is racked, fortified to 15–17% alcohol by volume, and matured in an oxidative solera system. A number of food caramels are also allowed for use in sherry. (*See* **Caramel**: Properties and Analysis.)

Sweetening Wines

A number of different sweetening wines are prepared. One is made from fortified free-run juice, which is racked, fined, and matured before use. A wine with more character (dulce pasa) is made by drying the bunches of Palomino grapes for 2 weeks in the sun. The juice is fortified to 17.5% alcohol by volume, and the wine is matured in a solera system, where it develops a deep golden color and raisin-like flavors. This dulce pasa is increasingly used, since it can be made more economically than the traditional sweetening wine made from Pedro Ximénez grapes. Pedro Ximénez wines have flavors which contribute to the character of blended sweet sherry. Pedro Ximénez grapes are dried in the sun for up to 20 days, until they have doubled in sweetness. During this process they develop a characteristic dark color and flavor, reminiscent of a rich Christmas cake. The grapes are pressed and the juice is fortified to about 9% alcohol by volume. Pressing these very dry grapes is difficult, and occasionally fresh grapes are added to aid the pressing. The Pedro Ximénez wines are usually matured in an oxidative solera system. Pedro Ximénez wine can be imported from the Montilla district, where the hotter climate lends itself better to the production of the grapes. Rectified concentrated grape musts, which are almost colorless and odorless, are also widely used to obtain pale cream sherries, by sweetening fino wines without altering their delicate flavor.

Volatile Compounds

The volatile compounds in sherry can be derived from the grapes, formed during the fermentation or maturation. It is during this last stage, especially when maturation under flor is used, that the aroma typical for the style of sherry is formed, and hence forms the most important stage for the formation of volatiles typical for sherry. Sotolon (4,5-dimethyl-3-hydroxy-2(^{5}H)-furanone) has been identified in sherry matured under flor only; it is present in sufficient concentrations to lend its nutty odor to the characteristic aroma of flor sherry. Solerone (4-hydroxy-5-ketohexanoic acid lactone) has been reported to contribute an aroma of premium-quality Pinot noir wine. Oak lactone (*trans*-3-methyl-4-hydroxyoctanoate acid lactone) extracted during maturation in oak gives a distinct woody note to sherry, and has also been found in other alcoholic beverages matured in oak. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Commercial Styles

The end products have very complex sensory characteristics. Sherry is fermented to dryness, and fino sherries are usually marketed dry. Finer and older wines can also be sold dry, but most of the wines are sold sweetened. Fino has a pale straw color, and is very dry but without acidity. Its bouquet is delicate yet pungent and the alcoholic strength usually lies between 15.5 and 17% by volume. Manzanilla, produced in the coastal town Sanlúcar de Barrameda, is a regional variation of the fino style, which has a delicate and highly individual aroma. It is very dry, with a clean and slightly bitter aftertaste, being slightly less full-bodied than fino. Manzanilla has a pale straw color much like a fino, and an alcoholic strength between 15.5 and 16.5% by volume. Amontillado is very dry and clean, with a pungent aroma reminiscent of fino but nuttier and fuller-bodied. The color is amber, and becomes darker with increasing age. The alcoholic strength is 17–18% by volume. Oloroso has a strong bouquet, being less pungent than fino or amontillado, but with more body, sometimes referred to as fatness. The sherries are dry, but have a sweet aftertaste. Oloroso has the darkest color, best described as dark gold, and its color intensity increases with age. Wines marketed as medium dry, medium, cream, or pale cream sherry are usually based on oloroso wine, with an addition of fino to lighten the color and flavor and a small amount of amontillado. The choice of sweetening and coloring material depends on the required end product. Pedro Ximénez is often added to round the flavor of the blend.

Final Processing

Most blends are prepared a few months before shipping, which allows the final blend to be stabilized. Especially since such different wines are blended, it is important to ascertain that no instabilities occur, and stabilization and fining techniques are commonly used to ensure a clear and stable wine in the bottle.

Background

Most sherry wines are produced in two southern regions of Spain, Jerez and Montilla-Moriles, where the grape varieties Palomino Fino and Pedro Ximenez, respectively, are preferentially grown. These grapes are used to obtain so-called fino, oloroso, and amontillado wines, which are three typical types of these wines. These are obtained starting from the same wine base but subjected to different aging conditions. Fino wines have a very light yellow color and an almond flavor with pungent notes. Like some Italian- and French-like sherry wines, they are obtained by biological aging under the action of flor yeasts growing on the wine surface. This aging procedure involves a complex series of wine transfers that leads to a mixture of different vintages in the same cask. Oloroso wines are obtained by oxidative aging, after fortification with ethanol, in order to prevent growth of flor yeasts. They have a very dark color that results from the oxidation of phenolic compounds, and a flavor with distinct notes of oak and walnut. Amontillado wines are produced by using the previous two aging procedures in succession (biological aging first and then oxidative aging). These wines are highly desirable, have a color in between those of fine and oloroso wines, but closer to the latter, and have a flavor with hazelnut notes that is the most complex among the three.

Musts and Wines. General Composition

The prevailing climate of the sherry-making regions of southern Spain determines to a great extent the general composition of the musts and wines they produce, and also some winemaking techniques. In summer, temperatures above 35 °C, or even above 40 °C in areas far from the Mediterranean coast, are usual during the grape-ripening period. A milder climate can be found in zones such as Sanlucar de Barrameda, on the coast, which produces a wine similar to the fino type (called Manzanilla) but with distinctive sensorial characteristics. Under these climatic conditions, grapes accumulate large amounts of reducing sugars, resulting in concentrations above $200\,g\,l^{-1}$ in the must (specific gravity $1.094\,g\,ml^{-1}$) or even more than $270\,g\,l^{-1}$ (specific gravity $1.113\,g\,ml^{-1}$) in warmer areas. As a result, the base wines obtained after alcoholic fermentation have a high ethanol content and are classified according to their suitability for producing the different types of sherry wines. Wines to be aged biologically are fortified up to 15% v/v ethanol content, if necessary, whereas those destined for the production of oloroso wines are fortified to 17–18% v/v.

The climatic conditions also result in musts with a low acidity (3–4.5 $g\,l^{-1}$ as tartaric acid) that is usually increased by addition of tartaric acid, although winemakers in some areas continue to use gypsum for this purpose. The musts are also supplied with SO_2 at concentrations of around $100\,mg\,l^{-1}$.

The special features of the process by which flor yeasts produce fino wine have aroused much interest among researchers. The yeast types most frequently used for this purpose are *Saccharomyces cerevisiae* varieties *beticus*, *cheresiensis*, and *montuliensis* in the Jerez region, and races *capensis* and *bayanus* in

the Montilla-Moriles region. These yeasts develop an aerobic metabolism, consuming ethanol (1–1.5% v/v) and glycerol (decreasing from 7–8 g to less than $0.5\,g\,l^{-1}$), in addition to some acids such as acetic (the concentration varying as the volatile acidity falls from 0.4 to $0.04\,g\,l^{-1}$) and lactic acid, which are converted to acetaldehyde and other byproducts. Quantitatively, changes during the biological aging process depend on the distribution of the yeast population and on the stability of the film they form; this results in some differences among fino wines produced in different zones. However, the development of flor yeasts is essentially influenced by the ethanol content in the wine (around 15% v/v) and the temperature during aging (below 22.5 °C). Any deviation from these conditions (e.g., higher temperatures) deteriorates the flor film and retards the aging process.

In the absence of flor yeasts, oloroso wines consume no glycerol, which remains at levels of 6.5–$8\,g\,l^{-1}$ during oxidative aging. However, their volatile acidity increases during aging (up to $0.68\,g\,l^{-1}$ as acetic acid), because of the oxidation of ethanol and acetaldehyde. Amontillado wines exhibit an intermediate behavior between those of the previous two as a result of the mixed aging procedure used.

The three types of quality sherry wines require very long aging times: at least 4–5 years for fino wines and more than 10 years for amontillado wines. In order to shorten the process, some authors recommend the use of various procedures to accelerate biological aging of the wine. Such procedures are based on an increase in the population densities of flor yeasts, which can be obtained by using containers with an increased surface-to-volume ratio or controlled aerations of the wine during aging. Oloroso wines have also been subjected to accelerated aging procedures involving higher temperatures or maceration with oak wood shavings.

Volatile Compounds and Flavor

Musts and Wines

Palomino Fino and Pedro Ximenez, the two grape varieties preferentially used to obtain sherry wines in the Jerez and Montilla-Moriles regions, are occasionally aromatic with an overall free terpene content in the musts of $0.27–0.37\,mg\,l^{-1}$ for the latter variety. In order to improve the sensory profile of the must, cold maceration with grape skin at 10 °C for 24 h has been found to increase the terpene content by a factor of 4.5, but these results probably do not offset the cost of the operations involved.

Traditionally, the musts are fermented with wild yeasts, the population consisting primarily of various *Saccharomyces cerevisiae* varieties. The content in higher alcohols (mainly isobutanol, isoamyl alcohols, and phenethyl alcohol) at the end of fermentation ranges from 207 to $405\,mg\,l^{-1}$. Compared with other types of white wines, the ester fraction is less concentrated, and so the wine has a stronger sensory profile prior to aging. This is also a result of a high fermentation temperature (frequently above 25 °C), which favors the formation of higher alcohols. Pure and mixed cultures of the yeasts have been tested with a view to softening the sensory profile of the base wine. In this sense, some authors have studied the enzymatic activity of acetyl transferase and esterase in pure cultures of the fermentation yeasts in order to determine the contribution of specific yeast varieties involved in the alcoholic fermentation process to the flavor of the base wine. However, the need to ferment large amounts of sugars, as a result of a high tolerance to ethanol, makes replacing the wild yeasts very difficult.

Wine Aging

Most of the analytical and sensory differences among sherry wines result from differences in the aging procedures to which the base wines are subjected. On the one hand, the biological aging process that yields fino wine is affected by flor yeasts, which use some compounds in the base wine as carbon sources, thereby altering its composition to a variable extent depending on the duration of the process. On the other hand, the oxidative aging process that produces oloroso wine allows for no biological transformation, so the changes involved should be preferentially ascribed to evaporation, chemical oxidation, and extraction from constituents of the wood casks. Because amontillado wine is obtained by a combination of both types of aging procedure, its analytical properties are inherited to a variable extent, even though its sensory profile is unique to this wine type.

More than 300 different compounds have been identified in sherry wine-type fino. Only a small fraction, however, can be specific to them, with most of the analytical differences observed being ascribed to changes in the concentrations of compounds also present in other types of white wines. At this point, the contents of acetaldehyde and derivatives such as 1,1-diethoxyethane and acetoin are noteworthy. The concentrations of these compounds increase during biological aging as a result of the aerobic metabolism of flor yeasts consuming the ethanol of the wine. Their concentrations in commercially available

wines are in the range of 400–500 mg l^{-1} for acetaldehyde, 40–75 mg l^{-1} for 1,1-diethoxyethane, and 8–19 mg l^{-1} for acetoin, depending on the duration of the aging process. Acetaldehyde is thus used as a measure of wine maturity, being largely responsible for the typical pungent flavor of fino wines. Some lactones and their oxygen derivatives also impart different notes to the flavor of wines obtained by biological aging. In fact, despite their low concentrations, some lactones such as sotolone (0.036–0.143 mg l^{-1}), γ-butyrolactone (27–54 mg l^{-1}) and pantolactone (3–8.5 mg l^{-1}) impart a caramel-like odor to these wines and increase their concentration during biological aging. In particular, the former is considered an important contributor to the flavor of fino wines, introducing nut-curry notes. One other distinctive feature of the biological aging process is the decrease in volatile acidity resulting largely from the consumption of acetic acid by flor yeasts, which reduces its typical odor and flavor.

Changes in other aroma compounds are not as clear as those in the aforementioned compounds. Although some authors have reported a decrease in the contents of major higher alcohols, others have found slightly increased or constant contents. These contradictory results are probably a consequence of differences in the experimental conditions used, particularly as regards the distribution of the flor yeast population and the aging temperature. In relation to the ester, changes during aging can also be observed giving contradictory results, although increased contents in ethyl lactate and diethyl succinate, and decreased contents in ethyl, isoamyl, isobutyl, and phenethyl acetates, appear to be the norm. Some authors have found that flor yeasts synthesize small amounts of terpenes such as linalool, α-terpineol and z-nerolidol.

The aroma fraction of oloroso and amontillado wines is mainly influenced by a concentrating effect during their lengthy aging; as a result, the contents in major higher alcohols and esters increase with increasing wine age. Also, chemical esterification is favored by a high ethanol content in the wine, so the concentrations of esters such as ethyl acetate, ethyl lactate, and diethyl succinate increase during aging.

Phenolic Compounds and Color

Color is the most obvious distinctive feature of sherry wines for the consumer. Thus, fino wines, which are obtained by biological aging, exhibit a very pale yellow color, whereas amontillado and, especially, oloroso wines, have a dark color.

Musts and Wines

More than 20 phenolic compounds in monomeric and simple oligomeric forms have been identified in base wines prior to aging. Although their concentrations depend markedly on the particular climatic conditions of each year and on the grape ripening status, flavan-3-ol derivatives invariably exhibit the highest concentrations of all (100–120 mg l^{-1}, most of which is contributed by catechin and epicatechin). The concentrations of hydroxycinnamic acids range from 1 to 5 mg l^{-1}, and those of their esters from 45 to 75 mg l^{-1}, in which *t*-caftaric acid is the best represented. Gallic acid exhibits the highest contents among hydroxybenzoic acids (the overall concentration ranging from 15 to 25 mg l^{-1}). Flavonols and coumarins are also present, at concentrations of 10–20 and about 50 mg l^{-1}, respectively.

Fino wine is a delicate product and it tends to get browner after bottling. This alters not only its color but also its sensory properties. Thus, fresh fino wine has an absorbance at 420 nm of 0.100–0.120 A.U. At 0.170–180 A.U., it is normally discarded. Depending on the particular production technique used, this absorbance threshold is reached within about a year after bottling. This has promoted the development of improved production techniques to balance supply and demand better in order to avoid overstocking. Because brown pigments in the wine are formed by oxidation of phenolic compounds, winemaking techniques such as must hyperoxidation have been used to decrease the contents in these compounds and increase the resistance of the resulting wines to browning. However, one should bear in mind the complexity of the aging process, by which a given cask contains mixed wines from different vintages. Reliable conclusions on this point can only be reached from a 'solera and criadera system' exclusively using hyperoxidized wines from various vintages, requiring a long-term research. Also in order to improve the resistance to browning, traditional practices such as the addition of SO_2 to grapes during the harvest period have been suppressed, because these result in an increased degree of extraction of phenolic compounds from the grape skin.

Wine Aging

Because of their differential aging processes, the three types of sherry wine differ in their contents in phenolic compounds. Thus, flavan-3-ol derivatives, predominate in fino wines (with concentrations of 60–80 mg l^{-1}), followed by hydroxycinnamic esters (15–25 mg l^{-1}), hydroxybenzoic acids (15–30 mg l^{-1}), flavonols (5–10 mg l^{-1}), and hydroxycinnamic acids

(1.5–2.5 mg l^{-1}). The contents in vanillic and ferulic acid, catechin, epicatechin, and procyanidin B2 and B4, have been found to decrease during biological aging, whereas those of syringic acid and procyanidin B1 appear to increase during the process. It should be noted that this type of wine does not brown under flor yeasts, thus preserving its pale color with slight variations for years. This has traditionally been ascribed to the flor yeasts that grow on its surface, making the diffusion of atmospheric oxygen across the flor film difficult and thus protecting wine from this. In addition, flor yeasts consume dissolved oxygen in the wine to maintain their aerobic metabolism, thereby preventing the oxidation of phenolic compounds. However, the only contribution of this protective effect to color stability in the wine subjected to biological aging has been partly questioned by some authors who believe that the wine is partially oxygenated over the years as a result of two actions. On the one hand, older wine is mixed with younger wine three or four times a year, which introduces some oxygen during the transfer operations. On the other hand, the flor film fails in some seasons because of its strong dependence on temperature. The lack of the flor film facilitates the access to oxygen. In fact, the absorbance values at 420 nm measured at the end of summer are normally higher than those recorded in late spring and autumn. Thereby, in addition to the aforementioned protective effect of the flor film, some authors think that yeasts may be able to retain brown polymers formed by oxidation of phenols.

Oloroso wines are considerably darker than fino wines as a result of their oxidative aging, showing absorbance values at 420 nm, ranging from 1.30 to 1.60 A.U.

The phenolic contents of these wines exceed those in fino wines, with levels of 35–45 mg l^{-1} for hydroxybenzoic acids, 5–20 mg l^{-1} for hydroxycinnamic acids, 20–25 mg l^{-1} for hydroxycinnamic esters, and 100–130 mg l^{-1} for flavanes. Oxidative aging usually takes place at a higher temperature than does biological aging, which results in volume losses in the aging wine, with a subsequent concentrating effect on the soluble compounds.

Amontillado wines show intermediate levels in between the previous two because of the combined aging process used in their production, so their corrected absorbances at 420 nm range from 0.950 to 1.100 A.U. However, in general, their phenol contents are similar to those of oloroso wines, with values of 45–75 mg l^{-1} for hydroxybenzoic acids, 5–15 mg l^{-1} for hydroxycinnamic acids, and 125–160 mg l^{-1} for flavanes.

Other Compounds

Amino acids are important compounds because they are used by the flor yeast as a nitrogen source. L-Proline is the predominant compound of this fraction in the wine base, accounting for about 60% of total nitrogen, with a concentration of 4.5–7.5 mmol l^{-1}. Other abundant amino acids include L-tryptophan (8%), L-phenylalanine (7.5%), L-cysteine (6%), and L-threonine (3%). L-Proline is the most heavily used nitrogen-containing compound and the principal source of nitrogen for the flor yeast, and so this compound is consumed most during biological aging. In the deficiency of L-proline, flor yeasts use other amino acids such as L-glutamic acid, L-alanine, L-arginine, and L-tryptophan. Oloroso wines show slightly increased amounts of amino acids as a result of the aforementioned effect of volume concentration during oxidative aging.

The most abundant polyalcohols quantified in sherry wines are inositol and erythrol, with variable levels depending on the method of wine-making. No significant changes have been observed during aging, because the initial variability of the wine base is greater than the contribution of the maturation processes. However, there is a general trend towards higher contents in these compounds for the oloroso and amontillado wines.

SHIGELLA

K A Lampel, US Food and Drug Administration, Laurel, MD, USA
R Sandlin, Towson University, Towson, MD, USA

Characteristics

Shigella spp. are the causative agents of shigellosis (bacillary dysentery). These organisms are endemic worldwide, resulting in high morbidity and mortality in third world countries. *Shigella* are small, slender, Gram-negative rod-shaped bacteria that are nonmotile and nonspore-forming. The genus is a member of the family *Enterobacteriaceae* and is closely related to *Escherichia coli*. *Shigella* spp. are divided into four major groups based on biochemical reactions and the O antigen type (**Table 1**). The four species are *S. dysenteriae* (A), *S. flexneri* (B), *S. boydii* (C), and *S. sonnei* (D), and are further subdivided into serotypes (except *S. sonnei*), based on differences in the O antigen. The severity of disease varies, depending on the particular species, from mild diarrhea to bacillary dysentery (stools containing blood, mucous, and inflammatory cells). *S. sonnei* produces the mildest form of disease, whereas *S. dysenteriae* produces the most severe. *S. flexneri* and *S. boydii* cause intermediate forms of the disease. Additionally, the geographic distribution and epidemiology produced by the different species are different (**Table 1**). For example, *S. dysenteriae* is responsible for epidemics of the disease, whereas shigellosis outbreaks in industrialized nations are usually caused by *S. sonnei*. In addition, *S. flexneri* is more frequently found in developing countries, and *S. boydii* is usually limited to the Indian subcontinent.

Shigella spp. are facultative anaerobes with relatively simple nutritional requirements. Typically, *Shigella* spp. are lysine decarboxylase negative and lactose nonfermenting (except for a slow reaction with *S. sonnei*), characteristics that separate them from closely related commensal *E. coli*. However, enteroinvasive *E. coli* (EIEC) share many properties with shigellae producing clinical symptoms indistinguishable from shigellosis. Moreover, EIEC has similar biochemical traits (e.g., nonmotile, lactose negative) and possess immunologically cross-reactive somatic antigens with several *Shigella* serotypes. Thus, similarities between EIEC and *Shigella* can complicate the accurate diagnosis of shigellosis.

The World Health Organization has estimated that worldwide, diarrheal diseases account for approximately 5 million deaths each year among children with nearly 10% caused by *Shigella* spp. *S. dysenteriae* type I is the only *Shigella* spp. known to produce shiga toxins, a common etiological agent of epidemic dysentery. *S. dysenteriae* has also been shown to persist in the poorest regions of the world, notably in parts of Africa, Central America and Asia, where malnutrition is common. In the USA, of the estimated 76 million people that contract foodborne illness

Table 1 Characteristics of *Shigella* spp.

Species	*Serogroup*	*Serotypes*	*Geographic distribution*	*Distinguishing characteristics*
S. dysenteriae	A	15	Indian subcontinent, Africa, Asia, Central America	Produce Shiga toxin, causes most severe dysentery, high mortality rate if untreated
S. flexneri	B	6	Most common isolate in developing countries	Less severe dysentery
S. boydii	C	19	Indian subcontinent, rarely isolated in developed countries	Biochemically identical to *S. flexneri*, distinguished by serology
S. sonnei	D	1[a]	Most common isolate in developed countries	Mildest form of shigellosis

[a]Forms I (smooth) and II (rough) are serotypically distinguishable.

annually, an estimated 300 000 cases are caused by *Shigella*. In a recent report from the US Center for Disease Control and Prevention, Emerging Infections Program Foodborne Diseases Active Surveillance Network (FoodNet; http://www.cdc.gov/foodnet), 2324 of the 12 631 confirmed cases of known foodborne illnesses reported (only nine diseases were followed), were caused by *Shigella* spp., which ranked *Shigella* as the third leading cause of diseases of bacterial origin. As expected, most of the reported *Shigella* cases were caused by *S. sonnei* (85%) and the remainder by *S. flexneri* (15%).

Shigella is principally a human disease, although outbreaks have been described in subhuman primates. One distinctive characteristic of the disease is its high communicability attributed to the low infectious dose required to cause illness. For example, ingestion of fewer than 100 organisms has been shown to result in clinical disease in volunteer studies. Thus, the low infectious dose is the primary reason cited for ease of *Shigella* spread in populations living under crowded and unsanitary conditions. The incubation period for *Shigella* is 1–7 days, with the onset of symptoms usually appearing in 3 days. The clinical presentation of shigellosis can vary from mild diarrhea to severe dysentery with symptoms including fever, cramps, and frequent bowel movements containing blood, pus, and mucus. Infections are associated with mucosal ulceration, rectal bleeding, and dehydration. Polymorphonuclear leukocytes in the stools is one characteristic feature of the inflammatory nature of dysentery. Mortality has been reported as high as 10–15% in some strains, but the infection is usually self-limiting and resolves without treatment within 1–2 weeks. Complications of shigellosis include reactive arthritis, and hemolytic uremic syndrome.

Asymptomatic carriers of shigellae may be partially responsible for the perpetuation of shigellosis outbreaks. Owing to socioeconomic factors that affect both living and sanitary conditions, adults, particularly those that have resided in one area for a long period of time, are thought to exacerbate the spread and maintenance of this pathogen. Furthermore, shigellosis appears to have the highest incidence in summer months, presumably because of increased contact of asymptomatic carriers with uninfected populations. Therefore, asymptomatic carriers may play a significant role in incubating this pathogen through the colder months.

Unlike most pathogens, *Shigella* spp. are not indigenous to any food. Most cases of illness are a result of close contact with infected individuals, with transmission most frequently occurring via the fecal-to-oral route. The organism is commonly found in water contaminated with human feces and can be spread via food, flies, fingers, and feces. In highly endemic areas, shigellosis is associated with children who frequently lack adequate personal hygiene habits. Children, ages 1–6, are most susceptible to infection by *Shigella* spp. The carrier state usually lasts 1–4 weeks, but long-term carriers have been described and are thought to be reservoirs of infection. It has been estimated that during the acute phase of the disease, 10^3–10^9 colony-forming units (CFU) per gram of stool are shed, whereas in convalescing patients, 10^2–10^3 CFU per gram of stool are shed. To control the spread of shigellae, infected individuals are monitored for the presence of the organism in stool until cleared.

Virulence Factors

Members of the genus *Shigella* are facultative intracellular pathogens. Following ingestion, the organisms are capable of surviving the acidic barrier of the stomach in order to reach the large intestine. Shigellosis is caused when virulent *Shigella* organisms induce their uptake into M cells and epithelial cells of the large intestine. After invasion, the bacteria are released from the phagosome into the cytoplasm and multiply intracellularly utilizing the host cell cytoplasm for nutrients. The infection is perpetuated by the spread of the organism to neighboring epithelial cells through projections from the originally infected cell. This cycle results in damage and destruction of the intestinal epithelial cell, resulting in

dysentery. *Shigella* spp. are also able to induce apoptosis or programmed cell death of macrophages. Virulence factors that contribute to these processes are both chromosomally encoded and present on a large 220-kb virulence plasmid (Table 2). The nucleotide sequence of the entire plasmid was recently reported (GenBank Accession No. AL391753). The virulence plasmid is essential for many virulence phenotypes, and in the absence of the plasmid, the organism is avirulent. A related virulence plasmid is also present in EIEC and is essential for this organism's ability to cause disease. The genetic factors involved in the virulence phenotype can be loosely grouped into genes that encode proteins involved in epithelial cell uptake, genes that encode proteins involved in the intercellular spreading phenotype, and genes involved in the regulation of these processes.

The expression of the virulence genes is regulated by a variety of factors, most notably temperature. Temperature is an important factor in the regulation of virulence genes in bacterial pathogens, including *Salmonella typhimurium, Bordetella pertussis, Yersinia* spp., and *Listeria monocytogenes*, as well as *Shigella*. Virulence gene expression in *Shigella* is repressed at 30 °C and induced at 37 °C by the action of three gene products. The virulence plasmid encoded VirF is a transcriptional activator that is a member of the AraC family of activators. VirF functions to upregulate expression of VirB. VirB is encoded on the virulence plasmid and is thought to induce the expression of a variety of essential virulence genes including the *ipa*, *spa*, and *mxi* genes. VirR (H-NS) is a chromosomally encoded global negative regulator that is involved in a variety of regulatory pathways. H-NS acts to block VirF activity at the *VirB* promoter. The exact mechanism is unknown, but several factors, including temperature, affect regulation at both the transcriptional and translational level. Mutations in H-NS result in an absence of temperature regulation and a constitutive virulent phenotype, whereas mutations in *VirF* or *VirB* result in an inability to produce the Ipa, Spa, and Mxi proteins and an avirulent phenotype.

Upon contact with a target epithelial cell, *Shigella* spp. are induced to secrete up to 25 proteins, including the Ipa B, C, D, and A proteins. Some of these proteins, including IpaC and IpaA, are translocated directly into the host cell cytoplasm. The Ipa proteins

Table 2 Virulence loci of *Shigella*

Locus	*Protein*	*Role in virulence*
Plasmid-encoded genes		
ipaA	70-kDa protein	Invasion; associates with vinculin
ipaB	62-kDa protein	Invasion; lysis of vacuole; induction of apoptosis
ipaC	43-kDa protein	Invasion; induces formation of filopodia and lamellipodial extensions
ipaD	38-kDa protein complex with IpaB	Invasion; forms antisecretion
ipgC	17-kDa protein	Chaperon for IpaB and IpaC
ipgD	59.8-kDa protein	Modulates invasion of bacteria into epithelial cells
ipaH	Family of proteins	Present in plasmid and chromosome
mxi/spa	20 proteins	Secretion of Ipa and other virulence proteins
icsA (virG)	120-kDa protein	Actin polymerization for intracellular motility and intercellular spread
sen	ShET2	Enterotoxin
virB	Transcriptional activator	Temperature regulation of virulence genes
virF	Transcriptional activator	Temperature regulation of virulence genes
osp	Outer *Shigella* proteins	Encoded proteins secreted by type III secretory system
Chromosomal-encoded virulence-associated genes		
virR (hns)	Histone-like protein	Repressor of virulence gene expression
rfa; rfb	Enzymes for LPS core and O-antigen biosynthesis	Unipolar localization of IcsA
stx[a]	Shiga toxin	Destruction of vascular tissue
vacB (rnr)	Exoribonuclease RnaseR	Posttranscriptional regulation of virulence gene expression
cpxR	Response regulator of *virF*	CpxA–CpxR two-component system
luc	Aerobactin and receptor	Acquisition of iron in the host
SodB	Superoxide dismutase	Defense against oxygen-dependent killing in host
set [b]	ShET1	Enterotoxin
dsbA	Disulfide bond catalyst	Facilitates secretion of IpaB and IpaC
sigA	139.6-kDa exported cytopathic protease	Intestinal fluid accumulation

[a]The *stx* locus and production of Shiga toxin are observed only in *S. dysenteriae* 1.
[b]The *set* locus and production of ShET1 is observed almost exclusively in *S. flexneri*.

are encoded on the virulence plasmid by the *ipaBCDA* operon and are recognized by convalescent patient sera. Ipa B, C, and D are essential for invasion and are thought to be involved in signaling the uptake of the bacteria by the host cell. Additionally, IpaB is hypothesized to be responsible for release from the phagocytic uptake vacuole and for induction of apoptosis in infected macrophages. The Ipas are secreted by a dedicated virulence protein secretion apparatus known as a Type III secretory system. Related secretion systems have been described for a variety of plant and animal pathogens and share both functional and sequence homologs. The group of proteins that compose this secretion apparatus are encoded by the *mxi/spa* loci present on the virulence plasmid. These proteins have been shown to comprise a needle complex with both cytoplasmic and transmembrane domains that span the inner and outer membrane of the bacterial cell to allow the release of the Ipa proteins as well as other secreted proteins. Mutation in any of these structural components of the secretory apparatus results in a loss of virulence, owing to the inability to secrete the Ipa proteins. The *icsA* (*virG*) locus on the virulence plasmid is another essential virulence factor. This outer membrane protein is asymmetrically localized at the old pole of the bacterial cell, where it catalyzes the polymerization of host cell actin. This results in the formation of an actin tail at one end of the bacterium that propels the organism through the host cell and allows the bacterium to enter the neighboring cell without leaving the initially infected host cell and encountering the exterior environment. Functional homologs of IcsA have been described in *L. monocytogenes, Rickettsia*, and *Vaccinia*.

In addition to the mucosal damage that results from the process of epithelial cell invasion and intracellular multiplication, shigellae also produce enterotoxins that are presumably responsible for the diarrheal component of the disease. One serotype, *S. dysenteriae*, elaborates a potent toxin (Shiga toxin) that inhibits protein synthesis and exhibits both cytotoxic and enterotoxic activity. Some *E. coli* strains also produce Shiga-like toxins and have been associated with outbreaks spread by contaminated meats and sprouts. The Shiga toxin is produced only in *S. dysenteriae*, which causes the most severe form of dysentery, and may contribute significantly to the severity of the disease.

Because the virulence plasmid-encoded genes are essential to the disease process, the ability of the pathogen to maintain the presence of the plasmid is critical for pathogenesis. It has been shown that the expression of the plasmid-encoded virulence genes destabilizes the maintenance of the plasmid, presumably owing to the high metabolic demand of synthesizing the virulence proteins. The virulence plasmid is lost from the bacterial cell at a higher frequency at 37 °C when virulence protein expression is upregulated than when the bacteria are grown under repressing conditions at 30 °C. This observation could affect the detection of the organisms from clinical, food, and environmental samples using DNA-based or serological assays.

Shigella in Foods

Regulatory Issues

Unlike other bacterial foodborne pathogens, such as *Salmonella* spp., *Shigella* spp. are not associated with any specific food. The contamination of foods with *Shigella* usually results from an infected food handler or from contaminated water, either from irrigation or after processing. In the former case, the poor personal hygiene of one or more individuals can lead to diarrheal diseases. Each year, there are a significant number of outbreaks of shigellosis from consumption of contaminated foods. Many of these outbreaks are confined to single countries, but international travel and global commerce have been influential factors in the spread of the disease. For example, in 1994, contaminated lettuce from one country was the source of an outbreak of shigellosis that occurred in several European countries.

Many shigellosis outbreaks have been traced to the consumption of raw or fresh vegetables, particularly in salads, seafood, bakery products, chicken, and hamburger. In response to the increasing number of foodborne outbreaks resulting from consumption of contaminated fresh produce, the US Food and Drug Administration published a document entitled 'Guidance for Industry-Guide to Minimize Microbial Food Safety Hazards for Fresh Fruits and Vegetables' (http://www.foodsafety.gov/~dms/prodguid.html). These voluntary guidelines address concerns in the following areas: agricultural and packinghouse water use, manure management, worker hygiene, field and packinghouse sanitation, and transportation. The aim of these recommendations is to reduce transmission of shigellae and other enteric pathogens via fresh vegetables and fruits.

Another factor in the spread of *Shigella* sp. is improper storage temperature of contaminated foods. For the consumer, steps can be taken to reduce risk in contracting shigellosis: purchase food at reliable sources, wash food adequately, store food at suitable (refrigerated) temperatures, cook food adequately, refrigerate left-overs promptly, and wash cooking utensils and equipment adequately. The transmission

of *Shigella* spp. via foods is very efficient, and because of its low infectious dose, action to remove contaminated food from commerce should be swift.

Probably the most effective means to reduce the spread of many bacterial and parasitic pathogens is proper handwashing. Many agencies, including the World Health Organization, have emphasized adequate hand washing before and during meal preparation by those that work in food establishments and the consumer as an effective means in reducing foodborne outbreaks.

To address the concerns of the introduction of pathogens during food processing, a program, Hazard Analysis and Critical Control Point (HACCP), was established to identify and control specific food-related practices. This analysis determines where tests should be implemented to assay for the presence of foodborne pathogens at critical stages of food production. HACCP is an alternative approach to the traditional method of analyzing the final food product. Although HACCP may be a good monitoring system for other pathogens commonly known to be associated with foods, such as *Salmonella* spp. and *E. coli* O157:H7, testing for the presence of shigellae in foods at this point may not be useful. For example, contamination of foods with *Shigella* spp. commonly occurs between the processing plant and the consumer. However, proper adherence to good manufacturing process, such as hand washing and temporary removal of employees with diarrheal illness, can reduce outbreaks of shigellosis as well as other forms of foodborne diseases. As an example, at a mass gathering, a large outbreak occurred with nearly half of the attendees (3000 people) developing shigellosis from consuming meals prepared where one food handler was found to be ill.

Survival

Since shigellae are not indigenous to any particular food, this pathogen may be found in any food matrix. In the past, foods containing contaminated raw vegetables have been implicated in many shigellosis outbreaks. Other foods that are common vehicles for the spread of shigellae include tossed salads, potato salads, chicken, and shellfish. In a recent study, the survivability of *Shigella* in packaged vegetables (sterile and unsterile) held at different temperatures (5 °C, 10 °C, and room temperature) was reported. The greatest reduction in number of shigellae recovered was from the first 24 h. However, the data indicate that shigellae do survive in the vegetables tested, albeit after a 3 to 7 log reduction, for at least 10 days (although the initial inoculum was high (10^{11}), the final numbers ($CFU\,g^{-1}$) were between 10^4 and 10^8).

In laboratory conditions, *Shigella* spp. can grow at temperatures between 6 °C and 48 °C and at a pH of between 4.8 and 9.3. In addition, *Shigella* can survive at room temperature for up to 50 days in foods such as milk, flour, eggs, clams, shrimp, and oysters, and only 5–10 days in acidic foods (e.g., orange juice, tomato juice, carbonated soft drinks) and 1–2 weeks in refrigerated, fermented milk. It should be noted that although shigellae do not survive well in acidic foods, these organisms are able to survive the acidic conditions of the stomach.

Detection of Shigella from Foods

Foods are not routinely examined for the presence of shigellae. An outbreak of shigellosis is usually identified initially from clinical findings and epidemiological investigations. Therefore, 7–10 days may have passed before the first individual becomes ill. During this time, the fate and condition of the contaminated food is unknown, presenting a challenge to the laboratory responsible for isolating the etiological agent. Moreover, the need to rapidly isolate and identify shigellae in foods is necessary to reduce the spread of this pathogen.

Bacteriological scheme The Bacteriological Analytical Manual describes one protocol to isolate *Shigella* spp. from foods. Twenty-five-gram sample portions are added to 225 ml of *Shigella* broth supplemented with novobiocin (0.5 $\mu g\,ml^{-1}$ for *S. sonnei*; 3 $\mu g\,ml^{-1}$ for other shigellae; this antibiotic is added to suppress the natural bacterial flora of the food) and held for at least 10 minutes at room temperature. The broth is contained in a 500-ml flask and incubated overnight at 37 °C with shaking. Alternative protocols use other enrichment broths, such as Gram-negative broth, where food samples are blended in a sterile stomacher bag, the contents poured into a flask and incubated at 37 °C with shaking for 16–20 h.

Recovery of injured cells owing to a lengthy time delay on foods and/or storage conditions before processing a sample for analysis is problematic. Bile salts and desoxycholate have an adverse affect on growth of impaired cells; therefore, selective media without these compounds are recommended. Food samples are added to 100 ml of tryptic soy broth, the pH adjusted to 7.0, and then blended. After 8 h of incubation at 37 °C, 125 ml of enrichment broth are added and the incubation extended for an additional 16–20 h.

After enrichment in broth, cultures can be plated on selective (low to high) agar medium. To optimize the recovery of shigellae from foods, two or three different ranges of selective agar plates should be used (see Table 3). MacConkey agar is a low-selectivity

Table 3 Growth characteristics of *Shigella*, *E. coli*, and *Salmonella* on selective media

Organism	*Medium*	*Colony appearance*
Shigella	MacConkey	Colorless (lactose nonfermentor); *S. sonnei* colonies are colorless to pink[a], translucent, flat with jagged edges
	Hektoen	Green and moist
	XLD	Colorless
E. coli	MacConkey	Lactose fermentor; flat, pink colonies surrounded by darker pink region (indicates sorbitol fermentors, nonsorbitol fermentors form colorless colonies)
	Hektoen	Yellow/yellow orange, salmon
	XLD	Yellow
Salmonella	MacConkey	Colorless (lactose nonfermentors)
	Hektoen	Green
	XLD	Red with black center

[a]*S. sonnei* may ferment lactose slowly (> 40 h). Form I vs. Form II; smooth to rough look as a result of the loss of a 120-MDa virulence plasmid.

medium. *Shigella* produce colonies that are translucent and slightly pink (*Shigella* are lactose-negative) with or without rough edges. Eosin methylene blue (EMB) and tergitol-7 agar are alternative low-selectivity agars containing lactose. Colorless colonies on eosin methylene blue plates or bluish colonies on the yellow–green tergitol-7 agar are indicative of *Shigella*. The preferred media for *Shigella* isolation are desoxycholate and xylose–lysine–desoxycholate (XLD) agars, intermediate selective media. *Shigella* colonies on XLD agar medium are translucent and red (alkaline), whereas on desoxycholate medium, *Shigella* produce reddish colonies. Although most *Shigella* spp. do not ferment xylose, some species, e.g., *S. boydii* (variable) may be missed, and therefore, plating on XLD and MacConkey agar plates is recommended. Highly selective media include *Salmonella–Shigella* and Hektoen agars, media designed to differentiate and isolate *Salmonella* and *Shigella* spp. from other enteric bacteria. However, some *Shigella* spp., such as *S. dysenteriae* type I, are unable to grow on highly selective *Salmonella–Shigella* medium. *Shigella* produce colorless, translucent colonies on this agar. Colonies of *Shigella* on Hektoen agar appear to be green and moist, as do colonies from *Salmonella* spp. (some are blue green with or without black centers); *E. coli* strains, and other coliforms, such as *Klebsiella* and *Enterobacter*, form yellow, yellow–orange or salmon colonies. All presumptive colonies are inoculated into semisolid (motility) test agar for further testing; *Shigella* spp. are nonmotile.

Biochemical tests are used to further identify *Shigella* spp. Suspected colonies that are Gram-negative, nonmotile rods are inoculated on to lysine iron, Kliger iron, or triple sugar iron agar. On triple sugar iron agar slants, *Shigella* typically produce acid from glucose utilization (yellow butt) with no gas production, and because they do not utilize lactose or sucrose, the slant retains its color (red); no black color is produced in the butt, indicating the absence of H_2S (Table 4). Further biochemical characterizations show that *Shigella* spp. are negative for phenylalanine deaminase, sucrose, and lactose fermentation, do not utilize citrate, acetate, KCN, malonate, inositol, adonitol, and salicin, and lack lysine decarboxylase. Shigellae are negative for the Voges–Proskauer test (*S. sonnei* and *S. boydii* serotype 13 are positive). However, all shigellae are methyl red-positive and are unable to produce acid from glucose and other carbohydrates (acid and gas production occur with *S. flexneri* serotype 6, *S. boydii* serotypes 13 and 14, and *S. dysenteriae* 3). *S. dysenteriae* type I is catalase-negative, and *S. sonnei* has ornithine decarboxylase activity.

Table 4 Tests to differentiate *Shigella* spp. from *E. coli*

Test	*Reaction*	
	Shigella	*E. coli*
Motility	−	+[a]
Gas from glucose	−[b]	+[c]
Lysine decarboxylase	−	+[d]
Christensen's citrate	−	+
Acetate	−	+
Mucate	−	+

[a]Most positive, some negative (enteroinvasive *E. coli* are nonmotile).
[b]Some strains of *S. flexneri* 6 produce small amounts of gas from glucose.
[c]Some exceptions.
[d]Enteroinvasive *E. coli* are also negative.

Table 4 and 5 show key biochemical reactions to differentiate *Shigella* from *E. coli* and also to distinguish each *Shigella* sp. from each other. Growth on Christensen citrate, sodium mucate, or acetate agar is one characteristic that discriminates between *E. coli* and *Shigella*; shigellae are unable to utilize citrate, acetate, or mucate as sole carbon source.

Other biochemical tests are used to identify the serotypes of *Shigella*. The ability to utilize mannitol, dulcitol, xylose, rhamnose, raffinose, glycerol, and indole and the presence of ornithine decarboxylase

Table 5 Biochemical differentiation of *Shigella* species

Test	*S. dysenteriae*	*S. flexneri*	*S. boydii*	*S. sonnei*
β-galactosidase	−[a]	−	−	+
Ornithine decarboxylase	−	−	−	+
Indole production	+/−[b, c]	+/−[c,d]	+/−[c]	−
Gas from glucose	−	−[e]	−[f]	−
Acid from				
Dulcitol	−[g]	−[h]	−	−
Lactose	−	−	−[i]	+[j]
Mannitol	−	+	+	+
Raffinose	−	+/−[c]	−	+[j]
Sucrose	−	−	−	+[j]
Xylose	−	−	+/−[c]	−

[a] *S. dysenteriae* type 1 are positive.
[b] *S. dysenteriae* type 1 is negative; *S. dysenteriae* type 2 is positive.
[c] Reaction is variable.
[d] *S. flexneri* 6 is negative.
[e] *S. flexneri* 6 is positive.
[f] *S. boydii* serovars 13 and 14 produce acid and gas.
[g] *S. dysenteriae* type 1 may be positive.
[h] *S. flexneri* 6 may be positive.
[i] *S. boydii* may be positive.
[j] Positive reactions may take 24 h or longer.
+/−, variable reaction.

have been used to discriminate physiologically between *Shigella* spp.

Serological testing, using polyvalent antiserum, is used to identify the *Shigella* group (A–D). A note of caution should be addressed, concerning EIEC. This pathogen causes the same disease, bacillary dysentery, as do the shigellae. In some cases, some EIEC strains share homology with antigenic structures of some *Shigella* serotypes. Several serotypes of *S. dysenteriae*, *S. flexneri*, and *S. boydii* have reciprocal cross-reactivity with *E. coli* O antigens of the Alkalescens-Dispar bioserogroup or EIEC.

DNA-based methods Initially, DNA probes were developed to detect *Shigella* spp. from clinical samples, a far easier task than from foods. In the former, shigellae are shed in large numbers (10^3–10^9 per gram of stool) in patients in the acute phase of infection, and 10^2–$10^3\,g^{-1}$ can be found in convalescent individuals. Identification and detection of shigellae from stool samples is relatively easy, owing to the high number of organisms in a relatively homogeneous sample. The analysis of foods is obviously much more complicated. The diversity of foods, such as composition (pH, fat content), microbial content of the natural flora, and the length of time from collecting food samples, as in the case of a shigellosis outbreak, to the laboratory are factors leading to a diminishing chance of isolating or detecting this pathogen.

The application of the polymerase chain reaction (PCR), as with DNA probes, was initially developed to detect *Shigella* from clinical samples. PCR primers are selected that target specific virulence genes. For detecting shigellae, primers to amplify a segment of the *ipaH* gene have an advantage over other virulence genes. The *ipaH* gene is present in multiple copies in *Shigella*, including the bacterial chromosome. A distinct advantage of this set of primers is that in cases where the large virulence plasmid is no longer present, a product can still be amplified from the *ipaH* genes present in the chromosome reducing the occurrence of a false-negative reaction. Another positive feature of this primer set is that having multiple copies as targets influences the sensitivity of the PCR-based assay. However, it is not only the quantity of template for PCR that determines the successful PCR: the quality of the DNA is as important. DNA contaminated with inhibitors of PCR can lead to false negative reactions.

Much attention has been given to the preparation of DNA template free of PCR inhibitors. Clearly, in the clinical milieu, protocols can be designed for one particular matrix; quantity of template should not be a problem. Even though convalescent patients shed 10^2–10^3 shigellae per gram stool for perhaps weeks after the onset of disease, this number is suitable for detection. The limit of detection ranges from 30 to 50 CFU for PCR-based assays for detecting shigellae. In foods, as discussed above, multiple factors will influence how to prepare template. Several commercially available kits provide procedures for the detection of bacterial pathogens from foods. These protocols involve an enrichment step in broth for 6–18 h followed by treatment, as described by the manufacturer. Since shigellae do not survive well in most foods, this step may prove futile. Recently, a method has been described in which a small volume of a food wash is applied directly to a filter. These filters have the capacity not only to bind bacterial cells, but also to lyze the cells on contact and sequester the DNA within the membrane. The advantage of these filters is that bacterial (and parasitic) cells are concentrated and lyzed simultaneously, and washing the filters removes PCR inhibitors. With a pure culture of bacterial cells or shigellae seeded in different foods, the limit of detection is usually less than 100 CFU. Unlike other methods, which may take several days to determine if *Shigella* spp. are present in foods, PCR-based assays can yield a result in less than 1 day.

A method that uses a combination of polymerase chain reaction and enzyme-linked immunabsorbent assay in lieu of identifying polymerase chain reaction products by gel electrophoresis was found to be suitable for processing a large number of clinical samples. Its application to food analysis has yet to be tested.

Treatment and Prevention

Shigellosis is a self-limiting infection in normally healthy patients, and full recovery usually occurs without the use of antibiotics. In cases where antimicrobials are administered, the antibiotic of choice is trimethoprim–sulfamethoxazole. Ampicillin and tetracycline are alternative antibiotics to use, but multiple drug resistance among isolates of *Shigella* is becoming more common. Clinical isolates resistant to sulfonamides, ampicillin, trimethoprim–sulfamethoxazole, tetracycline, chloramphenicol, and streptomycin have been found. Consequently, drug-resistant organisms emerge from extensive use of antibiotics, and therefore, many practitioners believe that antimicrobial therapy for shigellosis should be reserved only for the most severely ill patients. However, there are persuasive public health arguments for the antibiotic management of shigellosis. Effective antibiotic treatment limits the duration of the disease and shortens the period of fecal excretion of shigellae, thus limiting the carrier state. Prompt replacement of liquids and electrolytes is important to restoring the health of the patient.

Since an infected person or asymptomatic carrier can be a focal point for person-to-person and food and waterborne spread, antibiotic treatment of these individuals can have an immediate effect on public health by containing the spread of shigellae. In industrialized countries, *Shigella* are one of the leading causes of outbreaks of diarrhea in daycare centers and have a secondary attack rate of 10–30%. As noted, antibiotics are not a substitute for good hygienic practices to contain secondary spread of shigellosis. As promulgated by the WHO, the single most effective means of preventing secondary transmission is handwashing. Food handling and preparation are important processes that also deserve attention, and persons with diarrhea should be excluded from handling food.

Despite many years of intensive effort, an effective vaccine against shigellosis still has not been developed. Attenuated, oral vaccine strains of *S. flexneri* are currently being tested. However, one major drawback still to be resolved is the transient fever and mild diarrhea associated with administration of the vaccine. A persistent problem impeding the development of a safe *Shigella* vaccine is designing a strain that can induce a protective immune response without producing unacceptable side-effects.

Summary

Foodborne outbreaks caused by *Shigella* species remain a concern to public health. *Shigella* can spread quickly because of the low infectious dose required to elicit clinical symptoms. This pathogen is not indigenous to any particular food; its host is either humans or subhuman primates. Outbreaks of shigellosis, from a relatively small number of infected people in a confined environ or to a multitude of clinically ill people, can occur by the ingestion of contaminated foods. A primary source of contamination is food handlers with poor personal hygiene. The disease is self-limiting, but treatment with antibiotics can limit the extent and possibly the spread of the illness. Currently, there is no vaccine available for shigellosis.

SINGLE-CELL PROTEIN

Contents

Algae

M García-Garibay, L Gómez-Ruiz and A E Cruz-Guerrero, Universidad Autónoma Metropolitana, Mexico City, Mexico
E Bárzana, Universidad Nacional Autónoma de México, Mexico City, Mexico

Introduction

Single-cell protein (SCP) refers to crude or refined protein of algal, bacterial, mold, or yeast origin which is used either as animal feed or human food. The production and utilization of microbial biomass as a source of food proteins gained particular interest as an alternative source for proteins of agricultural origin due to its high content of protein. In addition to proteins, SCP contains other nutrients such as lipids and vitamins. Algae as a source of SCP is a term which refers to either microscopic single-cell true algae or prokaryotic cyanobacteria, and their growth is based on use of carbon dioxide and light energy (autotrophic growth). In contrast to other SCP-producing organisms, algae are grown in many cases by processes resembling traditional agriculture, since they depend on large areas and sunlight radiation. (*See* **Mycoprotein**.)

Organisms

The term 'algae' is generically given to photosynthetic organisms, either microscopic or macroscopic, living largely in water habitats, growing as undifferentiated or little-differentiated tissues. The designation is applied to taxonomically unrelated species, and in some cases includes groups like cyanobacteria or *Euglena*. However, the cyanobacteria is a group included in the Procaryotae kingdom, therefore they are more closely related to bacteria than to 'true' algae. However, they are sometimes known as blue-green algae, and for SCP purposes they are usually considered as such. *Euglena* is a genus of microorganisms belonging to the Protozoa kingdom; it is a strange case of an unicellular animal with chlorophyl, therefore it should not be considered as algae, and it is not commonly used as a source of SCP.

'True' algae belong to the Plantae kingdom, being the simplest plants. There are unicellular and multicellular organisms, some of them reaching huge sizes.

Many algae have been used as food for a long time. These include single-cell organisms as well as multicellular seaweeds, which have an important position in the diet of coastal communities. Table 1 shows the main genera of algae used as food and their cellular characteristics.

Macroscopic algae do not easily fit the SCP definition, due to their multicellular nature, and the low protein content of the final product (6–30% on dry-weight basis). They are mostly collected from the sea and, when cultivated, the production resembles farming more than a biotechnological process. The most widely consumed seaweed is *Porphyra* (an alga belonging to the Rodophyceae – the red algae), particularly *P. tenera*, which has a widespread distribution. It is mainly consumed in Japan, and also in the Philippines, Wales, and New Zealand. Among the most important species of seaweeds used as food

is *Ulva lactuca* (sea lettuce) which is used as a salad ingredient in western Europe. *Enteromorpha* is consumed in Hawaii and the Philippines in salads or as a flavor-enhancer for fish dishes. *Caulerpa* is also consumed in the Philippines. These three later algae belong to the Chlorophyceae – the green algae.

Both true unicellular algae and cyanobacteria have been consumed for centuries. This practice dates back to the Aztecs in Central Mexico, long before the discovery of the New World, when *Spirulina maxima* was harvested from natural habitats for human consumption. A similar species, *S. platensis*, is still used in Lake Chad in Central Africa for the same purpose. Both species *S. maxima* and *S. platensis* have been classified interchangeably in either the genus *Arthrospira* or the genus *Spirulina*. Figure 1 shows a picture of *S. maxima* from Lake Texcoco in Mexico. Other ancient cultures have used microalgae as food but on a lesser scale. For instance, *Nostoc* is consumed in Mongolia, China, Thailand, and Peru, while *Oedogonium* and *Spirogyra* are consumed in Burma, Thailand, and Vietnam; *Chlorella* is produced in Japan and Taiwan and *Scenedesmus* in China.

Table 1 Main genera of algae used as food and their cellular organization

	Prokaryote organisms (cyanobacteria belonging to the Prokaryotae kingdom)	*Eukaryote organism (true algae belonging to the Plantae kingdom)*
Unicellular growth	*Anabaena* *Nostoc* *Spirulina* (*Arthrospira*) *Tolypothrix*	*Chlorella* *Oedogonium* *Scenedesmus* *Spirogyra*
Multicellular growth		*Caulerpa* *Coelastrum* *Enteromorpha* *Porphyra* *Ulva*

Production

Besides the traditional harvesting of native algae in several regions, industrial and experimental efforts are being made in many countries, with either large and shallow ponds in areas of high sunlight, or bioreactors for the production of unicellular organisms.

Macroalgae cultivation is started by providing anchorage in sheltered bays for the initial culture; once a considerable growth of young plants is obtained, they are transplanted to nitrogen-rich tidal estuaries with low salinity.

Single-cell algae are produced by a variety of methods, ranging from cultivation in lakes or earthen ditches or ponds to technically advanced fermenters or bioreactors. Intensive cultivation was initiated in the 1940s in Germany, followed by technological developments in Japan and Taiwan during the 1950s and 1960s. Later on, commercial production systems were developed in the USA, Mexico, Thailand, and Israel. Currently commercial production is carried out in many countries around the world, though at a modest scale.

Figure 1 *Spirulina maxima* harvested from Lake Texcoco in Mexico, observed by scanning electron microscopy. Courtesy of Dr Jorge Sepúlveda, Universidad Nacional Autónoma de México.

Outdoor cultivation may be in open or closed systems. Growth occurs not more than 0.5 m from the water surface, as it is controlled by light penetration. In clean-culture systems a single species is inoculated and can be maintained over extended time periods; these are closed photobioreactors operating either outdoors or indoors, ranging from large closed areas exposed to sunlight to smaller reactors illuminated with artificial light.

Substrate Requirements

Algae are autotrophic organisms with the distinct advantage of using carbon dioxide as carbon source. Carbon dioxide represents the cheapest and probably most abundant carbon source for microbial growth. Due to such inexpensive requirements, these organisms are very convenient for SCP production. Some species can also grow heterotrophically using organic carbon sources.

The process is limited by the carbon source; the concentration of dissolved carbon dioxide is rather low, owing to its low solubility in aqueous solution. Carbon dioxide can be injected from combustion gases. Some additional sources of carbon enhance cell growth: cheap organic materials such as manure, molasses, or industrial wastes can be used. The added organic compounds are rapidly degraded by bacteria to make the carbon dioxide needed for algal reproduction. Lake Texcoco in Mexico has high concentrations of carbonate and bicarbonate, which are efficiently consumed by *Spirulina maxima*.

Nitrogen sources are generally nitrates, nitrites, ammonia, or urea. Oxidized nitrogen compounds require energy to be reduced, therefore ammonia is a more convenient form. Many cyanobacteria are able to fix atmospheric nitrogen; species of the genus *Anabaena* are particularly active in doing this.

Another nutrient of importance is phosphorus that can be incorporated in inorganic form. Micronutrients are needed in minimal amounts.

The use of waters polluted with organic wastes as input for algal ponds has the advantage of using a cheap raw material and promoting decontamination while obtaining a good source of SCP. Even more, the macronutrients needed (ammonium, phosphate) are normally present in domestic sewage, animal wastes, and food industry residual waters. (*See* **Effluents from Food Processing**: On-Site Processing of Waste; Composition and Analysis.)

Mass-Culture Open Systems

For open systems, lakes, ponds, and ditches are used. They can have an earthen floor or be lined with concrete or plastic. Open systems have low cell densities with large variation in productivity, depending very much on water properties and environmental conditions. In these kinds of systems the weather conditions, especially temperature and sunlight radiation, are critical. On the other hand, the needed facilities are constructed at low cost, and large areas are available.

It is a challenge to keep a monoalgal culture in an open-air system. The propagation of mixed populations and frequent problems of contamination by bacteria, fungi, protozoa, and invertebrates usually disturbs the productivity and lowers the quality of the product. However, under such nonsterile, mixed-culture conditions some algal species tend to predominate. The surface of the water in some ponds or ditches used for mass production is covered with polyethylene or other plastic material to reduce the risk of infection. Another possibility of avoiding contamination is the common practice of seeding a large inoculum to dominate the culture, at least during the first growth phase. Other approaches to promote single-species culture have been evaluated; for instance, the use of nitrogen-fixing species of the genus *Anabaena* in media without other nitrogen source has proved useful. Similarly, the selection of thermophilic species, such as *Scenedesmus obliquus*, has shown some preliminary potential.

Gentle agitation is very important to achieve high productivity. It prevents sedimentation, allows a more homogeneous exposure of algal cells to light, and reduces nutrient and temperature gradients along the depth of the culture. To this end, several designs have been implemented in ponds and ditches, including paddlewheels, gravity flow, and pump recycle, combined with special designs of slopes in oval ponds and horizontal raceways.

Productivities rarely exceed $30\,g\,m^{-2}\,day^{-1}$ and cell densities of $2\,g\,l^{-1}$, which are much lower than the values for other industrial fermentation processes. Some experimental improvements have been achieved by optimizing the use of wastes through the addition of nitrogen sources, adding aeration ports, and inoculating selected bacteria that efficiently degrade the diluted organic materials. By such means, the dry-weight productivities reach about four and three times the average figures obtained for maize and soybean respectively on a yearly basis. With intensive modes of cultivation, algal cultures can produce up to 20–35 times more protein than soybean for the same area of land.

An example of a typical mass-culture open system is that conducted by the Sosa Texcoco Company in Mexico, mainly during the 1970s and 1980s, in which an alkaline (pH 9–11) lake with 900 hectares of surface produced up to 1000 metric tons per year

of *Spirulina maxima* (equivalent to 0.111 kg m^{-2}). Weather conditions in Central Mexico, with high and practically constant temperature and solar radiation through the year, and the high alkalinity of the water favor effortless predomination of *S. maxima* on Lake Texcoco. The water of the lake flows by gravity into a sloped spiral raceway, maintaining gentle agitation. This factory stopped its production in the mid-1990s due to a long strike that led to the bankruptcy of the company.

The most advanced system developed so far is the high-rate algal ponds (HRAP) which combines the treatment of sewage with the simultaneous massive production of algae. The project was developed by the Technion Research Center at Haifa, Israel. Basic infrastructures are shallow canals that add up to a maximum of 1000 m^2, equipped with systems for gentle agitation and aeration. The process is operated continuously with retention times varying between 2 and 6 days, depending on the season. A steady multiculture is established in the system within a few days of operation. This includes bacteria that degrade organic compounds, and well-defined algal species, with *Euglena*, *Chlorella*, and *Scenedesmus* predominating. The maximum daily productivity reported at times of maximum solar radiation is 30 g m^{-2}, with an average annual production of 7 kg of algae per m^2. To recover the cells, aluminum sulfate is added as a flocculant; the float is then dewatered by centrifugation and dried in a drum drier to reach a final moisture content of 10%. The final product has been shown to have an excellent nutritional quality, containing 57.4 g of crude protein per 100 g, and an amino acid profile superior to the average for soybean protein. It has been used to complement at least 25% of fish diet and 10% of poultry diet with no toxic effects. The resulting effluent can be used directly for crop irrigation.

Chlorella ellipsoidea is produced in Taiwan for food use in open ponds with agitation or circulation. The product is recovered by filtration. In China, pilot-scale open systems have been used for the production of *Spirulina*, mainly *S. platensis*. Ponds about 100 m^2, covered with polyvinylchloride sheets, lead to a daily production of 10 g m^{-2} (equivalent to more than 3 kg per year per m^2 if the production could be maintained constant through the year). Other microalgae produced in China in open-air systems are *Scenedesmus, Chlorella*, and *Anabaena*.

Photobioreactors

Photobioreactors are closed systems working either outdoors or indoors, in which a single species is inoculated to keep a clean-culture operation. Closed cultivation systems offer better control of contamination and cell physiology than open systems, leading to higher growth and quality of the harvested product, but manufacturing costs increase.

Large systems operating outdoors consist of tubes covering large areas exposed to sunlight and can be operated either in batch or continuously. Many designs have been constructed or proposed at pilot scale. Tubes are made of either glass or plastic, such as polyethylene. Since the tubes behave as solar collectors, overheating is a problem. Hence, the tubular solar receptors must have a temperature control system, which is usually a water pool. Alternatively, the use of thermotolerant strains has been proposed to avoid cooling facilities. Generally, tubes are grouped in several modules to facilitate control, operation, and to offer flexibility to the system in terms of culture volume. CO_2 supply systems such as carbonation towers, pumps for circulating the medium, and tanks to mix nutrients are attached to the solar receptors. These photobioreactors have been used for the production of *Chlorella, Spirulina*, and *Scenedesmus*.

Other designs constructed in Chile up to a scale of 110 m^2 of solar irradiation area consist of a pond made of cement lined with epoxy resin and covered with a polyethylene dome. The agitation system is a paddlewheel. It has been used to produce *Spirulina* biomass, reaching a growth density of 450–750 mg l^{-1}.

An innovative design, operated in the USA, is based on the use of oval plastic bags floating on thermal waters.

Photobioreactors operating indoors necessarily have smaller sizes because artificial light is needed. Designs can be either plastic tubular systems, or stainless-steel fermenter-like reactors with internal illumination to allow maximum light incidence. Their use is rather limited for SCP production because of low throughputs; however, they are quite adequate for the production of algal metabolites with high added value, such as polysaccharides, carotenes, and other pigments, polyunsaturated fatty acids, etc.

Harvesting

The recovery of microalgal biomass after production is rather difficult, particularly in large-area lakes, or when low concentrations occur. Some species, such as *Spirulina platensis, S. maxima*, and *Coelastrum probiscideum*, are easily skimmed off or harvested by filtration through cloths or screens. Filter presses can be used as well. Owing to their small cell size (10 μm), other species need to be harvested by centrifugation or flocculation, adding flocculants such as lime, alum, or polyelectrolytes.

After harvesting, the algal biomass must be dewatered by centrifugation and/or dried. Operations to dehydrate biomass are normally done by

drum-drying, sun-drying, or spray-drying; drum-drying is the most widely preferred. In some cases, the product is not dried; for example, in China, *Scenedesmus* and *Chlorella* are fed to swine as fresh algal slurry.

Nutritional Value and Human Consumption

Algal SCPs have nutritional values similar to other SCP sources. The crude protein content (N × 6.25) varies between 45 and 73%, while lipid and mineral contents are 2–20% and 5–10% respectively. The chemical composition of some algal species is shown in Table 2. The protein content of algae is higher than the value for soybean (40 g 100 g^{-1}).

The amino acid content of algal SCP shows an adequate balance except, as any other microbial biomass, for the sulfur-containing amino acids methionine and cystine. They are rich in vitamins, especially some of the water-soluble ones, and essential fatty acids. The content of some vitamins, such as thiamin, riboflavin, folic acid, and carotene, is higher in algae than in many vegetable foodstuffs. However, the content of nutrients is highly dependent on cultivation and processing conditions. Table 3 shows some indices of protein quality of some algae. The protein efficiency ratio (PER), net protein utilization (NPU), and biological value (BV) of algal proteins are somewhat lower than casein. Nutritional tests have shown promise when algae supplemented with methionine and cystine are fed to broilers. However, monogastrics have problems digesting the whole cells and some processing is therefore needed.

Algal cell wall is not readily digestible, therefore any treatment to disrupt the walls will increase

Table 2 Composition of algal species. Main components in g 100 g^{-1} dry wt. Amino acids and vitamins as specified

	Spirulina maxima	Chlorella	Scenedesmus obliquus	Scenedesmus acutus
Crude protein (N × 6.25)	55–71	40–58	50–56	46–64
True protein	48–61			44–48
Amino acids (g 16 g^{-1} N)				
Alanine	5.0–6.1	4.2–7.4		5.3–10.4

digestibility and hence nutritional value. Many treatments have been suggested, such as mechanical disruptions, extractions with organic solvents, and treatments with alkalis and/or acids. The method of drying affects product bioavailability. In drum-dried algae compared to the air-dried product, NPU is increased to around 100%, while digestibility is increased to about 60%. This phenomenon may be due to the rupture of the algal cell walls when water is removed at controlled conditions. Figure 2 shows spray-dried cells of *Spirulina maxima*; it is clear that the drying process disrupts cells if the cellular structures shown in Figure 1 and Figure 2 are compared. The micrograph shown in Figure 2 was taken from a sample of the spray-dried commercial product (powder) shown in Figure 3.

Table 3 Parameters of protein quality of some microalgae

Product	*NPU*	*PER*	*BV*
Spirulina platensis	52.7		68
S. platensis + methionine	62.4		82.4
Spirulina spp.	65	1.80	75
Spirulina spp. + methionine	73		82

Chlorella spp. + methionine	78		91
Scenedesmus spp.	67	1.93	81
Casein	83	2.50	88

NPU, net protein utilization; PER, protein efficiency ratio; BV, biological value.

Many uses have been made of algal SCP, including the cultivation of daphnid and similar species that thrive on plankton as a food source in aquaculture. Particularly, some algal species rich in carotenoids have been used to feed salmon and trout to enhance the color of their flesh, and the US Food and Drugs Administration (FDA) has approved the 'all natural' statement for farm-raised fish. In addition to its use as feed for chicken and swine, algal biomass has been used as food worldwide. *Chlorella* is produced in Taiwan for food use; *Spirulina* has been produced commercially in the USA, Mexico, Taiwan, Japan, Thailand, and Israel with the same purpose.

Algal SCP has mainly been used for the preparation of nutraceuticals or dietary supplements, alone or mixed with other sources of protein and other food ingredients, sold as tablets, caps, powders, and other products available mainly in health food stores or nutrition centers, but also sold in groceries, drug and discount chain stores; they are promoted as protein and vitamin supplements, or to help people lose

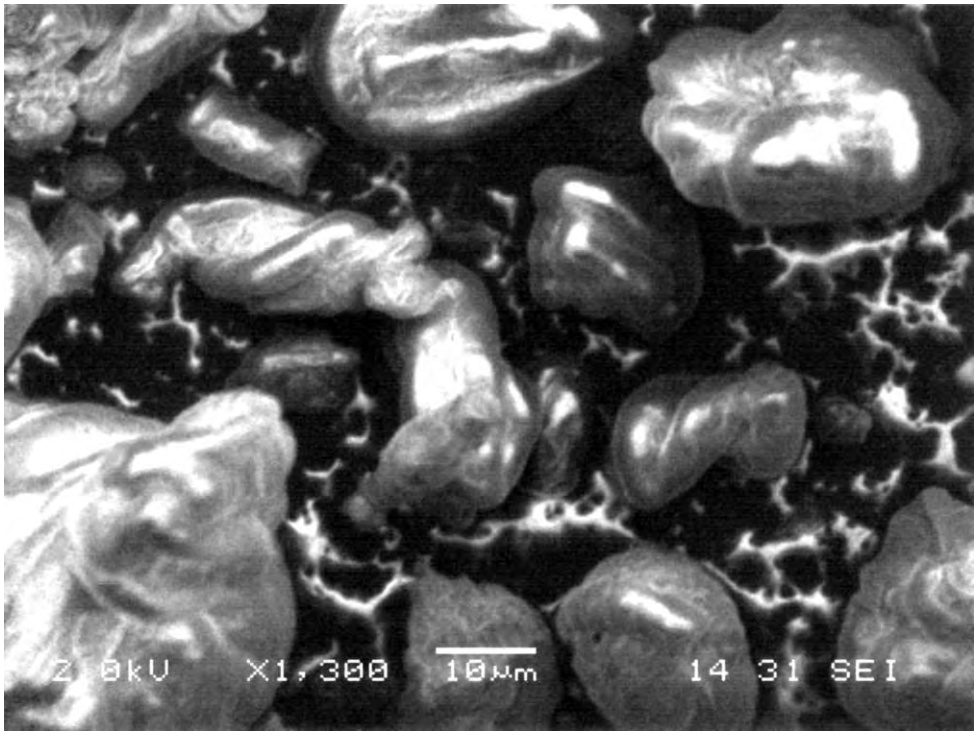

Figure 2 Cells of *Spirulina maxima* disrupted by the spray-drying process, observed by scanning electron microscopy. The sample was taken from a commercial powder.

Figure 3 (see color plate 126) Two commercial products elaborated with 100% dried *Spirulina maxima* biomass, sold as nutraceuticals in health food stores in Mexico City.

weight. However, very few indepth studies, if any, have been conducted to evaluate the nutritional or health-associated benefits of algal SCP. In countries such as the USA, Mexico, and Chile algal biomass is sold as tablets or powders, while in Japan and Taiwan it is sold either as dry powder or as pellets. Figure 3 shows two commercial products elaborated with 100% biomass of *Spirulina maxima*.

The FDA considers SCP from algae to be a dietary supplement; like any other dietary supplement, manufacturers do not need FDA approval to sell their product; this means that the FDA does not keep a list of manufacturers or products. However, claims on the product label other than nutrition content or approved health claims must be notified to the FDA. Examples of such claims are 'free radical defense' or 'helps combat free radicals,' used in some products containing algal SCP rich in astaxanthin, a carotenoid with antioxidant capability, or 'structure/function' claims such as 'promotes cellular health' or 'support immune system health' for a mixture of *Spirulina* and *Chlorella*, statements which had not been evaluated previously as health claims by the FDA. Another example is 'helps maintain healthy eyes' and 'helps support immune function,' claims used in a product sold as powder or tablets made by a strain of *S. platensis* rich in carotenoids.

A wide range of food formulations has been prepared with algal biomass. For instance, powder meals containing *Spirulina* plus soy proteins, oat bran, apple pectin and vitamins, either chocolate- or vanilla-flavored, are sold as energy supplement powders to mix with milk or juices. Algal SCP has been widely used as an additive or supplement to cereal foodstuffs, or as a garnish to salads. Experiences related to supplementation of cereal foods with algal SCP include mixtures with doughs for baked goods and pasta, such as bread, rolls, cookies, noodles, etc. In Mexico, *S. maxima* has been used as a supplement for cookies produced by a state company as part of a national breakfast program for schoolchildren. Also, the use of *S. maxima* has been suggested to enrich tortillas, increasing their protein content; however, these products have not found success in the market place.

Table 4 Functional capacities of a protein concentrate obtained from *Spirulina platensis*

Water absorption (g 100 g^{-1} protein)	145
Fat absorption (g 100 g^{-1} protein)	373
Emulsifying capacity (ml oil 100 g^{-1} protein)	113
Foam capacity (%)	205
Foam stability (1 h) (%)	27

Concerning functional properties, it has been reported that *S. platensis* flour had similar emulsion and foam capacities, slightly lower water and fat absorption capacities, and lower foam stability than soybean meal. Using the protein concentrate obtained from the flour, improved functional characteristics with the exception of water absorption ability are obtained. Some values obtained for functional capacities of a protein concentrate obtained from *S. platensis* are given in Table 4.

The major problems in acceptability of algal biomass are its unfamiliar and sometimes bitter flavor, as well as the presence of dark green pigments which are difficult to mask. In addition to chlorophyls, other pigments such as carotenes, xanthins, and phycocyanin are present in varying amounts. Flavor and color may be improved if algal biomass is treated during downstream processing to remove undesirable components.

Toxicological Problems

Algae have been consumed as food for generations, without ill effects. No toxic effects have been reported in animal evaluations. However, the following considerations must be taken into account.

A common problem for SCP from any microorganism is the high content of nucleic acids present in microbial cells. Consumption by humans of nucleic acids in amounts higher than 2 g day^{-1} can lead to accumulation of uric acid, which increases the risk of gout and/or kidney stones. The concentration of nucleic acids in algal biomass depends on several factors, such as species and growth conditions. Cyanobacteria have a nucleic acid content of 2.9–5 g

$100\,g^{-1}$ while microscopic plant algae have 1–17 g $100\,g^{-1}$. These amounts are higher than in most other foodstuffs.

In order to reduce nucleic acid content, protein concentrates or isolate can be prepared by cell disruption and protein separation. Figure 4 shows a flow diagram of a process for the preparation of protein isolate from *Spirulina*. However, this increases the cost of the product. In general, algal biomass is consumed by humans in small amounts and so the consumption of nucleic acids is below risk.

The cell wall of microalgal biomass represents about 10% of its weight. It is mainly composed of indigestible polysaccharides and some other compounds, e.g., murein in cyanobacteria. The bioavailability of protein from whole cells is therefore very low. The preparation of protein concentrates or isolates can be used to obtain products with a high nutritional value and free of undesirable pigments, although it represents a costly alternative.

Algae have the ability to remove heavy metals from polluted waters. Similar physiological phenomena account for the accumulation of pesticides and organochlorine compounds. This represents an objection when algae are intended for use as SCP. However, the causes are well identified and some steps can be implemented to maintain the final product composition within safety levels.

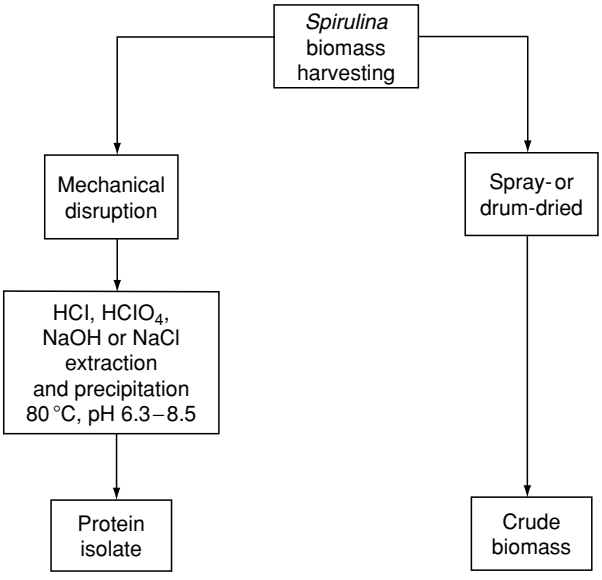

Figure 4 Process for *Spirulina* single-cell protein recovering either as crude biomass or as protein isolate.

The origin of the water used in cultivation ponds determines the need for pretreatment. In general, wastes generated in food industries carry low amounts of the contaminants mentioned. However, urban sewage and run-offs show high variability in the content of heavy metals and other toxicants. When these waste streams are subjected to standard secondary treatments, most organics are degraded, whereas metals remain associated with the activated sludge, rendering them safe as an input for algal growth. Furthermore, some studies have demonstrated that biological absorption of metals is a rather slow process, requiring more time than the usual retention time of the water within the bioreactor. It appears that fears concerning the presence of recalcitrant toxicants in algae might be excessive, although more research is needed to get a clear picture.

Another problem to consider is the possibility of contamination by pathogenic microorganisms. Certainly, the culture practices in open systems increase the risk of pathogenic infections. The downstream processes of SCP products are designed to destroy most of the viable forms present, although some could survive in the product. Recommendations have been established for microbiological standards of SCP products for use in animal feeds.

Introduction

The single-cell protein (SCP) concept is applied to the massive growth of microorganisms for human or animal consumption. Single-cell protein is a generic term for crude or refined protein whose origin is bacteria, yeasts, molds, or algae, microorganisms that usually contain above 40% of crude protein on dry weight bases. Yeasts and bacteria have been particularly important for SCP production and easily acceptable as their biomass has been consumed by man since ancient times in the form of fermented foods. The production of SCP has important advantages over other sources of proteins, such as its considerably shorter doubling time, the small land requirement, and the fact that it is not affected by the weather conditions. Much attention was focused on the use of petroleum derivatives as substrates for the SCP production during the 1960s and 1970s when the price of this reserve was low, but currently, the production of SCP is based on renewable resources, and its interest is also kept as a means to confer value to waste materials. The organoleptic and functional properties of SCP are not always competitive, and its main drawback has been its high production costs. However, recent advances in fermentation technology and genetic engineering could reevaluate SCP production.

Historical Developments and Implementation of SCP Production

The first developments in SCP production were achieved during war times when conventional foods were in short supply. During World War I, *Saccharomyces cerevisiae* was massively produced in Germany from molasses to replace up to 60% of protein imported. Similar measures were taken during World War II for the mass production of *Candida utilis* (known formerly as Torula yeast, or *Torulopsis utilis*) on sulfite liquor from paper manufacturing wastes. After the war, several plants were built in the USA and Europe, mainly for *C. utilis* production.

Accelerated industrial development and general welfare expectancy led to a renewed interest in SCP as an alternative to alleviating food shortages due to a growing imbalance between food production and demand by the world's population, mainly in developing countries. During the 1960s and 1970s, several SCP production plants were built in the UK, France, Italy, Russia, Japan, Taiwan, etc.

An important breakthrough occurred when the production of SCP from hydrocarbons was demonstrated by several petroleum companies during the 1950s and 1960s. During the 1970s, considerable research efforts resulted in the use of methanol and ethanol, derived from petroleum, as convenient substrates. In the early 1970s, the cost of *n*-paraffin was approximately US$80 per tonne, whereas crude molasses had an approximate cost of US$82 per tonne. However, concern about substrate safety and the increase in petroleum prices shifted interest back to the utilization of renewal sources, mainly food and agriculture byproducts like molasses and whey, or industrial wastes rich in starch, cellulose, and hemicellulose. The major SCP projects based on petroleum derivatives as substrates were abandoned in the 1980s.

In recent times, among the European Communist countries, Russia has had the greatest capacity for SCP production, with at least 86 plants in operation, using different substrates. Several other countries in Eastern Europe, like the former Czechoslovakia, had similar capacities. The Russian delegation reported the production of 1 million tonnes of SCP per year in 1983 at an international symposium on SCP, and estimated that they would be producing 9 million tonnes by the end of the 1990s.

To date, an enormous number of reports about SCP production have appeared in the scientific literature. Two main approaches have been followed: the utilization of convenient substrates and the use of waste materials where SCP production brings about pollution control.

Many industrial process have been developed world-wide; the most important are shown in Tables 1 and 2. The countries with important industrial outputs are the USA, UK, France, Russia, and Cuba.

Suitable Organisms and Substrates

The most frequently used yeasts are as follows: *Saccharomyces cerevisiae* (and related synonymous species such as *S. carlsbergensis*, *S. uvarum*, etc.), *Kluyveromyces marxianus* (including synonymous subspecies and asexual forms such as *K. fragilis*, *K. lactis*, *K. bulgaricus*, *Candida kefyr* and *C. pseudotropicalis*), *C. utilis* (and its sexual form *Hansenula jadinii*) and *Yarrowia lipolytica* (formerly

known as *Candida lipolytica* and *Saccharomycopsis lipolytica*).

Some yeasts have been widely used in the manufacture of human foods: *S. cerevisiae*, *K. marxianus*, and *C. utilis* have the generally recognized as safe (GRAS) status for human consumption by the Food and Drugs Administration in the USA. *S. cerevisiae* is also available as spent yeast from breweries and alcohol industries; Figure 1 shows an electron micrograph of this species. *K. marxianus* and related species are widely used, due to their capacity to assimilate lactose, the carbohydrate present in cheese whey, but it can also grow on inulin, a fructose polymer found in some plants, and other simple sugars such as glucose, fructose, and sucrose; therefore, sometimes, it is also grown in molasses. Since it is able to grow at temperatures as high as 45 °C, it has been used to produce biomass in tropical areas. Figure 2 shows an electron micrograph of cells of *K. marxianus*. *C. utilis* is used for a wide variety of substrates such as sucrose, ethanol, and sulfite-spent liquor. It can also grow on wood hydrolysates because of its ability to assimilate pentoses. Starchy solids or water streams from potato and maize industries require previous hydrolysis for yeast growth, as in the case of *C. utilis*, or as in the Symba process, which utilizes amylolytic yeast (*Saccharomycopsis fibuligera*). Yeasts able to assimilate

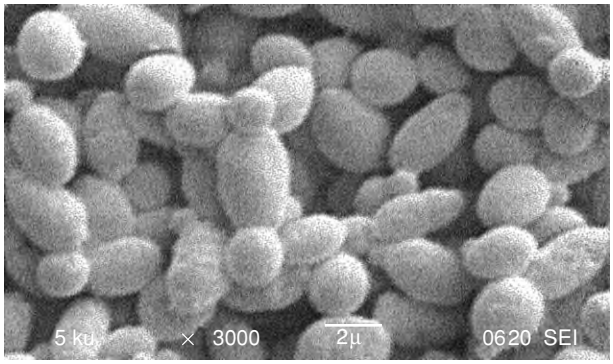

Figure 2 *Kluyveromyces marxianus* observed under a scanning electron microscope.

hydrocarbons include *Y. lipolytica*, *C. tropicalis*, *C. rugosa*, and *C. guilliermondii*, which usually can also grow on lipids. Methanol is the preferred alcohol for use as a substrate by *Pichia* species (*P. pastoris*, *P. methanolica*, etc.), *Hansenula polymorpha*, *Hansenula capsulata*, and *Candida boidinii*. The most important processes developed for yeast SCP production are shown in Table 1.

Bacteria have been used mostly for the production of animal feed. The most commercially important species utilize methane and/or methanol as substrates, as shown in Table 2. Methanol is usually preferred over methane because it is water-soluble and less explosive. The Ministry of Agriculture, Fisheries and Food in the UK allows the use of ICI's (Imperial Chemical Industries) product 'Pruteen' in animal feed. For the production of bacterial SCP from ethanol, either *Acinetobacter calcoaceticus* or *Alcaligenes* sp. have been used in laboratory or pilot-plant studies.

Other petroleum derivatives such as paraffins have been considered only to a minor degree for the production of SCP using bacteria; some studies have been carried out with *Acinetobacter calcoaceticus*.

To produce bacterial SCP from whey, several lactic acid and propionic bacteria have been investigated, frequently in mixed cultures with yeasts as in the Kiel process. In this case, *Lactobacillus delbrueckii* ssp. *bulgaricus* grows using the lactose, converting it to lactic acid; then, *Candida krusei*, which is unable to ferment lactose, uses the lactic acid as a carbon source. Both fermentations can be performed simultaneously, controlling the pH by adding ammonia, which is used as a nitrogen source by the yeast.

Lactic acid bacteria proposed for the fermentation of whey include species such as *Lactobacillus delbrueckii* subsp. *delbrueckii*, *L. delbrueckii* subsp. *bulgaricus*, *Lactobacillus casei* ssp. *casei*, *Leuconostoc* sp., etc. Fermentation of this substrate with rumen bacteria has also been proposed to produce biomass concentrated by ultrafiltration for use as feed.

Propionibacteria, such as *Propionibacterium freudenreichii* ssp. *shermanii* and *P. freudenreichii* ssp. *freudenreichii*, produce significant amounts of vitamin B_{12}, giving additional attractiveness to their utilization in the production of SCP. A process using a mixture of *P. freudenreichii* ssp. *freudenreichii* and *K. marxianus* has been proposed for the production of SCP from whey rich in vitamin B_{12} and sulfur amino acids.

Bacteria have been explored very little with regard to producing SCP from substrates such as starch and cellulose. A case in point is the project developed by Louisiana State University in USA to produce SCP from *Cellulomonas* sp. and *Alcaligenes* sp. from cane bagasse; this process was scaled up to pilot-plant level.

Generally, yeasts have been preferred for SCP production over bacteria, especially for human consumption. It seems that yeasts are more acceptable because they are more familiar to humans through ageless foods like bread or beer. However, bacteria have some advantages over yeasts such as a higher protein content (Table 3), higher yields (carbon source to protein conversion), and a faster growth rate, though a higher nucleic acid content (Table 4) limits their uptake in the diet. (*See* **Lactic Acid Bacteria**; **Yeasts**.)

Production Processes

Since the SCP must have a competitive price in the protein market, especially proteins of vegetable origin, it is essential to guarantee efficiency along all stages of the process. The carbon source accounts for up to about 60% of the operation costs, so high yields of substrate conversion are required, high productivity processes must be implemented, and the utilization of an inexpensive but easily assimilated carbon source has to be guaranteed. This explains the generalized use of molasses, whey, or industrial residues, depending on local availability, and the attempts to implement fossil fuels as substrates. An important advantage in using hydrocarbons is the yield, obtaining 1 g of dry biomass per gram of hydrocarbon, compared with carbohydrates, which typically yield around 0.5 g of dry biomass per gram of substrate.

The typical process stages for the production of SCP comprise: raw material preparation, fermentation, biomass recovery, cell disruption, and drying. Figure 3 shows a typical process for the production of yeast SCP.

Table 3 Nutritional parameters of SCP products

	Kluyveromyces marxianus	Saccharomyces cerevisiae	Candida utilis	Methylophilus methylotrophus	Methylomonas clara	*Soya meal*
Protein (grams per 100 g dry weight)						
Crude (N × 6.25)	43–58	48	42–57	72–88	80–85	44–50
True protein	40–42	36	47	64	69–73	48
Essential amino acids (grams per 16 g of N)

Table 4 Nucleic acid contents of SCP products (g per 100 g of biomass in dry weight basis)

Kluyveromyces marxianus	2.7–10
Saccharomyces cerevisiae	2.5–15
Candida utilis	6.2–10
Methylophilus methylotrophus	16
Methylomonas clara	10–15
Isolated protein from *K. marxianus*	1.4–5.7

To maximize carbon assimilation, the nutrients must be balanced. Sources of nitrogen, minor elements (P, K, S, Mg, etc.), trace elements, and vitamins are adjusted according to the general composition of the carbon source. This in turn is highly dependent on the strain used. In general, simple nitrogen sources such as urea, ammonia, and nitrate are used to keep costs down. Phosphate is supplied as phosphoric acid or as soluble phosphate salts.

Fermentation variables like temperature, pH, ionic strength, level of oxygenation, and, in the continuous fermentations, dilution rate, have a strong influence on cellular yield. In particular, an abundant supply of oxygen promotes aerobic metabolism and higher growth rates. However, due to the low solubility of oxygen in aqueous media, the cost of aeration, through air sparging and agitation, increases rapidly with the scale of operation, resulting in an important technical challenge. Assimilation of *n*-paraffins requires considerably high levels of oxygenation, and the growth of microorganisms on these water-insoluble substrates takes place on the hydrocarbon–water interface. The surface area becomes the limiting factor, and heat production is about twice that using sugars as substrates.

In general, when yeast biomass is produced, alcohol accumulates due to oxygen limitation. Some alternatives proposed for SCP from whey are the production of alcohol as a byproduct from fermentation or the use of *Kluyveromyces* in a mixed culture with *Candida pintolopesii*, where the latter consumes the alcohol produced by the former. The first approach has been followed by Amber Laboratories (Universal Foods, USA), and the second approach has been adopted by the Fromageries Bel in France; *Candida valida* has also been demonstrated to prevent ethanol accumulation when it is grown

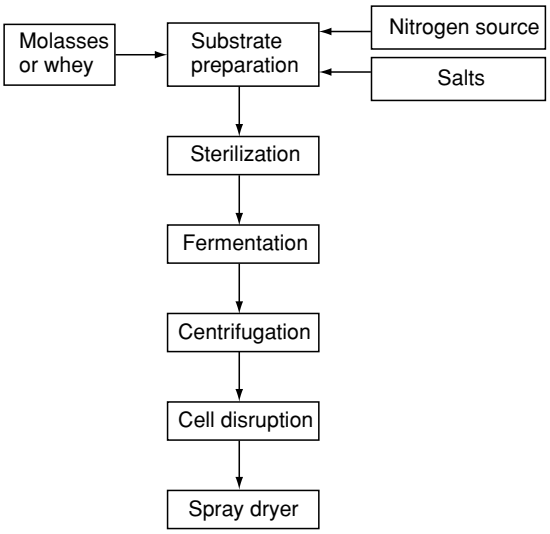

Figure 3 Typical process for the production of yeast SCP.

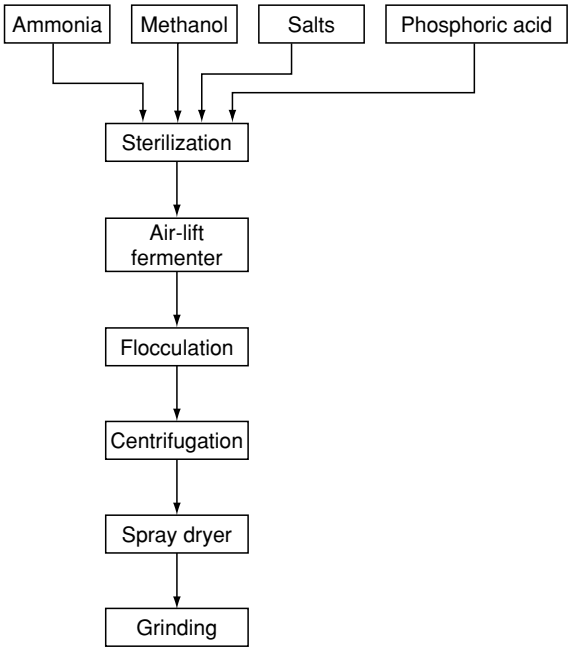

Figure 4 Industrial process developed in the UK by ICI for the production of Pruteen using *Methylophilus methylotrophus* grown in methanol.

mixed with *Candida kefyr* (the asexual form of *K. marxianus*), increasing the efficiency of whey conversion into biomass up to 20%. A limited oxygen supply, when hydrocarbons are used as substrates, has led to the production of some metabolites such as mono and dicarboxylic acids and ketones.

To sustain high oxygen transfer rates, large air volumes have to be supplied with high agitation rates. Alternative fermenter designs include the air-lift type, which leads to maximum oxygenation with minimum power requirements, diminishing aeration costs considerably. In fact, the largest fermenter ever operated is an air-lift ($3000\,m^3$) for the aerobic production of *Methylophilus methylotrophus* by ICI. Figure 4 shows a simplified diagram of the process developed by ICI, which is the most successful process developed for bacterial SCP production. Currently, the high-cell-density fermentation designs pioneered by Provesta (a company belonging to Philipps Petroleum) allows them to obtain up to $160\,g\,l^{-1}$ of yeast biomass, while traditional fermentation techniques yield at most $30\,g\,l^{-1}$. These fermenters have attached very efficient systems for heat removal and oxygen transfer.

Once obtained, the microbial biomass is recovered by filtration or centrifugation. The resulting cell suspension can be either spray-dried, or the cells can be broken to obtain extracts, hydrolysates, or autolysates. Finally, the protein can be concentrated, isolated, or texturized. In the Philipps Petroleum process, owing to the high cell density, the spent medium is fed directly to the spray-drier without prior concentration.

Nutritional Value

The main nutritional contribution of SCP either for human food or animal feed is its high protein content. Bacteria have a protein concentration ranging from 50 to 85% and yeasts from 45 to 70%. Protein quality is also quite acceptable, as compared with vegetable proteins. Generally, SCP from any source is limited in sulfur-containing amino acids; however, bacterial proteins tend to have better balances of essential amino acids than yeasts and other microorganisms, particularly with respect to sulfur amino acids. Some parameters of protein quality are given in Table 3. When methionine is added to SCP, the protein quality increases considerably and reaches values similar to those of casein. (*See* **Amino Acids**: Properties and Occurrence; Metabolism; **Protein**: Quality.)

SCP is also an important source of vitamins; actually, brewer's yeast has long been used as a vitamin supplement. Vitamin contents are also listed in Table 3.

Toxicological Aspects

Safety of both the microorganism and the substrate is an important consideration. Microorganisms used for SCP production have to be subjected to extensive toxicological clearance. Those microorganisms

normally present in fermented foods, such as *Saccharomyces cerevisiae*, are safe for human consumption. The main concern has been linked to the use of petroleum derivatives in which residual alkanes must be removed with solvents. However, some residual hydrocarbons may still be present, and several reports have stated the presence of unusually high amounts of odd-chain fatty acids and paraffins in tissues from animals fed with SCP from alkanes. These fatty acids, particularly unsaturated C17, have been suspected of having toxic effects, even though no evidence has been reported.

The high content of nucleic acids present in microbial cells also has some consequences. Human consumption of nucleic acids in amounts higher than 2 g per day could lead to the accumulation of uric acid, resulting in kidney stones and/or gout onset in susceptible people. The concentration of nucleic acids in the biomass is highly variable and depends on several factors. The first element is the nature, species, and strain of the microorganisms; normally, bacteria are present in higher concentrations than yeasts. Another factor is the growth conditions: the higher the growth rate, the higher the nucleic acids content in the cell. The nucleic acid content also changes with the growth phases. For instance, for *K. marxianus* grown on whey, the concentration of nucleic acids reached its peak at the middle of the exponential phase. Table 4 shows the nucleic acids content of several SCP products.

In order to reduce the nucleic acid content, two approaches have been followed: grow the biomass at low rates or isolate the protein by eliminating undesirable compounds. The later is usually applied, to eliminate not only nucleic acids but also the cell wall. In recent years, research has been conducted on the use of external (added) endonucleases to hydrolyze nucleic acids and so obtain protein isolates free from these polymers. Immobilized endonucleases have been proposed particularly for this purpose.

Yeasts and bacterial cell walls are difficult to digest, leading to poor bioavailability of proteins, flatulence and diarrhea, and allergic responses. Some cases of skin rashes, nausea, vomiting, and other allergic reactions have been reported, but they may be eliminated by reducing cell walls and nucleic acids.

Nucleic acid content in SCP for animal feed is not a problem, because animals have the enzyme uricase, which prevents uric acid accumulation. However, cell wall digestibility in monogastric animals is also poor.

Cell Disruption and Protein Isolation

Many processes to disrupt the cells have been developed. A common process is autolysis, in which the biomass is exposed to a heat shock or to chemical compounds, such as low-molecular-weight thiols. Yeast autolysis usually takes place when cells are heated to 45–55 °C, and it is enhanced by the presence of NaCl. Further incubation for around 24 h induces cellular enzymes, leading to complete cell lysis. The process also activates endogenous ribonucleases that reduce nucleic acids. Lysis can be facilitated by the addition of exogenous enzymes such as proteases, β-glucanases or lysozyme. The disadvantages of these techniques are the high costs involved and extensive proteolysis, which reduces the yield and functional properties of proteins. Chemical treatments with alkalis, organic solvents, or salts, which weaken cell walls, are also used. Alkaline treatment may result in undesirable side reactions, forming compounds such as lysinoalanine and off-flavors.

Hydrolysis requires the use of hydrochloric acid at temperatures as high as 100 °C, to treat a slurry with 65–85% solids content, followed by neutralization with NaOH. This process has many drawbacks such as the risk of accidents with concentrated acid, the need for anticorrosive equipment, which is cost-intensive, and the destruction of some amino acids and vitamins, reducing the nutritive value of the product.

Physical methods to break cell walls are the methods most widely used. High shear rates are achieved by means of homogenizers or colloidal mills and have been used extensively for SCP processes.

Once the cells have been broken, the protein is extracted using water or alkaline conditions; the cell wall debris is removed by centrifugation, and the protein is further precipitated with acid, salt, or heat treatment, while the nucleic acids remain in the supernatant. Usually, microbial proteins have their maximum solubility at pH 12, and the precipitation occurs at pH 4.5. The protein isolate is then obtained. Some chemical modification during protein extraction includes phosphorylation or succinylation, which facilitates protein separation from nucleic acids and improves its functional properties.

Utilization for Human Food

For food applications, besides toxicity and nutritional quality, organoleptic acceptability and functional properties are important considerations.

SCP has been used as a protein supplement in baked goods, cookies, crackers, snacks, soups, noodles, and special foods like geriatric or baby meals. Its use as an extender in sausages and other meat products has been important, mainly in Eastern European

countries. Despite the justified production of SCP in terms of the world's protein shortage and widespread malnutrition, a real demand for a protein is based on its favorability in terms of functional properties like solubility, water binding, emulsification capacity, gelation, whippability, and foam stability. The successful supplementation of existing products and the replacement of traditional proteins with SCP depend on the availability of proteins matching in functionality, price, and organoleptic acceptability.

For food applications, whole dried cells, disrupted cells, and textured protein products are useful. From disrupted cells, either protein concentrates or isolates can be obtained, which are better suited for the food industry. Moreover, SCP isolates can compete favorably with soy isolates from the functional point of view. However, isolation or concentration increases production costs dramatically.

Processes such as texturization, by spinning and extrusion, and enzymatic or chemical modification can improve the functionality of SCP. For instance, protein fibers obtained by spinning can form textured protein products such as meat extenders.

Enzymatic modification includes partial proteolysis to improve solubility, emulsification capability, and whippability, or the reverse reaction known as plastein (peptide bond formation) to improve the nutritional value through the addition of limiting amino acids. Promising chemical modifications include acetylation, which improves the thermal stability, succinylation, or phosphorylation to increase the solubility, emulsification, and foaming capacities. However, such modifications tend to reduce the nutritive value of the proteins. Experiences with phosphorylated yeast proteins have demonstrated that protein recovery can be improved, reducing nucleic acids. Functional properties such as water solubility, water-holding capacity, and thickening properties can be enhanced, whereas the emulsifying activity is better than soy protein isolate and equivalent to sodium caseinate.

Although dried whole cells have limited functional properties, they are frequently used as flavor-carrying agents and food binders. Dried yeast cells can act as oil-in-water emulsion stabilizers. (*See* **Emulsifiers:** Phosphates as Meat Emulsion Stabilizers; Uses in Processed Foods.)

The major market for microbial biomass is as a flavor enhancer for meat products, soups, gravies, barbecues, sauces, salad dressings, seasonings, and any food with savory, cheesy, or meaty flavors (flavor notes associated with the fifth basic flavor called 'umami'), including pizzas, snacks, chips, etc. In fact, yeast protein hydrolysates, autolysates, and extracts have long been used as food flavorings.

Prospects

SCP has to compete with other protein sources such as soy bean, fish meal, and milk proteins. It has been widely demonstrated that in proteins to be used as additives or to be incorporated into a food, the most important factors to be considered are their functional properties and price; therefore, these are the main challenges that SCP has to face. Unfortunately, production and isolation of protein from microbial biomass are rather expensive because they are capital- and energy-intensive. Its broad utilization has been limited for economical reasons. However, autolysates or hydrolysates prepared mainly from yeasts have gained a wide acceptability as functional food ingredients. In addition, recent biotechnological advances such as high-cell-density fermentations, more efficient downstream operations, and the possibility to genetically improve microorganisms could re-evaluate SCP.

High-cell-density fermenters have made possible a considerable reduction of equipment size, energy savings, very high productivities, and cheaper downstream processing. For instance, direct spray-drying from the fermenter is possible. These kinds of improvements could bring SCP to a competitive level. Currently, Philipps Petroleum is producing Provesta and Provesteen, trade marks for SCP from different strains, using this process (see Table 1).

The use of fed-batch fermentations has not been fully explored for SCP production. This technique is widely used for the production of bakers' yeast, increasing yields and avoiding ethanol accumulation. Some reports applying this strategy to yeast SCP production have demonstrated a yield increase up to 70%. The possibility of implementing continuous fermentation technologies to improve productivity has been explored for the production of SCP. A commercial process operated by Société des Alcohols du Vexin (SAV) in France is currently using a continuous culture for SCP production from whey.

Genetic engineering has focused on the possibility of improving substrate utilization. The first modified microorganism utilized in an industrial process and the largest-scale application for genetic engineering is a strain of *Methylophilus methylotrophus* developed by ICI in 1977. The improved strain, grown on methanol, is able to utilize the ammonium ion as a nitrogen source more efficiently than the wild strain, saving 1 mol of ATP per mole of ammonium assimilated, with an increase in efficiency of 4–7%.

Considerable research based on genetic engineering has been carried out to obtain yeasts able to utilize a broader range of carbon sources, such as lactose,

starch, cellulose, xylose, and chitin, in order to use cheaper and more available substrates.

Another interesting issue is to obtain easily and/or genetically controlled autolytic cells, for which different approaches have been followed, including the selection of mutants with weaker cell walls; also, the introduction of genes coding for lytic enzymes to facilitate cell disruption, and genes coding for nuclease activity to reduce nucleic acids content, have been explored. Recently, a system was developed that consists of a regulated promoter that controls two genes involved in cell wall biogenesis, which led to the possibility of triggering cell lysis of *S. cerevisiae* by the addition of methionine; this system can be extended to other yeast species. Also, an enhancement of the nutritional value by modification of the amino acid content, or obtaining proteins with better functional properties looks promising. All these possibilities have been investigated, but practical results will take longer to be implemented.

Another approach to improve the economics of SCP would be to produce it as a low cost byproduct in multiproduct microbial processes, such as during processing of food wastes to reduce the biological oxygen demand, or as a byproduct from high-added-value enzymes. Another possibility is the recovery of nucleic acids from bacteria and yeast biomass to produce 5′-nucleotides, which can be used as flavor enhancers.

SLIMMING

Contents

Slimming Diets

D L Miller, Central Soya Company Inc., Fort Wayne, IN, USA

Background

The prevalence of being overweight or obese in America is staggering. An accepted measure of overweight status and obesity is the body mass index (BMI). BMI is weight (kg) divided by height-squared (m^2). A BMI of 30 is generally accepted as the lower limit for obesity, whereas individuals with BMIs between 25 and 30 are considered overweight (Table 1). A recent survey has estimated that more than 33% of Americans meet the criteria for being obese, whereas 50% of American adults meet the criteria for overweight/obese.

It is not surprising, then, that a large number of adults are attempting to lose weight. Consumers are bombarded with endless commercially available weight-loss programs – many promising fast and easy weight loss. Some commercial programs recommend a low-fat diet, whereas others recommend low-carbohydrate diets, and protein intake varies among these programs. Still others advocate single foods, juices, or herbal remedies (Table 2). In order to review this topic in a concise method, weight-loss diets will be discussed, based on their macronutrient composition.

Concept of Macronutrient Composition

Foodstuffs are generally comprised of three major 'macro' nutrients: protein, carbohydrate, and fat (see Figure 1). Foods are not solely made of one macronutrient, but are composites of all macronutrients in various proportions. Macronutrients vary in their energy yield per gram: protein and carbohydrate both yield 17 kJ (4 kcal) g^{-1}, whereas fat is a much denser source of energy, yielding an average of 38 kJ (9 kcal) g^{-1}. Alcohol is also a dietary source of energy, with 29 kJ (7 kcal) g^{-1} but alcohol will not be discussed in this review. In terms of energy (kJ/kcal), the typical American diet comprises 10–15% protein, 50–55% carbohydrate, and 35–40% fat.

Energy Equation

In order to discuss the effects of alterating the macronutrient composition of a food on body weight, it is useful to discuss the basic concept of energy balance. To maintain a stable body weight, the total energy intake must equal the total energy loss or output, as shown by the following equation:

$$E_{\text{input}} - E_{\text{output}} = \text{E}_{\text{stored}}.$$

The simple interpretation of this equation, as it relates to human obesity, is that if more energy is consumed by an individual than is expended by that individual, the excess energy will be stored. This model becomes more complicated when the ingested and stored energy is subdivided into the three macronutrients. A normal-weight human being typically stores 585 760 kJ (140 000 kcal) of fat in adipose tissue, 100 416 kJ (24 000 kcal) of protein, mainly in muscle mass, and 3347 kJ (800 kcal) as carbohydrate in the form of glycogen (stored mainly in the liver, kidney, and muscles) plus glucose that circulates in the blood. In humans, stores of protein and carbohydrate remain rather constant, regardless of the level of intake, whereas theoretically, fat can be stored in an almost unlimited capacity.

Macronutrient Composition and Weight Loss

High-protein Diets

Protein makes up a small and relatively constant proportion (14–18%) of total energy intake of adults. There is much debate in the scientific community about the role of protein intake in weight loss. Some researchers theorize that, because dietary protein is essential for physiological processes (growth, tissue maintenance, enzyme production, hormonal synthesis, etc.), humans and other animals consume foods to deliver the protein needed to sustain these processes. As it relates to weight control, if an individual chooses high-carbohydrate and/or high-fat foods

Healthy; overweight; obese

Table 2 Various diet plans

Diet plan	*Type of diet*	*Comments*
Cabbage Soup/All You can Eat Soup Diet	Single-food, low-fat, low-carbohydrate, very-low-energy density	Based on continued consumption of a buillion-based cabbage and vegetable soup, which is not highly palatable; other foods permitted include fruit, but not bananas
Dr. Atkins Diets	Low-carbohydrate	Ketogenic diet, which encourages free intake of fat and protein foods with severe carbohydrate restriction (< 20 g per day). Compliance can be checked by urine ketostix
Grapefruit Juice Diet	Single-food, high-water	Grapefruit juice is touted as a energy burning catalyst with the specific foods recommended. No evidence exists regarding the validity of these claims
Russian Airforce Diet	Low-fat, low-carbohydrate, low-energy	Diet includes red meat, eggs, fruit, and salads with no starch sidedishes
Scarsdale Diet	Low-fat, low-carbohydrate, low-energy	Lean meats, high-water fruits (melons and citrus), and salads, no starch sidedishes
The Zone Diet	Low-carbohydrate	Touted to stimulate the ideal amount of insulin by consuming macronutrients in the ratio of 40% carbohydrate, and 30% each of protein and fat
Liquid Diets	Low-fat, portion-controlled	Simple to use and may be of use for those who have difficulty with portion control. Monotonous food intake may be difficult to maintain
Dieting, Italian Style	Portion-control, increased-fat	This diet advocates determining your individual energy needs (via table of metabolic test) and consuming a diet high in pasta, bread, cheese, avocado and olive oil. Portion-control is necessary on this diet

with little protein content, the individual would need to consume a larger volume of food to obtain the necessary amount of protein.

Indeed, researchers have found that high levels of protein (> 25% of energy) have been shown to have a suppressive effect on energy intake in humans and animals. In humans, the consumption of high-protein foods has been shown to acutely reduce subsequent energy intake relative to low-protein foods. However, the protein intake of adults in Western populations is generally higher than the recommended dietary levels. The US recommended daily amount (RDA)

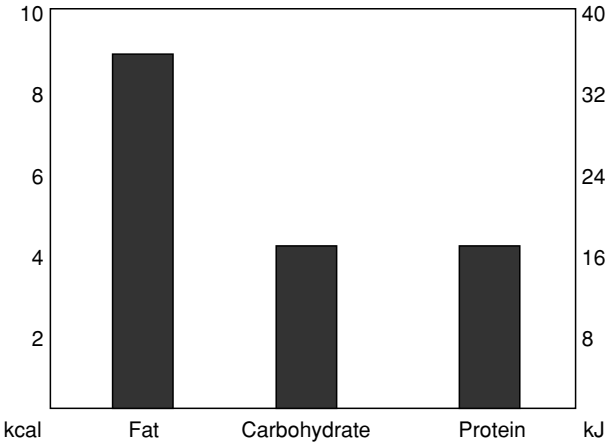

Figure 1 Energy content of macronutrients.

for protein is 63 g for males and 50 g for females; therefore, most American males eat 120% of their RDA for protein, and American females 158%. This adds confusion as to whether increases in protein intake are justified, and some have questioned whether a chronic high intake of protein could cause kidney damage or even osteoporosis. Currently, there are no compelling data to suggest a link with such damage.

The question of optimal protein intake during weight gain is controversial; however, alterations in the levels of fat and carbohydrate, which supply the bulk of total energy intake, are likely to have greater effects on weight loss. Some diets, which claim to be 'high-protein,' are actually based more on lowering or eliminating carbohydrate intake and replacing it with protein and fat energy. These diets will be discussed below.

Low-carbohydrate Diets

In the 1960s and 1970s, the 'bad nutrient' was carbohydrate or, more specifically, sugar. In his 1972 text, Craddock states, 'sugar is indeed the great enemy.' During this time, the low-carbohydrate diet grew out of the frustration of physicians who had documented that just telling patients to 'eat less' or restrict calories was not producing positive results. Thus, the notion of restricting a particular macronutrient, instead of calories, with free access to other macronutrients was proposed. Reducing protein intake was illogical, as protein represents a relatively small proportion of the total diet. At this time, before the advent of fat replacers and low-fat food technology, a diet low in fat was very unpalatable. This was further reinforced by the fact that protein and fat both have dietary requirements, whereas carbohydrate does not. Reducing carbohydrate intake from 350 g per day (average intake) to 50–60 g per day, therefore, seemed to be the logical nutrient to restrict as a reasonably palatable diet could be designed and maintained with 50–60 g of carbohydrate per day.

The low-carbohydrate diet encouraged participants to eat as much as they wanted of foods low in carbohydrate (meat, fish, cheese, butter, and green leafy vegetables and 330–670 ml of whole milk per day). It was assumed that the quantity of these foods consumed would be similar to the typical intake and, with the elimination of the carbohydrate energy, produce a deficit of 3360–4200 kJ (800–1000 kcal) per day. This energy reduction thus shifted the individual into a negative energy balance in which increased levels of fatty acids would be oxidized – or burn fat – and result in a significant weight loss.

Ketogenic diets An extreme form of the low-carbohydrate diet is a regimen almost devoid of carbohydrate. This diet encourages *ad libitum* consumption of meats, cheeses, eggs, and butter. Low-starch (mainly water-containing) vegetables (lettuce, peppers, tomatoes, onions, zucchini) are permitted in limited amounts, depending on the carbohydrate content. Sugars and other monosaccharides and complex carbohydrate sources (breads, grains, pasta, rice) or any digestible carbohydrate that would in turn provoke an insulin response are strictly restricted.

On this diet, glycogen stores are depleted within 24 h, and within 48 h the individual becomes ketotic – a metabolic state in which glucose is no longer available in adequate quantities to serve as a fuel. In ketosis, large amounts of the ketone bodies, acetoacetic acid, beta hydroxybutyrate, and acetone, are produced to be utilized as fuel. These compounds are produced in the absence of glucose/insulin as a method to spare glucose for use by the brain and other solely glucose-utilizing tissues. In the synthesis of ketone bodies, large amounts of fatty acids from adipose tissue are mobilized for use as fuel – utilizing stored fat as energy. In a starvation mode, which the body believes it is in with a ketogenic diet, the brain may obtain 30–40% of its energy from ketone bodies. Ketosis also occurs in uncontrolled diabetes and, if untreated, can lead to ketoacidosis and coma.

The evidence for the effectiveness of very low-carbohydrate diets is dated as far back as 1932, when the principle of reducing weight by a diet 'containing much fat but little carbohydrate' was introduced. However, not until the 1950s, following a series of experiments did low-carbohydrate/high-fat weight-loss diets begin to emerge in the popular press. In these experiments, the researchers fed overweight participants, isocaloric (4200 kJ or 1000 kcal) per

day diets comprising 90% protein, carbohydrate, or fat. Participants lost more weight on the low-carbohydrate diets (high in fat and protein) than the high-carbohydrate diet (low in fat). The mean weight loss on the low-carbohydrate diet was 2.33 kg over 5–9 days, but there is great intersubject variability with weight losses ranging from 0.6 to 3.2 kg. Also, the duration of the diet periods (5–9 days) is too short to adequately assess this diet composition on long-term weight loss. Further, it is well established that each gram of muscle glycogen that is converted to glucose for use as fuel yields 3 g of water. Thus, it is theorized that during the initial stages of a low-carbohydrate diet, when glycogen stores are being depleted, much of the weight loss is from water loss.

Some follow-up studies compared low-carbohydrate diets with low-fat diets and investigated the amount of weight and water loss on each regimen. One study showed that there was no significant difference in the rates of weight loss on either diet. In addition, when these diets were interchanged, deviations from the weight-loss curve occur mainly as a result of fluid balance. Another study found that a high-fat/low-carbohydrate diet resulted in weight loss, but the weight loss ceased after a few days and was explained largely by fluid loss. However, a study in 1981 measured sodium, potassium, and water losses on diets low or high in carbohydrates over a 28-day period and found conflicting results. In this study, although sodium and potassium losses were greatest on the low-carbohydrate diets (at least until day 14), water losses showed no significant differences at any time period, and the low-carbohydrate diet produced a significantly greater weight loss than the high-carbohydrate diet (12.5 ± 0.9 kg and 9.5 ± 0.7 kg).

Recent studies The 1990s saw a resurgence in the popularity of low-carbohydrate diets, and with it, new research has emerged. In a 1996 study, 43 obese participants were randomly assigned to consume diets of equal energy but which differed in macronutrient composition:

- low-carbohydrate diet: 32% protein, 15% carbohydrate, 53% fat;
- low-fat diet: 29% protein, 45% carbohydrate, 26% fat.

Similar to the studies done in the 1960s, this study found that weight, plasma glucose, cholesterol, and high-density-lipoprotein cholesterol changes were similar on both diets. Interestingly, however, the higher-protein/fat, lower-carbohydrate diet was found to be more beneficial on plasma insulin and triacylglycerides (triglycerides). It is important to note that this diet was not ketogenic, as were diets fed to the participants of the earlier studies. These results were consistent with other, more modern studies.

The current view of ketogenic low-carbohydrate diets is that at least 100 g per day or more of carbohydrate is recommended both to spare protein and to avoid large shifts in weight resulting from changes in water balance and electrolyte loss. When carbohydrate levels are below 100 g per day, insulin levels fall, and protein is catabolized to provide the glucogenic amino acids. Most diets providing under 100 g per day of carbohydrate or approximately 3360 kJ (800 kcal) per day are ketogenic. Also, dieters may have negative side-effects, including fatigue, postural hypotension, a fetid taste in their mouths (from increased acetone production), and elevated serum uric acid levels, and may be more subject to negative nitrogen balance. In addition, because consuming a low-carbohydrate diet often means consuming a diet higher in fat, cardiovascular health is of concern. A high intake of saturated fat, found mainly in meat and dairy products, has been linked to increased serum low-density lipoprotein cholesterol levels and is thus thought to be atherogenic; however, the beneficial effects of low-carbohydrate diets on insulin and triglyceride levels should not be dismissed. High triglyceride levels have begun to receive increased attention in medical research as a serious cardiovascular disease risk factor. Low carbohydrate diets which obtain the majority of protien from vegetable protein (nuts, soy, legumes) should be more healthful overall, but more research is needed.

Low-glycemic index diets Recent research focus has shifted away from low-carbohydrate diets to 'low-glycemic index' diets. The glycemic index was proposed by Jenkins to characterize the rate of carbohydrate absorption after a meal and is defined as the area under the glucose response curve after consumption of 50 g of carbohydrate from a test food divided by the area under the curve after consuming a control food (usually glucose). The glycemic index of foods became of interest as dieters following a low-fat regimen began replacing fat calories with carbohydrate calories. Many of the foods chosen to replace high-fat foods were high-glycemic index foods (Table 2). To compound this situation, ingested fat serves to slow the rate of absorption of concomitantly ingested carbohydrate. Thus, some researchers believe that low-fat diets have resulted in an increased intake of high glycemic index foods that are more rapidly absorbed, thus causing a functional hyperinsulinemic response. This hyperinsulinemic state may promote weight gain by preferentially directing nutrients

away from oxidation in muscle and toward storage in fat.

A number of studies have examined the effects of glycemic index on appetite and food intake regulation in humans. Two studies found lower blood glucose levels and a slower return of hunger after low-glycemic index meals compared with high-glycemic index meals. Another study investigated the hormonal response to high- and low-glycemic index foods. This study provided obese teenage boys low-, medium- and high-glycemic index meals. Relatively high insulin and low glucagon concentrations were observed following the high-glycemic index meal. Such hormonal changes would be expected to promote uptake of glucose in muscle, liver, and fat tissue, restrain the release of glucose, and inhibit lipolysis (release of fatty acids for fuel). In addition, a 'reactive hypoglycemic' period was observed following the high-glycemic index meal – high insulin levels effectively cleared the abundant blood glucose and lowered free fatty acid concentrations 3–5 h after the high glycemic index meal compared with the low-glycemic index meal. In this metabolic state, stimulation of appetite would be expected. Indeed participants consumed more energy after the high-glycemic index meal compared with the medium- or low-glycemic index meals. Thus, hormonal responses to a high-glycemic index diet appear to lower circulating levels of metabolic fuels, stimulate hunger, and favor storage of fat, events that may promote excessive weight gain if excess energy is consumed. A diet of low-glycemic index foods would include abundant quantities of vegetables, fruits, and legumes, moderate amounts of protein and healthful fats, and decreased intake of refined grain products, potato, and concentrated sugars.

Low-fat Diets

In contrast with the dated research done on low-carbohydrate diets, research on the effects of low-fat diets is more recent. Until the mid-1980s, there were few studies examining the effects of variations in the level of fat in the diet on energy intake and body composition. This was because, before this time, there was relatively little emphasis on the role of dietary fat in obesity and related disease states. Research from the 1980s suggested that the oxidation of protein and carbohydrate is closely tied to their intake, whereas fat oxidation is not closely correlated with intake. This suggests that fat, unlike the other macronutrients, does not promote its own oxidation, and to maintain fat balance, fat should be consumed in small amounts or coupled with behaviors that promote fat oxidation, such as aerobic exercise.

This work, coupled with several low-fat feeding trials (discussed below), effectively shifted the emphasis from sugar to fat as the 'bad' nutrient. Food manufacturers followed this trend by producing a large number of products that were low-fat or fat-free versions of traditionally higher-fat foods. The development of a number of functional, fat-replacing ingredients allowed food technology to develop palatable low-fat/no-fat foods in a range of food categories. However, although there have been a number of studies on the role of dietary fat in the etiology of obesity, there have been few well-controlled studies on diet composition and weight loss. Surprisingly, there are almost no data on the effects of fat-replaced foods on weight control.

Three large, controlled, laboratory studies from the 1980s and early 1990s investigated the effects of covert manipulations of the fat content of a diet consumed *ad libitum* on energy intake and body weight. In a study in 1983, participants were fed a low-fat diet comprising traditionally low-fat foods (fruits, vegetables, and grains) and a high-energy-density diet for 5 days. Participants could eat the foods freely or *ad libitum*. Participants reduced their energy intake by half when eating the low-fat diet compared with the high-fat diet [12 552 kJ (3000 kcal) vs. 6569 kJ (1570 kcal) per day]. However, no data were reported regarding weight loss.

Two other studies, conducted at Cornell University, are often cited in both scientific and popular literature as proof that *ad libitum* consumption of low-fat foods can reduce fat intake and lead to weight loss. In the first of these studies, overweight participants were each fed three diets: low-fat 15–20%, medium-fat 30–35%, and high-fat 45–50% of energy. Energy consumption increased as the level of fat of the diet increased, with the low-fat diet resulting in an average reduction of 2205 kJ (527 kcal) per day compared with the high-fat diet. Despite these daily differences, the diets did not produce any statistically significant weight changes over the 2-week periods. The second Cornell study was similar but extended the intervention period to 11 weeks. In this study, participants consumed an average of 1201 kJ (286 kcal) per day less on the low-fat diet than on the high-fat diet. Weight loss was significantly greater on the low-fat diet than on the high-fat diet, but weight loss occurred on both diets, making it difficult to conclude that the low-fat diet was more effective for weight loss. In addition, although statistically significant, the actual weight losses are quite small. This evidence indicates that low-fat diets consumed *ad libitum* may be somewhat useful for reducing the amount of fat consumed – important for cardiovascular health, but their effectiveness for weight loss is less impressive.

Another study examined the weight loss potential of restricting fat plus caloric intake compared with restricting just fat intake. Over the 16–20 weeks of treatment, the group with energy restriction lost significantly more weight (males 11.8 kg, females 8.2 kg) than the group only modifying fat intake (males 8.0 kg, females 3.9 kg). There was also a significantly greater loss of body fat in the energy restriction group. The authors concluded that it is more effective to instruct overweight persons to restrict both fat and energy intake than it is to restrict only fat intake as a weight loss strategy. Finally, a study from the US Department of Agriculture investigated the effects of varying the fat level of a reduced-energy diet on body weight and composition. In this study, the fat content of the diet of eight overweight males fed at 50% of maintenance was manipulated. No significant differences were found between the low-fat and high-fat diets in the extent or composition of body-weight loss. Body weight decreased by 5.2 kg for the high-fat group and 5.0 kg for the low-fat group. Subjects in the low-fat group, however, did lose more fat and less fat-free mass than did the high-fat groups. This research implies that weight loss is not dependent on the composition of the diet as long as the diet is reduced in total energy.

These studies taken together indicate that, although fat restriction may be of some use for weight loss, restricting total energy intake is the most important factor. The results regarding energy deficit and diet composition are consistent with other research reports that state that the most significant factor determining the amount and rate of weight loss is the degree of negative energy balance achieved. It may be that low-fat diets are most useful in preventing excess energy intake and obesity. There has never been a single study showing an advantage of high-fat diets over low-fat diets in reducing energy intake and preventing obesity. For the same reasons, fat restriction may also be beneficial as part of a weight-loss maintenance program.

Low-energy-density Diets

Another impediment to weight loss is the abundant availability of an energy-dense diet in Western culture. Energy density is a measure of the amount of energy in a given weight of food. It is reasonable to assume that when foods are more heavily packed with energy, even small portions can produce large energy intakes and increase the probability of occurrence of periods of positive energy balance. What may be key is reducing the overall energy density of the diet.

Energy-dense foods include those that are high in fat, those with large amounts of added sugars or processed flours, and those low in water. Some fat-replaced foods, sweet, and other snacks can have large amounts of added sugars/processed flours, making them low in fat, but also energy-dense. Because both high-fat foods and high-glycemic index foods are energy-dense; choosing foods less dense in energy may bring these philosophies together. Energy density is affected by the fat content of food, and processed flours contribute to energy density because large amounts of these nutrients can be incorporated into foods and not diluted with water, as in naturally occurring foods. Because it increases the weight of food but not the energy content, the amount of water in a food also greatly affects energy density. Fiber in foods holds a large amount of water and can provide a sensation of fullness in the gut.

The studies described in the low-fat diet section also illustrate the utility of a diet lower in energy density. Individuals in those studies tended to eat a constant weight of food. When the food consumed was lowered in energy-density, the same weight of food supplied fewer calories. It has been demonstrated that individuals tend to eat a constant weight of food, rather than eat a constant amount of any of particular macronutrient or amount of energy. Another study allowed lean women to consume *ad libitum* three different diets that varied in energy density but had constant amounts of carbohydrate, fat, and protein. The women also tended to eat the same amount or quantity of food but consumed 30% less energy on the low-energy-density diet.

In selecting foods appropriate for a low-energy-density diet, it is difficult to reduce the energy density of the diet without decreasing fat and added sugar intake and increasing dietary fiber intake, bringing together some principles of the low-fat and low-glycemic index philosophies.

Conclusions

It is clear, with the large number of individuals meeting the overweight and obese criteria at this time and attempting to diet, that weight loss is not simple or easy. It is also clear that no one dietary principle is applicable to all individuals. It may be that genetic influences such as those that influence fuel utilization, glucose metabolism, fat storage, etc., may make the restriction of one macronutrient result in a more substantial weight loss for one person while being less effective for another. The impact of genetic differences on the effectiveness of pharmaceutical products has received great attention recently, and such differences are being explored from a nutritional perspective as well. It may be that future dietary treatment for weight loss will be based (at least partially) on

one's individual genome to optimize diet manipulation effects and maintain/restore maximal health.

At present, the most beneficial aspect of altering the composition of the diet in terms of weight control may be that the alteration simply results in less energy being consumed. The data presented here, however, indicate that diet-composition changes alone are insufficient for significant weight losses. Weight loss is dependent upon creating a negative energy balance, which can be achieved in part by diet-composition changes but also must include reductions in overall energy intake.

Because eating patterns, personal habits, and food likes and dislikes vary so greatly between individuals, an individual seeking a weight-loss plan must decide which approach to reducing energy intake is best suited for their lifestyle. If an intake pattern can be established and maintained in which less energy is being consumed than oxidized, weight loss will occur. Weight loss will generally occur in proportion to the degree of energy restriction and the duration of that energy restriction.

The next level of concern regarding weight loss is the secondary effects of the weight loss diet on health and whether that diet is palatable and sufficient in nutrients so that it can be maintained long enough to produce the desired weight loss. From a health standpoint, reducing saturated fat remains supported by the literature, whereas following a diet very low in fat may not be, especially if healthy fats (such as monounsaturated fats and omega-3 fatty acids) are restricted. In addition, fat should not be replaced with high-glycemic index foods. The data for a hyperinsulinemic response following ingestion of high-glycemic index foods and the subsequent effects on energy storage and appetite are compelling. Ketogenic diets, however, are associated with few health benefits, other than reduced blood glucose and insulin – which, most likely, will not be maintained once carbohydrates are reintroduced.

So what is the healthiest method by which to reduce energy and lose weight? The concept of reducing the energy-density of the diet by decreasing consumption of high-fat/high-energy foods (cheese, bagels, butter, fried foods, some dairy products) and increasing consumption of low-energy dense foods (vegetables, fruits, legumes, and high-fiber foods) may be the best prescription for overall health. Health effects of increased intake of dietary fiber include reduced blood glucose levels and cholesterol as well as a balanced gastrointestinal function. The addition of healthy fats in moderate amounts should also be considered; however, even healthy fats are high in energy – thus, smaller portion sizes may be needed to reduce energy when such fats are included. A low-energy-density diet should result in a reduced energy intake and produce a steady weight loss unless unusually large portions are consumed.

Metabolic Consequences of Slimming Diets and Weight Maintenance

E Rasio, Hôpital Notre-Dame, CHUM, Montreal, Quebec, Canada

Introduction

In many societies today, a plethora of individuals pursue weight reduction diets for a variety of reasons,

ranging from social pressures to medical concerns. Dieters usually fail to perceive that the phenomena underlying weight gain and weight loss may be quite different in complexity. Weight gain, as a consequence of excess energy intake, is a relatively simple process whereby fat stores are increased. To a large extent, it is independent of the quality of food eaten. Thus, whenever calories are ingested in excess of calories expended, be they in the form of sugars, proteins, lipids, or alcohol, the balance is stored in the most compact, weight-efficient form, as fat. The only exceptions to this rule are growth, pregnancy, muscle building, and rehabilitation following malnutrition, where excess calories, with adequate amounts of protein, can also be retained as protein.

Weight loss, as a consequence of insufficient energy intake, has a greater variety of effects which depend upon nutritional status, energy content of the diet, and balance of nutrients. Thus, an excess daily intake of 1250 kJ (300 kcal) in the form of 75 g of sugars, or 75 g of protein, or 35 g of lipids, will result, in most individuals, in a gain of 35 g of body fat. A deficient daily intake of energy of 1250 kJ may induce a considerable range of changes in body weight and body composition. In appropriately chosen conditions, the subject will lose 35 g of body fat, but electrolytes and protein shifts will often alter the body weight response so that not all of the weight lost will be in the form of fat. (*See* **Energy**: Energy Expenditure and Energy Balance.)

Regimens for Weight Control

The ideal diet should deplete body fat stores, which are excessive, without reducing the protein pool out of proportion to the small increment always associated with the obese state itself. For this to occur, the chosen diet should meet stringent qualitative and quantitative requirements. Brain metabolism requires 150 g of glucose per day: with the exception of prolonged fast when ketone acids can be oxidized, the need for glucose is mandatory and cannot be met by transformation of lipids, whether supplied by the diet or mobilized from body reserves. Glucose can be generated from protein, from the glycogen pool, or provided in the diet. Consequently, diets which provide at least 2500 kJ (600 kcal) per day in the form of carbohydrate, and a substantial portion of protein, will spare the waste of endogenous protein and mobilization of the glycogen pool. Many slimming diets do not satisfy the brain's need for glucose, and therefore deplete glycogen and protein stores. These diets may be grouped into first, total fasting and certain very-low-calorie diets, or 'modified fasts,' which do not contain enough glucose and protein precursors, and second, diets which supply adequate calories but mostly in the form of fat. With both groups of diets, body proteins are mobilized and converted by the liver to glucose, which is then oxidized by the brain. The loss of body protein entails a loss of weight which is 10 times that of adipose tissue for an equivalent calorie content. A total fast will induce a protein loss not too dissimilar to that of a 5000 kJ-per-day diet, composed mainly of fat. In both instances, the weight loss will be very important: the high-weight-low-calorie protein waste will overwhelm the low-weight-high-calorie changes of fat stores. Concurrent major fluid losses will compound the phenomenon. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism; Requirements and Dietary Importance; **Fats**: Digestion, Absorption, and Transport; Requirements.)

Dietary strategies other than a reduction in calorie content have not been thoroughly evaluated for the treatment of obesity. There is some evidence that macronutrients may act directly, by their nature rather than energy, on mechanisms which regulate body weight. Furthermore, the potential of micronutrients to affect fat storage has not been explored.

Behavior modification targeted at overeating is also advocated to help reduce body weight. Some obese individuals may suffer from specific behavioral syndromes characterized by excessive consumption of certain foods, at particular times, e.g., carbohydrate cravings have been associated with seasonal affective disorders.

The major obstacle to dietary and behavioral treatment of obesity is that the voluntary control of energy intake is difficult and requires strong motivation. This is particularly true in affluent societies where food is plentiful and varied. The success rate of dieting can be disappointing: studies published in the medical literature indicate that weight loss after 1 year is usually less than 10% of entry weight. However, most people who determine that they should control their weight, or are advised to do so, are never part of medical surveys. Thus the real success rate for populations are not known.

Metabolic Consequences of Weight-reducing Diets

Negative Nitrogen Balance

Whenever a diet, irrespective of its calorie content, does not have sufficient protein to maintain required rates of protein synthesis, or a sum of protein and carbohydrate to meet the brain's energy requirements, it will induce a negative nitrogen balance, with protein tissue waste. Obese individuals have an

increased lean body mass and a higher metabolic rate than control individuals of 'ideal' body weight. Therefore, protein waste will be tolerated to some extent during dieting. Unfortunately, there is no evidence that protein is lost from those tissues where it accumulated during weight gain, i.e., from adipose tissue as a consequence of cell hyperplasia and hypertrophy, and from muscle and supporting tissues as a response to increased gravity. On the contrary, the protein loss may occur from all tissues. The digestive tract and the heart are particularly prone to functional alterations. In conditions of excessive negative nitrogen balance, thinning of the skin and loss of brain tissue have been reported.

Water and Electrolytes Losses

Elimination of excess water is a common feature of weight loss, particularly during the early stages. A negative calorie balance reduces insulin secretion and has a diuretic effect which enhances weight loss beyond that expected from endogenous fat oxidation. The diuretic effect varies with the quantity and quality of energy consumed. In general, the lower the energy content as carbohydrate, the greater the diuretic effect. Concurrent loss of sodium and potassium in the urine reflects the contraction of the extracellular and intracellular water compartments. Cardiac arrhythmia, including ventricular fibrillation and death, have been reported, probably as a consequence of electrolyte changes in the serum and cells. The use of diuretics alone or in combination with diets, especially when markedly carbohydrate-restricted, is therefore dangerous or, at least, superfluous in the treatment of uncomplicated obesity. Before counteractive adaptive mechanisms are set in motion, water loss at the initiation of low-calorie-low-carbohydrate diets may induce an extra weight loss of 0.5 kg per day, or even more. (*See* **Water**: Physiology.)

Water loss will confound changes in body fat weight. In extreme situations, such as those created by regimens very high in calories and fat, protein waste and dehydration will induce weight loss while fat stores are actually increased. Other diets, along the same principles, will also reduce weight with little fat loss.

Lowering of Blood Pressure

Overeating stimulates the release of catecholamines and insulin. Consequently, renal reabsorption of sodium is increased, and higher blood volume and cardiac output may then raise blood pressure. Hypocaloric diets will reverse this sequence of events and frequently reduce the hypertension associated with obesity, without medication or sodium restriction. (*See* **Hypertension**: Physiology.)

Weight-reducing diets, in particular those low in carbohydrate, induce relaxation of arteriolar tonicity and lowering of diastolic blood pressure. This, in combination with fluid volume contraction mentioned above, is responsible for orthostatic hypotension, a frequent side-effect, characterized by the inability to redistribute blood from the lower limbs when standing. Salt supplementation can diminish such an effect, but not abolish it, as a new steady state is reached in which the extra sodium is simply excreted. (*See* **Hypertension**: Hypertension and Diet.)

Lowering of Blood Lipids and Glucose

Although most obese individuals are free of metabolic complications such as dyslipoproteinemias and non-insulin-dependent diabetes mellitus, many patients with these metabolic anomalies are obese. When energy and carbohydrate intake are excessive, high levels of triglycerides and low-density lipoprotein cholesterol may accumulate in plasma. Obesity is also often associated with a diminution of circulating high-density lipoproteins. These changes in plasma lipid composition will contribute to the development of atherosclerosis and increase the risks of cardiovascular disease. Hypocaloric diets can rapidly blunt or eliminate hypertriglyceridemia, by the plasma-clearing action of lipoprotein lipase, and hypercholesterolemia, by reducing both the endogenous and exogenous flow of atherogenic lipoproteins. Concomitantly, the level of high-density lipoproteins in the plasma increases. Weight reduction can therefore often help to control dyslipoproteinemia without the use of pharmacological agents. (*See* **Atherosclerosis**; **Lipoproteins**.)

Blood glucose abnormalities in obese subjects are frequent. They range from mild glucose intolerance to overt noninsulin-dependent diabetes mellitus. These anomalies of glucose homeostasis are characterized by the presence of normal-to-high levels of circulating insulin which are insufficient to overcome the resistance by target tissues to its biological effects. Excess plasma insulin is a potential, albeit still controversial, risk factor for atherosclerosis. One of the most impressive effects of energy-restricted diets is the improvement or normalization of the altered glucose homeostasis associated with obesity. In a matter of days, even without significant losses of body weight, the obese subject can be switched to a normal glucose metabolism. A negative calorie balance can rapidly restore insulin sensitivity in a dieting individual. The mechanisms of this spectacular metabolic regulation are not known. The treatment of diabetes in the obese requires oral hypoglycemic agents only when

energy-restricted diets have proved unsatisfactory. Insulin may also be required to control blood glucose levels, in spite of possible atherogenic changes of the plasma lipid profile.

Reduced Resting Metabolic Rate and Postprandial Thermogenesis

With the loss of significant amounts of body weight, oxidative metabolism decreases, as does energy expenditure. This occurs both at rest and following meals. At rest, most of the energy produced is utilized to maintain body temperature and vital processes. Following the ingestion of a meal, additional oxygen is required for mechanical work associated with digestion, and for chemical reactions involved in processing the nutrients. The energy cost of disposing of food in the body varies with the caloric content of the meal, its composition, and sapidity. It represents only a small percentage of the overall resting metabolic rate. The main factors responsible for slowing of the oxidative metabolism are hormonal adaptive changes. Faced with reduced energy intake, the body responds by lowering the circulating levels of hormones which stimulate energy expenditure. Thus, the activity of the sympathetic nervous system is diminished and catecholamine production is lowered. Furthermore, the conversion of the thyroid hormone thyroxine into the more powerful hormone triiodothyronine is also reduced. These changes combine their effects in reducing mitochondrial oxidation and, therefore, energy output. This adaptive sparing of body weight varies with the energy restriction and the composition of the diet. It may represent approximately 850 kJ (200 kcal) per day after 2–3 weeks of fasting, but less if the diet has energy, particularly in the form of carbohydrates. Finally, when significant glycosuria is present in obese diabetic patients, the rapid lowering of blood glucose levels at the start of a hypocaloric diet will reduce or abolish the glucose caloric output in the urine and slow down weight loss accordingly. On the other hand, exercise, by implementing energy expenditure and by blunting the drop in metabolic rate associated with a negative energy balance, enables the weight loss to continue unmitigated. (*See* **Hormones**: Thyroid Hormones; **Thermogenesis**.)

A more chronic effect of weight-reducing diets is the loss of significant amounts of body weight when lean tissue is also wasted. The ensuing cell atrophy will contribute to lowered oxygen consumption.

Patterns of Weight Loss

After the initiation of a hypocaloric diet, a combination of behavioral and metabolic mechanisms takes place wherein the rate of weight loss decreases with time, despite a constant dietary intake.

On the behavioral side, many dieters tend to reduce their energy expenditure as a reflex in the face of scarce energy intake. Probably the most common cause for plateaus in weight loss is that, even with adherence to appropriate pattern and composition of the diet, portion sizes tend to increase.

On the metabolic side, a number of predictable adaptive reactions slow the rate of weight loss. First, water and electrolyte losses are rapidly blunted by sensitive hormonal counterregulatory responses. These may involve, depending upon the degree of water loss, the liberation of antidiuretic hormone by the hypothalamus or the stimulation of the renin–angiotensin–aldosterone axis. These responses are more decisive when diuretics are prescribed with the diet. Second, the body adapts by shifting its oxidative metabolism from glucose to fat and ketone acids. The reduced need for glucose spares the energy-diluted protein tissue at the expense of the energy-dense fat stores. Thus, the rate of body weight loss declines to very near the theoretical level expected from conversion to fat as the primary source of energy utilization. Third, the oxidative metabolism diminishes *pari passu* with the activity of the thyroid gland and sympathetic nervous system. Fourth, the loss of lean body mass, with time, lowers the resting metabolic rate, thus reducing the energy deficit.

Occasional interventions in the course of dieting may also slow down the rate of weight loss. Rotating diets, depending on their sequence, may induce rapid shifts in water and protein pools. For example, when a 3500 kJ per day ketogenic diet is followed by a diet of the same calorie content but richer in carbohydrate and protein, the weight loss may be temporarily reduced and weight may even increase as a consequence of water and protein gains. This same diet would have the opposite predictable effects if administered *de novo*. Thus, the same hypocaloric diet is capable of inducing either weight and protein gain, or weight and protein loss in the same individual, depending on the previous metabolic balance at any given total body weight. These considerations emphasize the extent to which the dependence of the dieter upon body weight measurement as a source of feedback information can be misleading.

A less common but interesting situation is created when dieting individuals embark on exercise programs. This leads to loss of body energy, without the expected concurrent loss of weight. It is possible, for example, to lose 1 kg of body fat as a consequence of a negative calorie balance, and to gain 1 kg of tissue protein as muscle is built up. The body weight has not changed, but the individual has lost in the process

30 000 kJ of body energy. Recent studies have shown that a similar protein-sparing effect, with negative calorie balance, can be achieved by administration of appropriate doses of insulin or growth hormone. The usefulness of these hormonal manipulations in the dieting individual has not yet been established.

Maintenance of Weight Loss

Whenever the stability of body weight is disrupted, the hypothalamic counterregulation will tend to restore weight to its initial value. This phenomenon applies in general to any level of weight equilibrium, whether the subject is thin, of 'ideal' weight, or obese; it is also operative for whichever direction the change of weight takes place, be it a gain or a loss. It is therefore recommended, in order to overcome the constraints of the 'ponderostat,' that slimming strategies aim for a moderate rather than rapid rate of weight loss, interspersed with periods of weight stabilization.

Physical exercise has the ability, within a wide range of intensity, to maintain and possibly reestablish the regulatory functions of the brain concerning energy balance. Exercise programs should therefore complement the slimming diet, with the reasonable expectation that they will help the dieter to maintain the weight loss.

The temporary use of anorectic drugs has been advocated to promote weight maintenance between episodes of weight loss. The administration of thyroid hormones, to offset their lowered secretion during weight loss, or to raise their plasma levels to the high range of normal values during weight stabilization, is likely to increase nitrogen loss. Drugs designed to reduce the intestinal absorption of carbohydrates or lipids may prove beneficial in weight maintenance programs, when dieters tend to regain weight. Today, there is not sufficient evidence to recommend the regular use of any of these pharmacological agents.

Finally, therapies intended to improve the will to lose weight are an essential part of slimming programs. Group support therapy, as provided by associations such as Weight Watchers, or individual psychotherapy, may be successful in some individuals, while knowledge of nutrition principles seems to improve the incentive to lose weight and maintain the loss.

Benefits of Exercise

Exercise has many beneficial effects for weight maintenance. The most acknowledged effect, albeit not the most important, is that exercise increases calorie expenditure above the resting metabolic rate. The energy cost of exercise is often overestimated by dieters and easily annulled by food self-reward. For example, a brisk 1-h walk has approximately the equivalent energy of three small slices of bread.

Exercise, of some intensity and frequency, has anorectic properties that are probably mediated by changes in hypothalamic neurotransmitters and sex hormone production. With more moderate ranges of physical activity, as previously stated, the hypothalamic regulation of energy balance seems to be better able to adjust energy intake to energy expenditure on a day-to-day basis, thereby improving the chances of weight maintenance.

Exercise has powerful effects on fuel utilization in general and glucose metabolism in particular. Acute exercise accelerates the net rate of glucose utilization through the actions of humoral and hormonal factors on adipose tissue, muscle, and liver. The blood glucose-lowering effect of exercise may be rapid and important. It mimics the effect of intravenous injections of significant amounts of insulin, with the added characteristic that it manifests itself in most instances, whether the subject is insulin-resistant or not. Furthermore, chronic exercise counteracts insulin resistance associated with obesity, hence improving glucose and lipid metabolism. The metabolic properties of acute and chronic exercise should therefore be advantageously used in the treatment of obesity. SMOKED FOODS

Contents

Principles

L Woods, Woodside Consulting, Camberley, UK

Introduction

The foods most commonly smoked are meats, fish, shellfish, and cheese, although some snack foods and nuts are smoke-flavored. Meats or fish grilled over an open fire are exposed to smoke during cooking, but are not normally considered to be smoked foods as such. In general, smoke is produced by substantially raising the temperature of wood, and limiting the air supply so as to prevent combustion but allow destructive distillation.

Smoke flavors and essences may be prepared by condensation of smoke obtained by pyrolysis of wood in a limited supply of air, when the product is known as pyroligneous acid. The initial condensate separates into an aqueous phase and a tarry phase. The smoke condensate may be separated into fractions by physical separation techniques or by solvent extraction. These fractions may be further purified to remove hazardous substances known to be present in smoke. Smoke flavorings include smoke condensates, fractions thereof, and mixtures of such fractions.

The temperature at the center of a heap of smoldering sawdust may be 700–1000 °C, but the temperature gradient is steep, with the temperature falling to 300 °C or less a short distance from the center. Above approximately 200 °C, the wood undergoes destructive distillation, and the desired decomposition products are best generated in the 200–400 °C range. This smoke is allowed to diffuse over, or more commonly is blown over the food to be smoked, with varying levels of control depending on the technology available.

The thermal decomposition of wood can be influenced by numerous factors such as temperature, wood composition, amount of oxygen present, and amount of water vapor available during pyrolysis. Temperature is the most important and the various constituents of wood react at different temperatures. The first major component to undergo thermal decomposition is hemicellulose, which decomposes between 200 and 260 °C to yield furan and its derivatives, as well as a series of aliphatic carboxylic acids. Cellulose is the next major wood component to undergo thermal decomposition, pyrolysis occurring between 260 and 310 °C, which in turn leads to the formation of carbonyls, acetic acid, and its derivatives, together with water and occasionally small amounts of furans and phenols.

The lignin fraction is the most resistant, thermal decomposition occurring at 310–500 °C, and the derived compounds include phenols and phenolic esters along with their homologs and derivatives. Thus, if a relatively low temperature is used, lignin may not be completely degraded, and the resulting smoke will have a different chemical composition from smoke produced at a higher temperature. (*See* **Cellulose**; **Hemicelluloses**; **Lignin**.)

When first formed, smoke is generated as a vapor, but as it cools, some less volatile components condense to form a disperse liquid phase, which, along with soot particles, if present, constitute visible smoke. The remaining more volatile components distribute between the gaseous and disperse phases according to their solubility and volatility at the

prevailing temperature and humidity. Studies of wood-smoke composition have shown the presence of over 400 volatile components comprising 48 acids, 22 alcohols, 131 carbonyls, 22 esters, 46 furans, 16 lactones, 75 phenols, and some 50 miscellaneous compounds. The precise composition of woodsmoke and the extent to which the food absorbs smoke constituents depend on several factors.

Factors Affecting the Composition of Woodsmoke

Type of Wood

Wood generally contains some 40–60% celluloses (β-glucans), some 20–30% hemicelluloses (heteroglycans containing pentose and hexose residues), some 20–30% lignins (complex three-dimensional phenolic polymers), and a small amount of protein. In addition, there is a quantitatively minor, but chemically complex, low-molecular-mass fraction in which phenols and terpenes often dominate, particularly in softwoods, and variable water content.

Commonly woods are classified as hard or soft, depending on their botanical origin, the former from broad-leaved angiosperms, and the latter from needle-leaved (often evergreen) gymnosperms, but the terms 'hard' and 'soft' in this context are not good guides to physical properties. Compared with softwoods, hardwoods have larger contents of hemicelluloses, those in softwoods having a greater proportion of pentosans. Softwoods have greater lignins contents, with more guaiacyl (2-methoxyphenyl) residues relative to syringyl (2, 6-di-methoxyphenyl) residues than is usual in hardwood lignins.

There is a general belief that smoking with hardwoods such as oak (*Quercus* spp.), hickory (*Carya* spp.), beech (*Fagus* spp.) and alder (*Alnus* spp.) produces superior smoked foods compared with smoking with softwoods. Hardwoods generate more syringyl derivatives relative to guaiacyl derivatives and more acid smokes (see Table 1), due to structural differences in the lignins and the greater pentosan content of hardwood hemicelluloses, respectively. These acids produce smoked foods with lower pH values and hence a greater microbiological stability, and this may explain the traditional preference.

Wood Combustion Temperature

The temperature of smoke generation influences its composition. The total carbonyls concentration increases in the temperature range 200–600 °C, total phenols concentration in the range 400–600 °C and polycyclic aromatic hydrocarbons (PAH), while virtually absent below 400 °C, increase rapidly thereafter with increased generation of methylene radicals. The PAH have implications for product safety, and modern methods of smoking are designed to keep the generation temperature below 400 °C or otherwise remove the PAH. The balance between individual compounds within these broad groups is also affected by combustion temperature, with guaiacol, acetovanillone, and acetosyringone dominating the phenols fraction at 380 °C, but with acetosyringone and propiosyringone dominating at 560 °C. Some further data are shown in Table 2.

Smoke House Humidity

It is thought that smoke components enter the food primarily by absorption into the interstitial water in the food, at least for low fat foods. Initially, most foods being smoked will contain about 80% moisture and have a high water activity, both of which decline progressively during the smoking process. The absorption of smoke components is thus more rapid at the start of smoking and declines as the water content declines.

The rate of water loss from the food is greatly influenced by the absolute humidity of the air in the kiln relative to the surface water activity in the food. More rapid loss of water due to the use of hotter and/or dryer smoke gives rapid surface drying and a firm 'skin' to the food, which may inhibit absorption of smoke components. The use of wetter smoke slows dehydration, but if insufficient drying occurs, the product may be microbiologically unstable due to its high water activity. Often, wet sawdust is used so as to keep the smoldering temperature low and prevent combustion, but excessive damping must be avoided,

Table 1 Effect of wood source on composition of smoke

Source	Aroma fraction (mg per 100 g of wood)			
	Total	Phenols	Carbonyls	Acids
Oak (*Quercus seriata*)	1800	151	117	1140
Oak (*Quercus acuta*)	1600	225	323	820
Cherry	1490	101	111	660
Pine	1180	166	53	640

Table 2 Effect of combustion temperature on smoke composition

Combustion temperature (°C)	Content in smoke (mg per 100 g of sawdust)		
	Phenol	Guaiacol	Syringol
450	20	60	85
550	30	80	150
650	55	125	260

otherwise the very wet atmosphere created will inhibit drying. Smoke composition is in any case influenced by the moisture content of the wood that is used – see Table 3. (*See* **Water Activity: Principles and Measurement.**)

Some woodsmoke phenols have antioxidative and antimicrobial properties and, together with other chemicals such as formaldehyde, can increase the stability of smoked foods relative to unsmoked foods. However, it is generally accepted that the main preservative effect of traditional smoking is through drying, especially in combination with salting. Modern smoked foods have comparatively low salt and high water contents (thus increasing the yield and palatability of the product), but due to the relatively high water activity that results, the product shelf-life must be extended by chilling, freezing, or canning.

Effect of Air Flow Rate

Air flow is essential to keep wood smoldering, to transfer smoke from the generator to the kiln, and to minimize nonuniform smoke distribution within the kiln. As discussed above, air flow rate and humidity influence the rate at which the food surface dehydrates and thus the rate of smoke absorption. It has been demonstrated that the dispersed particles of the smoke act as a reservoir for the volatile vapor constituents. Diluting the smoke with air at constant temperature, or raising the smoke temperature, drives volatiles from the dispersed droplets into the vapor phase and encourages rapid and extensive transfer of these volatiles to the food, whereas dilution of smoke with cold air has the opposite effect.

Time of Smoking

The moisture content in the surface layers of the food decreases as smoking time increases, and this affects the rate and extent of smoke absorption. The distribution of fat on the surface of the food may also change during the process, particularly where high temperatures will cause greater protein denaturation and shrinkage, and movement of fat from the interior to the surface of the food, which will modify smoke absorption. Since smoke absorption is a first-order process, the rate declines as surface saturation is approached, since inward diffusion is slow and limiting. Even after extensive smoking, the smoke concentration falls markedly over the first 5 or 10 mm below the surface.

It should be noted that factors such as kiln temperature, kiln humidity, air flow rate, and smoke density are difficult to control in traditional kilns where these parameters are strongly influenced by weather conditions. In modern mechanical kilns, such factors can be controlled within much closer limits.

Table 3 Influence of wood moisture content on smoke composition

Moisture content (% as is)	*Yield per 100 g of sawdust (as is)*			
	Condensate (g)	*Phenols (mg)*	*Acids (mg)*	*Formaldehyde (mg)*
1.8	28.2	236	3203	122
21.5	41.5	136	3288	81
24.5	43.5	100	3003	78
31.2	32.8	33	890	

Smoke-generation Technology

Conventional Smoke Generators

In this type of generator, the smoke is produced by the slow combustion of sawdust using heating coils or gas flames. The sawdust is gently agitated continuously, in the presence of sufficient oxygen. The resulting smoke is then either drawn or pushed into the actual smoking chamber and allowed to interact with the food. The amount of tar and solid particles that enter the chamber can be controlled by varying the distance of the smoldering unit from the smoking unit; with a longer distance, there is more opportunity for tar to settle out. Various baffles and filters can be placed in line to remove tar. Smoke production or generation temperature using the smoldering technique can vary over a fairly wide range, dependent upon the available air. If a large quantity of air is present, the actual smoldering temperature may be in excess of 800 °C, but if the amount of available air is controlled, lower smoldering temperatures will result. The smoke-production temperature can be lowered by controlling the moisture content of the sawdust. Low smoldering temperatures also produce smoke generally lower in polycyclic aromatic hydrocarbons, which has significant health implications.

Friction Smoke Generators

Some processors use the friction method, whereby an intact wood block is pressed against a rapidly rotating metal friction wheel. Heat produced by friction is sufficient to cause wood pyrolysis. Air enters through the center of the friction wheel, thus producing a cooling effect on the resulting smoke. The more air that is present, the lower the resulting smoke temperature. This is in direct contrast to the smoldering technique. The temperature can be regulated by adjusting the pressure on the block of wood, the

wheel speed (which also governs the amount of air used), and the shape of the friction edges. The actual temperature during wood pyrolysis using friction is in the region of 450–560 °C; since rapid cooling occurs, the actual smoke temperature is relatively low.

Moist Smoke Generator

In the wet smoke or condensate smoke method, sawdust and superheated steam containing varying amounts of heated air are blended, causing sawdust pyrolysis. The resulting smoke has a temperature of approximately 80 °C and is moist because of condensed water from steam. This represents another flameless method, and pyrolysis normally occurs in the 300–400 °C range. Advantages cited for the process include a short treatment time and improved smoke yield.

Fluidized-bed Smoke Generator

With this technique, air is heated to between 300 and 400 °C by means of an electric heater, and under high velocity, mixed with sawdust. Because of the resulting turbulence, the sawdust is 'suspended' or fluidized; pyrolysis occurs at approximately 350 °C in around 10 s. A cyclonic separator is used to yield smoke and charred sawdust.

Two-stage Production of Smoke

The two-stage procedure is a modification and extension of the fluidized technique. The first stage involves initial wood pyrolysis by the action of nitrogen or carbon dioxide at a temperature of 300–400 °C on sawdust. In the second stage, the reactants of the first stage are mixed with oxygen or air heated to 200 °C, and further pyrolysis occurs. The second stage promotes oxidation, condensation and polymerization reactions, resulting in a more complex mixture of flavor compounds in the smoke.

Production of Smoke by Carbonization

In this method, sawdust is compressed in a cylindrical pipe by a screw, so that most of the air is squeezed out. An electrical resistance heater situated at the end of the cylinder heats the sawdust to 3000–4000 °C, and because of a lack of air in the compressed sawdust, the product gives off smoke during carbonization.

Smoking Techniques

Smoking of food products may be performed in various ways; the two main methods are cold or hot smoking, but techniques such as electrostatic smoking and treatment with liquid smoke condensate are also in use. The physical processes taking place during the action of the smoke on the product are adsorption, adhesion, condensation, diffusion, and absorption, and the smoking technology uses one or more of these processes.

Cold Smoking

In cold smoking, the temperature is maintained between 15 and 25 °C. The temperature of the smoke is regulated either by regulation of air or by passing smoke through a heat exchanger. The duration of treatment can range from a few hours to several days. It is suitable for cooked, raw, fermented, or dried products. Examples of foods that are typically cold-smoked are raw ham, bacon, salami and dried sausage.

For dried products, the rate of circulation of smoke must be controlled since too high a flow rate will cause crust formation on the surface, which will retard the subsequent drying process.

Hot Smoking

Depending on the temperature at which this is performed, the product undergoes either partial or complete cooking. Hot smoking is carried out at temperatures in the range of 55–80 °C. The activity of smoke is considerably enhanced under these conditions, allowing the treatment to be greatly shortened, relative to cold smoking. Some processors practice what is called moist smoking, which involves using a smoke temperature of 24–48 °C and relative humidities in excess of 30%. Typical hot-smoked foods include cooked ham, frankfurters, salami, and cocktail sausages.

The choice of operating temperature is largely determined by the nature of the product and the desired organoleptic attributes, as constrained by microbial safety. Guidelines on safe operation have been published by MAFF, USFDA, and FAO, among others.

Electrostatic Smoking

In this type of smoking, a continuous tunnel type arrangement is used, where the product is positioned between live electrical wires that are charged between 20 and 60 kV. Smoke passing through this system is charged according to its phase (smoke is a two-phase system, particulate and vapor), and smoke components can then precipitate on the oppositely charged food surface. This stage is usually followed by infrared irradiation, which dries the product surface.

Treatment with Smoke Essences or Condensates

This technique relies on obtaining a liquid essence of the smoke produced in a conventional smoke generator. Generally, condensed smoke can be obtained

dissolved in aqueous solutions (e.g., water or vinegar), as an organic solution (e.g., in oil or alcohol) or as a dry powder (e.g., on a salt, spice, starch, or gum arabic carrier).

These liquid smokes can be introduced into the product by various means, for example by addition to the recipe or by dipping, injection, or atomization. For comminuted products such as sausages, frankfurters, and salami, smoke with a dry carrier can be added to the mix during the chopping sequence.

For products manufactured using liquid processes, smoke essence can be incorporated by dipping. This is generally for a period of 5–60 s, and, while dipping imparts a smoked appearance, the smoked taste is weak. For injected products such as bacon and ham, smoke essence can be included in the injection brine at a concentration of 0.25–1%.

There are several advantages in using liquid smoke. Flavor can be incorporated throughout a product in a uniform manner instead of having a higher concentration on the outside than on the inside, as occurs in traditional smoking. There is also a closer control on the amount of smoke flavor a product receives. The liquid smoke condensate can be fractionated to intensify the smoke flavor and to remove potentially harmful compounds before it is used in food. It is also cheaper, as wood and smoking equipment are not required as part of a food-smoking plant.

Effects of Smoking on Food

Changes in Nutritive Value

Smoking, particularly hot smoking and especially as practiced in the tropics, can lead to destruction of tryptophan, cysteine, lysine, and other basic amino acids whether free or protein-bound. The losses recorded for lysine are variable, reflecting the variations in the smoking process (and analytical procedure), but may reach 55%. Such losses are concentrated in the outer 5–10 mm where conditions are harshest. It is clear that these losses are not just a function of temperature, but are due in part also to interactions with woodsmoke constituents and ingredients such as nitrate and nitrite, which may be added during the curing stage. Among the products detected are imines from carbonyl–amino interactions, some of which contribute to the characteristic yellow or reddish brown surface coloration of traditionally smoked foods. In the case of certain amino acids, these imines react further, yielding various β-carboline carboxylic acids (from tryptophan and woodsmoke carbonyls), and at least one nitroso-thiazolidine carboxylic acid (from cysteine, formaldehyde, and nitrite). (*See* **Amino acids**: Properties and Occurrence.)

Sensory Properties of Smoked Food

Texture

European cold-smoked products will generally have a texture that is soft and tender, whereas the equivalent hot-smoked products will have a firm dry surface with softer interior, being more succulent, the higher the fat content. The main determinants of texture are:

1. the extent and rate of water loss, with a greater loss giving a firmer texture, and a more rapid loss giving a greater difference in texture between the surface and interior;
2. the fat content and its distribution, largely a function of the food, with a food with a higher fat content being more succulent;
3. the extent of denaturation of structural and connective tissue protein, denaturation being more extensive for higher temperatures and higher salt contents, with fish in general being more susceptible than meat, and with greater denaturation giving a firmer texture;
4. the extent of autolysis, particularly proteolysis, with ungutted fish being most susceptible, and greater proteolysis giving softer texture. (*See* **Sensory Evaluation**: Texture.)

Color

As referred to above, carbonyl–amino interactions are important, with model system studies suggesting that interaction of lysine with glycolic aldehyde, 2,3-butane-dione, pyruvaldehyde, coniferaldehyde, or sinapaldehyde are particularly important. Colour may derive from colored substances in the smoke being deposited directly, or from permitted colorings (such as the azo food color Brown FK (for kippers) or natural carotenoids) incorporated during processing. (*See* **Colorants (Colourants)**: Properties and Determinants of Synthetic Pigments.)

Flavor

The presence of an odoriferous or sapid compound in woodsmoke or smoked food does not necessarily equate with organoleptic importance, since the quantity present must be sufficient to exceed the odor or flavor threshold of the consumer (see Table 4). (*See* **Sensory Evaluation**: Taste.)

Many investigators consider the phenolic constituents of woodsmoke, especially 4-methyl-guaiacol, guaiacol, and eugenol to be particularly important, at least in providing those smoky flavor notes that are

Table 4 Threshold values, sensory index values and described odor for some woodsmoke phenols

Compound	In water				In oil		Odor description
	Taste threshold	Taste index	Odor threshold	Odor index	Odor threshold	Odor index	
Guaiacol	0.013	6 400	0.021	4 600	0.07	1 000	Sweet, smoky, and somewhat pungent
4-Methyl-guaiacol	0.065	90 000	0.09	58 800	0.4	18 000	Sweet, smoky
2,6-Dimethoxyphenol	1.65	1 400	1.85	1 200	0.34	7 000	Smoky

essentially unique to smoked foods. There is no doubt, however, that other classes of smoke volatiles are also very important, and attention has been directed towards the pyrazines and lactones.

Aqueous extracts of smoke condensates may be prepared as flavoring ingredients and to avoid the potentially hazardous PAH fraction. Analysis of commercially available extracts indicates that there can be considerable variations in composition, depending on the method of manufacture. Whether friction smoking or electrostatic smoking duplicates the flavor achieved by the traditional process is also a matter of some debate. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Assessment of Toxic Hazard

Concern about the possible safety of smoked foods centers primarily on the presence of PAH. Thirteen PAHs have been detected in smoked foods, at least one of which, benzo[a]pyrene, is a known carcinogen. The greatest levels appear to be associated with products such as charcoal broiled steaks, which are only incidentally smoked, rather than those products normally described of as smoked. It has been estimated that the average daily per-capita intake of benzo[a]-pyrene in the UK is less than 4 μg, and that smoked foods do not contribute significantly to this burden in the UK. (*See* **Carcinogens**: Carcinogenicity Tests; **Polycyclic Aromatic Hydrocarbons**.)

The safety of smoke condensates was reviewed by the Joint FAO/WHO Expert Committee on Food Additives (JECFA) in 1987. Their concern centered mainly on the hazard that would arise if nitrosamines and carcinogenic PAH were present. The evidence available to JECFA indicated that neither class of substance was detectable in the preparations tested. More recently, a limit of 1 μg kg^{-1} has been suggested as an upper limit for benzo(a)pyrene, although studies have shown that some foods, particularly ethnic foods and the outer layers of smoked fish, may contain levels above this.

Concern has also been expressed regarding the presence of heterocyclic aromatic amines in foods, particularly in grilled meat and fish, and presumably also in the corresponding smoked foods. These compounds are pyrolysis products derived from amino acids, such as tryptophan, glutamic acids, or creatinine and products of the Maillard reaction. Some are potent mutagens in certain *in vitro* mutagenicity tests.

Recently, varying amounts of three β-carboline-3-carboxylic acids have been detected in some smoked foods produced in Europe. Although some β-carbolines are known to be pharmacologically active, for example inhibiting monoamine oxidase, there has been no evaluation of the significance of any of those detected in smoked foods.

Background

Smoking is an ancient process for preserving and flavoring food, and is a traditional part of the diet of a large section of the world population. Smoking processes are mainly applied to flesh food (meat and fish), but other foodstuffs such as cheese can also be smoked.

The original principle of preservation was due to a combination of lowered water activity of the product and the uptake by the product of bactericidal and antioxidant components of smoke. The secondary objective is to impart sensory characteristics such as smoke color and smoke flavor to the product. With the exception of some African and Asian countries, where a refrigeration chain is not widely established, nowadays, smoking is used mainly to give the product a characteristic flavor, the preservative effect being slight, and many smoked fish products keep in good condition for very little longer than the fresh product from which they were made.

Smoking fish is a very traditional and ancient process in Northern European countries. However, smoked meat products, mainly from pork meat, have a huge impact on the economy of Mediterranean countries, where a great variety of smoked meat products are industrially or traditionally produced.

In industrialized countries, despite globalization and standardization of smoking processes and products, the elements that differentiate and identify a product have an increasing importance for producers and consumers to whom it is important to link products to the region where they originated and to their specific means of production. Within each country, local resources represented by traditional smoked products, although produced on a small scale, now have a great economic impact owing to the creation of organizations and schemes to exploit diversities and complementarities and consequently allowing the achievement of considerable profits.

Smoke Production

A smoked product can be defined as a product that was prepared by subjecting the raw material to the direct action of smoke from pyrolysis of wood, wood shavings or chips, and sawdust.

In most parts of the world, wood is still preferred to sawdust. Wood leads to a hotter fire, and the products might be charred, rather than smoked. However, commercial smoked products in industrialized countries are usually smoked by a sawdust fire where, unless there is a forced rapid air flow, the sawdust smolders rather than burns. This lower smoke temperature gives more flavor and preserving substances to the product. Higher temperatures and more oxygen oxidize these substances.

Smoke is composed of two phases:

1. A particulate or dispersed phase (droplet phase) – the visible portion of smoke composed of tars, wood resins, high-boiling phenolic compounds, and lower boiling compounds that vary with temperature and smoke concentration.
2. A gaseous or dispersing phase (vapor phase) – most of the characteristic flavor associated with smoke is present in this gas phase:

Conventional smoke generation methods can be:

1. Simple – smoke is generated from pyrolysis of sawdust and woodchips in a simple fire box. These wood chips burn the sawdust, and smoldering starts.
2. Continuous – Modern smoke producers use a continuous smoldering by feeding the sawdust slowly on to a very hot surface.

In both methods, smoke generation temperatures are dependent on the rate of burning of the wood to produce heat.

Reducing the temperature to which wood is heated to minimize the production of undesirable smoke components such as polycyclic aromatic hydrocarbons (PAH) has been an important issue. (*See* **Polycyclic Aromatic Hydrocarbons**.)

Two methods of smoke generation, in which the temperature is controlled externally, have been developed for reducing PAH levels:

1. Fluidized bed generator – sawdust is fluidized by hot air at 350 °C, and smoke with a high proportion of acids is formed;
2. Steam smoke generator – high-pressure steam at 350 °C is passed through a bed of sawdust and smoke with a high proportion of water is formed.

Electrostatic precipitation has also been shown to reduce the concentration of PAH. It can be performed in a continuous tunnel-type kiln, in which the product is placed between electrical wires with a charge of 20–60 kV. The smoke moving through this system is charged according to its phase, and smoke components can precipitate on the oppositely charged product surface. Electrostatically filtered smoke was found to be lower in acids, phenol, and carbonyls than untreated smoke, giving a product with less smoky aroma and color development. However,

reducing the electrical wires spacing can lead to similar phenols levels as untreated smoke.

When using traditional smoke generators, by merely extending the distance between the smoke generator and the smoking chamber, most of the particulate phase of the smoke is allowed to settle before it makes contact with the product, thereby removing much of the PAH.

Smoking Kilns

As smoking is an ancillary process for increasing the storage life of food products, an enormous variety of smoking kilns and smoking processes are used for that purpose all over the world.

If smoking in industrialized countries is mainly a pleasurable alternative to the consumption of freshly cooked food, preservation, nevertheless, is still the prime objective of smoking in many parts of the world. In these countries, the smoking process usually takes place in simple boxes, or products are just placed over a fire place.

In European Mediterranean countries, traditional local smoked products can be produced in chimney structures many centuries old, usually coupled to a brick oven, and may still used for different purposes – every day cooking, as a heater in cold days, and for smoking meat in winter time (**Figure 1a**). These traditional kilns were built inside the house, the operation is dependent on the weather conditions, and production is seasonal, taking place in winter time. Hams, sausages, and sides of bacon were suspended and exposed to smoke from fires of hard wood (usually *Quercus* sp.). This produced a hotter fire because wood was used in preference to sawdust. However, as the flames were formed under an iron pot, they were not in direct contact with the products. During daytime, a mixture of smoke, water vapor and air reached the products. During the night, as no fire was needed for cooking, the smoking process continued by means of a wood brazier kept alight by the high brick temperature, but the process was flameless. Of course, as nowadays most of the chimneys are no longer used for cooking, the smoking process is kept flameless as it was during night.

Northern European countries still have chimney-like kilns hundreds of years old, but most of them were built even in that time with one single purpose – to smoke food, mainly fish. These traditional kilns, built outside the house, can vary in size from 1–2 m (hot smoking) to over 20 m in height (cold-smoking) (**Figure 1b**). Production takes place throughout the year, but in summer usually during the night when the ambient air is cooler. Traditional smoking involves the generation of smoke from hard woods (oak, beech, and hickory in Europe). Whole fish, fish fillets, sides of bacon, ham, and other meat products are suspended in the brick kilns and exposed to smoke from smoldering fires of wood chips or sawdust.

In these primitive techniques, smoke generation and application steps are accomplished in the same chamber. Hot air is less dense than cold air and moves upwards, carrying the smoke with it (**Figure 1a and b**). As temperatures are higher and smoke more dense lower down the kiln, the products have to be moved to different parts of the kiln so that all items receive the same smoke treatment.

These traditional kilns are notoriously difficult to control and have been replaced by a modern type of smoker in which the smoke is generated externally and blown into a metal chamber containing the products to be smoked (**Figure 1c–e**). Also, in most of these modern kilns, the air movement is across, rather than up, and smoke is drawn across the products by means of an electric fan to ensure that all products are dried/smoked to the same extent (**Figure 1d and e**). In modern smoking kilns primarily designed for hot-smoking (**Figure 1d**), the smoke is introduced by a series of ducts into the smoking chamber, but smoke distribution is less uniform than in the tunnel-type kiln (**Figure 1e**).

In recent commercial developments (**Figure 1e**), the direction of the smoke flow can be reversed automatically at frequent intervals, which obviates the need to move the product. However, there is still little chance of an even smoke or temperature treatment in all parts of the kiln because, as the smoke/air mixture passes from one rack to another, it becomes less smoky, more humid, and cooler. But, as racks are placed on a trolley, they can be easily moved into another part of the smoker.

These horizontal kilns – mechanical kilns – have different sizes for large- and small-scale productions. They can be used for cold- and hot-smoking by the use of electric heaters in the smoking chamber. In large kilns, the heaters can be placed at different points in the smoke path to keep the temperature more even throughout the smoking chamber. Humidity can also be controlled, and the consistency of smoking is high. Owing to the concern over PAH in smoke, some generators are equipped with a purification stage that involves the removal of undesirable compounds either by water sprays or by precipitation.

The Smoking Process

The preservative effect of smoking combines the effect of salting, drying, heating, and smoking. Although the general operations in all smoked processing plants are similar, the specific processing procedures vary considerably, owing to differences in equipment, national

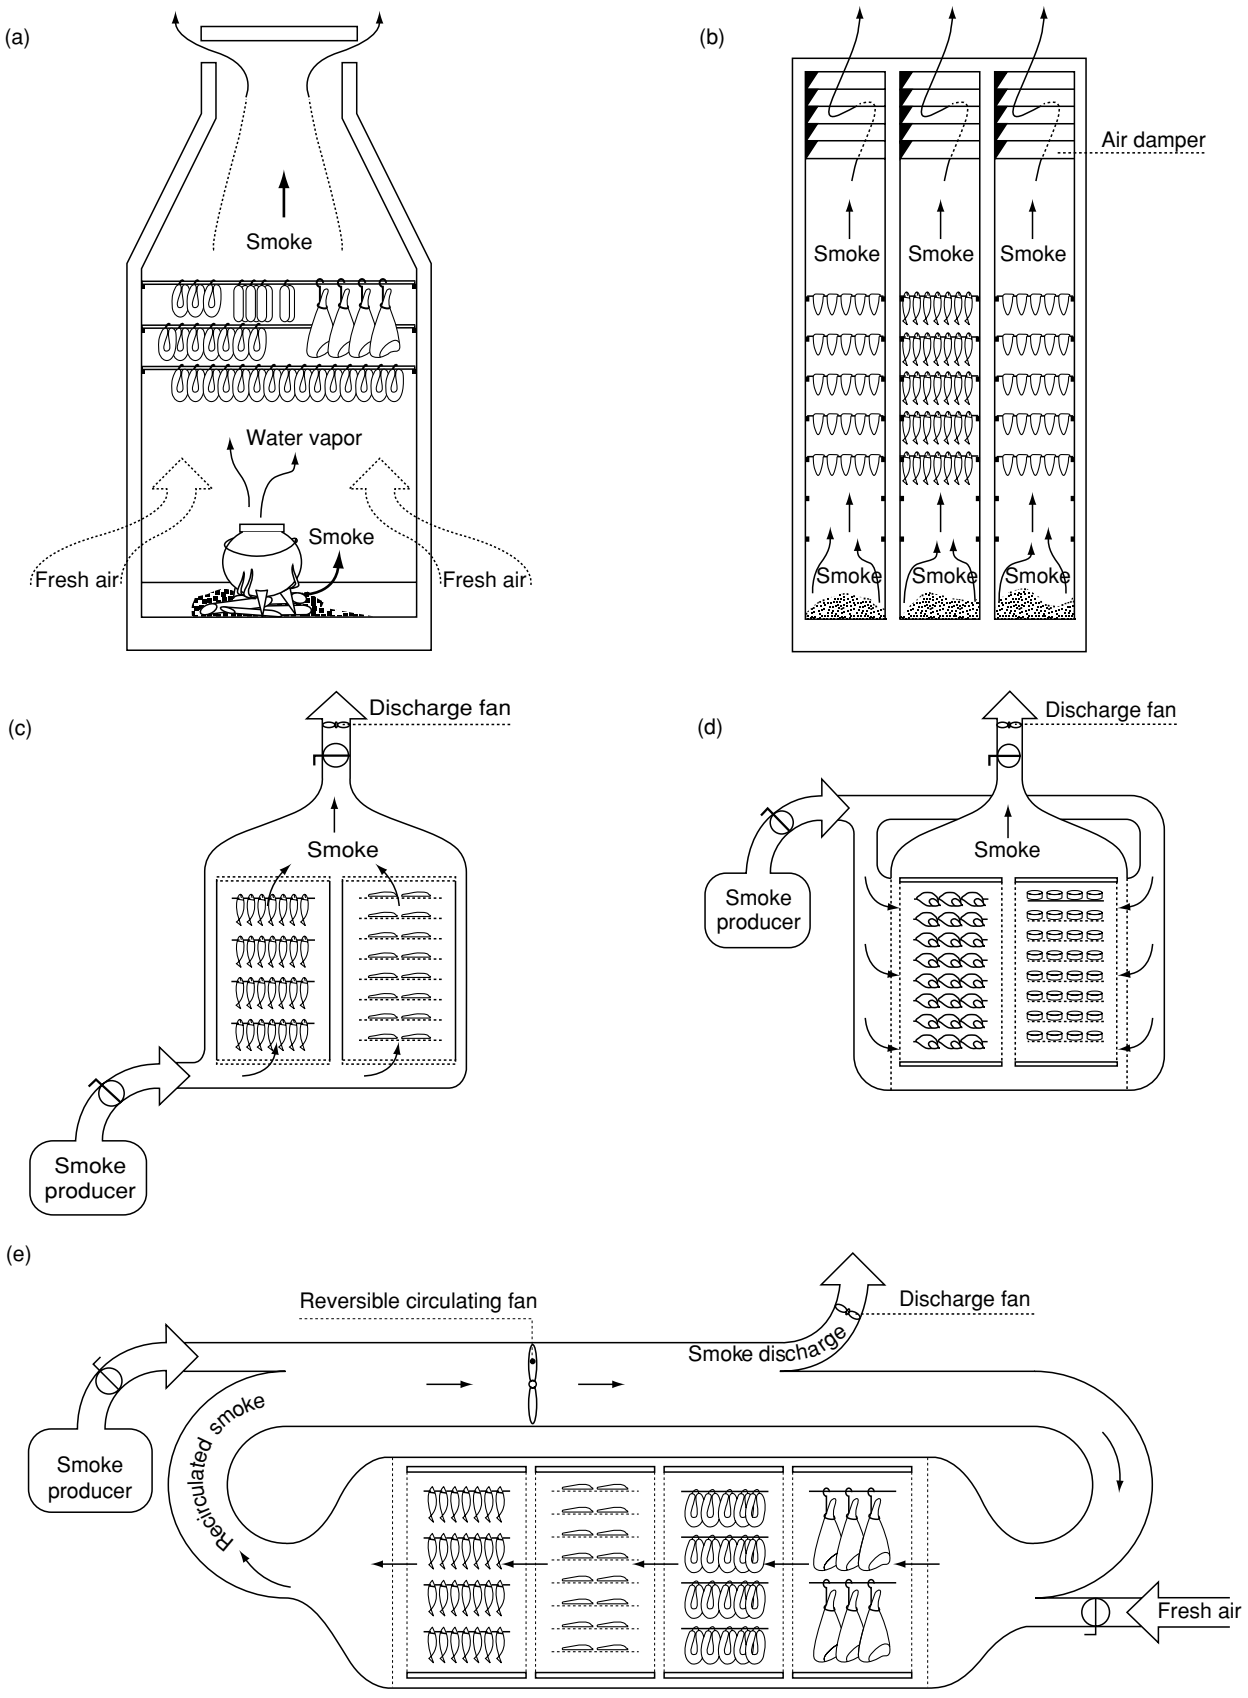

Figure 1 (a) Traditional Mediterranean smoker; (b) traditional north European smoker; (c) mechanical smoker (vertical smoke flow); (d) mechanical smoker (horizontal smoke flow); (e) mechanical smoker (horizontal smoke flow – tunnel type).

and regional consumer preferences, raw materials, and tradition.

Salting

Salting can be done by soaking or injecting the product with a prepared salt solution or by embedding or rubbing the products with salt. Excess of salt on the surface of the product, in these last methods, should be removed by showering with water. In both methods, salting nowadays, rather than for preserving, is used mainly to firm the flesh and impart flavor to the product.

In terms of safety, for cold-smoked fish, the aim is to obtain a concentration of 3–3.5% of salt in the water phase throughout the product to minimize the growth of *Clostridium botulinum*. The salt content in the water phase means the percentage of salt in the water contained in the fish. Salt in the water phase links the two conditions of moisture and saltiness. This should be distinguished from the salt content, which is the percentage of salt in the whole weight of fish, that is, water plus protein plus fat, etc.

The uptake of salt by products from brine or dry salt is a diffusion-controlled process dependent on the temperature, water content, salt concentration, and the amount of fat. The time required for a given product to absorb a given amount of salt is approximately inversely proportional to the square of the half thickness of the product. (*See* **Curing**.) The salt used should be of food-grade quality, low in calcium and magnesium, and essentially free of iron and copper.

In dry-salted products when the surface of the product dries out too quickly, owing to the small grain size of the salt, it can inhibit the diffusion of the water from the bulk of the product to the surface, which can lead to the decomposition of the center of thick muscles before it reaches the level of salt concentration sufficient to prevent spoilage.

The main objective of the brining method of salting is limitation of air penetration during processing, thus limiting the amount of rancidity that can develop. This is why it is the preferred method for fatty products. It also gives an attractive glossy appearance to the smoked fish fillets. However, as the water content of the product is increased, more drying is required after brining, than after dry salting.

A 70–80% saturated brine is commonly used. A 100% saturated brine can leave powdery salt crystals on the surface of finished product, whereas a 50% saturated brine would cause the product to swell, necessitating a longer drying period.

Making and maintaining brine quality involve the use of good-quality water and ingredients, the control of brining temperatures, and assuring high standards of equipment hygiene.

When products are brined or brine-injected, curing agents are added to the salt in the solution, e.g., for whole pieces of meat. Curing agents can be added to the ingredients together with salt, e.g., chopped or minced products. Nitrates, nitrites, ascorbic acid, sodium glutamate, polyphosphates, and sugar are the main additives used. Nitrates and nitrites are used in smoked meats to deliver the characteristic color by reacting with the heme pigments, contributing to flavor and, owing to its antimicrobial activity, inhibiting particularly *Clostridium botulinum* growth and toxin production. (*See* ***Clostridium***: Occurrence of *Clostridium botulinum*; **Curing**; **Nitrates and Nitrites**.)

Drying

In conventional smoking, drying can be performed before or after the smoke uptake or can be concomitant to smoke production. During smoking, the drying continues. It is important to balance the drying rates and quality/safety issues. The amount of moisture transfer from the product to the air is dependent on the relative humidity: the lower the humidity, the better the moisture transfer. However, if the rate of water removal is too high in comparison with the diffusion rate, the surface will form a hard case (case hardening) creating a barrier to water transfer and evaporation; consequently, the diffusion of the bulk water to the surface of the product is blocked. Thus, spoilage and possibly *Clostridium botulinum* growth might occur in the bulk of the product. To prevent this, the protein must be set or denaturated with low-temperature drying before applying higher temperatures. In conclusion, the product must be dried slowly enough to avoid case hardening, but fast enough to avoid spoilage caused by bacterial and enzymatic activities.

A large proportion of the drying of flesh food muscle usually occurs during constant-rate drying – while the surface of the product being dried remains moist, water is considered to evaporate as from a free water surface. The evaporation rate is thus controlled by the conditions of the drying air, namely speed over the surface, temperature, and humidity. As evaporation takes place at the product surface, water travels to the surface by diffusion and by capillaries formed by structural components. When the movement of this water through the product can no longer keep pace with the evaporation rate, the surface becomes dry, and this point in the drying sequence is referred as 'critical moisture content.' Thereafter, the rate of drying falls progressively and is dependent on the permeability of the already dry part of the product. During this stage, humidity and air velocity do not significantly affect the process, whereas temperature,

as it affects diffusion rate, should be adjusted during this period of falling. (*See* **Drying**: Theory of Air-drying; **Water Activity**: Principles and Measurement; Effect on Food Stability.)

Drying for cold- or hot-smoked fish usually takes place inside the smoker before smoke production starts – the diffusion distance between the center and surface of the fish or fish fillets is small, and water activity is reduced rapidly.

For whole pieces of meat (smoked hams), separate chambers are needed because the maturing/drying process can last for several days before products are exposed to smoke. The temperature and humidity of those chambers must be carefully controlled and are set according to the level of dehydration required for each particular product. It is important to evaluate the maximum temperature to which the drying air can be heated in order not to cause the product surface temperature to rise above the upper limit for maintaining specific product quality.

Modern equipment is designed to accelerate the drying process by increasing the evaporation rate or by using faster air speeds to remove the water vapor and increase the surface heat transfer rate.

Smoking

The smoking process takes anywhere from a few hours to a few days. A combined heating/drying/smoking process entails application of smoke, at temperatures below 30 °C for cold-smoked products or alternatively 60–80 °C for a hot-smoked product. In cold-smoking processes, the product is subjected to heat for a period of time that does not coagulate protein. Cold-smoking does not cook the flesh or coagulate protein, so refrigerated storage and further cooking are necessary before consumption. Cold-smoked fish like salmon, salmon-trout, swordfish, and tuna fish are not cooked before consumption. The maintenance of temperatures below 30 °C avoids protein coagulation, and the cold smoke is more dense, thus allowing the deposition of smoke on the fish surface giving the product the desirable appearance and flavor. Drying should be minimal at the start but will increase towards the end of the process. The length of the smoking process for such products is much greater than for hot-smoked fish, but a 'safety' (i.e., pasteurization) temperature is not achieved in any stage of the process. In a hot-smoking process, the product is subjected to heat for a sufficient period of time to coagulate protein throughout. The hot-smoking process adequately cooks the flesh, and so the products are ready to eat.

The uptake of wood smoke components from the particulate and vapor phase of wood smoke is dependent on the nature of the product, temperature, humidity, and velocity of smoke. The deposition of volatiles is maximum at the beginning of the smoking process whilst the surface remains wet. As the surface becomes dried, the uptake of volatiles decreases, and the proportion of smoke constituents arising from the particulate phase increases. The particulate phase acts as a reservoir of volatile and nonvolatile smoke components, releasing more volatiles as they are adsorbed from the vapor phase. Raising the smoke temperature or diluting the smoke with air at a high constant temperature drives the volatiles from the droplets into the vapor phase, and from here, rapidly to the food product, whereas dilution of smoke with cold air has the opposite effect.

Cold-smoking involves keeping the smoke temperature below 30 °C throughout the smoking process. A humidity of 70% RH seems to be a good compromise between maximum smoke adsorption and minimum case hardening in cold-smoking of fish. In a mechanical smoker, hot-smoking of fish usually undergoes a typical three-stage process: initially, cold-smoking for 1 h, then at 50 °C for 30 min, and finally at 80 °C for 2 h.

In a mechanical smoker, the temperature regime most often used for hot-smoked pieces of meat, smoked directly after curing, follows a two-stage process. The first, cold-smoking (low temperature/long time) involves smoking at 32–38 °C for 15–18 h; the second, hot-smoking (high temperature/short time), uses a temperature of at least 60 °C for 2–4 h).

When large pieces of meat are smoked after a long curing/maturation process, cold-smoking takes place for a few days.

Alternatively, in either cold- or hot-smoking methods, the product can be smoked by means of smoke-flavoring processes with liquid smoke, which imparts to a product the flavor of smoke. The classical liquid smoke is a natural aqueous condensate of wood smoke that has been aged and filtered to remove tars and particulate matter, and is dissolved in water, oil, or organic solvents.

For preparing a smoked-flavored product, after the salting step, the product can be smoked by adding smoke extracts to the mixture (smoked sausages), injecting (smoked ham) or dipping (smoked sausages, smoked ham) in a solution of liquid smoke or applying the liquid smoke by pulverizing it or using it as an atomized spray within a modern automatic smoke kiln. According to some recent research, spraying is preferable because it is easiest to control flavor and acceptability with this method.

In conventional smoking, it is expected that phenol components are at much lower concentrations towards the center of the product compared with liquid smoked products, where their levels should be very

uniform throughout the product. This is true if products are dipped or injected with the liquid smoke, but not if liquid smoke is only sprayed on to the product surface.

The composition of commercial liquid smoke can vary widely, depending on the method of manufacture. Natural smoke extracts, synthetic smoke flavors, and substances unconnected with smoke, such as yeast derivatives but with a smoky flavor or smell, are used.

The use of liquid smoke also reduces the undesirable PAH levels in smoked foods. The European Scientific Committee for Food, in its Directorate-General Industry Guidelines (1995) established that smoke flavorings (liquid smoke) added to a food product must assure a level lower than 0.03 μg of benzopyrene per kilogram and less than 0.06 μg of benzoanthracene, another PAH compound, per kilogram.

In the meat industry, liquid smoke is commonly used in place of traditional smoke. However, smoke-flavored fish represents a small percentage of the total smoked fish industry output.

Smoked Food Products Quality and Safety

Microbiological Safety

The intrinsic microbiological stability of smoked foods is dependent on the ingredients, additives, and processes. In one extreme are traditional products usually heavily cured and smoked, which can be stable for many months at ambient temperatures; at the other extreme, there are lightly cured and smoked products, whose stability is dependent on extrinsic factors such as refrigeration, vacuum, or gas packing.

The length of the smoking process for cold-smoked products is much longer than for hot-smoked products, but a pasteurization temperature is not achieved in any stage of the process. Thus, the temperatures and times used in processing cold-smoked products are very favorable for the proliferation of food spoilage and food poisoning types of microorganisms.

Most of the commercialized smoked products in Western countries are sold vacuum-packed and stored at refrigeration temperatures, and so spoilage and food poisoning flora of the finished products are mainly anaerobic or microaerophilic, and psychrotrophic or psychrophilic.

Cold-smoking, or any smoking process where temperatures in the interior of the foodstuff do not reach 50 °C for a significant period of time, will have a different residual postsmoking microflora than those hot-smoked products where a high internal temperature is reached.

The temperature achieved during hot-smoking kills vegetative microorganisms but not all spores, so the most probable spoilage agents will be spore formers or postsmoking contaminants. Refrigeration of hot-smoked fish greatly reduces the number of organisms able to grow and lengthens the shelf-life of the product.

Cold-smoked products will contain a microbial flora representative of that of the raw material. The salt in the water phase must be high enough to inhibit the growth of *Clostridium botulinum* ($\geq 3\%$), but this will not stop the growth of spoilage bacteria. Immediately after vacuum packing, bacterial counts in cold-smoked salmon, commonly range between 10^4 and $10^5\,g^{-1}$, and at the end of the shelf-life (6 weeks), the product typically contains a microflora dominated by lactic acid bacteria at levels of 10^7–$10^9\,g^{-1}$. The use of drying and/or salt to lower the water activity and smoke to add chemical preservatives limits the types of microorganisms capable of growth, and the production process affects the microbial flora present on the product; therefore, both of these affect the spoilage patterns. Spoilage needs to be defined carefully for each product.

Listeria monocytogenes has been found consistently in smoked fish products. Nitrites, usually added to smoked meat products, are known to inhibit growth of *C. botulinum* and also can inhibit *L. monocytogenes* growth. (*See* ***Listeria***: Properties and Occurrence.) Nitrites also can be added to cheese to prevent very late fermentation and gas production by *Clostridium tyrobutyricum* or *C. butyricum*.

For *C. botulinum*, levels of salt higher than 3% in the water phase together with refrigerated storage can prevent growth and toxin production in cold-smoked fish products, even when nitrites are not added. However, with respect to *L. monocytogenes*, which is able to grow at salt levels up to 10% and temperatures as low as 1 °C, when nitrites are not allowed in fish products (EU) there is no step in the cold-smoked process that is able to prevent its growth.

The International Commission for Microbiological Specifications for Foods recognized that numbers of *L. monocytogenes* not exceeding $100\,g^{-1}$ at the time of consumption are of low risk to the consumer. Therefore, for ready-to-eat, not heat-treated, foods, where the presence of *L. monocytogenes* cannot be fully avoided, the critical points are to limit the occurrence of *L. monocytogenes* in foods but, more importantly to control its growth and survival in order to keep levels below the $100\,g^{-1}$ at the point of consumption. This policy is followed by some European countries but is considered a hazard by USA, which maintains a zero-tolerance policy regarding *Listeria* incidence in ready-to-eat foods. If a zero-tolerance policy were to be established in EU countries, where nitrites or other antimicrobial additives are not allowed to be added to fish products, this

would lead to the cessation of sales of cold-smoked fish products where the presence of *L. monocytogenes* cannot be fully avoided. For cold-smoked fish products, using reliable raw material and good manufacturing practices (GMP), keeping storage temperatures under 4 °C, and reducing the shelf-life to 3 weeks, has been reported to be sufficient to maintain *L. monocytogenes* numbers below $100\,g^{-1}$.

Nisin, the only approved bacteriocin allowed to be added to foodstuffs, and commonly used in milk products to prevent *C. tyrobutyricum*, is also capable of preventing *C. botulinum* and *L. monocytogenes* growth in smoked products. Recent studies on the application of different bacteriocins from *Carnobacterium* spp. to cold-smoked fish products to inhibit *L. monocytogenes* growth have yielded encouraging results on inhibiting the growth of this pathogen.

Cold- and hot-smoked foods, like every food commodity, can potentially cause safety problems. To improve the safety of commercially smoked products, producers should use reliable raw materials, improve smoking technologies (temperature and humidity control), assure plant equipment and personnel hygiene, and implement GMP and hazard analysis and critical control points. (*See* **Hazard Analysis Critical Control Point**.)

Chemical Safety

Preventing the occurrence of carcinogens during smoking has been an issue for several years. There are two groups of chemicals of concern in smoke: PAH and *N*-nitrosamines (NNAs), both of which are considered potential carcinogens. The compound benzopyrene, the most concerning PAH, is regarded as an indicator of carcinogenicity.

As mentioned before, there are several means for reducing PAH formation. The use of a separate smoke generator, maintaining the temperatures of pyrolysis between 200 and 425 °C, electrostatic filtration of the smoke, smoke generated by superheated steam or the use of liquid smoke are some of the ways of reducing the PAH levels in smoked foods. Reports on the quantification of PAH in smoked fish, meat, and cheese have suggested that as, in this last product, the rinds are removed before consumption, the PAH intake would be much lower. However, in some traditional cheeses, where manufacture includes heating the milk on an open wood fire, or in commercial hot-smoked cheeses, the levels of PAH are considerably higher compared with liquid smoked samples.

The NNAs in smoked food are primarily formed by the reaction of nitrogen oxides (generated from nitrites) of the wood smoke with, mainly, secondary amines present in the flesh. (*See* **Nitrosamines**.)

Nitrates and nitrites used in smoked meats to impart color and flavor and due to its antimicrobial ability are an additional risk factor, as they may react with both secondary and tertiary amines of the products leading to the formation of NNA. The reaction can occur during processing, reactive substrates are amino acids, and many of the resulting NNAs have been identified as carcinogens. Reducing agents, like ascorbic acid, added together with nitrites to the brine to improve NO_2 activity, also can act as efficient factors inhibiting NNA formation. Considerable research attention has been paid to determining the levels of occurrence and formation of these substances in foods. It is currently considered that nitrite levels in smoked meat are such to ensure the stability of the product and to control *C. botulinum*, while not presenting a significant risk from NNA.

Although nitrites are legally added as preservatives to smoked products elsewhere, in EU countries, they are restricted to smoked meats and prohibited in the fish industry. Therefore, it is expected that smoked fish products from EU countries are poor sources of nitrites, and consequently of nitrosamines, compared with smoked fish produced elsewhere and compared with smoked meat products.

Applications of Smoking

J I Ahmad, University of Lincolnshire and Humberside, Grimsby, UK

Introduction

Smoke used for curing of foods consists of a suspension of minute particles in a vapor phase making up an aerosol. It is produced by controlled thermal combustion of sawdust, wood shavings, coffee husk, sugar cane pulp, coconut husk, and rice straw, etc. The composition of smoke varies with the choice of wood, the temperature of pyrolysis (**Table 1**), relative humidity and the moisture content of the wood (**Table 2**). The relative concentration of different components depends on the type of wood used and the controls adopted during its combustion (**Figure 1** and **Table 3**).

Table 1 Influence of the glowing temperature on the phenol, carbonyl, and acid yields in smoke (in milligrams per 100 g of sawdust)

Temperature °C	*Total phenols*	*Total carbonyls*	*Total acids*
380	998	9 996	2 506
600	4 858	14 952	6 370
760	2 632	7 574	2 996

Table 2 Mechanism of smoke formation

(a) *Pyrolysis of wood*	
Up to 170 °C	Thorough drying
200–260 °C	Pyrolysis of hemicellulose
260–310 °C	Pyrolysis of cellulose
310–500 °C	Pyrolysis of lignin
(b) *Secondary reactions of the pyrolytic products at about 200 °C*	Oxidation, polymerization, condensation, pyrolysis

Polycyclic aromatic hydrocarbons (PAH), which are believed to be carcinogenic, are a well-known group of constituents of wood smoke (**Figure 2**). These compounds are probably formed through condensation of naphthalene. Their concentration strongly increases when other organic materials are added during combustion of wood. (*See* **Polycyclic Aromatic Hydrocarbons**.)

Apart from providing desirable color and flavor to foods, wood smoke contributes to preservation by acting as an effective antioxidant and a bacteriostatic and bactericidal agent. Phenolic components of the smoke contribute to the flavor and aroma of the product. Smoke also provides a protective film on the surface of the smoked product, thus providing a barrier against development of rancidity. Combined chemical constituents of smoke together with heating and drying processes are responsible for bactericidal and bacteriostatic effects. (*See* **Antioxidants**: Natural Antioxidants; **Phenolic Compounds**.)

Methods of Smoking Foods

Basically, three methods are used in the production of smoke-flavored foods.

The Traditional Method

This is the direct incomplete thermal degradation of wood to produce smoke. It may be carried out either as *hot smoking* or as *cold smoking*, i.e., the criterion is the maximum temperature to which the product is exposed. (*See* **Drying**: Theory of Air-drying.)

Hot smoking Hot smoking involves exposing the product to at least 80 °C and probably up to 100 °C, the intention being to cook the product as well as smoke and dehydrate it. Duration of smoking depends on the level of curing required, e.g., light, mild, or strong and the thickness of the product. Techniques of smoke generation vary in different parts of the world. It may be a simple barrel-type smoke oven, inverted drums with a fire pit at the bottom or located remotely, or the very latest high-tech equipment as available in the UK with automatic smoke density, temperature, and humidity controls.

The principles of hot smoking are simple. Smoke is generated from desired wood (e.g., oak) with a controlled air supply. The product is usually prebrined for an appropriate period from a few minutes up to several hours before being placed on the racks where the smoke is allowed to circulate at a selected rate and temperature. Modern kilns yield a uniform, clean product with little waste. There are basically three

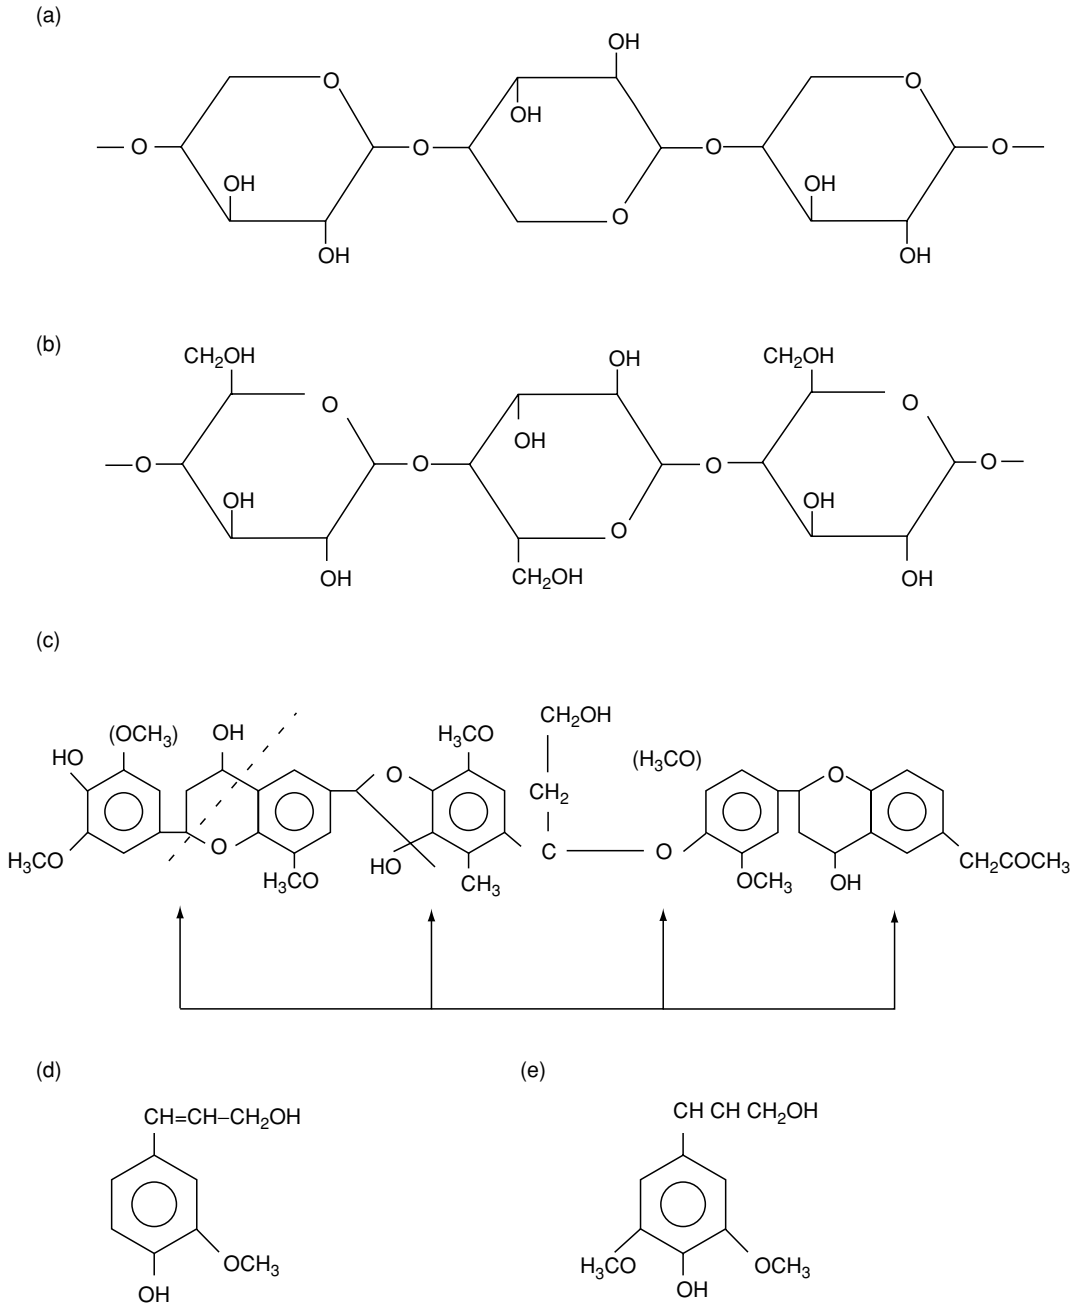

Figure 1 Main chemical constituents of 'hard' and 'soft' woods: 25% hemicellulose (a); 50% cellulose (b) and 25% lignin (c) from softwood and, with ... OCH_3, from hardwood. Arrows in (c) show splitting points during pyrolysis. Also shown are (d) coniferylalcohol and (e) sinapinalcohol.

types of smoke houses: (1) with natural air circulation, (2) air-conditioned or forced air, and (3) continuous. There are many modifications of these three types. Air-conditioned or forced-ventilation smoke houses have largely replaced the natural-air type. They allow much more precise control of smoking through uniform air movement and good control of temperature. Smoke houses with endless revolving chains have been developed specifically for frankfurter production.

Cold smoking Cold smoking was introduced as an alternative to hot smoking in the early part of the last century. Its general purpose is to impart a desirable flavor to the product, rather than preservation, which is achieved by refrigeration at low temperatures. In the kilns, the smoking temperature is maintained below 30 °C, and the time of smoking may vary from a few hours to several days, depending on the product. The shelf-life of the product can vary and

Table 3 Smoke compounds from different species of wood

Compound	*Amount of compound (grams per 100 g of sawdust)*					
	Acacia	*Beech*	*Oak*	*White beech*	*Spruce*	*Pine*
Monocarbonyls	1.70	1.77	2.40	2.50	3.06	3.10

Acetaldehyde	0.81	0.66	0.63	0.65	1.15	1.00
Acetone	0.64	0.74	0.37	0.69	0.69	0.54
Furfural	0.24	0.18	0.35	0.26	0.21	0.18
NaOH reducing substances	4.56	6.94	4.68	9.75	7.83	7.40
Reducants	0.13	0.16	0.17	0.32	0.21	0.29
Dehydroreductants	1.56	1.32	0.66	2.16	2.10	1.80
Total acids	2.94	4.06	3.56	6.79	3.07	3.17
pH	4.3	4.8	4.0	4.1	3.8	4.7
Esters	8.48	6.69	10.47	10.35	8.08	11.16
Phenols	0.36	0.14	0.16	0.32	0.29	0.29

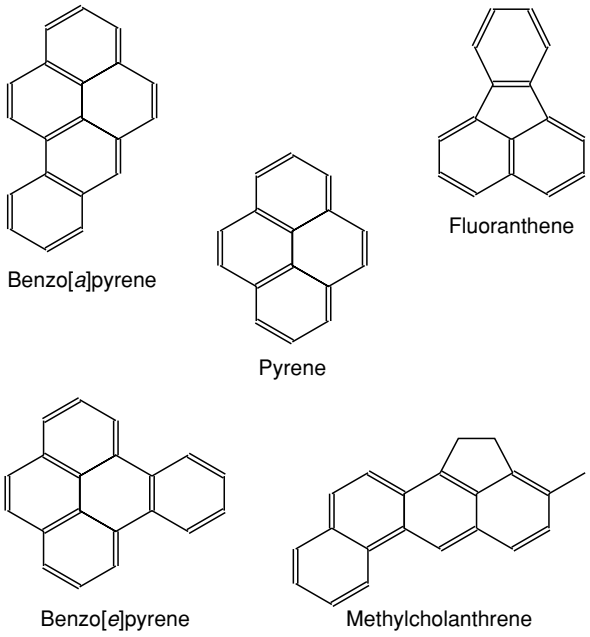

Figure 2 Structures of a few important polycyclic aromatic hydrocarbons found in smoke.

may depend on whether the product was brined or not prior to smoking.

Liquid Smoke

Manufacture Low-moisture saw dust is heated to 500–600 °C in a combustion reactor, and the resulting smoke vapor is passed to the primary tar and ash separation vessel and then on to a packed tower of ceramic beads. Here, the vapor smoke is condensed. The condensate is composed of (1) an aqueous phase made up of a mixture of low-boiling-point fatty acids, carbonyl compounds, and alcohols (pyroligneous acid, formalin, and furfurol in particular; formalin is responsible for immediate sterilization of the food surface, and the carbonyl compounds are claimed to be responsible for the formation of a desirable color) and (2) an immiscible tar or 'liquid smoke' (see Table 4). The tarry phase contains cresol, guaiacol, eugenol, methyl guaiacol, and pyrogallol to mention a few compounds (Table 5). These substances are credited with the antibacterial and antioxidant effect that smoking is supposed to have. The liquid smoke is stored in holding tanks for 2–4 weeks to allow separation of tars and other colloidal particles containing high levels of PAH, including benzo[*a*]pyrene. The remaining filtrate is a clear liquid that may be used as such, or it may be further concentrated by fractional distillation and extraction with selective solvents (see 'Smoke Flavors'). A schematic method of making PAH-free liquid smoke on a laboratory scale is shown in Figure 3.

Table 4 Composition of marketable smoke condensates from France, Germany, and the USA

Group	*Level (%)*
Water	11–92
Phenols (determined by GC)	0.2–2.9
Acids	2.8–9.5
Carbonyls	2.6–4.6

The tastes of the tarry and aqueous phases are different, and opinions differ as to which is to be preferred. When liquid smoke from different parts of the world are examined for their relative chemical constituents, it is confusing to note that some consist chiefly of acids, others of esters and carbonyl compounds, and some chiefly of phenols (Table 6).

There are four basic principles of application of liquid smoke: atomization, drenching, dipping, and direct addition. Further technical developments of these methods can be found under Application of Smoke Flavors.

Application of liquid smoke offers several advantages over the traditional smoking processes in that it offers consistent quality and a uniform and

Table 5 Sensorial judgment of a few phenols

Substance	*Best judged concentration (mg per 100 ml)*	*Smell*	*Taste*
Guaiacol	3.75	Phenolish, smoky, aromatic, sharp, sweet	Phenolish, sharp, spicy, smoked-sausage-aromatic, sweet, dry
Syringol	7.5	Smoky, spicy, aromatic, smoked-sausage-toned, phenolish, sharp, sweet	Phenolish, smoky, like freshly charred wood, like whiskey, dry, sharp
4-Methyl-guaiacol	1.9	Sweet, like vanilla, fruity, like cinnamon, somewhat smoky, pleasantly sharp, phenol tones	Sweet, like vanilla, caramel-like, aromatic, pleasant, smoke tones, burning
i-Eugenol	9.8	Sweet-fruity, like vanilla, like rhubarb, phenol tones	Sweet-fruity, mild smoke tones, dry, sharp
o-Cresol	7.5	Phenolish, sweet-fruity, aromatic, like caramel, smoked-sausage-tones	Sweet, sharp, unpleasantly smoky, burning
Dimethyl-phenol	0.9	Phenolish, like ink, aromatic, sweet	Phenolish, sharp, somewhat charred, sweet, dry

Formic acid	0.38
Acetic acid and acids of higher molecular weight	1.71
Methanol	0.96
Tar	4.81
Phenols	0.07
Residue	4.21
Water	82.42
Total	**95.92**
Extracts from activated charcoal	4.08

Table 7 Composition of a synthetic smoke aroma

	Percentage	*Level*
Furfural	0.17	0.05–0.8
Valeraldehyde	0.002	0.002–0.05
Dihydroxiaceton	0.0012	0.003–0.004
Diacetyl	0.0002	0.0001–0.001
Acetic acid	0.9	0.2–1.5
Formic acid	0.06	0.01–0.1
Propanoic acid	0.14	0.03–0.25
Butyric acid	0.016	0.001–0.03
Valeric acid	0.06	0.01–0.1
Caproic acid	0.008	0.003–0.05
Caprylic acid	0.006	0.001–0.01
Guaiacol	0.001	0.0002–0.01
o-Cresol	0.001	0.0002–0.01
Hexylamine	0.00016	0.00005–0.0008
Ethylamine	0.00016	0.00005–0.0008

reproducible product. Since the polycyclic aromatic hydrocarbons, tar and soot are removed in its manufacture, it is safer to use. It is economical in terms of time and ease of application, and there are no fire hazards.

Smoke Flavor

The toxicological problems associated with conventional smoking of foods have attracted a great deal of interest in recent years. There is evidence that the consumption of smoked meats, sausages, and fish over prolonged periods may be a causal factor in the development of cancer of the alimentary canal. For this reason, extensive efforts are being made to develop toxicologically safe smoke flavors. To achieve this, flavor technologists world-wide have attempted to split the smoke condensate into a number of subdivisions. Using a variety of countercurrent techniques, the fractions obtained are then examined to establish the elimination of PAH. Of all of the chemical constituents of smoke – alcohols, aldehydes, ketones, phenols, amines, tar, and cresol resin – it is the PAH typified by benzo[*a*]pyrene that are known to be carcinogenic and have thus attracted the most medical attention. Techniques are now known that can measure PAH down to 0.001 p.p.m. (*See* **Amines**; **Carcinogens**: Carcinogenic Substances in Food: Mechanisms; **Flavor (Flavour) Compounds**: Production Methods.)

Opinions still differ as to which of the chemical constituents produce the characteristic smoke flavor. A study of the oil-soluble fraction of smoke condensate has been made by gas–liquid chromatography. After purification by extraction, the smoke flavor has been shown to contain some 20 different aromatic components, most of which are phenolic in nature. A few aromatic aldehydes have also been shown to be present (Table 7).

Organoleptic studies of the individual components or group of components showed *cis*-iso-eugenol, 2,6-dimethoxyphenol and 2,6-dimethoxy-4-methylphenol to be the compounds contributing most markedly to the characteristic smoky flavor. (*See* **Sensory Evaluation**: Taste.)

Optimum flavor characteristics can only be achieved by applying proper concentrations using appropriate technology. The concentration required to achieve the optimum flavor development depends on the type of product, its fat content, and the processing method. Examples of concentration of smoke flavor using one such commercially available preparation are: ham 45 p.p.m., bacon 32 p.p.m. (in both cases, added to brine), and sausages, cod roe, fish paste, and fish sausages 15–45 p.p.m. The object of conventional smoking is to increase the shelf-life of the product. It is thus imperative to ascertain what effect application of smoke flavor or liquid smoke has on the keeping qualities of the product. Recent research indicates that 2,6-dimethoxy-4-hydroxybenzaldehyde, one of the active components of smoke flavor, has marked antioxidative and antibacterial properties.

Application of Smoke Flavors

The flavor components are available in three physical forms: aqueous, oil-soluble, and dry. They may be applied to products by any of the following methods based on their suitability.

Spinning head spray system This method utilizes a variable-speed air motor that spins an atomizing disk at between 1000 and 18 000 rpm, creating a very fine atomization. The liquid is fed to the gun via an air-operated vernier-controlled pump, and an electrostatic charge is applied at the gun tip. This system can be used for spraying aqueous solutions of smoke extracts and flavor on to bacon, ham, and chicken, and in a solvent-based form on to a product such as salmon, where little or no water is required.

Airless spray system An airless pressure pump feeds the liquid through a spray nozzle. The electrostatic charge is applied by a probe at the spray tip. Various spray nozzle designs are available for achieving the desired pattern of application. Applications of this technique are in aqueous systems – extracts in brine solutions that allow smoking and curing of fish products in a single operation.

Powder spraying Powder flavors are obtained by mixing the flavor components with dextrose or starch base. The application system consists of a powder hopper and spray gun. The hopper has two regulators to control air supplied to a Venturi pump and to the air fan of the gun; a third regulator controls the degree of vibration at the base of the hopper. The gun has interchangeable heads that allow for variation of the spray pattern.

Flavor coating of savory snacks This system incorporates positive charging of the product and negative charging of the flavor medium. The plant consists of variably controlled fluidized bed vibrator feeding the flavor over a knife edge where it picks up a negative charge and projects it into a stream of positively charged product falling freely into the air. Thus, the flavor adheres all around the falling product. In addition to these high-tech systems, smoke flavors, brined or unbrined, can be injected directly to the product and absorbed during curing in massaging machines and tumblers. The advantage of this technique is that it simplifies application and improves control and hygiene.

It has been shown that water-based as well as salt-based smoke flavors can be used in the production of sausages and other comminuted meat products. They are ideal for pork, beef, horse meat, and reindeer meat. In the fish industry, smoke flavor is successfully used in the preparation of fish pastes, sausages, caviar, roe, and sprats. Smoke flavor is also applied to processed cheeses. It is reported that panelists could not differentiate between traditionally smoked and cheese to which smoke flavor had been added.

In canned products, smoke flavor can be added directly to the oil, thus enabling flavor penetration during heat processing of already sealed cans.

Technology of Smoking Fish, Meat, and Cheese

Fish

Operations necessary for production of smoked fish will depend on species, consumer preference, and product specification. However, the general procedure is as follows. Fresh grade A fish should always be used. They are washed to remove scales and surface lime, etc., and gutted and headed if required. The belly cavity is cleaned to remove traces of blood and bellywall lining. Fish are then usually brined before smoking. Brining is recommended on grounds of safety. It is recommended that to exclude *Clostridium botulinum* completely, fish should be brought to an internal temperature of 82 °C for 30 min during smoking if 3.5% brine solution is used, or 65 °C for 30 min with 5% brine. (*See* ***Clostridium***: Occurrence of *Clostridium perfringens*; **Fish**: Processing.)

After brining, fish are suspended or laid horizontally on racks in the smoking kilns. If equipment permits, smoking may be carried out in stages, for example, initially at 30 °C for 60 min, followed by 50 °C for 30 min, and finally at 80 °C for 2 h or more until the product has attained the required color and texture (Table 8).

Cold smoking of fish is commonly practiced on the leaner varieties of fish such as cod or haddock and may utilize traditional or liquid smoke. Depending upon the type of smoke, brined or unbrined fish is drenched with a suitable quantity of liquid smoke, which is then allowed to drain before being put through a drier to remove the excess moisture if long-term storage is envisaged. Nowadays, after addition of smoke, the fish may be vacuum-packed or refrigerated for transport to the point of sale. Virtually all types of fish may be smoked. The most popular varieties in the UK are smoked herrings (kippers), haddock, mackerel, and sprats. Smoked salmon is a great delicacy.

Meat

Common salt is the basic curing ingredient, although other compounds such as sugar, nitrite, and/or nitrate may also be added. (*See* **Meat**: Preservation.)

Salt in Cures

Salt is the basic ingredient necessary to all curing mixtures. It dehydrates and alters the osmotic pressure. It inhibits mold growth and subsequent bacterial spoilage. Its use tends to give a hard, dry, salty product that is not very palatable. It is therefore generally used in combination with nitrite/nitrate. A 65% 'pickle' cure is the most popular strength used for meats. (*See* **Curing**.)

Sugar in Cures

The addition of sugar is primarily for flavor. It also moderates the harshness of salt. During cooking, it forms browning products that enhance the flavor of cured meats.

Table 8 Fish smoking in a torry kiln

	Time in kiln (h)	*Temperature (°C)*	*Desired weight loss (%)*
Kippers	4	29	14–18
Kippers for canning (mild cure)	2.5	29	12–14
Kipper fillets	2.5–3	29	10–12
Cod or haddock fillets	3–5	27	10–12
Finnans	4–6	27	12–14
Pale cure	2–3	27	8–12
Golden cuts	2–3	27	10–12
Bloaters	3	32	14–16
Red herring	36*	29	20–25
Silver cure	8	29	20–25
Salmon	8–12	29	10
Cod roe	8	38	20–25
Buckling	2–3	27–71	10–12
Sprats for canning	0.25–0.5	27–71	10–12
Kielersprotten	1–1.5	27–71	10–12
Smokies	2	27–71	30
Trout	3	27–71	30
Eels	2	27–71	10–15

Nitrite and/or Nitrate in Cures

The addition of nitrates and/or nitrites offers the following advantages: (1) stabilization of the colour of lean tissue; (2) contribution to the characteristic flavor of the cured meats; (3) inhibition of growth of spoilage organisms, thus reducing the risk of food poisoning; (4) retardation of development of rancidity in the fatty constituents of the meats.

The processes of traditional smoking of meats may vary, but the general principles are the same. Prime quality meats are trimmed of most excess fat and then cured in a curing mixture (containing salt, nitrates and nitrites in water) for anything up to 7–10 days at 1–4 °C; meats may be pump-injected with curing mixtures before being smoked in a traditional wood-chip smoker for several hours. Depending upon the temperature of smoking, they may be cooked further in an oven until they are judged to be just right. Appropriately sized pieces may then be vacuum-packed and transported to the point of sale.

Nowadays, cured meats may be cooked in a mixture of liquid smoke before being packed, but evidence suggests that consumers prefer the traditionally smoked product and are prepared to pay more for it.

The most popular varieties of smoked meat products include the well-known hams, beef, horse, and reindeer meats. In addition, smoked poultry, turkey, and a variety of game birds can be found in specialist delicatessen shops. A number of different types of smoked meat sausages are available throughout the world.

Cheese

Certain varieties of cheeses, e.g., Seretpenir (Iran), Caramakase (Germany), Bandal (India), and Volgodski (Russia), are traditionally smoked. They may be smoked by hanging in a smoke-charged atmosphere without the necessity for higher temperatures. Both oak and applewood shavings may be used for smoke generation. Nowadays, incorporation of liquid smoke is becoming popular. The smoke preparation may be added to the milk or sprayed on to the curds before pressing. Occasionally, smoke flavor with salt may be applied as a spice. In another method of preparation, cheese is enclosed in a permeable membrane and immersed in a solution of smoke liquor.

Traditional smoking brings fat to the surface of the cheese, evaporates moisture, and incorporates smoke vapors containing phenolic substances that aid in giving a preservative effect as well as imparting a savory flavor to the cheese. The fat on the surface is also a deterrent to mold growth if the cheese is kept dry.

SMOKING, DIET, AND HEALTH

M Indira, University of Kerala, Thiruvanathapuram, Kariavattom, India

Background

Smoking is the single largest avoidable cause of ill health. In addition to its effects on the physical and mental health of the individual, social, psychosocial, and economic consequences of cigarette smoking cause serious problems in the individual, the immediate family, and society at large. However, many hectares of land are used for the cultivation of tobacco plants, millions of dollars are pumped into the manufacture and advertisement of cigarettes, and huge amounts are being spent for the treatment of cigarette-related problems. All this could have been diverted for the health and nutrition of the underprivileged throughout the world.

Smoking cigarettes for as few as 5 years can cause permanent damage to the lungs, heart, eyes, throat, urinary tract, digestive organs, bones and joints, and skin. These effects may persist even if the smoker quits smoking after a few years of smoking. Many studies have proved that tobacco-related health effects decline substantially as the period of abstinence from smoking increases. Some of the benefits begin within months after quitting. Quitting improves pulmonary function by about 5%, prolongs life, and reduces the risk of tobacco-related cancers, myocardial infarction, cerebrovascular disease, and chronic obstructive pulmonary disease (COPD). Smoking directly irritates and damages the respiratory tract. This irritation and damage cause a variety of symptoms, including bad breath, cough, sputum production, wheezing, and respiratory infections such as bronchitis and pneumonia. One of the proposed mechanisms of smoke-induced toxicities is injury caused by free radicals. Hence, a diet rich in antioxidants and low in fat is recommended to counteract the injuries caused by smoking.

What is Smoking?

Smoking entails drawing the tobacco smoke from the cigarette, cigar, or pipe with the mouth, inhaling into the lungs, and puffing the smoke out.

Tobacco

Tobacco is an annual shrubby plant whose leaves are used chiefly in making cigarettes and cigars. Its leaves are large, with a color ranging from light green to dark green. The tobacco of commerce is derived almost entirely from *Nicotiana tobacum* L; Fam. Solanaceae. Certain other species, namely *N. rustia* (wild tobacco), *N. attenuata*, *N. trigonophylla*, and *N. quadrivalis* are also used, but to a lesser extent.

History

The Indians in the northern part of South America were the first to cultivate tobacco. When Christopher

Columbus and other early explorers arrived in America, they found the natives using tobacco much in the same manner as it is used today. They used it in their religious ceremonies. The Indians believed that it possessed medicinal properties, and that was the chief reason for its introduction in Europe. Indians used it as a remedy for aches and pains, snakebites, abdominal and heart pains, chills, convulsions, epilepsy, skin diseases, fatigue, hunger, wounds, sores, and numerous other ailments. From Europe, tobacco culture practically spread to the rest of the world. Jean Nicot, the French ambassador at Lisbon port, in whose honor the generic name '*Nicotiana*' was named, is said to have sent the seeds of *N. tabacum* to the queen of France, Catherine de Medici. Blessed with medical virtues and a quality to induce trance, smoking became very popular. Some of the factors that have contributed to its popularity include income from excise duty, automatic manufacturing machines, which lowered its price, advertising campaigns, and, above all, social acceptability. All this led to an increase in the number of smoking addicts. But at present, the world is turning away from cigarette smoking, following the American lead. The decline in smoking in the USA was initially triggered by the Surgeon General's reports on smoking and health. These reports were first published in 1964 and thereafter almost every year. Extension programs through mass media communications have led to a decline in smoking throughout the world. But now the challenge is to sustain this decline. Recent studies have shown that smoking is on the increase among teenagers and youths.

Composition

The cigarette burns at about 880 °C, and this burning of the cigarette produces smoke. The lit cigarette has a steep temperature gradient, 880 to 40 °C, which can be demarcated into three zones: (1) high-temperature zone (900–600 °C); (2) oxygen-depleter pyrolysis zone (600–100 °C); and (3) low-temperature zone (< 100 °C). Cigarette smoke consists of a heterogeneous mixture of gases, condensed vapor, and minute particles. Approximately 4000 chemicals have been detected in the mixture of gases and tarry droplets that comprise the cigarette smoke. The major components in the tobacco smoke are listed in Table 1. Of these, over 30 components have been suspected to be responsible for various health hazards, and of these, the major components causing or promoting various diseases are nicotine, carbon monoxide, and tar.

The gas phase accounts for about 60% of the total cigarette smoke. At least 11 of the gases have been found to be harmful to lung tissue. These are formaldehyde, carbon monoxide, acetaldehyde, acrolein, menthol, acetone, methyl ethyl ketone, ammonia, nitrogen dioxide, hydrogen cyanide, and hydrogen sulfide. Carbon monoxide makes up about 3–5% of the cigarette smoke.

Table 1 Major components in tobacco smoke

Acetaldehyde
Acetone
Acrolein
Ammonia
Anabaisine
Antabine
Arsenic
Benza(a)antracine
Benzo(a)pyrene
Cadmium
Carbon dioxide
Carbon monoxide
Copper
Cotinine
Formaldehyde
Hydrogen cyanides
Hydrogen sulfide
Menthol
Mercury
Methyl ethyl ketone
Nickel
Nicotine
Nitrogen dioxide
Nitrogen oxides
Nitrosamines
Nornicotine
Polynuclear aromatic hydrocarbons

Nicotine is a dense, oily alkaloid. Pipe tobacco contains 0.6–1.43% nicotine by weight. Cigars and cigarette tobacco have 0.75–3% and 0.9–1.96% nicotine, respectively. Nicotine has been reported to stimulate the release of adrenaline (epinephrine) and noradrenaline (norepinephrine), which have direct influences on the nerve centers controlling blood pressure and heart rate. It has been found to raise the tissue lipid levels and stimulate platelet adhesion.

The particulate phase contains a vast number of compounds, of which more than 250 have been isolated from cigarette smoke. About 30 metals are present in the tobacco smoke particulate phase. Several of these have been found to be carcinogenic. Tar is a dark brown viscous material composed of condensed particles from cigarette smoke after moisture and nicotine have been removed. Strong carcinogens like polycyclic aromatic hydrocarbons, nitrosamines, phenols, fatty acids, and their esters, etc., are some of the constituents that have been detected in tar. The tar component of cigarette smoke consists of all the particulate phase and much of the condensable components of the gas phase. The burning of an average-sized cigarette produces 3–40 mg of yellowish brown tar and about 1–2 mg of nicotine.

Why do People Smoke?

This habit stems mainly from psychological and social drives. It is a psychological tool, helping the smoker to relieve their stress, to relax, and to be at ease in social situations. Nicotine is the only psychoactive ingredient in tobacco smoke. It stimulates the production of powerful chemical messengers such as epinephrine, norepinephrine, dopamine, etc. The net effect is a temporary improvement in brain chemistry that is experienced by the smoker as enhanced pleasure, decreased anxiety, and a state of alert relaxation.

Second-hand Smoke, Environmental Tobacco Smoke (ETS), and Passive Smoking

The term 'passive smoking' describes the inhalation by a nonsmoker of the smoke of tobacco products from a smoke-filled atmosphere. The *Journal of the American Medical Association* has reported measurable levels of cotinine in the blood of 88% of all nontobacco users. Cotinine, is a metabolite of nicotine, and its presence is proof of a person's exposure to tobacco smoke.

The chemical constituents of ETS are derived from two main sources: (1) mainstream smoke and (2) side-stream smoke. The mainstream smoke emerges from the tobacco product during puffing. The side-stream smoke is produced during smoldering of the cigarette at the peak temperature inside the glowing cone. The chemical compositions of the side-stream and mainstream smoke are different. The temperature of combustion of the tobacco is different during puffing and smoldering. The substances are partially absorbed from the mainstream smoke by the smoker, depending on the characteristics of the substance, filter, additives, and depth of inhalation by the smoker. Analysis of the side-stream smoke has shown that it contains more combustion products of tobacco than mainstream smoke. In fact, it contains five times more carbon monoxide, three times more tar and nicotine, and four times more benzopyrine. Concentrations of nitrosamines can be up to 50 times higher in side-stream smoke than in mainstream smoke. The smoke in a smoke-filled atmosphere is mainly from side-stream smoke, which is a great threat to the health of the nonsmokers, especially children.

In 1992, the US Environmental Protection Agency (EPA) studied the respiratory health effects of environmental tobacco smoke. Their report, a compilation of 30 epidemiological studies, concluded that there is a strong association between ETS exposure and lung cancer. Scientists estimate that ETS is responsible for approximately 3000 lung cancer deaths per year among nonsmokers in the USA. On the basis of the health hazards of ETS, the EPA has classified second-hand smoke as a Group A carcinogen. ETS has also been linked with eye and nasal irritation in adults and middle ear infections in children, it also affects the cardiovascular system and causes acute and chronic coronary heart disease. ETS has also been linked with other cancers, including those in the nasal sinus cavity, cervix, breast, and bladder. Animal experiments support the view that second hand smoke can induce tumor formation.

In adults, ETS can worsen existing pulmonary symptoms for people with asthma and chronic bronchitis, as well as for people with allergic conditions. Even individuals who are not allergic can suffer eye irritation, sore throat, nausea, and hoarseness. Contact lens wearers can find tobacco smoke very irritating. Pregnant women, newborn children, and asthma sufferers have an increased vulnerability to cigarette smoke. It affects the development of the fetus and causes impaired growth, low birth weight, and sudden infant death syndrome (SIDS). Children are at particular risk from passive exposure to cigarette smoke, since they are more vulnerable to air pollutants and respiratory pathogens. Moreover, an infant or toddler has little opportunity to move away from the smoking parent.

Effects of Smoking on the Body

There is now an extensive body of evidence – including epidemiological, experimental, pathological, and clinical studies – to demonstrate that smoking increases the smoker's risk of death and illness from a wide variety of diseases.

Tongue

The pollution begins from the tongue. The surface of the tongue of a smoker who smokes on average 50 cigarettes per day results in a loss of taste. Inflammations are also found in the mouth cavity. The smoke causes pathological changes in the lingual papillae and adversely affects the mucous membrane of the mouth.

Ears

Smoking weakens hearing too. Even 20 cigarettes per day can weaken normal reception of speech.

Eyes

Researchers at the Johns Hopkins University have found evidence linking cigarette smoking and formation of cataracts. The eyes are quite sensitive to nicotine. Within a few seconds of the first puff, irritating gases (formaldehyde, ammonia, hydrogen sulfide and

others) begin to work on sensitive membranes of the eyes. Adverse ophthalmic effects of active smoking include glaucoma, cyanide-induced optic neuritis, corneal arcus, and vascular changes in the retina. The associated problems include a restriction to visual field, impaired reactions to dazzling light, etc. Smokers tend to have a deficiency of vitamin B_{12}. This deficiency is responsible for a disease called amblyopia. Tobacco amblyopia can produce dimming of vision in the central part of the visual field. Sufferers find it difficult also to distinguish between red and green.

Nose

Heavy smoking causes chronic inflammatory swelling of the nasal mucosa and damages the receptor cells, thus impairing the sense of smell. There is also an increase in the risk of nasal carcinoma in heavy smokers. Chronic exposure leads to damage of the olfactory cells, causing insensitivity to odors.

Lungs

Smoking directly irritates and damages the respiratory tract, and the respiratory rate increases. Irritating gases can damage the tissues of the lungs, and the airways leading to the lungs. This speeds up the production of mucus and leads to an increased tendency to cough up sputum. The excess mucus serves as a breeding ground for microbes. The lining of the bronchi begins to thicken and predisposes to cancers of the bronchi. The smoke weakens the free moving scavenger cells that remove foreign particles from the air sacs of the lungs, and continued smoke exposure leads to a variety of symptoms, including bad breath, cough, sputum production, wheezing, and respiratory infections such as bronchitis and pneumonia.

Many compounds that are inhaled are deposited as a layer of tar on the lining of the throat and bronchi and in the delicate air sacs of the lungs. This tar is rich in carcinogenic compounds. Lung cancer accounts for nearly 30% of all cancer deaths in the USA, and smoking accounts for nearly 90% of cancer deaths. The risks of dying from lung cancer are 23 times higher for male smokers and 13 times higher for female smokers than for nonsmokers. Additionally, smokers are at increased risk for cancer of the larynx and the oral cavity, and smoking causes a fivefold increase in the risk of dying from chronic bronchitis and emphysema.

Cardiovascular System

The effect of smoking on the heart and blood include an increased blood clotting rate, increased level of catacholamines, increased heart rate, decreased oxygen supply to the heart muscle, increased irritability to the electrical conducting system of the heart, and increased blood pressure. Blood pressure increases by 10–15%. Smoking increases the risk of vascular diseases of the extremities. Carbon monoxide from the blood binds competitively to the oxygen receptor sites of blood cells. Hemoglobin bound to the carbon monoxide is converted to carboxyhemoglobin, and so, less oxygen reaches the brain and other vital organs.

Cigarette smoking is now recognized as a major risk factor for atherosclerosis. A number of studies have indicated a close association between cigarette smoking and development of arterial lesions. Increased levels of tissue and serum cholesterol, triacylglycerols, and low-density lipoproteins (LDL), and low levels of high-density lipoproteins (HDL) have also been reported. A greater concentration of very-low-density lipoprotein cholesterol and a lower concentration of apoprotein 1 and HDL-C with a predominant decrease in the subfraction HDL2 have been observed in smokers. Alterations in the lipid profile have also been reported in the offspring of dams exposed to cigarette smoke. Lipid peroxidation and associated lipoprotein oxidation caused by cigarette smoke also accelerate the development of cardiovascular problems. Oxidized LDL is selectively taken up by monocytes/macrophages, unlike native LDL, resulting in the formation of cytokine-producing foam cells.

Skin

Smoking constricts the blood vessels of the skin, thus decreasing the delivery of oxygen. Hence, a smoker's skin becomes more susceptible to wrinkling. Smokers are at a particular high risk for a medical syndrome called smoker's face, which is characterized by deep lines around the corners of the mouth and eyes, a gauntness of facial features, a grayish appearance of the skin, and certain complexion abnormalities.

Male Reproductive System

Impotency has been observed in male smokers. Researchers have concluded that decreased potency might result from the detrimental effect of smoking on the blood vessels leading to the reproductive organs. Smoking can cause erection problems, decreases in sperm count and sperm motility, and impaired sperm morphology.

Female Reproductive System

Women who smoke experience gender-specific health consequences, including an increased risk of various adverse reproductive outcomes. A decline in fertility and earlier menopause have also been observed in women smokers, and smoking has been consistently associated with an increased risk for cervical cancer.

Smoking alters the level of estrogens and other hormones and interferes with hormone-related disorders. Some studies have suggested that cigarette smoking might alter menstrual function by increasing the risks for dysmenorrhea, secondary amenorrhea, and menstrual irregularity.

Fetus

Scientific literature published in the twentieth century has indicated that cigarette smoking during pregnancy adversely affects the fetal development and the development of the baby. A variety of mechanisms have been suggested, whereby maternal smoking habits could influence fetal health. These include the underlying constitution of the smoker, changes in nutrition, and impaired oxygen delivery, as well as specific effects of nicotine and polycyclic aromatic hydrocarbons upon the parents, uterus, and fetus. Placental transfer of nicotine has been observed. Nicotine has also been detected in the breast milk of female smokers. Fetal hemoglobin has a stronger affinity for carbon monoxide than maternal hemoglobin. In addition to this, nitrogen oxides oxidize hemoglobin iron in the ferrous form to the ferric form, to produce methemoglobin. Cyanide combines with methemoglobin, forming cynomethemoglobin. Cyanide also inhibits cytochrome oxidase. The combined effect of all of these leads to a hypoxia condition and affects fetal growth and delivery process. Infants born to women exposed to environmental tobacco smoke during pregnancy have a small decrement in birth weight and a slightly increased risk of intrauterine growth retardation compared with infants of nonexposed women. The risk for perinatal mortality – both stillbirth and neonatal deaths – and the risk for SIDS are increased among the offspring of women who smoke during pregnancy.

Paternal Smoking

A few studies have revealed the effects of paternal smoking and genetic damage to the fetus. The tobacco smoke containing carcinogens may reach the gonads through the blood. Since spermatogenesis continues throughout the male's reproductive period, these carcinogens may genetically alter the sperm. There is an increased risk of genetic defects to the offspring of fathers who smoked at the time the child was conceived.

Immune System

Cigarette smoking weakens the immune system by depressing the antibody response and decreasing cell-mediated reactions to foreign invaders.

Brain

A reduced level of oxygen carried to the brain can produce lethargy, confusion, and difficulty in thinking clearly.

Oxidative Damage and Pathogenesis

One of the major mechanisms for smoke-induced injury is the oxidative damage. Five per cent or more of the oxygen is converted to reactive oxygen species (ROS) such as O_2^-, H_2O_2, and $^{\cdot}OH$. This process can be represented as

$$O_2 \xrightarrow{e^-} O_2^- \xrightarrow{e^-} H_2O_2 \xrightarrow{e^-} OH^- \xrightarrow{e^-} H_2O.$$

Super oxide anion — Hydroxyl radical

The super oxide radical is formed in almost all aerobic cells by three ways:

1. Normal oxidative metabolism.
2. Microsomal cytochrome P_{450} activity that is inducible by a variety of foreign compounds.
3. Respiratory burst of stimulated phagocytes.

Free radicals have an odd electron in their outer orbital, and so they tend to be hyperactive to attain a stable form. They either abstract electrons from, or donate their odd electrons to, other molecules in their proximity. In this process, they modify and damage biomolecules. Metal ions like cadmium, iron, and copper are powerful promoters of free-radical generation.

The gaseous and tar phases of cigarette smoke contain high levels of carbon and oxygen-centered free radicals as well as $NO^{\cdot}$ and NO_2 (which are capable of attacking compounds with >C═C< bonds), which can directly initiate and propagate the process of lipid peroxidation of membrane lipids both *in vivo* and *in vitro*. Their approximate concentrations in the gaseous and tar phases are, respectively, 10^{15} per puff and 10^{17} per puff. Cigarette smoke also contains traces of metal ions – cadmium, copper and iron – that are powerful promoters of free-radical generation. They can react with H_2O_2 to form $OH^{\cdot}$, the most reactive oxygen radical known. Cellular antioxidants (vitamin C, E, glutathione, selenium, etc.) and free-radical scavengers (super oxide dismutase, glutathione peroxidase, catalase, etc.) normally protect a cell from the toxic effects of ROS, but when the balance between ROS production and antioxidant defenses is lost, oxidative stress results, which, through a series of events, deregulates the cellular activity leading to various pathological conditions. These reactions can alter the intrinsic membrane properties like fluidity, ion transport, and loss of enzyme activity, protein cross-linking, inhibition of protein synthesis, DNA damage, and,

ultimately, cell death. This is the underlying mechanism of the formation of various diseases, including cardiovascular dysfunction, neurodegenerative diseases, gastroduodenal pathogenesis, metabolic dysfunction of almost all vital organs, cancer, and premature ageing. Polyhydroxyl aromatic compounds present in tar have been proposed to bind to genetic material, leading to the generation of H_2O_2, which in turn causes DNA strand breakage via a hydroxy radical-dependent mechanism.

Other Forms of Smoking

Cigar Smoking

Cigar smoking is increasing in the USA, since it is considered to be a safer alternative to cigarettes, but this is not so. It is a risk factor for cancer of the mouth, throat, larynx, esophagus, and lungs.

Beedi Smoking

In India, Beedi (tobacco wrapped in tendu (*Diospyros melanoxylan* Roxb.; Fam: Ebenaceae) leaf) is used for smoking, mostly by people belonging to lower socioeconomic strata. Other forms of smoking are chutta, a type of homemade cigar smoked with the lit end placed inside the mouth, hookahs (or water pipes), and pipes. Contrary to the belief that traditional forms of smoking are less dangerous than smoking cigarettes, it was found that the relative risk of cancer and cardiovascular problems were higher in the users of beedi, chutta, or hookhas.

Strategies to Keep Healthier

Quitting cigarette smoking is the best measure to keep healthy, but some may find it difficult to give up the habit. A reduction in the number of cigarettes smoked, and a change in the life pattern may provide some protection from smoke-induced toxicities.

Exercise

In addition to the psychological benefits, a few studies have suggested that smokers who begin exercising regularly may also obtain a small degree of protection against the health risks of of smoking.

Nutrition

It is widely accepted that smoking tends to reduce nutrient intake, but it is not known for sure whether it acts directly upon the satiety centers, affects the sense of taste or smell, or operates less directly through psychological mechanisms. Smoking itself reduces the intake of vitamins such as ascorbate, tocopherols, and folate. Smokers have low levels of vitamin C and carotene. An *in-vitro* study showed that a wide spectrum of lipophilic micronutrients (retinal, carotene, vitamin E) undergo degradation when exposed to the gas phase of cigarette smoke. Experimental and epidemiological studies have found some deficiencies of antioxidants in smokers.

The toxicities caused by smoking are mediated through ROS. Hence, a diet rich in vegetables and fruits is especially beneficial in reducing the toxicities induced by smoking. Their beneficial effects are due to the presence of antioxidants and anticancer nutrients (vitamins A, C, and E, selenium, isothiocyanates, indoles, calcium, fiber, vitamin B_{12}, etc.). Many human studies have supported this view. There is a fivefold decrease in risk ratio for cataracts in persons consuming ≥ 1.5 servings of fruits and/or vegetables. Vitamin B_{12} helps to detoxify the cyanide found in tobacco smoke. Smokers excrete more of this vitamin. This condition is treated with large doses of vitamin B_{12}. Hence, supplementation of antioxidants, either through increased intake of vegetables and fruits or through supplements, is essential in a smoker's diet.

Smoking is an independent risk factor for atherosclerosis. It increases the lipid content of tissues and serum, and so a low-fat diet rich in fiber is ideal.

SNACK FOODS

Contents

Range on the Market

A S Bawa and J S Sidhu, Guru Nanak Dev University, Amritsar, India

Introduction

The term 'snack' or 'snack food' is difficult to define or categorize. The dictionary meaning of snack is a 'titbit' which is a small meal in the broadest sense. Snacking can be described as the problem-free consumption of easy-to-handle, miniature-portioned, hot or cold products in solid or liquid form which need little or no preparation and are intended to satisfy the occasional pangs of hunger. Thus snacks should be in convenient manageable portions satisfying short-term hunger. The different categories of snack foods are given in Table 1.

Snacks can be sweet or savoury, light or substantial, and they may be endowed with attributes such as healthy or just for fun. In European markets the word 'food' is omitted. This article deals with various aspects of different snack foods and the quality checks involved.

Snack foods are a significant part of the food industry. The dominant leader is still potato chips (crisps), followed by extruded snacks, corn chips, nuts, meat snacks, pretzels, and popcorn.

Potato-Based Products

Potato-based snacks can be made either exclusively from fresh, sliced potatoes or from potato dough. The chips in the latter case are called simulated potato chips. The steps involved in potato chip processing include selection, procurement and receiving, storage under optimum conditions, peeling and trimming of potato tubers, slicing, frying in oil, salting, or the application of flavored powders and packaging. (*See* **Potatoes and Related Crops**: Processing Potato Tubers.)

Potato must be of high specific gravity in order to obtain superior yield, low oil absorption, and low reducing sugar content. Peeling should remove only a very thin layer of potato, leaving no eyes, blemishes or other material for later removal by hand trimming. The chips from peeled and unpeeled potatoes are similar in appearance, flavor, and shelf-life. The chips from unpeeled potatoes have higher oil contents but omission of the peeling step results in a 7% increase in potato solids and a reduction in waste.

The peeled potatoes are cut into slices 10–17 mm thick by rotary slicers. Slices must be very consistent in thickness in order to obtain uniformly colored chips. Slices with torn surfaces lose excess solubles from the ruptured cells, and absorb large amounts of fat. Starch and other materials released from cut cells are washed away prior to frying and the surface of the

Table 1 Snack food categories and examples of products in each category

Category	*Product*
Hot snacks	Minipizzas, pizza baguettes, etc., toasts au gratin, cup noodles, spring rolls, filled croissants
Cold snacks	
Milk and dairy products	Yogurt, plain or with fruit, mini cheese cubes
Bakery products	Cake bars, minitarts, biscuits
Bars	Granola or muesli bars, chocolate bars, minibreak bars, energy bars
Savory products	Chips (crisps), sticks, crackers, pretzels, salt sticks
Other products	Popcorn, puffed cereals, rice snacks, fruit sticks, dip sticks, tortilla chips, fruit snack bar
Confectionery	Plain cookies, deposit cookies, macaroons, wire-cut cookies
Extruded snacks	Potato sticks, cereal-based tubes with cheese filling, corn pellets and chips
Low-pressure extruded fried snacks	Sev, omumbadi, murukku
Nut-based snacks	Roasted peanuts, fried peanuts, coated and fried peanuts, toasted and salted pecans, roasted and salted almonds, sugared and spiced nuts, flavored nuts and nut mixtures
Legume-based Indian snacks	Fried green peas, chick peas, lentils, dhals, fried products from bengalgram meal
Meat-based snacks	Expanded pork rinds or skeen, jerky, chimni

From Tettweiler P (1991) Snack foods worldwide. *Food Technology* 45: 58.

slices dried; this step shortens the frying time and increases the capacity of the cooking unit.

The rinsed and dried potato slices are conveyed directly to the frier. The fried slices are removed from the tanks and drained on mesh belts. The temperature of oil in friers is held within a narrow range. Temperatures normally used are 176–190 °C at the receiving end and 160–173 °C at the exit end of the frier.

The oil used for deep-fat frying of potato chips has two functions: (1) it serves as a medium for transferring heat from a thermal source to the tuber slices; and (2) it becomes an ingredient of the finished product. The oil should be highly refined. The flavor and appearance of chips are affected both by the amount of oil absorbed and its characteristics as it exists in the chips. The amount of oil absorbed by potato slices is affected by: (1) the solids content of the tuber; (2) the temperature of the fat; (3) the duration of frying; and (4) the thickness of slices. Fat pick-up by potato chips is 10–15% lower when the chips are fried in liquid oil as compared to fat which is solid at room temperature. Reducing slice thickness increases the oil content of chips. A hot-air blast at the point where the slices emerge from the fat reduces fat absorption, and partial drying of sliced potatoes before frying also reduces the oil content of chips. Leaching raw slices with hot water results in an increased uptake of oil. The treatment of slices with glucose oxidase produces a chip of higher uniform color and lower oil absorption, without off-flavors.

Baked Snacks

Soda Crackers

Soda crackers and variants, suck as saltines, oyster crackers, etc., are themselves used as snacks, and also serve as a basis for combination snack foods either made in the home (crackers and cheese) or by manufacturers (cheese crackers, peanut butter and cracker sandwiches, etc.) The soda cracker is made from a lean, fermented dough. It does not contain much shortening, sugar, or milk. (*See* **Biscuits, Cookies, and Crackers**: Nature of the Products; Methods of Manufacture; Wafers.)

Flour constitutes 80% or more of finished crackers. Its qualities are important in determining the machining qualities of the dough, as well as the texture of the end product. Weak flours and lengthy fermentation times combine to yield flat, tender crackers. Flour for thick saltines should be stronger than for thin crackers. Thin saltines require a weaker flour; salt may be added at a rate of 2–5% to the dough.

Sprayed crackers are rich crackers, round in shape, and usually made from chemically leavened dough. Many of the representatives of this class could be considered a cross between crackers and cookies because they are not only leavened but also sweeter than saltines. The leavening system for these is adjusted so that the pH of the finished products is below neutrality. A pH of 6.5 is regarded as desirable. Sprayed crackers are coated with 20–25% (w/w) of a blend shortening. Coconut oil is preferred, but peanut oil or even hydrogenated vegetable shortening can be used. The oil is applied either by spraying at 65–71 °C, or by a device similar to an enrober, in which the crackers pass through a flowing curtain of oil. The oil must be applied when the crackers are still hot. The crackers may be salted very lightly on the cutting machine.

Cheese Crackers

Cheese crackers are usually made from fermented dough and they must be on the acid side of neutrality to yield a typical cheese flavor. The formulation is based on the soda cracker, except that fat and moisture added in the fresh cheese have to be compensated for. Paprika (0.25%) and a very small amount of cayenne are added to Cheddar cheese crackers to intensify the color and to add a flavor which is complementary to cheese crackers to impart certain desirable characters. Natural cheese should be finely ground before being placed in the mixer. Sometimes a premix of ground cheese and shortening, kept previously in the fermentation room for 24 h, is added at the doughing stage. This holding stage encourages the development of more flavor, and leads to a better dispersion of cheese in the dough. Artificial Cheddar and blue cheese flavors are also used whenever required.

Pretzels

Pretzels are considered to be the world's oldest snack food, and may have originated around AD 610 on the borders of France and Italy. Pretzels then become a popular snack food in Germany and Austria, where they were called 'pretzel,' later to be altered to today's pronunciation, 'pretzel.' Originally, all pretzels were soft, like unleavened bread. Accidentally, some pretzels were left in a cooling oven and the remaining heat dried them, removing the moisture and giving them a hard crisp texture and a golden coating. This led to the introduction of hard pretzels.

Soft pretzels today are baked, not dried, and have a texture resembling that of a fresh, soft roll, as well as a high moisture content. Soft pretzels are popular as a snack purchased at street vendors' stands. Hard pretzels have an extremely long shelf-life, especially when stored in airtight containers. Hard pretzels can be thin or thick, and shaped as twists, sticks, nuggets, logs, or

rings. They can be buttered, wholewheat, sesame-coated, chocolate-dipped and 'teething.' It is the drying which gives the hard pretzels their distinctive crunch, and this crunchiness is fundamental to the appeal of hard pretzels.

Pretzel doughs are made very stiff so that they can withstand the punishment of machining without becoming sticky or misshapen. The sponge is fermented for a shorter time than with cracker dough. Doughs receive a short proof stage but machinery steps, including formation of the pretzel, are handled automatically in all but a very few small plants. The characteristic gloss of the pretzel is the result of a lye dip. The lye dip solution contains about 0.5% sodium hydroxide or 2% sodium carbonate and is maintained at about 100 °C. The immersion time is about 10 s. The solution may also be applied by spraying. Immediately after the pretzels leave the caustic solution they are salted. The general aim is to achieve 2% salt in the finished product, but it is necessary to keep the initial application rate at 8–10%, to allow for losses in processing. A long drying time is required to reduce the moisture content to 2–2.5%, and temper the pretzel so that it does not break too easily during packaging. The long pretzels can be twisted or stick-type. Stick pretzels are extruded using a group of five extruding heads having 10–12 holes each. Logs and nugget-type pretzels are made in a similar manner to that used for the sticks, except that they are cut into short lengths at the extruded head. The stick pretzels can be made from almost any flour, but the choice of flour used in twisted pretzels is critical.

Filled pretzel sticks or nuggets are also available. These are produced by drilling a hole in the completely baked pretzel stick, and then inserting a paste-like filling of peanut butter and cheese, along with oil and sugar or a nonsweet agent such as lactose or dextrin.

Confectionery (Sugar-Rich Products)

Plain cookies are the cookies made in one operation, and this group does not include filled, coated, sandwiched, and other multiple-component cookies. The continuous structure of a cookie arises from the flour, and this basic framework is tenderized with sugar, invert sugar, egg yolk, ammonia, soda (or baking powder), and shortening. It is firmed or toughened with water, cocoa, egg white, whole egg, milk solids, and the leavening acids. Shortening is one of the principal agents for increasing tenderness, at least as far as rich, sweet biscuits are concerned. Too much shortening leads to a greasy smeary cookie which is susceptible to rancidity because of the free fat, while too much sugar results in hard and excessively sweet cookies.

A wide variety of flours can be used, varying from a soft cookie flour to a rather strong sponge flour. The stronger the flour, the more shortening and sugar are required to obtain an acceptable texture. High protein contents lead to hardness of texture and coarseness of internal grain and surface appearance. Chlorine-bleached flours should not be used for soft cookies where relatively large amounts of tenderizing and moisture-retaining ingredients, such as sugars, shortening, and egg yolk, are used. Cookies may become fragile if the quantity of flour is decreased too much.

Deposit Cookies

Deposit cookies are machine-made counterparts of the 'hand-bagged' cookies. They contain about 35–40% sugar, 65–70% shortening, and 15–25% liquid whole egg. The flour should be from soft wheat, unbleached with 8–8.5% protein and 0.35–0.40% ash. It should have a viscosity of 40 Ns/m^2 and a spread factor of 79–80. The flour should be able to carry sugar and shortening without too much spread, so that the top design is preserved through baking. The flour or other ingredients must contribute enough adhesive properties to the dough so that it will adhere to the band and pull away from the main column of the dough in the deposit stage.

Macaroons are made by a cold, or hot syrup cooking process, but they should not be made by the cold process unless they are to be consumed within 3 days.

Wire-Cut Cookies

The dough composition varies over a wider range for wire-cut cookies than for any other type. Thus the dough material should be sufficiently cohesive to hold together as it is extruded through an orifice, and yet be nonstick and short enough so that it separates cleanly as it is cut by wire. These cookies can be further subdivided as follows: (1) drop-type, which are used in sandwich cookies filled with a marshmallow or imitation cream, and usually containing equal amounts of sugar and flour; (2) sugar cookies, molasses cookies, coconut, raisin, date and honey varieties; (3) shortbreads, in which the shortening content is usually 50–70% of the flour content; and (4) macaroons, with little flour and large proportion of sugar.

Nut-Based Snacks

Nuts are often used to upgrade popcorn-based snacks, and are also themselves sold for snacks either as the individual variety or as mixed nuts.

Peanuts

The chemical composition of peanut is approximately 46% fat, 26% protein, 18% carbohydrate, 6% water, 2% ash and 2% fiber.

Roasted Peanuts

Peanuts are sorted, blanched, roasted, and salted. Blanching for peanuts and other nuts means removal of the skin or testa. During roasting, the kernels become dehydrated, and browning reactions occur throughout the kernel. The texture, flavor, and appearance change markedly. Toasting can be continuous or batch-type, and dry or in oil. The unique nutty flavor of roasted peanuts results from browning reactions of the Maillard type. The type of roasting affects the course of browning reactions because of variations in the rate of heat penetration and exposure to high temperature in different parts of the nut. Adhesion of salt to dry-roasted nuts is achieved by adding about 2% (w/w) coconut oil as a dressing to the warm nuts, and immediately applying the salt. The salt must have small particles of irregular configuration to obtain maximum adherence.

Fried Peanuts

Peanuts are fried at different temperatures depending on the flavor the customer wants to impart. Most peanuts are fried at temperatures around 140–160 °C but some customers prefer a slightly higher temperature in order to impart a roasted-burnt flavor into the peanut.

After the peanuts are removed from the frier, it is essential to reduce their temperature rapidly as they retain a lot of heat and will continue to darken as the Maillard reaction continues to occur with elevated temperatures. When they are cooled glazing oil can be applied to allow salt or flavoring to adhere to the peanuts. When nuts are fried in hydrogenated fat, the salt is applied before they are cooled to room temperature and while the fat on the surface is still molten. As the fat cools and sets, the salt granules are held firmly.

Coated and Fried Peanuts

A typical process would involve the peanuts being placed into a coating pan with a small quantity of starch. The peanuts will be roasted to insure they are completely coated. An adhesive solution will be placed on to the edge of the coating pan and the drum rotated. Starch is added on top of the peanuts and they are again rotated to insure the coating is smooth. This process is repeated until the desired coating thickness is achieved.

When the peanuts are deposited into the frying system, the starch contained within the coating will begin to gelatinize. This causes the exterior of the product to become sticky and the peanuts must be agitated to prevent them from sticking together. The peanuts are fried at a temperature of approximately 145 °C. The frying time varies due to different types and levels of coating on the peanuts. Peanuts that are completely coated require a longer fry time and lower temperature than peanuts that are only partially coated. The recommended frying temperature is lower than the temperature at which caramelization of sugars begins (i.e., 160 °C). This limits the color development of the coating and allows the moisture to be removed from the center of the peanut before the outside coating darkens. The moisture content of the interior of the peanut needs to be reduced to below 2.0% to produce a shelf-stable product. After frying the peanuts are cooled and can be flavored if desired. (*See* **Peanuts**.)

Pecans

Toasted and salted pecans are used directly as snacks. Blanching is never required in pecans. Pecans can either be dry-toasted or cooked in oil. Much less heat treatment is required than for peanuts, because the initial moisture content of pecans is lower, and the development of a true roasted flavor is seldom desired. Frying gives a more uniform roast and causes less mechanical damage. Roasting is performed, on an average, for 12–15 min at 190 °C. After roasting, the kernels are quickly cooled in tunnels or perforated bins, with forced air circulation to remove any undesirable odors. The cooled product is cleaned to remove any debris, foreign matter, and scorched nuts. The roasted kernels are coated with about 1% (w/w) finely ground salt. Pecans may be coated with cinnamon, sugar, barbecue-flavored powders, etc. Since toasted pecans have a very limited storage life, they are vacuum-packed.

Almonds

Almonds are a common constituent of mixed-nut packs, and are popular as the roasted and salted variety. The kernels are not generally blanched for the production of salted almonds. For blanching, the nuts are soaked in hot water until the skin loosens sufficiently to be removed by rubbing. Almonds may be dry-roasted or fried, but oil roasting is the more common method. In dry roasting, hot air is passed through rotating perforated cylinders or a fluidized bed to reduce the moisture content to 1%. Oil roasting is carried out by immersing the nuts in oil, preferably coconut oil, and heating to between 121 and 176 °C. After frying, they are cooled, salted, and

dressed with oil. They can also be coated with smoke-flavored salt, cinnamon, sugar, or similar flavored powders. (*See* **Almonds**.)

Sugared and Spiced Nuts

Sugared and spiced nuts are prepared by adding nuts and spices to water and sugar heated to 115 °C in a revolving pan. After coating, the nuts are dried for 1 h at 48 °C, or 2 h at room temperature, and packed in hermetically sealed containers, preferably under vacuum. The nuts must be dried to below 4% moisture before coating. This product should be refrigerated if not consumed within a month.

Extruded Snacks

Single- or twin-screw extruders are used to get extruded snacks. There are three types of extruded snacks: (1) direct expanded snacks, (2) coextruded snacks, and (3) indirect expanded snacks.

Direct Expanded Snacks

This category gets its name from the fact that products expand directly out of the extruder die and require no further processing, such as corn curls, both baked and fried, onion rings, and potato sticks. The puffing of direct expanded snack products is created by heating the ingredients to temperatures over 100 °C. Inside the extruder the water in the dough mass remains a liquid because the dough is under pressure. When the dough exists the extruder through the die opening, the superheated water is exposed to atmosphere. The vaporization of water into steam during this rapid pressure loss causes stretching and expansion of the starch matrix. The equipment used to make such products ranges from simple collect extruder to twin-screw extruders. Potato sticks are made from 65% potato starch and 35% corn meal. Blend is extruded to cook and puff. The high level of potato starch gives this product a unique flavor. The baked collet is then coated with oil, salt, and other seasoning.

Coextruded Snacks

Coextrusion technology became popular in the snack food industry around 1984. A coextrusion process is a technique where two materials (usually dissimilar in nature) are combined in an extrusion die. The two materials can come from two extruders or from an extruder and a pump. This process gives the manufacturer the ability to make a product which has two textures, or two colors or two different flavors. In snack food industry the most common form of coextrusion is the extrusion of a cereal-based outer tube with a cheese filling pumped into the center of the tube.

Indirect Expanded Products

Indirect expanded snack products are also referred to as 'third-generation snacks' and 'half-products.' These products are not expanded directly through the die. The additional process steps which contribute to the appearance or texture include frying or hot-air puffing to remove moisture and achieve the final texture. There are two subcategories of indirect expanded products: (1) pellets; (2) fabricated chips.

Pellets

Snack pellets are products cooked in an extruder and forced through a die at temperatures below 100 °C. The shape of the dough at low temperatures prevents the puffing forces of water turning into steam, thus intricate shapes can be made in pellets which would normally be destroyed in the direct expanded extrusion process. Snack pellets are extruded at 25–35% moisture and then dried to around 12% moisture for stability. Since the snack pellet is unexpended and dense in this stage, drying must be done at low temperatures and high humidity to allow the moisture to migrate out of the pellet. So snack pellets can be held for longer periods, shipped to long distances, or distributed to the snack food manufacturers or consumer directly. The pellets are characterized by a translucent appearance, due to above 90% level of starch gelatinization. Then pellets can be expanded by heating them rapidly to cause the water in the pellet to turn into steam in an explosive manner which puffs the pellet. This can be accomplished by frying, baking, or microwaving, then coating with seasoning and packing. Frying is the most common method because it is less expensive and works well. Frying conditions depend on the pellet thickness, shape and composition. Frying temperatures usually range between 170 and 210 °C for 10–60 s. For low-oil snack products, baking and microwaving have been explored. Due to rapid heat transfer rates required to expand a pellet uniformly, the ordinary snack dries and a baking oven will not puff a pellet. Microwaving of pellets also requires a rapid heat transfer rate, therefore high-powered continuous microwave expanders are commercially used. Expanded pellets have a moisture content of 1–2%. They are usually flavored in coating drums as for direct expanded products.

Fabricated Chips

There are many fabricated chip products (FCP) made through a wide variety of processes. One of these

processes is extrusion-based, similar to the process for making pellets. The main difference is that FCP are not dried to below 12% moisture to be stored or sold. They are also cooked less during the extrusion step. After extrusion, they are fried to remove moisture and complete the cooking process. Fabricated chips are usually sheeted out of the extruder and cut into a shape which simulates a potato or a tortilla chip.

Corn Chips and Simulated Potato Chips

Commercial simulated potato chips have assumed great importance. The corn chips and tortillas prepared from alkali-treated corn dough have similar flavors and textures. The ground, alkalized corn dough, or masa (Table 2) is conveyed to the hopper of the tortilla cutting head by means of a screw-type extruder. A thick sheet of masa is extruded between sizing rolls, and the resulting ribbon is cut into dices of appropriate size. Tortilla blanks are baked in gas-fired ovens at 315 °C for 30–32 s. Tortillas discharged at 79 °C are cooled to 29–32 °C in an atmospheric multilayered conveyer.

Corn chips are prepared from a mixture of white and yellow corn, varying in ratio depending upon the color desired in the final product. The alkalized dough is cut into pieces of desired length and shape, and transferred directly into cooking oil held at about 190 °C. After the moisture content has been reduced to a few percent, the chips are salted, cooled, and packaged.

Cereal grains other than corn can also be formed into chips and fried; the alkalizing process is omitted in these cases. Shredded wheat, formed into multiple layers, salted and baked, forms the basis of Triscuit.

The high-fiber, high water-holding capacity (WHC) and low calorific value of corn bran makes it suitable for low-calorie and variety-baked snack foods, e.g., cookies, crackers, etc.

Fabricated potato snacks can be classified into four groups: (1) dry collet processes; (2) single-screw extrusion of dry potatoes; (3) forming and frying of moist dough; and (4) forming of a high-solids dough into a thin sheet which is then cut into pieces and fried. The latter process is used in the manufacture of simulated potato chips.

Simulated potato chips may be formed by methods resembling those used in the cookie and cracker industry. It is necessary to formulate the dough with physical properties that make it suitable for rolling out into a thin sheet. This is achieved by the inclusion of substantial amounts of cereal flour. Another approach is to use ungelatinized starch in the dough, and then steam-treat the pieces after all the forming operations have been completed. After sheeting, the dough is cut into pieces of the desired shape and size, and then fried or baked. Simulated potato chips can also be prepared from reconstituted dehydrated potatoes.

Low-Pressure Extruded Fried Indian Snacks

A lot of legumes are manufactured into flours and are used as the basis for formulations that are extruded in low-pressure systems. One prominent market is in the Indian snack food area that produces a large variety of snack food-type noodles (sev, omumpodi). The number of shapes, sizes, and ingredients used is diverse, but basic principles involved in producing such products are quite similar. In extruded gram flour-based snacks, flour is produced from chickpea, which is one of the main legumes grown in India. The composition of gram

Table 2 Parameters for the major steps in the manufacture of an alkaline-processed corn snack

Operation	*Tortilla chip*	*Corn chip*
Lime content	1% of corn weight	1% of corn weight
Cooking	4–10 min > 93 °C. Moisture: 29%	14–45 min > 93 °C. Moisture 42–44%
Quenching	Quickly, < 66 °C	Quickly, < 66 °C
Steeping	8–24 h, 46–60 °C. Moisture > 45%	8–24 h, 46–60 °C. Moisture 50–52%
Washing	Wash temperature < 27 °C	Wash thoroughly and drain: < 27 °C
Grinding	Stone, masa at < 38 °C. Water added, moisture 52–54%	Stone, masa at 46–54 °C. Moisture 50–52%
Masa sheeting and forming	Promptly, 21–27 °C	Masa is extruded or sheeted and cut directly into frying oil
Baking	12–18 s, 399–454 °C. Moisture 40%	
Cooling and equilibrating	Cool to 60 °C within 15–30 s. Moisture 38% after equilibration	
Frying	2 min at 179 °C	1.5 min at 210 °C
Chip moisture	1.0–1.2%	1.0–1.5%
Oil content	25%	35%

From Gomez MH, Rooney LW and Waniska RD (1987) Dry corn masa flours for tortilla and snack food production. *Cereal Foods of the World* 35: 372.

flour is approximately 11.2% moisture, 22.5% protein, 5.2% fat, and 58.9% carbohydrate. Other flours that are commonly used as base ingredients for this type of extrusion include soybean and pea flour.

Gram flour is mixed with other ingredients to obtain a dough that is suitable for extruding and has an acceptable texture and taste. Other ingredients that are commonly used in the formulations for Indian-style extruded products include rice flour, urad dhal powder, ghee, sodium bicarbonate, chilli, cumin, paprika, coriander, turmeric, asafetida, and pepper. Gram flour is typically mixed with rice flour, other spices, and water to obtain dough that is extremely sticky. The moisture content of this dough varies depending on what the manufacturer requires but typical moisture levels vary from 40 to 60%.

The type of die that is used for extruding will determine the style of product manufactured. Common shapes include a round product with diameter varying from 1.2 to 6 mm. Other shapes include a star or a ribbon. The diameter of the die and the number of holes on the die plates will produce different production volumes.

The noodles are fried using a single-zone, indirectly fired frier. The temperature used is approximately 180 °C and the frying time varies from 30 s to 5 min, depending on the moisture content of the dough, diameter, and shape of the extruder die.

Corn Snacks

Corn-based snacks fall into three categories: extruded from corn meal, baked and fried from masa, and corn chips or simulated potato chips.

Extruded snacks are made of corn meal with, occasionally, a small amount of another grain, such as rice or wheat, added. The moistened meal is passed through extrusion cooking equipment, giving a collet, which is an expanded matrix of gelatinized starch. The dimensions are determined by the kind of die used, the cut-off knife speed, and other mechanical factors. The collet has a moisture content of 8–10% and is quite tough and chewy, an aspect which is remedied by baking or deep-frying to obtain a final moisture level of around 2%. The dried collets are flavored with cheese (applied in a powdered form), chilli, barbecue sauce, sour cream and onion, or a number of other flavors. Other extruded snacks consist of hollow extrudates which are modified to make rectangles, ovals, or ornamental shapes, and filled with all kinds of savory or sweet fillings. These snacks are quite popular, and the most popular flavors for extruded snacks are chocolate, butterscotch, and peanut butter. Delicate fruit creams, such as wild strawberry, lemon-lime, bitter orange, sour cherry, kiwi, peach, and cola, are also being used to fill extrudates.

Baked and fried snacks make up the largest share of the corn-based snack market. They are produced using centuries-old processes that have been modified by the adoption of modern technology. Cleaned corn is placed in steam kettles and covered with a dilute solution of lime ($Ca(OH)_2$). The mass is brought to near-boiling temperature, and held for a period of time depending upon the nature of the corn used. It is then cooled and allowed to steep for 8–16 h. During steeping, water penetrates the kernel and gives the desired degree of friability to the endosperm. The cooling and steeping also loosen the outer hull and germ, which are removed from the corn by washing. The washed kernels are ground to produce masa, a cohesive, plastic corn meal with a moisture content of approximately 50–60%. Masa is the raw material for corn and tortilla chips. To make corn chips, masa is extruded through a slot to give a ribbon of dough. Cut off by a knife, the raw chips fall into hot fat for deep-frying. They are transported through the frying tank by a traveling belt in 2–5 min. During this time, the starch is gelatinized and the moisture level is reduced to approximately 2% to give the crisp bite of the finished chip. After the traveling belt brings the chips out of the bath, they are given a light dusting of salt and flavoring poser, if required, and then packed. Whole kernel corn can be heat-expanded by selecting a corn variety, drying, soaking, separating the corn kernels from water, heating the soaked kernels in edible oil to expand, and cooking the interior starch. The fried kernels are separated from oil and seasoned.

Tortilla chips are produced more or less as in a traditional process. The masa is rolled out into a thin sheet, cut into the desired shape, and transported into an open-flame oven. The heat sets the structure, drives out most of the moisture, and changes the flavor slightly by creating small amounts of Maillard reaction products. The chips are held in a tempering chamber to equilibrate moisture and stresses throughout the chip. Finally, they are deep-fried to create a crisp texture, salted or seasoned, and packaged. Use of dry corn masa in the preparation of corn tortillas and other corn-based snacks is advantageous as it eliminates the capital cost of cooking, washing, and grinding equipment, avoids the problems associated with high solids, high biological oxygen demand waste water; minimizes variability, and improves consistency and quality as well as the partial size distribution requirement of the end products. (*See* **Tortillas**.)

Legume-Based Indian Snacks

Fried Green Peas

Fried peas can be eaten as a fried snack or consumed as a part of a mix of snack food products.

After the variety of pea has been chosen it is necessary to soak the peas in sodium bicarbonate solution containing green food coloring (within Asia). The purpose of adding green food colouring is to enhance the green pigmentation of the surface of the peas.

The peas are obtained in the dehydrated form and rehydrated in water at room temperature for approximately 8 h. If the temperature is too high, it will cause the starch within the peas to gelatinize and the protein to denature. The moisture content of the peas increases to approximately 48–57%. After soaking, the peas swell to approximately twice their original size. The soak time is critical to minimize the level of fines produced as peas soaked for longer than 9 h tend to produce a higher level of fines as their skins get removed more easily during the cooking process. If the peas are soaked for excessively longer periods of time, they may ferment and cannot be utilized by the manufacturer.

The addition of sodium bicarbonate produces a multitude of effects. Initially it will increase the pH of the soak water and brightness will occur to a greater extent with the presence of green food coloring in the soak water. The increase in pH of the soak water insures that the water absorbed into the peas has a higher pH than the one it contained. It acts as a form of chemical leavening. The reaction involves the acid (contained within the pea) and soda (sodium bicarbonate). One of the main purposes of using this chemical is to produce carbon dioxide when the peas are fried. This gives fried peas a lighter texture and a better mouth feel.

After soaking, the peas are fried to reduce the moisture content below 2.5%. By having the flexibility to vary the temperature of the frying oil, the product quality of the peas can be improved. If the frying oil temperature is not controlled then the moisture content in the final product may be too high or too low, the texture may be too hard, the surface of the peas may blister, there may be an overexpansion of the peas giving excess fines, and product capacity may be reduced.

Fried Chickpeas

Due to their high protein and low fat content, fried chickpeas are a healthy alternative to other snack foods. The dried chickpea contains 7–10% water, 12–31% protein, 4–10% fat, 58–68% carbohydrates, 3–5% fiber, and 2–5% ash.

Chickpeas are soaked for approximately 10 h at room temperature, increasing the moisture content to approximately 53%. The chickpeas are removed from water, rinsed, and drained to insure excess surface moisture is removed.

The chickpeas have an anatomy that resembles the green pea and therefore the problems experienced during frying are very similar. It is necessary to insure the frier has the flexibility to vary the initial and final frying temperature (as was the case with green peas). If a single zone temperature is used, either the oil has to be set at a low temperature, or if the temperature is too high this will cause problems with rupturing of the skin and increase in level of fines. If the temperature is too low then the product output will be reduced and oil absorption will increase. The slow increase in temperature during frying will increase the output obtained and decrease oil absorption.

Fried Lentils

The chemical composition of dried lentils is approximately 23% protein, 1% fat, 1% fiber, 61% carbohydrates, and 14% water.

The lentils are soaked for 3 h in water at room temperature to a final moisture content of 52%, rinsed and drained to remove excess water.

This legume performs differently when fried, as compared to green peas or chick peas. A single temperature zone can be used because the product is not as susceptible to thermal shock when it initially enters the frier. A temperature of 180 °C is used to obtain a rapid decrease in moisture content of the legume. The time required to fry this legume is very short because of the large surface area of the product and the rapid heat transfer into the product.

Meat-Based Snacks

There are a few snacks that are composed primarily of animal-derived raw materials. Expanded pork rinds, also called broken skins or skeen, have been popular as a between-meal snack in the southern USA for many years. These are pieces of hog skin which have been processed so that they puff to many times their original volume. The flavor is bland and reflects the oil in which the skin has been processed. The texture is very crisp and friable; they are not as hygroscopic as many other puffed snacks.

The raw materials are green belly skins, green fat hog skins and green ham skins from any type of hog; belly skins give the best finished product. The skins are first dipped into an air-agitated brine solution held at 100 °C for 30 s. The brine may contain 12 kg dextrose, 11 kg sucrose, and 68 kg salt in 909 l in

water. After dipping, the skins are drained and cooled at room temperature. Then the skin is diced into 127- or 254-mm squares, ready for further processing.

Chimni, a processed seafood snack popular in Japan, is gaining popularity as a main dish rather than a snack consumed with drinks, but it involves high labor.

Jerky

The name 'jerky' is derived from a dried-meat product which is popular in the USA. Many countries have their own form of dried-meat products. The product name varies, as does the form in which it is eaten. The Americans call it 'jerky' and eat it as a leathery whole tissue, or comminuted into strips. The American Indians call it 'pemmican;' they grind the diced meat and mix it with fat before eating it. In South Africa it is called 'biltong.' The French version is called 'grisons;' before being eaten, the dried meat is smoothed with hot cheese.

Meat jerky was originally prepared by the American Indians, who salted strips of muscle tissue from deer, buffaloes, and other game animals and cured the strips in sun or over smoky fires for long periods of time. Commercially, beef jerky is made by marinating strips of beef, drying the marinated meat, and finally cutting the dried strips to the desired dimensions. Beef jerky can also be prepared by subjecting a mixture of ground and chunk beef to a saline treatment for 12 h or more and then to freezing temperatures for 1–3 weeks. The meat preparation is then sliced into strips and dried.

Other Snack Foods

The future of traditional snack foods depends upon the development of new forms and flavors. Pretzels and salt sticks, crackers, and nut mixtures have been modified, and the market of these products has been increased.

Soft pretzels available in fresh, frozen, and microwavable forms have resulted in growth of the pretzel market. In most countries, the market of pretzels and salt sticks has increased with the introduction of health-oriented products that are salt-free, cholesterol-free, and possess increased fiber content. Other new pretzels and salt stick products are produced in various shapes and sizes. The new products are also available in such varieties as savory-flavored, sweet-flavored, chocolate-coated, brightly colored, and peanut-butter-filled.

Along with the salted peanuts and nut mixtures that continue to be popular all over the world, the current market for nut-based snacks is influenced by: (1) an increased demand for flavored nuts; (2) the growing popularity of high-quality exotic nut and dried-fruit mixtures; and (3) the increasing success of premium nuts such as cashew, pistachio, and macadamia nuts. The development of flavored nuts and nut mixtures has resulted in a virtually limitless list of new products, including products such as hickory-smoked and honey-roasted nuts, nut mixtures containing rice, lentils, coconut, and vegetables, and nuts of all types flavored with garlic, soy sauce, herbs, ham, barbecue, and many newly developed flavors.

Khao kriap wane (KKW) is a popular Thai glutinous rice-based snack food made from pounded, gelatinized glutinous rice which is sun-dried and puffed by direct flame roasting. Puffed KKW does not stay crunchy for more than 3 h after puffing. It can be stored for less than 2 months in low-density polyethylene (LDPE) or for greater than 6 months in aluminum/polyethylene laminate or polypropylene and retains crunchiness.

Novelose, a speciality starch, consists of at least 30% dietary fiber and functions well in direct expanded extruded products. It also has a synergistic effect with traditional cellulosic fiber and counteracts negative processing aspects. (*See* **Cashew Nuts and Cashew Apples**.) Specialty and modified starches can provide a number of functional benefits to snack foods like replacement of fats and oils, satisfying consumer demand for healthier snacks for tasty and appealing reduced-fat products.

A fruit snack bar, prepared using apricot pulp and soyabean slurry, contains 15.3% moisture, 7.8% protein and 16.5 mg ascorbic acid $100\,g^{-1}$, with good flavor. A snack product comprised of dried agglomerated, sugar-soaked fruit or vegetables like apples, carrots, and beets, followed by drying, has a low water activity, bulk density, and crisp tender eating quality.

A bagged expanded cooked snack comprises a number of individual morsels with several added vitamins, such as thiamin, riboflavin, niacin, ascorbic acid, vitamin D, and at least one added mineral other than sodium. It may be a savoury product with an oil or fat content of 5–40% by weight.

Rice flour can improve the texture and handling of multigrain products or substitute completely for another type of grain. Blending long-grain rice flour increases the crispiness in fried or baked snack chips based on wheat or corn. Waxy rice flour can reduce chip hardness and at the same time can provide a melt-in-the-mouth texture which is usually achieved with extra fat. Adding 5–10% waxy rice flour to a baked or fried chip product diminishes chip breakage during packaging.

Shelf-stable grain-based Indian snacks include fried products (paras, fried products made from bengal

gram meal, fried products made from rice and legumes, fried dhals); moist fried products, popped and puffed cereals, expanded cereals, beaten (flaked) rice, and extruded foods (extruded pellets, ready-to-eat expanded products, corn and tortilla chips). Kokoro, an indigenous corn-based snack food product prepared using deep frying of a corn, onion, and shrimp blend, is popular in Nigeria.

Quality Control for Snack Foods

The extent of quality control analysis in the snack food industry is quite variable, ranging from completely subjective testing procedures to series of elaborate instrumental analyses performed on a continuous basis. The maintenance of uniform quality in snack foods is essential for the very existence of the business. Quality control expresses the objectives of a group of people who do the sampling, testing, and other activities related to the evaluation of product conformance to predetermined standards. It is the expended responsibility of the group to correct problems which could result in a defective product. (*See* **Quality Assurance and Quality Control**.)

Quality control aims at maintenance of quality at levels and tolerances acceptable to the buyer, while minimizing costs to the vendor. It can also be defined as the application of sensory, physical, and chemical tests in industrial production to prevent undue variation in quality attributes, such as color, viscosity, and texture. In addition to satisfying the consumer, the product must meet the requirements of government regulatory agencies. A snack food which does not meet the minimum acceptability requirements of all customers may result in only a few complaints, but a product which does not meet all of the legal requirements may be confiscated and the manufacturer subjected to punitive fines and other penalties. A product may look good, taste good, have good texture, and perform well in its intended application, and still be unfit for distribution. To be suitable for sale it must also be wholesome, conform to all applicable labeling and packaging requirements, and be prepared and stored under conditions tending to prevent contamination by noxious or esthetically undesirable materials.

The quality of the finished product is inseparable from the quality of the components. Seldom can processing operations compensate for raw material inadequacies. Unless the raw materials are of good quality, it is very difficult to obtain a good-quality finished product. Standards must be developed and strictly adhered to while processing the various ingredients, during the production and processing steps, as well as during handling, packaging, and storage of the finished snacks.

During pretzel production, a number of problems, particularly in the cooking process, may arise. These include brittleness, dark or light color, wrinkling, loss of glaze, breakage, browned interior, and lack of crispness.

In the production of corn-based, baked, and fried products, the consistency of the masa is very important. If excess starch granules are gelatinized during cooking and steeping, the masa is too sticky to process smoothly. On the other hand, inadequate cooking may give a dry, crumbly mass which does not work in the equipment. Potato chips undergo a visual inspection at the end of the process, and excessively dark ones or those containing discolored portions or possessing some other defect are manually removed by picking. In a modern industry, this may be performed by computerized optical scanners. The sensitivity of the computer scanner can be adjusted to pick up all less-than-perfect chips, or selectively to remove only the least desirable. Blistering of chips on frying is quite a problem. Such chips break in conveying, filling, or handling the filled bags. Another factor affecting the quality of chips is the shift to thicker chips: it results in significant reduction in oil absorption owing to a decreased surface area relative to the volume. Ridged chips solve the blistering problem.

In general, snack foods are believed to be 'empty calories,' however, lately manufacturers have started supplementation with vitamins, minerals, or proteins. Vitamins can affect flavor and some can also cause off-flavors. While supplementing with nutrients, it is necessary to establish a quality control program to insure the claimed amounts in the product. Most snacks are poor sources of protein, and the protein, which is present, is often of poor nutritional quality. Protein supplementation is possible by increasing the protein efficiency ratio of the protein already present or increasing the protein content through addition of casein, soya protein isolates, or egg white. Certain combinations of cereals and legumes are very desirable from a nutritional point of view. The high snackers have low energy and low macronutrients from the meals; however, snacks do make an important contribution to energy and nutrients. A high snacking frequency and choosing from a wide variety of snack foods can result in a balanced intake of nutrients.

Dietary Importance

A S Bawa and J S Sidhu, Guru Nanak Dev University, Amritsar, India

Background

This article deals with the dietary importance of processed snack foods with a passing reference to fruits and fruit bars. However, these as well as fruit juices may be included under the term 'snack foods.' In general, snack foods are considered as 'junk foods' or 'empty calories.' Our diet is generally based upon three principal meals a day, and the role of snack foods is to offer a light, convenient, and enjoyable food option, when, for reasons of hunger or sociability, a food selection is required at a time between that allotted for principal meals. Thus, snack foods are not designed to be alternatives for three main meals a day. They are convenient to eat, involving no preparation time or effort by the consumer. Snacks are eaten not only to satisfy hunger or supply the nutrients to our body, but also for social reasons. On many occasions, the inclusion of snack foods in our diet is not justified in terms of nutritional demands. The nutritional value of different snack foods, extent and frequency of consumption by different people, and the need for fortification have been discussed.

Snack items and processed foods are presumed to have a high sodium content, and this should be avoided. Teenage boys are most likely to have a low intake level of calcium, iron, magnesium, and vitamin B_6, and teenage girls consume these nutrients at still lower levels. The food items most frequently consumed by both sexes between meals are cakes, cookies, pies, candy, and desserts. The most popular foods are salted snack foods, such as chips (crisps), pretzels, and popcorn. Males incorporate more breads, wafers, and other bread products into their snacks than females, whereas females eat more snacks containing condiments, fat spreads, and dips than do males. (*See* **Calcium**: Physiology; **Iron**: Physiology; **Magnesium**; **Sodium**: Physiology; **Vitamin B_6**: Properties and Determination.)

The real nutritional concerns about snack foods center on the sodium, energy, vitamin, mineral, and dietary fiber contents.

Nutritional Value of Different Types of Snack Food

Potato Chips (Crisps)

Nutritionally, 28 g (1 oz.) of potato chips provide 647 kJ (154 kcal), contributed by 2 g of protein, 14 g

of carbohydrates, and 10 g of fat. A portion of potato chips (25 g) contains 8% of the recommended daily allowance of vitamin C, 3% of thiamin, 11% of nicotinic acid, 8% of iron, 11% of vitamin B_6, 4% of phosphorus and 4% of magnesium. Potatoes are also an important source of dietary fiber. Refer to individual nutrients.

Cookies and Crackers

The principal ingredient in cookies and crackers is unbleached, soft wheat flour, and most of the nutrients in these products are derived from the flour. It can range from more than 90% for saltines and similar products to less than 25% in products such as enrobed wafers. The soft wheat flour used in cookies and crackers contains 8–10% protein, with the higher-protein flours generally being used for crackers and the lower-protein flours for more tender sweet goods. With certain exceptions, the quality does not deteriorate on baking. Most cookies and crackers are made from enriched flour. The main component present in flour is carbohydrate, which is a good source of energy. (*See* **Flour**: Dietary Importance.)

Other ingredients added to cookies and crackers influence the nutrient content of products either by their own nutritional composition or by diluting the nutrients contributed by enriched flour: for example, sugar contributes energy and carbohydrates; shortening contributes fat, essential fatty acids, and energy; salt contributes sodium; leavening agents contribute sodium, potassium, calcium, and phosphorus; peanut contributes fat and nicotinic acid; fruits and vegetables contribute vitamins A and C, fiber, and minerals; chocolate contributes iron and fiber; and other grains contribute minerals, fiber, and other nutrients similar to wheat flour. The potassium content of cookies and crackers is 25–200 mg and 30–80 mg per 28 g (1 oz.), respectively. During baking and storage, the main nutrients lost are thiamin and vitamin C. Lysine reacts with reducing sugars and becomes unavailable, especially at a high pH. Plain and sandwich cookies have similar nutrients. However, nut-containing cookies provide comparatively more protein, vitamins (such as nicotinic acid), and minerals. (*Refer to* individual nutrients.)

Pretzels

The average energy content of a 28-g of serving pretzels is 462 kJ. One pretzel rod contains 231 kJ; one Dutch-style pretzel contains 460 kJ, and a handful of twisted, three-ring pretzels contain approximately 419 kJ. Pretzels are low in energy and fat, and have no sugar, but contain a large amount of sodium. The average amount is 450–700 mg of sodium per 28-g serving of pretzels. However, low-salt pretzels, containing 300 mg per 28-g serving, and unsalted pretzels are also available for sodium-conscious consumers.

The typical ingredients of pretzels are flour, water, yeast, soda, and salt. The flour is from soft wheat with a protein content of 8.50–9.50% and an ash content of 0.40–0.50%. A 28-g serving of pretzels offers approximately 3 g of protein, 23 g of carbohydrates, and 1 g of fat. Pretzels also provide several vitamins and minerals, including thiamin, riboflavin, nicotinic acid, iron, magnesium, and copper. Although the quantities of these nutrients are moderate, the nutritional value of pretzels is significant, since they contain no chemical additives or preservatives. However, some pretzels also offer calcium, phosphorus, and other nutrients in significant amounts. (*Refer to* individual nutrients.)

Corn Snacks

Corn snacks are accused of being junk food and without nutrient content. Flour tortillas are low in moisture and high in fat, protein, and carbohydrates, compared to corn tortillas. The energy content is, on average, 25% higher than that of corn tortillas. The phosphorus and calcium contents in corn tortillas are substantive. The iron content in corn tortillas is similar to that of wheat flour tortillas. Both the flour and corn tortillas are significant sources of zinc; corn tortillas are also a significant dietary source of copper and magnesium. Tortillas contain modest amounts of sodium and potassium, but because of the significant losses during processing, they are an insignificant source of thiamin and riboflavin. All tortilla products are substantial sources of nicotinic acid. Tortillas do not contain measurable quantities of vitamin C or β-carotene. Refer to individual nutrients.

A fruit bar containing apricot pulp and soy slurry in the ratio 70:30 has been found to be most acceptable in terms of sensory properties. This bar contained 15.3% moisture, 7.8% protein, and 16.5 mg of ascorbic acid per 100 g, and had a good flavor (not beany) and texture.

In one study, consumers in Newcastle perceived cereal bars to be healthiest. However, an analysis of seven popular cereal bars revealed that they are only marginally healthier than traditional cereal snacks. The varieties containing chocolate chips were preferred but were not necessarily the healthiest.

An assessment of the perception of fruits in relation to manufactured snack foods has revealed that fresh fruit and a canned snack fruit product were both perceived as healthy and refreshing by working women in the UK, manufactured snack foods were considered more convenient and suitable for comfort eating, and bananas and apples were

perceived as more convenient than orange and kiwi fruit.

The Nigerian snack foods, robo, kulikuli, and kokoro, prepared from watermelon seeds, groundnut, or maize kernels, have 23.4–42.0% fat and only 1.5–7.3% moisture, and a maximum shelf-life of about 150 days at 30–31 °C.

An extruded snack prepared from a blend of tapioca, wheat flour, maize grits, spirulina, etc. is quite nutritious and contains: energy 411 kcal, protein 8.7 g, fat 7.6 g, carbohydrates 77.2 g, Ca 68.0 mg, Fe 2.8 mg, vitamin A less than 3 IU, thaimin 0.1 mg, riboflavin 0.2 mg and vitamin C less than 0.35 mg per 100 g. It is low in fat and relatively high in Ca and Fe, compared to other similar snacks.

Overall, corn snacks can contribute positively to the diet by providing certain nutrients and minerals necessary for nutritional balance and they have a good flavor and a pleasing texture.

In potato chips and nuts, the salt is on the surface of the foods, so the immediate taste perception is of saltiness – much more so than if the salt were uniformly distributed, as in most other foods. Many snack foods contain moderate to high amounts of salt on a percentage basis. The average serving of snack foods is much less than 100 g, ranging up to 40 g and averaging about 35 g; in comparison, many sodium-containing staple foods are eaten in quantities greater than 100 g. It is more sensible to examine the sodium content of snack foods on a per-serving basis (Table 1) because the sodium content of snack foods is much lower than that of certain commonly consumed foods, such as bread and butter, sandwiches, and other foods at the bottom of the table. The sodium content of a packet of chips, for example, is less than that of a plain sandwich, and over six packets of salted chips would have to be consumed to obtain the same amount of sodium contained in a single hamburger.

The second aspect of concern is the energy content of snack foods. It is generally believed that snack foods are both rich in energy and fattening, since they are cooked in, or blended with, oil. A comparison of energy content of foods on a per-serving basis (Table 2) shows that the consumption of lightly cooked vegetables instead of snacks can reduce the energy intake and that the energy content of snacks is not as high as is popularly perceived, since hot dogs and hamburgers have much higher energy contents. A packet of chips does not contain much more energy than a cup of milk or a plain yogurt, and somewhat less than a bread-and-butter sandwich. It is much more difficult to control the energy and fat content of snack foods than it is to control sodium content. The technology to produce fat-reduced potato chips does not exist, but the level of fat can be controlled by careful regulation of cooking parameters. Oil is essential in cereal snacks to give an acceptable mouthfeel, and with nuts, the oil is already present before cooking. The only way to control the energy consumption via snack foods is to reduce the size of the serving; Table 3 shows gives the effect of serving size on energy content.

The vitamin and mineral contents of snack foods are another area of concern; Table 4 lists the vitamin and mineral contents of some selected snack foods.

Table 1 Sodium content of some foods

Food	*Sodium content (mg per serving)*
Most fresh fruits and vegetables	Negligible
Eggs (one medium)	54
Rump steak (130 g)	121
Fried chicken leg	122
Whole milk (1 cup, 237 ml)	128
Salted peanuts (25 g)	197
Toasted CCS (25-g packet)	220
Salted chips (25-g packet)	234
Flavored chip crisp sticks (25-g packet)	280
Flavored chips (25-g packet)	306
Bread-and-butter sandwich	367
Cheese Twisties (25-g packet)	440
Scrambled egg	534
Fritz or Devon (two slices)	650
Hot dog	1102
Hamburger	1591

Data from Delroy B (1985) The role of snack foods. *Food Technology in Australia* 37(4): 154–158.

Table 2 Energy content of some foods

Food	*Energy content (kJ) per serving*
Lettuce	17
Peas	163
Boiled egg (one medium)	301
Baked fish (one fillet)	326
Salted peanuts (25 g)	584
Whole milk (1 cup, 237 ml)	644
Plain yogurt (1 cup, 237 ml)	690
Potato chips (25-g packet)	739
Twisties (25-g packet)	810
Chip crisp sticks (25-g packet)	814
Bread-and-butter sandwich	865
Hamburger patty	932
Flavored and fruit yogurt (1 cup, 237 ml)	982
Fish, buttered and fried (one fillet)	1041
Hot dog	1342
Grilled steak (130 g)	1822

[a]4.2 kJ is equivalent to 1 kcal. Data from Delroy B (1985) The role of snack foods. *Food Technology in Australia* 37(4): 154–158.

The potassium content of chips is higher than sodium in spite of the added salt, and this is significant in view of the criticism that high sodium levels in processed foods are associated with depleted potassium levels. However, since snack foods are designed to be occasional between meal snacks, their contribution to the diet may be of little significance to the average person. Cereal snacks can be fortified with added vitamins and minerals to any desired level, but it is not common practice, since snack foods are not considered to be suppliers of significant quantities of minerals and vitamins. (*See* **Food Fortification**.)

The importance of dietary fiber in snack foods is still not very clear, partly because of problems with analytical methods; Table 5 compares the dietary fiber content of snack foods with that of a bread sandwich. The figures indicate that the four snack foods contain more dietary fiber than a white-bread sandwich, and chip crisp sticks more than a brown-bread sandwich. Since bread is one of our best sources of dietary fiber, and the cereals and root vegetables from which snacks are developed are sources of the highest-quality fiber, snack foods cannot be rejected on the basis of their fiber content. Snack foods are neither an important source of micronutrients nor simply 'empty calories.' Snack foods prepared from whole cereal grains can be a good source of dietary fiber, and the addition of a few per cent of bran in place of the purified cereal fractions improves the fiber content of the finished products. Dairy and meat products have negligible fiber contents, and potatoes are rather low in this component. (*See* **Dietary Fiber**: Physiological Effects; Effects of Fiber on Absorption.)

Table 3 Effect of serving on energy content

Food	*Energy (kJ) per serving*	*Fat (g)*	*Sodium (mg)*
Small apple	222.0	0.3	Negligible
Twisties (15-g packet)	460.0	5.9	250.0
Salted chips (20-g packet)	565.0	8.8	179.0
Milk (1 cup, 237 ml)	644.0	8.7	128.0
Bread-and-butter sandwich	865.0	8.6	267.0

Data from Delroy B (1985) The role of snack foods. *Food Technology in Australia* 37(4): 154–158.

Levels of Snack Foods Eaten

The results of various previous studies (Table 6) reveal that children and teenagers have at least one snack during the day. Adults tend to snack less frequently, and the percentage of adults who 'snack' decreases with age. Snacks provide at least 20% of energy for those who eat at least one snack a day and account for 12% of the average protein intake, 16% of the fat intake, and 25% of the daily carbohydrate intake. 'Snackers' obtain, on average, 14% of their daily iron intake, 18% of their phosphorus intake, 21% of their magnesium and calcium intakes, 13–14% of their vitamin A, thiamin, preformed nicotinic acid, vitamin B_6, and vitamin B_{12} intakes, and 16–17% of their vitamin C and riboflavin intakes. As the number of snacks eaten increases, the amounts of nearly all nutrients and energy also increase. An increased level of snacking makes a significant contribution to children's intake levels of magnesium and zinc, and to adolescents' intake of vitamin B_6, calcium, iron, magnesium, and zinc. On days when no snacks are eaten, the intake of fat, sugar, and sodium is decreased, and more food is eaten during the main meals. Snacking has little impact on the nutritional quality of the diet of elderly individuals. Crisps are the most popular snack among 7–8-year-old children in Scotland and are eaten by 92% of the children. Snacks contribute 26% of energy intake and a large proportion of macronutrient intakes. Low and high snacking habits have no significant effect on the anthropometry of children. (*Refer to* individual nutrients.)

Children aged 9–13 years eat dessert items between meals followed, in descending order of frequency, by fruit and milk. The snacks most frequently eaten by 3–5-year-olds, in descending order of frequency, are bakery products, milk, soft drinks, fruit, mild desserts, candy, and bread. For 6–11-year-olds, the snacks in order of importance are bakery products, soft drinks, milk, milk desserts, candy, fruit, salty snacks,

Table 4 Vitamins and minerals in snack foods

Snack food	*Vitamin B_1 (μg)*	*Nicotinic acid (mg)*	*Vitamin C (mg)*	*Calcium (mg)*	*Iron (mg)*	*Potassium (mg)*
Potato chips (25-g packet)	37.0 (3%)	1.2 (11%)	2.4 (8%)	8.5 (1%)	0.8 (8%)	445.0
Twisties (25-g packet)	7.0 (1%)	0.2 (2%)	0.0	44.0 (6%)	0.1 (1%)	70.0
Chip crisp sticks (25-g packet)	78.0 (7%)	0.5 (4%)	0.0	46.0 (7%)	0.9 (9%)	64.0
Peanuts (25 g)				8.0 (1%)	0.3 (3%)	135.0

Figures in parentheses are the percentage of the recommended dietary allowance, as defined in the NH and MRC Food Legislation (1983). Data from Delroy B (1985) The role of snack foods. *Food Technology in Australia* 37(4): 154–158.

Table 5 Dietary fiber in various snack foods

Snack	*Insoluble dietary fiber (gram per serving)*
White-bread sandwich	0.2
Brown-bread sandwich	1.4
Wholemeal-bread sandwich	3.1
Twisties (25-g packet)	0.3
Potato chips (25-g packet)	0.6
Chip crisp sticks (25-g packet)	1.5
Peanuts (25 g)	1.6

Data from Delroy B (1985) The role of snack foods. *Food Technology in Australia* 37(4): 154–158.

Table 6 Consumption of nuts and nut mixtures

Country	*Quantity (kg per capita)*
The Netherlands	1.28
Germany	0.95
UK	0.66
France	0.65
USA	0.60
Belgium	0.56
Switzerland	0.18
Italy	0.10

Data from Tettweiler P (1990) *Snacks – Food, Fun and Fashion. Dragocco Report 3*, pp. 79–104. Holzminden, Germany: DRA-GOCCO.

and bread. Among teenage boys, the most popular snacks are soft drinks, milk, bakery products, bread, mild desserts, salty snacks, meats, and fruit, while teenage girls prefer soft drinks, bakery products, milk desserts, salty snacks, fruit, milk, candy, bread, and meat. Among adolescents, the preference for snack foods is bakery products, milk, fruit and fruit juices, milk desserts, salty snacks, and bread. Table 6 lists the per capita consumption of nuts and nut mixtures. (*See* **Adolescents**; **Children**: Nutritional Requirements.)

Nutritional Improvement of Snack Foods

In order to counter the belief of consumers and nutritionists that snack foods are 'empty calories,' a number of manufacturers of snack foods have started the development of products supplemented with vitamins, minerals, or proteins. Vitamin supplementation is somewhat simpler than mineral or protein supplementation. The cost is reasonable; a small fraction of a per cent per portion of a supplement is restricted to five vitamins, but vitamins can affect the flavor, and some can cause off-flavors. Riboflavin is highly colored, but its yellow hue is compatible with many snacks. Storage deterioration of these labeled substances is compensated for by the addition of extra amounts, so that the consumer should obtain the full claimed quantity. When supplementing with any nutritional factor, the manufacturer must establish a quality-control program that will ensure that every lot contains the claimed amount. Storage loss of minerals is not generally observed, except for iodine.

Most snacks are poor sources of protein, and the protein that is present is often of a poor nutritional quality. Protein supplementation is possible by increasing the protein-efficiency ratio of the protein already present, or increasing the total amount of protein present by adding some purified nitrogenous material, such as casein, isolated soya protein, or egg white. Untreated corn is a staple food in South America, and there is a need to develop more nutritious, corn-based snack foods. These foods could serve as vehicles for nutrients while at the same time being readily accepted by the population. Certain combinations of cereals and legumes are very desirable from a nutritional point of view. Legumes are a better source of lysine and total protein than cereals, and the latter are a better source of sulfur amino acids. Many attempts have been made to raise the protein value of tortillas by combination with legumes. Snack foods are generally preferred by children and teenagers; in these stages of life, the amount and nutritional quality of proteins are important because of their essential function in physical and mental development. Baked snack foods containing high levels of fiber and fat can be produced using specialty (100% fat-free) starches, e.g., Novelose. Fried snack formulations containing carboxymethyl cellulose absorb less oil during frying, which is advantageous for low-fat applications.

The high snackers have low energy and low macronutrients from meals, so snacks make an important contribution to energy and nutrients, even though a high intake of snacks affects the quality of children's diets. A high snacking frequency and choosing from a wider variety of snack foods results in a balanced intake of nutrients.

An extruded snack food (soyabari snack sticks) based on soybeans and maize (corn) rich in crude fiber and protein contents can be produced by adding different ingredients such as pepper, onion, salt, palm oil, plantain, and banana. This product is acceptable to Nigerians. A high-protein, shelf-stable, expanded extruded snack food resembling bread sticks has been prepared using mechanically recovered poultry meat and wheat. (*See* **Protein**: Quality.)

Consumption of olestra, a fat replacer in savory snack foods, has been found to be age- and gender-dependent, with mean chronic and acute olestra intakes for all ages and both genders of 3.1 and 10.2 g per day.

A study evaluating the nutrient density of snacks and meals, and the effect of eating frequency on mean daily nutrient intake in female students (aged 17–26) has shown that as the eating frequency increased, the number of snacks and the number of different snack items in the diet increased, while the number of meals remained constant. Snacks had lower nutrient densities than meals for nonstarch polysaccharide, minerals, and vitamins, except vitamin C.

Mango bars fortified with desiccated coconut powder or soyprotein concentrate are quite acceptable initially, but storage beyond 90 days lowers their rating, compared to plain mango.

A low-calorie, low-cholesterol, shelf-stable expanded snack product can be prepared from raw or mechanically separated, comminuted meat mixed with pregelatinized flour and processed through high-temperature, short-time screw-type cooker extruder. A gun-puffed, extruded snack food, low in fat and high in carbohydrates, prepared by incorporating fruit and vegetable extracts with oat flour, starch, and sugars, is low in fat and high in calories.

Substantial efforts have been made to reduce the 'snacking habit' of various populations, but snack-food consumption continues to increase. Consequently, there is a tendency to increase the production of more nutritious snacks, including those made from corn. Composite flours using corn, chickpea, soya bean meal, and methionine can be formulated, extruded into snack foods, and fried. These products have higher protein-efficiency ratio values than the controls, while the color, flavor, texture, and overall acceptability remain similar. These products are a good alternative to commercially available snack foods.

Properties and Determination

R Moreno Rojas and M A Amaro López, University of Córdoba, Córdoba, Spain

Background

Sodium, prepared for the first time by the British chemist Humphry Davy in 1807, is the eleventh element of the periodic table (atomic number 11). Its symbol is Na, and it is included in group 1 (or IA), thus corresponding to the alkali metals. It is an extremely soft silvery metallic element, so much so that it can be cut with a knife (hardness of 0.4). It is a very reactive element that tends to be used extensively in the chemical industry. It rusts very quickly when exposed to air and reacts violently with water, forming sodium hydroxide and hydrogen, and producing a yellowish flame. It has a fusion point of 98 °C, a boiling point of 883 °C, an atomic weight of 22.98977, and a relative density of $0.97\,g\,cm^{-3}$.

Sodium has an electronic structure of [Ne] $3s^1$, and consequently, it always acts with valence 1. It has only one external electron, in orbital 3s, and so the degree of attraction that it suffers with respect to the nucleus rivals the repulsion of the lower orbitals, making it very easy for this electron to disappear, forming the Na^+ cation, its most common state.

Two per cent of the earth's crust comprises sodium, making it the sixth most abundant element in nature, where it is always found in a combined state. Sodium is currently manufactured by electrolytic procedures on melted sodium chloride. Its combining facility yields numerous compounds; with oxygen it forms Na_2O, Na_2O_2, and even NaO_2, an important whiting and rusting agent. However, the most abundant form and one of the main sources for man is in combination with chlorine in the form of sodium chloride (NaCl), which is usually extracted from the sea, salt lakes, or in mineral form as rock salt. Sodium can also be found in the form of sodium carbonate (Na_2CO_3), sodium bicarbonate ($NaHCO_3$), and sodium sulfate (Na_2SO_4). Also worth mentioning is sodium hydroxide, known as caustic soda, which is used throughout industry, from the manufacture of soap to rayon, paper, rubber, oilskin, in petrol refineries or in the textile industry. Sodium fluoride (NaF) is used as an antiseptic, as a poison for rats and cockroaches, and in the manufacture of ceramics. Nitrate from Chile (sodium nitrate) is used as a fertilizer. Sodium thiosulfate ($Na_2S_2O_3{\cdot}5H_2O$) is used in photography as a fixing agent and is even used in the nuclear power industry as a cooling agent.

All these specific uses of sodium are only a few examples, since this cation is one of the most common companions of different molecules, both in nature and when created by man for different purposes.

In terms of the nutritional characteristics of sodium, we could say that 90% of sodium provided in the diet is obtained from the sodium chloride that we consume. The rest of the sodium that reaches our organism may originate from other sources such as bicarbonate or sodium glutamate. Of the total sodium intake, it has been shown that only 10% originates naturally from foods, around 15% from salt added to cooking or to season food once cooked, and the remaining 75% from the processing and manufacturing stages of foods.

Given the physiological need to supply the human body with sodium (*see* **Sodium: Physiology**) in order to maintain extracellular osmotic pressure, and as a result of the obligatory losses through urine and sweat, we need to consume sodium on a regular basis, just like most animals. In ancient times, this meant a dependence on salt deposits, and a huge value was placed on what is now common salt, so much so that this gave rise to the Latin word *salarium*, corresponding to the payment in the form of salt made to soldiers in ancient Rome, and it was also used as money in Tibet and Ethiopia, as a tax in Asian countries, and as a ritual element in Greek, Roman, Hebrew, and Christian religions.

This physiological need for sodium may explain why our language contains specific receptors corresponding to the taste of salt and our appetite for this taste in food. For this reason, and because of the tradition of preserving certain foods in salt, which is

today probably unnecessary, although culturally and gastronomically unnoticeable, we have reached a situation in which salt is consumed, and with it sodium, in developed societies. Consumption is estimated to be normally more than 6 g per day, the minimum amount required for the control of blood pressure in hypertense individuals. (*See* **Hypertension**: Hypertension and Diet.)

Preparation of Samples for Sodium Analysis

The determination of sodium in foods may be achieved using a variety of sample preparations, ranging from noninvasive methods, such as those used for determining sodium by selective electrodes, to complete incineration of the sample and subsequent solubilization of the ash in acid solutions. Each analytical technique requires specific preparation of the sample, since the instrumental requirements in each are very different.

In any case, and since sodium is usually found in soluble form in foods, the simplest method of preparing samples involves washing and then analyzing the sodium from the solution sample; for this purpose, the food often only has to be crushed, solvent added, homogenized, and filtered or centrifuged. Solvents to be used may be simple water or slightly acidic or alkaline solutions.

Some methods even propose the direct use of food (particularly liquids) in the detection equipment. Although these may yield good analytical results, other food components such as fats, sugars, or proteins can also deteriorate or stain the instruments.

Given the stable character of sodium, the most aggressive techniques usually yield very good results in terms of the recovery of analyses; hence, the use of incineration at around 500 °C overnight and subsequent recovery in weak acid solutions can be used as a standard sample preparation method for a wide range of foods, modifying temperature and time according to the food in order to obtain soft ash, evidence of good interaction.

Other methods for destroying organic matter, such as acid hydrolysis, can also be used without fear of undermining the detection of sodium, and a wide range of acids may be used in variable concentrations, without significantly affecting results in terms of the determination of sodium content.

The use of methods for destroying organic matter by incineration or by acid hydrolysis is particularly recommended, because of the possibility of obtaining solutions in which other cations of interest for food can be analyzed, such as K, Ca, Fe, Cu, Zn, etc.

Methods of Analysis

Although sodium may be determined by means of a wide variety of instrumental techniques, in line with the applications recommended in scientific publications and the most suitable instruments, the technique used most often is atomic spectroscopy, either by emission or by absorption (Table 1).

This technique is based on the atomic properties of the elements, and more specifically on their capacity to react in response to specific stimuli, modifying their orbital distribution, for which purpose they absorb light at a specific wavelength for each element, passing on to a state of higher energy, or lower energy if passing from the previous stage, emitting light at the same wavelength. In the case of sodium, the recommended specific lengths are 589.6 and 589.0 nm.

In order to achieve the passage of electrons to a state of higher energy, it may be necessary to increase the temperature, usually by means of a flame, or the incidence of a beam of light of a specific wavelength (Table 2). The latter technique enables the determination of the analytical concentration by determining the difference between the energy supplied to the sample and that which remains after crossing – this is genetically known as atomic absorption spectroscopy. In contrast, if the energy of the element is increased by another method (flame), what is usually measured in order to determine the concentration of the analyte is the emission of characteristic wave light when returning to the state of lower energy; this technique is known as atomic emission spectroscopy.

Emission Spectroscopy

Atomic spectrophotometers and emission flame photometers can be used to determine sodium content. In both cases, a sample in a liquid state is introduced into a fuel carrier (acetylene or propane) and combined with atomized or nebulized N_2O_2 air or oxygen. This dispersion is led to a lighter where the fuel combusts. The heat of the flame prompts an increase in the energy of the sodium atoms, which, upon returning

to their fundamental state, emit a light beam of characteristic wavelength that is quantified by a detection system. The amount of light emitted is proportional to the concentration of the analyte in the sample. In addition to the option of atomic absorption, in which a hollow cathode lamp must be used in order to generate the specific lengthwave, most atomic spectrophotometers enable emission spectroscopy to be performed, an option that requires a lamp and provides good results.

With this technique, the optimum gain is adjusted to the highest standard of sodium used, and an attempt is made to keep the lighter free of sodium impurities emitted by the actual samples and standards analyzed, since these impurities may introduce undesirable emissions or obstruct the passage of fluids through the lighter; when the flow decreases, the signal obtained will also decrease. Avoiding samples with high concentrations of sodium (such as undiluted sea waters, cheese sera, etc.) is considered good practice.

A further potential problem lies in small fluctuations that may occur in the flame or in the carried mixture; these may lead to inaccurate and variable results. To correct this problem, some devices are equipped with a second detector that enables the emission of a second element (usually lithium) to be estimated, with a different wavelength to that of sodium. This second element must be added to solutions of both samples and patterns in a stable and known concentration. When there is a variation caused by the flame or the flow, both detectors must reflect this simultaneously, distinguishing this from variations in the analyte.

Another precautionary step that must be observed when working in atomic emission with sodium involves adjustment of the calibration line, since, in most cases, this is not linear; instead, it displays a decrease in the slope when concentrations increase. This is due to the fact that the area of linearity between the analytical concentration and atomic emission is exceeded. The simplest solution involves diluting the samples until the standards that include them present a straight adjustment; however, it is feasible to make a logarithmic adjustment between the emission and the concentration of the type $E = a^*\ln[\mathrm{Na}] + b$, or by means of a simple logarithmic transformation of the concentrations prior to the calculation of the regression line, and the subsequent retrotransformation when applying the linear equation in order to calculate concentrations. This type of adjustment is usually extremely useful when the sample values are high but not very different from one another, the results of the equation being valid, provided that all samples are located between the minimum and maximum values of the patterns used. As a result of this restriction, calculations such as those corresponding to the detection or concentration limit cannot be performed reliably on the standards used, although the high concentrations used guarantee that the readings can never be confused with the fluctuation of the baseline of the device.

Atomic Absorption Methods

Although the basis of the technique is the same as that for atomic emission, and in many cases, the same equipment is used for both analyses, it is true that this technique is favored by fewer analysts, owing in part to the fact that for normal concentrations of sodium in foods, calculations may be performed for emissions with little need to perform dilutions, and because of the added cost of using a hollow cathode lamp for analysis, without this being justified by the analytical improvements achieved. However, the existence of multielement lamps provides researchers with the possibility of using this technique with their samples at no further cost. This technique tends to be recommended more than the emission technique when the sample concentrations present very low values, and lower detection limits may be obtained.

Ion-selective Electrodes

Together with the optical techniques of absorption and atomic emission, this is one of the most common

techniques used for analyzing sodium content in foods; one of the reasons is the low cost of the instruments required, their ease of use, speed, noninvasive nature, and even the possibility of using them in food production lines without causing any interruptions.

The technique is based on the capacity to enable the passage of ions through a glass membrane, each type of membrane being specific to an ion or small group of ions. In the case of sodium, the probe is capable of detecting this activity once the membrane has been crossed; this activity is proportional to concentration. Possibilities of interference with other ions exist, i.e., specificity is not as high as with spectromorphometric methods, and the formation of complexes with other substances reduces sodium activity and therefore its capacity for determination. However, its usefulness becomes clear when the expected levels of sodium are high, as is the case with salted products, such as ham, cheese, etc., in which controlling salt penetration may be recommended. (*See* **Potassium**: Properties and Determination.)

Inductively Coupled Plasma Atomic Emission Spectrometry (ICPAES)

ICPAES enables samples with a high degree of variability and minimum interferences to be used, and these can be prepared either by wet oxidation or by dry ashing. A wide range of concentrations can be used without the need for dilution or concentration, and many of the mineral elements can be quantified, thus reducing analysis time. These advantages, together with the high speed and excellent instrument stability, make the ICPAES method highly attractive in view of its analytical applications.

Other Techniques

A large number of other analytical techniques have been described that may be used to determine sodium content in foods, ranging from classical gravimetric methods, now virtually obsolete, to techniques that involve the use of instruments that are expensive and sophisticated, this factor substantially limiting their use. The most noteworthy techniques described in the Further Reading list include the following: nuclear magnetic resonance (NMR) spectroscopy, ion chromatography, capillary ion electrophoresis analysis, electron-probe microanalysis, helium glow photometry, ion-microprobe analysis, laser probe analysis, ion-scattering spectrometry, auger spectroscopy, impact radiation analysis, enzymatic determination, microwave-induced plasma atomic emission spectrometry and α-particle backscattering analysis. (*See* **Potassium**: Properties and Determination.)

Of all these less common methods, NMR spectroscopy been used increasingly in recent years for determining sodium content, mainly in living tissue or biological samples. Therefore, it can be used for foods, particularly for establishing sodium distribution in such samples. In this technique, Na^+ has a nuclear magnetic moment of 3/2, which allows it to undergo nuclear magnetic resonance; ^{23}Na is extremely easy to detect in biological samples. For more information on this technique (*see* **Spectroscopy**: Nuclear Magnetic Resonance.) Nevertheless, this technique must be used with caution, since comparative studies indicate discrepancies in terms of results obtained in connection with the quantification of sodium when using this technique, which may only detect 60% of sodium.

In contrast, other methods are merely variations on the major analytical techniques, such as emission spectrometry or selective electrodes, are normally used in microsamples such as blood serum or other body products, and are rarely used in foods.

Physiological, Clinical and Nutritional Importance of Sodium

Despite the fact that the body contains more calcium and potassium, sodium is arguably the most important cation because it dictates the volume of extracellular fluid (ECF) and its concentration affects osmotic concentration of both ECF and intracellular fluid (ICF). Abnormalities of ECF sodium concentration cause movement of water into or out of cells, thus altering the osmotic concentration of ICF in parallel and causing swelling or shrinkage of cells. The main impact of this is on the brain because its cells are rigidly enclosed by the cranium.

Sodium depletion is mainly caused by enteric, renal, or adrenal disease, and sodium retention is caused by renal disease; healthy kidneys are well able to excrete excess dietary salt. However, chronic ingestion of excess salt, whether or not it increases ECF volume, is a predisposing or exacerbating factor in hypertension. Until the 1980s, knowledge of the regulation of body sodium mainly concerned defenses against depletion, whereas the last two decades have seen a rapid growth in knowledge of the mechanisms which excrete excess sodium. This seems appropriate since most species, especially humans, dogs, and laboratory rats, are exposed to dietary sodium intakes well above their nutritional requirement. (*See* **Renal Function and Disorders**: Kidney: Structure and Function.)

The nutritional requirement is a reflection of obligatory losses (maintenance) and the needs of growth, pregnancy, and lactation. Abnormal losses owing to disease, or in animals such as humans and horses which sweat extensively, raise the requirement. The impact of equine sweating is different from that in humans. Human sweat always contains sodium at concentrations well below plasma levels (and when aldosterone secretion is raised, levels of sweat sodium fall very low); horse sweat is hypertonic but this helps to offset the osmotic effect of the increased respiratory water loss during exertion, i.e., it may be a defense against hypernatremia, rather than a potential cause of sodium depletion.

Consideration of the physiology of sodium thus includes its distribution in the body, regulation of total content and concentration, causes of and responses to depletion or excess, and their nutritional implications.

Distribution

Sodium behaves physiologically as a cation, i.e., a positively charged ion; its distribution and effects are fairly independent of the negative ions (anions) which originally accompanied its ingestion, though they may affect its absorption and excretion. Most sodium is in ECF (Table 1), kept there by the sodium pump, an enzyme system, (Na^+-K^+)-ATPase, which uses substantial amounts of energy (adenosine triphosphate; ATP) in maintaining a low intracellular sodium concentration and a high intracellular potassium (K^+) concentration. Sodium transport is a central issue in the physiology of sodium for a number of reasons:

1. It helps to maintain the ionic environment of ICF and the volume of ECF.
2. It prevents cell swelling (the Na^+ efflux exceeds the K^+ influx).
3. It establishes gradients which, in various tissues, allow transport of other cations in exchange, other anions in parallel or organic solutes – these are often cotransported with sodium down concentration gradients which are secondary to the low sodium environment created by the pump.
4. It establishes the membrane voltages on which excitability and secretory activities frequently depend.
5. The energy expenditure of the pump is a substantial portion of total metabolic activity and contributes to thermogenesis.
6. Sodium transport is not only a key factor in the retention and loss of sodium in the kidney, gut, salivary, and sweat glands but also influences the excretion or retention of many other solutes. Thus, for example, diuretics intended to promote sodium excretion may also cause unintentional losses of potassium and magnesium. Similarly, when renal

1 mmol = 23 mg Na^+, 58.5 mg NaCl.

sodium excretion increases appropriately in response to ingestion of excess salt, there may also be unwanted losses of calcium and in postmenopausal women these may contribute to loss of bone mineral. (*See* **Electrolytes**: Analysis; **Thermogenesis**.)

Bone also contains substantial quantities of sodium but, as yet, its significance is unknown since it does not appear to be mobilized during sodium depletion. Gut fluids contain considerable amounts of sodium, mostly secretory rather than dietary, and mostly reabsorbed in more distal regions of the intestine.

Extracellular Sodium

Of the extracellular fluid, most is in interstitial fluid (ISF) in the tissue spaces, providing the transport medium between capillaries and cells. The sodium concentration in plasma is slightly above that in ISF because plasma contains more proteins, notably albumin, which do not readily escape into ISF across the capillary membranes, and the effect of their negative charges is to hold more positively charged ions, notably sodium, in circulation (Gibbs–Donnan equilibrium).

The main effects of excess ECF volume are seen as expanded ISF, visible clinically as edema (or ascites, when fluid accumulates in the abdomen rather than the tissue spaces). Mild edema is merely a cosmetic problem in itself but pulmonary and cerebral edema, or severe ascites, are potentially serious forms. Edema can result from excess ingestion or retention of sodium (overall expansion of ECF) or leakage from plasma to ISF, with plasma volume continuously replenished by renal sodium retention. Such maldistribution of ECF occurs if plasma albumin is very low (renal leakage, hepatic impairment, or severe malnutrition), or with excessive capillary blood pressure (venous blockage, inactivity, heart failure, or arteriolar dilation, e.g., from heat or allergy), capillary damage, or lymphatic blockage. Lymphatic blockage prevents the removal of proteins which have leaked into ISF. Accumulation of protein in ISF undermines the osmotic gradient which normally favors uptake of water at the venous end of the capillary, where the pressure is lower. Since edema involves the expansion of a larger compartment (ISF) from a smaller one (plasma), it is only possible as long as the latter is replenished; hence the kidney, while seldom the primary cause of edema, is always the enabling cause; the use of diuretics is therefore appropriate in the treatment of nonrenal as well as renal causes of edema.

The main effect of inadequate ECF volume is to reduce plasma volume and thus to compromise cardiovascular function, in extreme cases by causing circulatory shock.

Regulation of ECF Sodium

In a mature, nonpregnant, nonlactating, healthy animal, sodium excretion matches sodium intake and is often used to estimate it, although this is not reliable, especially when intake is low. Dietary sodium is readily available, i.e., readily absorbed; thus the traditional view of sodium regulation emphasizes renal regulation of urinary Na^+ loss. This oversimplifies the more subtle interplay seen, for example, in herbivorous animals, where salt appetite may contribute to regulation by intensifying during sodium depletion. Moreover, in many herbivores the feces, rather than urine, may be the major route of sodium excretion and the gut may therefore be an important regulator of sodium balance. Indeed, it is interesting that sodium transport mechanisms in the small intestine show considerable similarities to those of the proximal part of the renal tubules (e.g., linked transport of Na^+, glucose, and amino acids) whereas the colon, like the distal nephron, responds to the salt-retaining (and potassium-shedding) hormone of the adrenal cortex, aldosterone.

Provided that the adrenal gland is healthy, urinary and fecal sodium loss can be reduced virtually to zero. Sweat loss can also be very low, although with severe exertion in hot climates the volume of sweat may exceed the ability of aldosterone to reduce its sodium concentration and net loss of sodium can occur. Aldosterone also reduces salivary sodium (and raises $[K^+]$). (*See* **Potassium**: Physiology.)

There are two components to the regulation of ECF sodium: the total amount of sodium retained, and its concentration. The former is regulated by mechanisms which directly affect sodium, whereas the latter is essentially regulated via water balance. Thus whatever sodium is retained in ECF is 'clothed' with the appropriate amount of water to maintain the normal plasma sodium concentration within narrow limits; deviations of less than 1% (hard to measure in the laboratory) trigger corrective responses. Thus a raised plasma sodium concentration (e.g., after water loss) stimulates both thirst and renal water conservation; antidiuretic hormone (ADH) from the posterior pituitary reduces urine output through its effect on the renal collecting ducts. Even one of these mechanisms can defend body water; thus diabetes insipidus (inadequate production or effect of ADH) does not cause severe dehydration but polydipsia (increased fluid intake; thirst is a sensation).

Excess salt intake does not raise plasma sodium concentration (hypernatremia) if water is available and the patient can drink; the excess sodium is diluted. The resulting increase in ECF volume then stimulates increased sodium excretion. Sodium also enables ECF to hold water against the osmotic 'pull' of the solutes in ICF and sodium thus functions as the 'osmotic skeleton' of ECF; it is the main determinant of its volume.

Plasma sodium concentration is therefore only indirectly related to sodium balance. When ECF volume, notably circulating volume, is severely reduced, this stimulus, rather than Na^+ concentration, becomes the main drive for thirst and ADH secretion. Until ECF volume is restored, water is retained (to protect ECF volume) even though this undermines the protection of ECF Na^+ concentration and, as a result, plasma sodium falls. Thus, during sodium depletion, contraction of ECF volume precedes significant reductions of plasma Na^+ and is therefore a poor index of sodium status.

Sodium-Retaining Hormones

Sodium depletion, by reducing plasma volume and renal perfusion, stimulates the production of renin (from the kidneys) which generates angiotensin in circulation. This hormone is a vasoconstrictor (so protects blood pressure), stimulates thirst (so helps to restore ECF volume) and, above all, stimulates sodium retention both directly (renally) and indirectly (by stimulating adrenal secretion of aldosterone); it thus reduces the sodium concentration of urine, feces, saliva, and sweat, but not milk. (*See* **Hormones**: Adrenal Hormones.)

Indices of aldosterone secretion (reduced sodium or potassium concentration in urine, feces, etc.) are often taken as evidence of sodium depletion or inadequate sodium intake, but the following points apply:

1. Aldosterone secretion is also stimulated directly by hyperkalemia (elevated plasma K^+) and promotes potassium excretion.
2. Such interpretations involve a subjective judgment concerning adequate or excessive sodium intake. Because physiologists and clinicians were traditionally more concerned with sodium depletion as well as its consequences and the defenses against it, elevated aldosterone secretion was readily seen as a warning signal. However, if sodium intakes associated with increased aldosterone have no other harmful effects, and especially if excess sodium intakes cause concern, low levels of aldosterone secretion might equally indicate excessive salt intake.

While sodium reabsorption in the distal nephron, influenced by aldosterone, is particularly important because it can produce sodium-free urine and promote potassium loss, the great majority of renal sodium reabsorption occurs elsewhere: about 25% in the loop of Henle and most in the proximal tubule. The loop is also a main site of magnesium reabsorption, hence the tendency for loop diuretics to cause hypomagnesemia.

The factors controlling proximal reabsorption are incompletely understood but their effect is clear: proximal reabsorption of sodium increases or decreases according to the need to enhance or diminish plasma volume. Since the fluid in the proximal tubule is similar to plasma, having been formed from it by glomerular filtration, it has the ideal composition for this purpose.

Natriuretic Hormones

Excretion of excess sodium involves not only suppression of salt-retention mechanisms but also activation of sodium-shedding (natriuretic) mechanisms. Two types of hormones are involved: atrial natriuretic peptide (ANP), produced by the cardiac atria when they are overstretched (reduction of ECF volume being an appropriate response to cardiac overload), and active sodium transport inhibitors (ASTIs), probably produced within the brain. These were probably the original molecules associated with the receptors binding cardiac glycoside drugs and are therefore also called endogenous digitalis-like inhibitors (EDLIs); their exact identity remains uncertain. ANP has various effects which essentially oppose those of the salt retention induced by aldosterone: it increases sodium excretion, lowers arterial pressure, and promotes movement of ECF towards the interstitial compartment.

Other hormones (e.g., sex steroids, parathyroid hormone, calcitonin, thyroid hormone, prolactin) affect renal sodium retention or loss but are not thought to regulate it. (*See* **Hormones**: Thyroid Hormones; Pituitary Hormones.)

Adequate, Inadequate, and Excess Sodium

It is unlikely that adult daily maintenance requirement exceeds 0.6 mmol per kg body weight and could well be below this in many mammals. Newborn, growing, pregnant, or lactating animals have increased requirements. The appropriate sodium intake for humans remains controversial, with some cultures managing on less than 1 mmol day^{-1}, while western intakes may be in the range 200–300 mmol day^{-1} – more where processed foods are heavily

consumed. There has been insufficient awareness among physicians and human nutritionists of just how high such intakes are, compared with requirement in other animals. Granted that humans are bipeds with a stressful lifestyle quite different from those of animals, there is no real evidence that human obligatory losses or sodium requirements are significantly greater. Rather, there is an ingrained tradition of regarding sodium intake as a benign pleasure, involving a harmless and healthy dietary constituent. The main warnings against this view come from the fact that hypertension is virtually unknown in low-salt cultures and that they do not even have an age-related rise in normal blood pressure. Moreover, there are numerous studies which, when rigorously analyzed, indicate that human arterial pressure and salt intake are positively correlated – sufficiently to anticipate large reductions in the prevalence of hypertension in response to manageable reductions in dietary sodium. Unfortunately, such reductions are handicapped by inadequate food labeling and the fact that most sodium is added by the processor rather than the consumer.

Because obligatory losses of sodium are so low, dietary sodium depletion is hard to induce and sodium deficiency usually results from losses caused by renal, adrenal, or enteric disease; renal disease may cause either retention or loss of sodium. Globally, both in humans and animals, the most common cause of sodium deficits is acute diarrhea. Fortunately, sufficient gut usually remains unaffected for uptake of sodium and water to be stimulated by suitably formulated oral rehydration solutions. These essentially restore ECF volume (and acid–base balance), allowing natural defenses to overcome the underlying cause of the diarrhea. Despite some species variations, such solutions usually work best if their glucose:sodium ratio (in $mmol\,l^{-1}$) is close to unity and they are virtually isotonic (i.e., they have a similar osmotic concentration to ECF; hypertonic solutions draw water into the gut). The function of glucose in these solutions is to promote sodium uptake; its nutritional contribution is trivial. Anions such as citrate, acetate, propionate, bicarbonate, and amino acids (e.g., glycine and alanine) may further enhance the uptake of sodium and therefore water. These sodium cotransport mechanisms are very similar to those of the proximal renal tubule.

Sodium is thus central to the management of two of the most widespread clinical problems: hypertension (in humans) and diarrhea. Indeed, the World Health Organization (WHO) regards the discovery of oral rehydration, which depends on restoration of enteric sodium uptake, as the main life-saving development in twentieth-century medicine. This powerful clinical application rests on a simple physiological observation concerning an elementary but vital dietary constituent. (*See* **Hypertension**: Physiology; Hypertension and Diet; Nutrition in the Diabetic Hypertensive.)

SOFT DRINKS

Contents

Chemical Composition

K Jorge, Brewtech Ltd, Jacarepagua, Rio de Janeiro, Brazil

Introduction

The forerunner of soft drinks began more than 2000 years ago when Hippocrates first suspected that mineral waters could be beneficial to our well-being, for relaxation and bathing.

More than 1000 years passed before mineral waters made the transition from therapeutic bath to refreshing beverage.

Scientists produced artificially carbonated water in the laboratory, and it was only a matter of time before soft drinks made it into the hands of the public. Pharmacists believed they could add curative properties to the water by experimenting with several interesting flavors and tastes. The soft-drink industry started as a seasonal business, operating primarily during the summer months.

Gradually, demand grew for soft drinks to be consumed at home. Bottling the products proved to be difficult, since pressure from the carbon dioxide forced corks out of the bottles. Then, in 1892, the 'crown cap' was invented, revolutionizing the soft-drink industry. Since that time, considerable transformation occurred, making the soft-drink industry more efficient and productive with a high degree of mechanization, together with the use of new containers and the addition of attractive flavors.

Product Definition

Typically, soft drinks are nonalcoholic (less than 1% alcohol by volume), carbonated, flavored beverages, which are usually drunk cold. They are available in bottles, cans, or dispensing systems. They include lemon, orange, and lime drinks, or other fruit-flavored beverages such as colas, ginger, sodas, tonics, and cocktail mixers.

Regular soft-drink ingredients are listed on the label or cap in descending order of importance. The precice recipes are valuable corporate properties that are kept secret. The basic ingredients of most soft drinks are: water purified to the exacting standard required; high-fructose corn syrup, sugar, or a combination of the two to achieve the desired sweetness; carbon dioxide, which creates the bubbles that stimulate the palate and heighten taste sensations; some sodium (in the majority); and flavors. Diet soft drinks use calorie-reduced sweeteners. The flavors used may be very complex. For example, the orange flavor contains up to 400 individual ingredients. Flavor concentrates from international manufacturers are constant throughout the world. Table 1 lists a typical soft-drink composition.

Flavors

Flavors are used to give soft drinks a pleasant taste. It is the flavoring that gives a soft drink its specific taste, smell, and appearance. Although it is only added in very small quantities, flavoring is one of the most important raw materials of a soft drink plant.

Usually, it is a balanced composition with different aromatic substances from different types of fruit. Fruit, berries, and a number of other plants contain substances that have an agreeable aroma, and are commonly called 'tastes.' 'Taste' comprises only four taste sensations – sweet, salt, sour, and bitter. All other 'tastes' are smell in combination with one or more of these basic tastes.

When eating, the smell passes not only through the nose, but also through the throat up to the area in the nose that is sensitive to smell. The brain puts together

Table 1 Illustration of a typical soft-drink formula

Ingredient	*Percentage by weight*
Carbonated water	87–89
Sugar	10–12
Acids, colorings and flavorings	< 1.0

these sensations, which are translated as 'aroma.' According to international praxis, flavors are divided into three categories – natural, nature identical, and artificial. (*See* **Sensory Evaluation**: Taste.)

Natural flavors are mainly based on essential oils and extracts where natural aromatic substances dominate. In addition to the aromatic components, they also contain constituent parts from the fruit, which change during storage and can worsen the taste of the drink. For this reason, these natural aromatic substances are sometimes strengthened with certain identical aromatic substances that contain aromatic components only and give a better stability to the taste. (*See* **Essential Oils**: Properties and Uses; Isolation and Production.)

Nature-identical flavors are based on ingredients as they occur in the natural fruit but which are produced by chemical methods. They have a good solubility, a reasonable price and a long shelf-life, which makes them very suitable for soft drinks production.

Artificial flavors contain chemicals that do not occur in nature but have a familiar taste such as vanillin, which has the taste of vanilla. This is an ever-decreasing category and in time will be replaced by nature-identical flavors.

Water

Water is the main raw material in soft drinks. In weight terms, a soft drink is 90% water. Water of high quality is therefore important. It must be pure and from a source approved by the regulatory authorities for drinking purposes. This means that it must be free from biological and chemical pollutants, such as bacteria and poisonous substances. It should also have the cleanest taste and be least interactive and microbiologically stable. The quality of water has an impact on the quality and taste of the soft drink.

Sweeteners

Sweeteners can be divided into two main categories: nutritive or caloric sweeteners and nonnutritive or low calorie sweeteners. We will discuss only the sweeteners important for the soft-drink industry.

Sugar

Sugar is a generic name for a class of sweet carbohydrates, including fructose, glucose, maltose, sucrose, and lactose, that are readily soluble in water, colorless, odorless, and usually crystallizable.

For soft drinks, the most commonly used is sucrose, which can be supplied either as a liquid or in granulated form. Liquid sugar is dissolved granulated sugar in water, normally at 67° Brix.

Sugar is an important ingredient for soft drinks, not only because of its properties as a sweetener, but also because it is highly nutritious and is an important carrier of the fruit aromas. The different fruit aromas require different quantities of sugar, depending on which fruits are in the drink. This means that the composition of the sugar solution is critical if the drink is not to be too 'thin' or taste too sugary. Two other types of sugar are found in fruit – fructose (fruit sugar) and glucose (grape sugar). Fructose is 50% sweeter than ordinary sugar, but contains the same number of calories per gram. A smaller quantity of fructose gives the same sweetness. It is therefore sometimes used to reduce the number of calories. Honey is another less commonly used sweetener that also contains glucose and fructose. (*See* **Carbohydrates**: Classification and Properties; **Glucose**: Properties and Analysis; **Honey**; **Lactose**; **Sucrose**: Properties and Determination; Dietary Importance.)

Nonnutritive Sweeteners

In the past, low-calorie drinks were only marketed as diabetic products. Now, they have become increasingly popular for both weight-watching and economic reasons. Low-calorie drinks are an important part of the total soft-drink market. When using a nonnutritive sweetener, it is important to have up-to-date information about the food regulations concerning this subject, as they differ greatly from country to country and are subject to many changes.

A sweetener has to comply with the following standards, assuming it is allowed by the food laws concerned:

- It should not be hazardous to health.
- It should give no off-taste.

Saccharin

Saccharin is a synthetic, white, crystalline powder, of formula $C_6H_{16}CONHSO_2$, which, in its pure state, is 550 times sweeter than sugar. In its commercial form, saccharin is estimated to have a sweetening power 375 stronger than that of sugar.

The only synthetic, nonnutritive sweetener presently allowed in most countries in soft drinks is saccharin. It has been in use continuously since 1900. The use of saccharin is mostly restricted to special dietary foods and beverages appropriately labeled as such.

For several years, saccharin has been under investigation as a potential cause of cancer. Warning labels were required on saccharin-containing foods. The most recent studies indicate that it is a weak carcinogen in laboratory animals but does not, in moderate use, present an increased cancer risk in humans. The

recommended acceptable daily intake (ADI) is 1 g per person per day. The tolerance level for soft drinks is 0.4 mg ml^{-1}. This is an interim tolerance level, and safety studies are continuing. (*See* **Cancer**: Epidemiology; **Carcinogens**: Carcinogenic Substances in Food: Mechanisms; Carcinogenicity Tests; **Saccharin**.)

Cyclamate

Cyclamate is an odorless, white crystalline powder. The name usually denotes either calcium cyclamate or sodium cyclamate, both of which are salts of cyclohexylsulfamic acid. They have a very sweet taste, with about 30 times the sweetening power of sucrose.

After saccharin, cyclamate was the most commonly used sweetener until it was banned in the USA in 1970, after which many countries followed suit. Much of the scientific community doubted that cyclamate was hazardous but for new FDA approval more very costly research is needed and people would rather concentrate on other sweeteners. (*See* **Cyclamates**.)

Aspartame

Aspartame is a sweetener made from the natural amino acids L-aspartic acid and L-phenylalanine. L-Aspartic acid is tasteless, and L-phenylalanine is slightly bitter, so the taste of aspartame could never have been predicted. Aspartame was discovered by accident in the laboratories of the Searle Company in 1965 and was first approved for use in food products in Canada 15 years later. In 1983, approval was granted by the FDA, followed by many authorities in other countries. The only negative aspect of aspartame is that it can be hazardous for people who suffer from phenylketonuria, an inherited disorder that can lead to brain damage in those exposed to phenylalanine. This disease is rare, however. Since aspartame is so sweet (about 200 times sweeter than saccharin), only a small quantity is needed, and it is therefore put into the same category as energy-free sweeteners. The calorie content can be reduced by 95% compared with corresponding drinks sweetened with saccharates. During digestion, aspartame is treated as protein, and so diabetics are able to eat and drink food sweetened with aspartame. (*See* **Amino Acids**: Properties and Occurrence; **Aspartame**; **Protein**: Chemistry; Food Sources; Determination and Characterization; Requirements; Functional Properties; Interactions and Reactions Involved in Food Processing; Quality; Digestion and Absorption of Protein and Nitrogen Balance; Synthesis and Turnover; Deficiency; Heat Treatment for Food Proteins; Sources of Food-grade Protein.)

Acesulfame-K

Acesulfame-K was developed by Hoechst in 1973, was approved by the British Food Regulations in 1983, and has since been adopted in countries like Germany, Belgium, and Denmark. Acesulfame-K is not metabolized at all and therefore has no calorific value. It is absorbed quickly in the intestine, and excretion is similarly fast. (*See* **Acesulfame/Acesulphame**.)

Stevia (*Stevia rebaudiana Bertoni*)

Stevia contains natural compounds, especially stevioside and rebaudioside A, that are estimated to be 150–400 times sweeter than saccharose. Used for centuries in parts of South America, stevia has been discovered in recent years by much of the calorie-conscious modern world. It is now widely and legally consumed by millions of people, from South Korea, Israel, and the People's Republic of China, but no country has done more to demonstrate stevia's dietary and economic potential than Japan, where the herb and its extract have been used since 1970s.

The Japanese, having subjected stevia extract to extensive safety testing and found it without health risk, now incorporate it in numerous food products, including soft drinks.

Sucralose

Sucralose was approved by the FDA in 1998 for use in a wide variety of food products including soft drinks. Sucralose is a low-calorie, high-intensity sweetener that is about 600 times sweeter than sugar. It is sold under the brand name of 'Splenda.' Sucralose and sucrose (sugar) have been shown to have similar taste and flavor profiles.

A number of other fascinating low-calorie sweeteners are currently undergoing safety evaluations for future use. These include alitame, a compound similar to aspartame that is remarkably 2000 times sweeter than sucrose, and various naturally occurring plant derivatives, such as stevia and thaumatin.

Acids

Acids are used as pH buffers in beverages and to impart an astringent taste that offsets the sweetness of the sugar and enhances or complements the associated flavor. Thus, the characteristic flavor of a beverage is developed in part through proper acidulation. Acids also help in preventing microbiological spoilage.

All acids used in beverages must be 'edible grade' or 'food grade.' Those commonly used are citric-, phosphoric-, and malic acid. Each has the property of being weak and nonharmful at the concentrations

used. Inherent chemical differences in the various acids impart different taste characteristics, and in substituting one acid for another, these differences have to be kept in mind. Table 2 shows the acidification strength of some acids relative to citric acid.

The kind of acid and the concentration employed are very important for adjusting the flavor of the beverage.

Citric Acid

Traces of citric acid are found in numerous plants and animals, because it is a nearly universal intermediate product of metabolism. Large amounts of the acid are found in the juice of citric fruits. Fermentation of sugar by *Aspergillus niger* is the chief commercial source of the acid. Since it is a natural ingredient of citrus fruits, it adapts itself well to beverages with such a flavor.

Citric acid may be used in the anhydrous form or containing one molecule of water. It occurs as colorless, translucent crystals or as a white, granular-to-fine crystalline powder. It is odorless with a strong acid taste, and the hydrous form is efflorescent in dry air. (*See* **Citrus Fruits**: Types on the Market; Composition and Characterization; Oranges; Processed and Derived Products of Oranges; Lemons; Grapefruits; Limes.)

Phosphoric Acid

Phosphoric acid is a very popular acidulant because of its strength and very low cost; in fact, it is the cheapest acid used in the industry. It is used mainly in cola-type beverages, in which it improves not only the acid taste but also the typical cola bite.

Malic Acid

Malic acid is found in fruits such as apples, apricots, and cherries. The food industry finds the tartness of this additive a valuable flavor booster for candies, jams, ice creams, fruit, and soft drinks. (*See* **Ice Cream**: Methods of Manufacture; Properties and Analysis; Dietary Importance; Microbiology; **Jams and Preserves**: Methods of Manufacture; Chemistry of Manufacture; **Sweets and Candies**: Sugar Confectionery.)

Table 2 Acidification strength (%) relative to citric acid

Type	*Strength (%)*
Citric acid	100
Tartaric acid	93
Malic acid	100
Ascorbic acid	43
Lactic acid	60
Phosphoric acid	125

Carbon Dioxide

Carbon dioxide is present in the air in very small quantities (approx. 0.03%) and is about 1.5 times as dense as air. It is a colorless, odorless, and tasteless gas and has a good solubility in water. When confined within a suitable pressure vessel, CO_2 can exist as a solid, liquid, or gas.

When drinking a carbonated beverage, the development of CO_2 in the mouth, because of the warmth of the throat, causes a light anesthetic effect on the taste buds, which diminishes and sometimes even stops the sensation of thirst. Carbon dioxide makes the drink more refreshing through its stimulation of the mouth's mucous membranes. This adds to the sensation that the soft drink is colder than it actually is and also brings out the aroma.

Carbon dioxide also checks microbiological growth, which means that the product lasts longer. Many bacteria die after a certain time in carbonated drinks. This applies equally to carbonated soft drinks, mineral water, and beer. There are good grounds for advising people, for hygienic reasons, to drink carbonated drinks, particularly in hot climates. (*See* **Beers**: History and Types.)

Preservatives

The low pH value of soft drinks is good for the life of the product from a microbiological point of view since bacterial growth is checked. Carbon dioxide also has a positive effect. Sometimes, however, this is not enough, and preservatives have to be used.

Preservation denotes any method that extends the shelf-life of a product. Methods such as pickling, freezing, drying, sterilizing, smoking, or the addition of a chemical agent with a bactericidal activity all have undesirable effects on the odor, taste, or digestibility of the foodstuffs. (*See* **Drying**: Theory of Air-drying; **Freezing**: Principles; **Pickling**; **Smoked Foods**: Principles; Production; **Sterilization of Foods**.)

The history of the soft-drink industry has demonstrated that beverages are good nutrient media for certain acidophilic microorganisms, particularly yeasts. It has been demonstrated by various investigations that over 90% of all cases of microbiological spoilage of soft drinks are caused by yeast. Spoilage of soft drinks by yeasts is evidenced by visible sediment, gas formation, off-odor, off-taste, and changes in beverage color and clarity.

To prevent soft drinks spoiling, it is necessary to use good manufacturing practices to control the growth of microorganisms. High hygienic standards should be applied during production, together with the creation of unfavorable environments for microorganisms, such as acidifying, cooling and pasteurizing, and, if necessary, chemical preservation. Only small quantities of preservatives are allowed in soft drinks. The preservatives allowed are subject to the food and drugs laws of the different countries involved. However, chemical preservation alone is not sufficient. Therefore, these types of products must always be pasteurized.

The most common preservatives are sodium benzoate (sodium or potassium sorbate can be used as a replacement) and sulfur dioxide, particularly if it is required to prevent the color darkening.

Benzoic Acid

Benzoic acid or benzene-carbonic-acid is a monobasic aromatic acid, moderately strong, white crystalline powder, very soluble in alcohol, ether, and benzene, but poorly soluble in water (0.3 g of benzoic acid in 100 g of water at 20 °C).

Benzoic acid has the advantage that it does not affect the odor or taste of the soft drink, if used in small quantities. The preserving quality of benzoic acid is based on its activity to delay the multiplication of several groups of microorganisms, which, however, are not killed by this product. The low solubility of benzoic acid in water complicates its application in products containing large amounts of water. Therefore, the water-soluble salt sodium benzoate is used.

This product, which is the salt of benzoic acid, has no preserving activity by itself. Therefore, after addition of sodium benzoate, the acidity of the soft drink is increased (pH < 3.5), with the result that free undissociated benzoic acid is formed, which has a preserving property. In an alkaline environment, benzoic acid is split into ions and thus loses its preserving activity.

Sodium benzoate is the sodium salt of benzoic acid used as a white crystalline or amorphous (without crystal structure) powder, very soluble in water (66 g of sodium benzoate in 100 g of water at 20 °C) but poorly soluble in alcohol.

Sorbic Acid

Sorbic acid, potassium sorbate, and calcium sorbate are novel, highly efficient, safe, and nonpoisonous food preservatives. They are the substitute for the benzoic acid as a traditional preservative. Sorbic acid, potassium sorbate, and calcium sorbate approved worldwide are often now successfully used as standard products in many branches of the food industry. As they are acidic preservatives, it is better to use them at pH 5–6.

Sorbic acid, potassium sorbate, and calcium sorbate are unsaturated fatty acids and salts of unsaturated fatty acids, which participate in the normal fat metabolism in human body and are oxidized into carbon dioxide and finally water. They do not accumulate in the human body. (*See* **Fatty Acids**: Properties; *Trans*-fatty Acids: Health Effects.)

Sulfur Dioxide

The preservative effect of sulfur dioxide, like benzoic acid, is greatly increased by a corresponding decrease in pH. Undissociated H_2SO_3 is responsible for most of the preservative action. In contrast to sodium benzoate, sulfur dioxide kills microorganisms instead of delaying their growth.

Sulfur dioxide also combines regularly with many compounds present in juices and soft drinks, and the combined SO_2 exhibits little or no preservative effect. This must be taken into account when deciding on the levels required to preserve soft drinks, but it must be remembered that the legal limit is often based on the total free and combined SO_2 in the product. Sulfur dioxide can be added as the salt of sodium or potassium metabisulfite or as a solution of sulfurous acid. This compound gives off SO_2 gas and therefore must be stored in airtight containers. A disadvantage of the use of SO_2 as a preservative is its relatively bad taste at a dosage above 10 mg l^{-1}. (*See* **Sodium**: Properties and Determination.)

Coloring Matter

Food that looks beautiful when served, e.g., nicely served and has a beautiful color, affects the consumer's experience of taste positively. Color is an important signal of identification that complements the label and is a dominant factor in consumer acceptance of a beverage. An attractive, natural-looking color tempts one to taste and consume a beverage.

Before the mid-1970s, many more colorings were used than is the case today. The soft-drinks industry, itself, has reduced the number of coloring matters used. However, the pure fruit-juice content of soft drinks makes it difficult to create the right colors. For this reason, identical coloring agents of the sort found in the fruits are used extensively. The most important is β-carotene, which is the predominant coloring agent in carrots and oranges.

Brown drinks are colored with caramel. Different drinks require caramel with different qualities. This

can be achieved by having different nitrogen compounds present during the heating phase of caramel production.

Colors can be either natural or artificial. Natural colors include: anthocyanins (from berries and grapes), caramel, xanthophyl, and carotenoids. Artificial colors include: tartrazine NS, yellow FCS, and Amaranth AS. (*See* **Caramel**: Properties and Analysis; **Carotenoids**: Occurrence, Properties, and Determination; **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Legal requirements for colors used in soft drinks differ from country to country, as do the required declarations for each country. The overall move toward more health-oriented products has increased requests for natural colors. When using natural colors, ascorbic acid has to be added to improve the stability (better resistance to light). A positive side-effect of using ascorbic acid is a reduced incidence of can corrosion. The disadvantages of natural colors are the high cost, the complication of the manufacturing process, and the poor stability. (*See* **Ascorbic Acid**: Properties and Determination.)

Antioxidants

Antioxidants prevent reactions, which destroy aromatic substances. The most common antioxidant is ascorbic acid, i.e., vitamin C. Sulfur dioxide, named above as a preservative, is also used as an antioxidant. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

Other Additives

Emulsifying agents, stabilizing agents, and thickening agents are all used to ensure that the contents of the drinks remain evenly distributed. The fat peel oil from oranges, for instance, would otherwise form lumps and create a ring around the neck of the bottle. Since the oil is the carrier of the aroma and sometimes the coloring agents, the drink would soon become uneven in taste and look unattractive. Examples of stablizing agents and thickening agents are pectins, which are obtained from citrus fruits or apples, and alginates and carragheen, which are obtained from algae. (*See* **Emulsifiers**: Organic Emulsifiers; Phosphates as Meat Emulsion Stabilizers; Uses in Processed Foods; **Pectin**: Properties and Determination; Food Use; **Stabilizers**: Types and Function; Applications.)

Soft drinks generally contain no significant amounts of protein, fat, fiber, or vitamins. The small amounts of minerals (calcium, iron, magnesium) and trace elements (copper, manganese, zinc, fluoride) that may be naturally present will vary depending on the local water supply. However, some soft drinks now contain added vitamins (C, niacin, B_6, B_{12}, biotin, pantothenic acid, and folic acid) and/or increased levels of potassium (from added juice).

Production

C Matthews, NET International, Gloucester, UK

Introduction

Soft drinks have been consumed, in one form or another, for thousands of years from the first time it was discovered that the addition of acid materials such as lemon juice and/or the incorporation of only 5% of alcohol from fermentation of grape and other juices resulted in the preservation of dietary water. Although milk, wine, and beer have all been around for well over a thousand years, and tea and coffee for many centuries, carbonated soft drinks are approximately 200 years old, dating from the commercial production of seltzers and sodas in the late 1700s. Revitalization of the squashes, syrups, or concentrated still soft drinks market has been facilitated in the last few decades by the introduction of aseptic packaging techniques, enabling continuous filling of juices and ready-to-drink squash-type products into foil laminates, pouches, and cartons. Some would argue, with justification, that this is a completely new sector of soft drinks made possible by advances in production and packaging technology.

The production of soft drinks falls into three main areas of activity:

1. Supply, handling and treatment of ingredients (including the water supply).
2. Blending of these ingredients and the processing of the blends/combinations so achieved.
3. Packing or packaging of these blended ingredients into the finished product for distribution and sale (this may involve a further processing step, as in the case of aseptic filling or dilution, and carbonation, as with carbonated soft drinks).

Supply, Handling, and Treatment of Ingredients

Most ingredients will be supplied in a user-friendly and stable form by the ingredient manufacturers or suppliers, with detailed specifications and usage instructions. During the time these ingredients are held at the site of the soft drinks manufacturer it will simply be necessary for them to be stored according to the storage instructions of the supplier and used within shelf-life. Some of the storage conditions and shelf-lives of usually encountered raw materials will be found in **Table 1**. (*See* **Storage Stability:** Parameters Affecting Storage Stability.)

It is normally the responsibility of the quality control department to approve the quality of all incoming materials and insure correct rotation for use prior to expiry of shelf-life.

This leaves the main ingredient in soft drinks – water – which requires special treatment to insure sensory, microbiological, and physical acceptable quality. The chemical quality of water may be characterized as follows.

1. Appearance free from sediment, color, and cloud.
2. Taste free from taint or materials such as chlorine, hypochlorite, or nitrates which are capable of reacting with other components or materials (e.g., cans).
3. Free from toxins of any description.
4. Free of water hardness which can destabilize fruit colloidal suspensions via the calcium and magnesium which cause water hardness. (*See* **Quality Assurance and Quality Control.**)

This is achieved in a soft drinks production plant in a number of ways and the following list comprises the main parameters covered in the specification (and

Table 1 Storage conditions of soft drink raw materials

Material	*Storage conditions*	*Recommended shelf-life*
Fruit		
Frozen	Below −18 °C	2–3 years
Preserved	Ambient	3–9 months
Aseptic	*c.* 4 °C	Up to 6 months
Sugar syrup	Dependent on concentration	
	Some may be stored at ambient	48 h
Glucose syrup (GS)/high-fructose GS	35 °C	48 h–1 week
Citric acid solution	Ambient	1 week
Volatile and natural flavoring materials	4 °C	3–6 months
Nature-identical and artificial flavoring materials	Dark UK; ambient	6–12 months
Water	Ambient	On demand

hence treatment, where necessary) of water: appearance; pH; total dissolved solids; total hardness; alkalinity; nitrogenous compounds; chloride; organic content; microorganisms; phosphate; silicates; trace metals; chlorinated compounds.

Water Treatment

Chemical coagulation is widely used in soft drink production plants as a means of removing unwanted impurities. The incoming water passes into a reaction vessel where coagulating chemicals are added. The reaction products and impurities are precipitated and form a gelatinous sludge through which the treated water flows to a clear zone at the top of the vessel. Since small particles of the flocculant will travel with the treated water, it is normal practice to pass water treated in this way through a sand-bed filter. A typical system of this type is illustrated in Figure 1. (*See* **Water Supplies**: Water Treatment.)

The types of coagulants used are ferrous sulfate, aluminum sulfate, and Lapofloc PAC (a solution of polyaluminum chloride).

Chlorination is the next stage in the treatment of water. Free chlorine is usually used as the sterilizing agent at a level of about 6–8 $mg\,l^{-1}$ of chlorine after the sand filter to insure completion of the reaction. Either chlorine gas or hypochlorite solution may be used. Where ferrous sulfate is employed as the coagulant, free chlorine oxidizes the ferrous salt to ferric salt and is usually added to the coagulation tank where the residence time may be included as part of the contact time necessary for sterilization. Where aluminum sulfate is used, the chlorine is usually added after the sand filter and residence time in the coagulant tank is not part of the contact time.

Organic matter, sulfites, nitrites, and ammonia (or its compounds) absorb or react with chlorine and the bactericidal action of chlorine will not be effected until after these reactions have taken place. Chlorine is best added to the coagulation tank or immediately after, since contact with raw, untreated water containing humic organic substances produces trihalomethanes (THMs) which would result in an unpleasant taint to the water if present in quantities in excess of 100 $\mu g\,l^{-1}$. Via the chlorination process all impurities will be oxidized, removing all taste and odor, including those due to phenol and its derivatives.

The next stage in the process is the dechlorination of the water after sterilization by passing the water through an activated carbon filter which is housed in a vessel similar to that of the sand filter (Figure 1). The quantity of carbon will be selected to achieve a contact time of approximately 5 min with the water, removing all of the chlorine and any remaining organic molecules. Carbon filters are fitted with steam injection at the base to allow sterilization when required to reduce the gradually increasing microbiological contamination from its use.

Quality control on a continuous basis of all aspects of the process must be effected to insure optimum performance of the process. In particular it must always be able to indicate an imminent breakdown of the carbon bed when it requires regeneration.

The above process is the classical procedure for water treatment. There are, however, other methods of either total treatment or treatment for specific requirements of the water. They are as follows:

- Ion exchange will perform softening; dealkalization; nitrate removal; organic compound removal.
- Reverse osmosis will effect removal of high levels of dissolved solids, resulting in a water which may be used directly or further treated for carbonated soft drinks production.
- Ultrafiltration removes colloidal substances and may be substituted for the polishing filter in a conventional process.
- Alternative sterilization processes include ultraviolet light, ozonization, and micropore filtration.

Blending and Processing of Key Ingredients in Soft Drinks

There are two basic methods of manufacture of soft drinks; these are the single batch production and continuous production. Batch manufacture is the process where a tank with a capacity of up to 25 000 may be employed to manufacture the product and/or intermediate syrup to feed the filling line over a period of time. Continuous production utilizes two tanks of only 50–100 l each, with a computer, continuously making one batch after another in a type of tandem operation. The main advantages of the latter system are associated with line problems and interuptions, particularly where a heat treatment is part of the process, since only the 50 or 100 l of product already manufactured will be affected, and may easily be 'ditched' without significant economic consequences. In the case of batch manufacture, however, the 25 000 l of product or intermediate syrup will either remain under nonoptimum conditions or, at worst, continue to be heat-processed (with a return to the batch tank) for the duration of the line downtime.

In each case the steps and safeguards it is necessary to take in the production process are the same and will be covered in the same way. The schematic representation of the production of a soft drink is shown in Figure 2. It can be seen that the processing required for the production of a soft drink involves blending the individual ingredients with heat treatment and/or homogenization where necessary. In reality all ingredients are not added separately to the main blending vessel, since this would cause significant logistical problems for items that are difficult to handle, such as solid sugar (dissolution problems) or thickeners or stabilizers (localized viscosity build-up, lack of powder wetting). There are basically four streams of ingredients:

1. Colors, flavorings, etc.
2. Sugars (i.e., all carbohydrates).
3. Fruit materials.
4. Citric acid, stabilizers, emulsifiers, etc. (this stream utilizes a premix blending vessel with a significantly increased blending power-to-volume ratio for difficult-to-dissolve/disperse ingredients).

Many soft drink production sites are now converting to tanks located on load cells so that the vessel may be tared and ingredients weighed directly into them.

If liquid carbohydrates are being used, these may be added directly from their optimum storage position to the main blending vessel via an inline sieve or

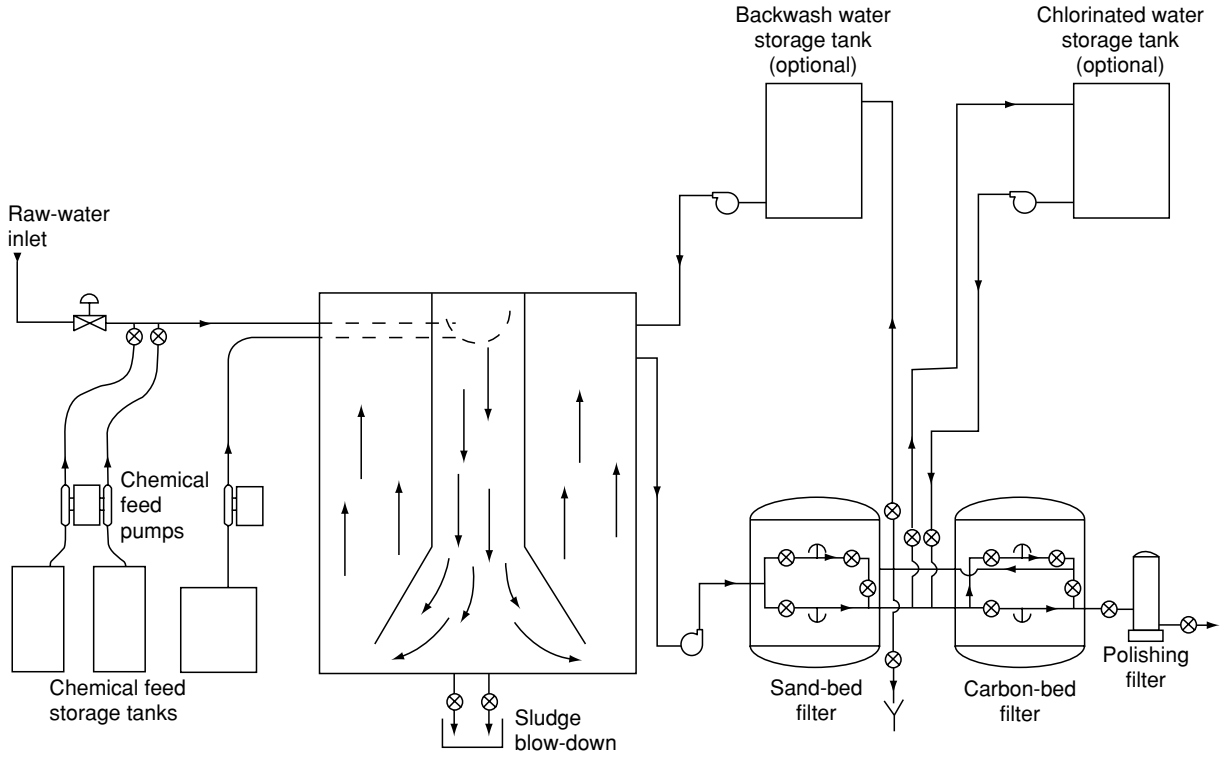

Figure 1 Typical water treatment process in the production of soft drinks.

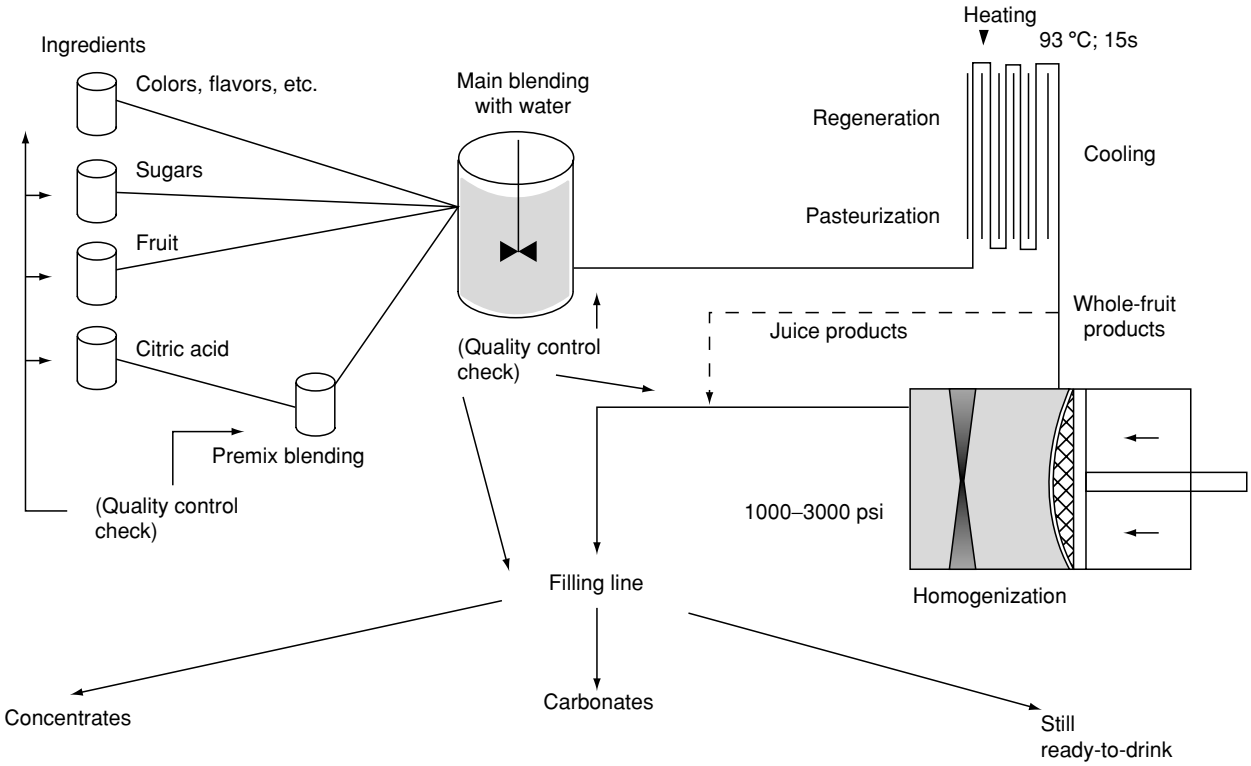

Figure 2 Schematic representation of the production of soft drinks. See Figure 3 for individual key stages.

filtration system to remove any small particles. If solid sugar is used, a simple syrup must be prepared of the sugar and water at approximately 50 °C to aid dissolution; this is then cooled before addition to the main blending vessel. All other ingredients are added to the carbohydrate syrup in the blending vessel in an order which takes into account their chemical reactivity with other ingredients. For example, sodium benzoate must always be added prior to the citric acid, since benzoic acid is only sparingly soluble in acid solution. Certain clouding agents and stabilizers must not be added in close proximity to a flavoring that contains a high level of an alcohol as solvent, since they will interreact.

With a high level of carbohydrate or thickening agent in the syrup in the main blending vessel, it is very easy to entrain air with too much vigorous agitation, and this would result in fobbing during filling, particularly of carbonated products. As long as agitation has not been excessive, then 2 h standing after mixing, with gentle agitation to keep all ingredients evenly dispersed, will be sufficient to allow entrained air to escape. This gentle agitation should be continued for the duration of any pumping or direct bottling so that particulate materials, such as fruit comminute, are evenly dispersed throughout the liquid.

Homogenization

This process is used for many fruit-containing concentrates as part of the finished beverage manufacture enroute to the bottling line and for intermediate syrup processing for some fruit-containing carbonates and ready-to-drink still beverages. The process is a means of reducing the particle size of particulate matter (e.g., fruit comminute) by means of energy input resulting in a more stable suspension and hence better appearance. The conditions which are normally used are 1000–3000 psi at ambient temperature.

Carbonation

The simplest type of carbonator is a pressure vessel in which the liquid and the carbon dioxide are allowed to stay in contact with each other. There are three basic ways to achieve this: (1) vessel partly filled with liquid and pressurized with carbon dioxide; (2) liquid falling through carbon dioxide in a pressurized container; (3) carbon dioxide bubbling through liquid in a pressurized vessel or pipeline. All carbonators operate on one or more of these principles.

One of the essential requirements of a production carbonation system is control over the degree of saturation of the carbonated product, i.e., how close to

the maximum possible volume of carbon dioxide is allowed to dissolve. An uncontrolled release of gas from solution is known as fobbing. Partially saturated solutions are more stable than saturated ones owing to the additional pressure available over the equilibrium pressure. This additional pressure is known as the overpressure and is used in the control of the process. When the necessary degree of overpressure may be maintained over a range of temperature and carbonation, this is known as variable saturation. The ready-to-drink, dilute product may be carbonated by a reduction in temperature and injection of carbon dioxide via one or more of the above techniques, or the concentrated intermediate syrup may be blended with a stream of carbonated water on line to the filling apparatus, resulting in the correctly diluted, carbonated, finished product in the pack.

Hygiene

Throughout the production of all types of soft drinks it is essential that plant hygiene is maintained at the optimum level, whether chemical preservatives and/or heat processing are used.

Good manufacturing practice is a vital and integral part of insuring minimal microbiological contamination of the product and will only be achieved if attention is paid to certain areas of operation:

- Hygienic practices in receiving, handling, and processing materials.
- Tight specifications for clean raw materials.
- Hygienic attitudes and understanding in all personnel.
- Hygienic design of plant and equipment.
- Hygienic operations of suppliers (especially of fruit and carbohydrate materials).

Heat Processing

An examination of the different types of processing for concentrates, carbonates, and ready-to-drink soft drinks is shown in Figure 3. This shows clearly that, in addition to chemical preservation, blending, carbonation, and basic hygiene and quality control requirements, heat processing is a vital part of the production of soft drinks.

Although a manufacturer's main protection against microorganisms is the hygienic operation of the manufacturing plant and that of suppliers, it may still be necessary with certain microbiologically sensitive formulations to enlist the help of both chemical preservatives and heat processing. The use of heat during the processing of soft drinks is covered in outline here as it relates to the microbiological integrity of the product formulation. (*See* **Preservation of Food**.)

Heat processing, or pasteurization, may be subdivided into four main categories for soft drinks and/or material processing: (1) hot-fill; (2) in-pack (or tunnel) pasteurization; (3) flash pasteurization: (a) nonaseptic conditions or (b) aseptic conditions; and (4) microfiltration. The selection of the required/desired heat-processing conditions for any given soft drink, intermediate syrup/blend, or raw material is determined by a number of factors relating to the following:

- Presence of fruit materials and their origin, quality, and microbiological status.
- Presence of chemical preservatives – qualitative and quantitative factors apply.
- pH of the product.
- Solids content and hence water activity.
- Any other relevant processing conditions – holding of syrup at ambient/raised temperature, use of homogenization, filtration, etc.
- Type of packaging to be employed.
- Desired shelf-life.
- Microbiological conditions (and history) of the filling line and ancillary equipment to be employed. (*See* **Pasteurization**: Principles.)

Hot-fill This can only be used for finished still products or intermediate raw materials when being packed for storage and shipment. The product/material is heated in a heat exchanger to a temperature of 85–90 °C; filled into the pack (glass, cans, etc.) so that the temperature of the contents is in excess of 85 °C; sealed via capping or seaming; inverted for a minimum of 1 min; and cooled as quickly as possible. Any flaws in the capping/seaming will result in contaminated cooling water or air entering the package and this will cause spoilage.

The disadvantage of this system is the large amount of heat that is put into the product/material during the whole process, which results in flavor, color, and clouding degradation on storage, producing a reduction in total shelf-life on the product/material.

In-pack (or tunnel) pasteurization In its simplest form, this type of pasteurization involves immersing the filled, capped, or seamed pack of either still or carbonated product in a tank filled with hot water at 60–90 °C in a removable basket and holding at the selected temperature for the required period of pasteurization holding time. In reality the packs are placed in water at a temperature lower than that required and the temperature of the water is raised until the specified temperature has been reached.

Examples of pasteurization conditions for this type of processing are:

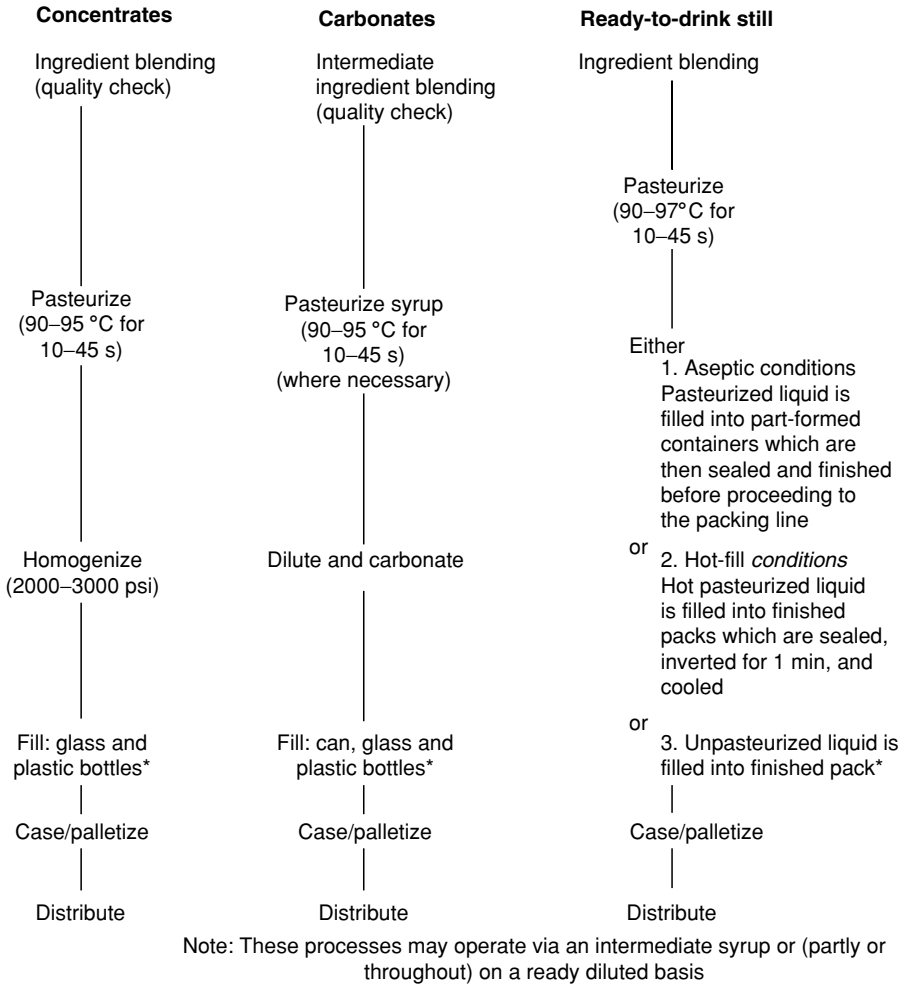

Figure 3 Key stages in the processing of soft drinks.

- 63 °C for 10 min: typically used for shandies
- 70 °C for 10 min: typically used for squashes
- 75 °C for 15 min: typically used for susceptible products such as high-blackcurrant-juice products.

Tunnel pasteurization may be considered as a continuous version of in-pack pasteurization.

After the product has been filled, packed, and seamed, the packages are transported through a tunnel made up of different heat zones by means of water of different temperatures being sprayed over the packages, which gradually increase in temperature to the selected pasteurization level where they are then held for the desired time (holding time) before being cooled slowly to ambient temperature. Processing time is approximately 40–50 min, resulting in very effective pasteurization at relatively high cost (it is energy-intensive and filling has to proceed at the speed of the pasteurizer).

Flash pasteurization

Nonaseptic conditions This system may be used for carton, polyvinylchloride, polyethylenetetraphthalate (PET), and all other nonglass/metal drinks packaging materials, and is suitable for both still and carbonated beverages. The heat exchanger is connected in line with the product mixing tank in the case of still products and the intermediate syrup tank in the case of carbonated products. The syrup or finished product is heated very quickly to the specified pasteurization temperature, held for the specified time (usually quoted as seconds), and cooled rapidly to the filling temperature. The final drink may also be passed through the heat exchanger in this way *en route* to the carbonator if required.

The advantage of this type of pasteurization is that the total heat input to the product is only a fraction of that required for in-pack pasteurization and results in considerably reduced flavor, color, and shelf-life

effects. The disadvantage is that contamination may occur during filling and/or capping and rigorous standards of hygiene and microbiological control must be adhered to by fully trained and committed staff. It may even be necessary to fill some products/packs in enclosed areas with overpressure sterile air rooms.

Aseptic conditions Before a discussion on the types and methods of aseptic flash pasteurization, it is necessary to consider exactly what this means in real terms.

Asepticity is sometimes referred to as commercial sterility, but it is necessary to recognize the important microbiological differences between the two types of processing employed.

With sterility it is realistic to expect that all measurable organisms have been killed by the process, which is almost always carried out at temperature conditions well in excess of 100 °C in hermetically sealed containers, thus insuring the microbiological integrity of the whole pack (product plus packaging).

In aseptic packing the product is heat-treated separately from the container and maintained in positive air pressure conditions (thus excluding any potentially contaminating organisms) until filled and sealed into the selected pack, which has been separately treated to reduce any microbiological contamination on its surface. Examples of aseptic conditions are those which apply to the Tetra Pak process where the product is flash-pasteurized at 96 °C for 13 s and filled into cardboard previously treated with hydrogen peroxide; this is formed into a tube and the individual pack seams are carried out through the product.

With aseptic processing/packaging it is generally recognized that, independently of any pack integrity problems, the normal failure rate will be of the order of one pack in every 10 000 produced. A better rate than this is rarely achieved and aseptic conditions are sometimes quoted with failure rates as high as one in 3000, as in the case of carbonated products packed in PET containers.

Microbiology

M Stratford and C J Capell, Unilever Research, Sharnbrook, UK

Background

'Soft drinks' is a term often used to describe all beverages with the exception of alcoholic or hot beverages. This includes a vast array of products ranging in composition from mineral waters, sports drinks, diet formulations, colas, mixers, and tonics to fruit juices. Some soft drinks are sparkling (carbonated), whereas others are still. Some are manufactured with a designated shelf-life greater than a year, whereas others are sold for immediate consumption (freshly squeezed juices). As a consequence of this variation in composition and packaging, the microbiology of soft drinks also shows considerable variation. Some soft drinks form an environment so hostile, or so deficient in nutrients, that the microflora is nearly nonexistent, and spoilage is consequently rare. Other soft drinks, such as fruit juices of a higher pH (**Table 1**) form an environment ideally suited to rapid proliferation of yeasts, molds, and bacteria. For the purposes of this article, the average soft drink will be considered to have a pH between 2.5 and 3.5 (**Table 1**), sugar at 5–10%, 1–3 $g\,l^{-1}$ citric acid (or titratable acidity equivalent), and fruit juices or vegetable extracts sufficient to comprise a source of minerals and vitamins for microbial growth.

In theory, the presence of microbes in a food product can have any one of three possible effects. It can be a positive attribute, growth of specific microbes creating desirable organoleptic changes, as in

Table 1 pH range and acids prevalent in various soft drinks and fruit juices

Beverage	*pH range*	*Acids*
Apple juice	2.9–4.5	Malic, citric
Orange juice	2.6–4.3	Citric, malic
Blackcurrant juice	3.0–3.8	Citric
Grapefruit juice	2.9–3.6	Citric
Lemonade	2.8–3.2	Citric
Cola	2.5–2.8	Phosphoric

fermented foods or alcoholic beverages. It can be a negative attribute, causing illness in the consumer or spoilage of the food, or it can be entirely neutral, the presence of microbes having no effect whatsoever on the food or on the consumer. In soft drinks, microbes are almost never beneficial, a possible exception being the oriental acidic tea, Kombucha, fermented by yeasts, molds and acetic acid bacteria. In the great majority of instances, the presence of microbes in soft drinks is entirely neutral. Most bacteria are sensitive to the acidity of soft drinks, whereas the majority of yeasts and molds may be suppressed by a lack of oxygen within the soft drinks packaging (Table 2). Any such organisms tend to arrive in bottles of soft drinks in low numbers and have no impact whatsoever on the beverage. Most will die in this environment within a few hours to a few weeks, depending on the organism.

A small minority of microbes, however, find the soft drink environment suitable for proliferation and growth to substantial populations. These are the soft-drinks spoilage flora (Table 2). Although the occasional microbe per liter of beverage has little impact, growth to 10^5 cells per milliliter results in visible spoilage, and 10^6–10^8 cells per milliliter are sufficient to cause very considerable changes to the chemistry of the beverage. Such changes are almost always organoleptically unacceptable and in themselves constitute spoilage.

Manufacturing Process of Soft Drinks

Process

Fruit-juice manufacture typically occurs close to the area of production. Fruit is processed to remove leaves, stems, etc., washed, milled, and crushed. The juice is usually extracted from the crushed pulp by pressure. Single-strength juice is bulky and is often concentrated at the site of production. Juices are heated to near 100 °C, a vacuum is applied, and water is removed by evaporation. Volatile components are recovered and added back after cooling. To ensure microbiological stability, concentrates may then be frozen, preserved, or aseptically filled into drums.

Soft-drinks manufacture (Figure 1) essentially involves dissolving weighed amounts of flavors, juices, acids, antioxidants, and sugars into water. This is then dispensed into the appropriate packaging. Sugar enters the syrup room of the factory either as granules, which are dissolved in hot water, typically 85 °C/30 s or as 67 °Brix syrup, known as 'simple sugar syrup.' Other components of the soft drink, acids, flavors, fruit juices, vegetable extracts, antioxidants, etc., are weighed out and dissolved in water. These are added to the simple sugar syrup, forming the final syrup at 40–50 °Brix. The final syrup is piped from the syrup room to the proportioning pump in the filling hall (Figure 1). Here, it is proportioned with water to form the product, typically, 7–10 °Brix. This is filled into bottles/cans/tetrapaks at the filler, which are then sealed at the capper.

Sources of Infection

Microbes may enter soft drinks and their production facilities from a number of sources. These may directly infect products or may colonize various sites within the factory and subsequently cause infection from these sites. Entry to the factory is most common on raw materials, returned bottles, via insects or aerial vectors.

Aerial contamination obviously depends on the microbial loading and composition in the air. Nearby sources of microbes greatly increase the microbial load, e.g., breweries, dust sources (harvesting or building work), fruit storage, or processing of fruit or vegetables. Fresh fruit are routinely heavily surface-contaminated with yeasts and molds, 10^3–10^6 per gram. Factories processing fruits will inevitably become contaminated with the molds associated with those fruits' spoilage flora. Ascomycetous molds produce conidiospores for dispersal and ascospores for survival. Conidiospores are often airborne; ascospores often are not, making the presence of the heat-sensitive conidiospores generally more common as airborne contaminants. Aerial contamination is highly seasonal, with mold spores predominating,

Table 2 Summary of the growth, spoilage, and safety significance of microbes in soft drinks

Microbe	*Growth*	*Inhibition*	*Spoilage*	*Safety*
Spoilage yeasts	+	−	Excess gas	Exploding bottles
Other yeasts	−	Low O_2	−	−
Spoilage molds	+	−	Mycelium	Possible mycotoxins
Other molds	−	Low O_2	−	−
Vegetative bacterial pathogens, e.g. *Salmonella* spp., *E. coli* VTEC (enteropathogenic *E. coli*)	−	Low pH	−	Food poisoning, in fresh, unpasteurized, fruit juices
Acid-tolerant bacteria	±	Low O_2	Taints, slime	−
Most bacteria	−	Low pH	−	−

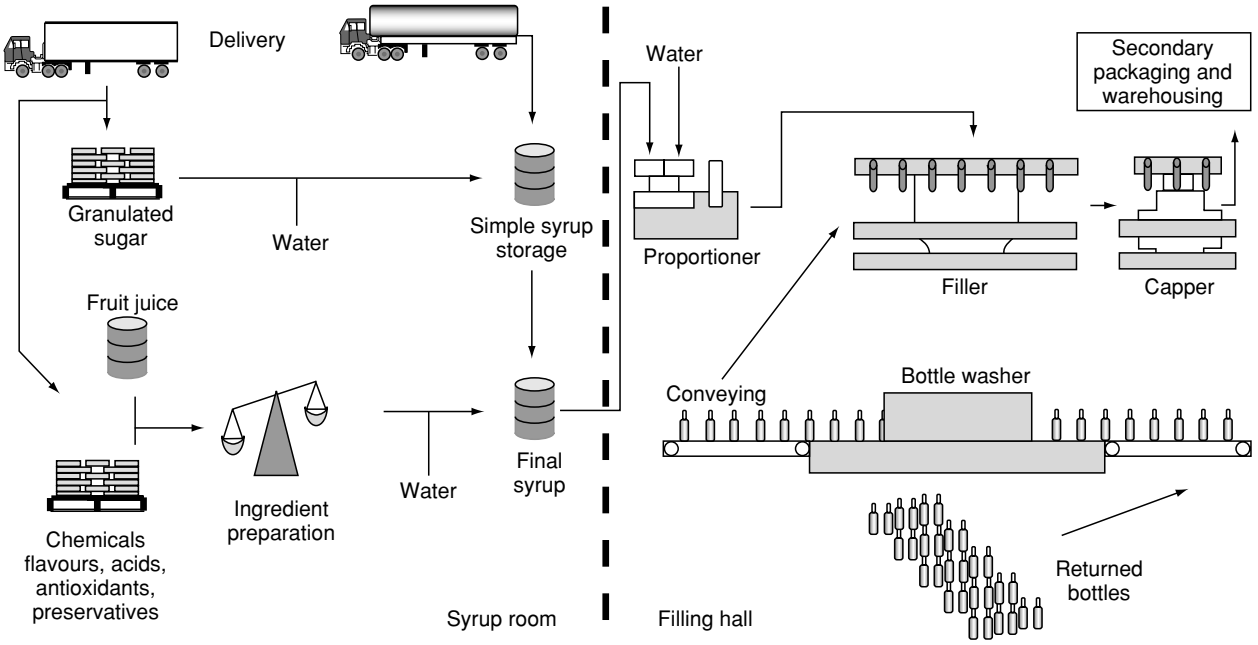

Figure 1 Schematic diagram of a soft-drinks production facility. In the syrup room, sugars are dissolved in water to form simple syrup, and juices and flavors are added to form the final syrup. This is pumped into the filling hall, diluted with water by the proportioning pump, and filled into bottles. Bottles are then capped, packaged, and distributed. Tunnel pasteurization is applied to capped bottles or 'in-line' pasteurization between the proportioner and filler.

and is probably the most significant cause of mold spoilage. (*See* **Microbiology**: Classification of Microorganisms.)

Insects are becoming increasingly recognized as a vector for yeasts. Many insects carry yeasts and acid-tolerant bacteria between flowers, actively consume yeasts as part of their diet, and benefit from yeast colonization of their digestive systems. Insect frass, notably from fruit flies (*Drosophila* spp.), is particularly rich in soft-drink spoilage yeasts.

Returned bottles, when brought into the factory, form a potent source of microbial infection of soft drinks. Returned bottles are frequently cap-less and unwashed, often containing a residue of soft drink. Storage at ambient temperature allows selective growth of spoilage microbes in the residue up to high levels and formation of stationary-phase survival mechanisms, such as heat-resistant ascospores by yeasts and molds. Stringent bottle-washing removes almost all residues, but fungal debris and viable ascospores can persist through the whole process. Fruit-flies, attracted to the sugary residues in returned bottles, can also spread infection around the factory.

The microbial loading of raw materials is normally low where materials have been selected from good quality sources. Sugar granules, 67 °Brix syrups, or fruit-juice concentrates are a potential source of contamination. Fruit juices are often heavily contaminated; citrus fruits are especially associated with mold spoilage, as the fruit defense is most susceptible to pectinolytic molds. Pasteurization of the single-strength juice or the concentration process should result in a near-sterile product, except for rare heat-resistant molds. *Byssochlamys* spp. and *Talaromyces* spp. have been the cause of spoilage in pasteurized fruit juices. The ascospores of these molds are relatively uncommon, but significant growth of the mold on the raw material must have occurred for the presence of problematic numbers of ascospores. Similarly, mold spores in small numbers may survive the sugar refining process. Both fruit juice concentrates and sugar syrups are more likely to acquire an osmophilic flora through mishandling after cooling. Owing to the low water activity, only osmophilic yeasts and, more rarely, molds can grow, albeit very slowly in sugar syrups. Other ingredients, such as water, flavors, acidulants, colorings, antioxidants, and preservatives, are also possible sources of spoilage microorganisms.

Build-up or colonization of a spoilage flora within the factory is probably the most significant source of infection. It has been estimated that 95% of yeast infections of soft drinks are caused by poor plant hygiene. Soft-drink manufacture is generally a very high-volume throughput operation, with up to $36\,000\,l\,h^{-1}$ passing through each filling line. Little time is therefore allowed for growth of microbes within the bulk volume of liquid, before pasteurization or addition of preservatives. Microbial build-up is therefore most significant in dead spaces or on

surfaces proximate to the product stream. Areas most at risk include the proportioning pump, filler and filler heads, and capper. Other areas of concern include old, dried splashes of fruit juice or soft drink, the syrup room, particularly where ingredients have been spilled or allowed to become damp, and drains into which sugars are washed. (*See* **Contamination of Food.**)

Microbial Stability

Microbial stability can be achieved by preventing viable microbes entering the product, (aseptic filling), sterilization (pasteurization), or by factors preventing microbial growth in soft drinks (preservation). Pasteurization is the most effective method of eliminating microbes in soft drinks (Table 3). Vegetative yeast and mold cells are generally heat-sensitive, almost all being killed in 10 min at 60 °C. Pasteurization of fruit juices, such as orange juice, which are typically heavily contaminated with yeasts and molds, range from 10 to 15 min at 70–75 °C. Such pasteurization will not eliminate heat-resistant forms of molds, such as ascospores.

The microbial stability of soft drinks can be achieved most simply and effectively by 'in-pack' sterilization, downstream from the capper using a tunnel pasteurizer (Table 3). This insures absence of microbes in the bottle and cap as well as the product. Alternatively, products may be sterilized 'in-line' using a plate pasteurizer and aseptically filled into sterile bottles, or products may be given a flash in-line pasteurization to lower the microbial loading and preservatives added to prevent the growth of surviving microbes. Fresh-pressed fruit juices that would normally spoil within 2 days may be preserved by chilled storage for a limited period of time, e.g. 2–3 weeks.

Some factors suppressing microbial growth are intrinsic to the composition of soft drinks, such as the phosphoric acid in cola or the low pH that inhibits or kills the majority of bacteria. Pressurized CO_2 in carbonated soft drinks has a pronounced antimicrobial effect, particularly against molds and bacteria. Fermentative yeasts are more resistant, particularly *Brettanomyces* spp., but growth can be inhibited at high carbonation. The lack of nutrients in many soft drinks, such as vitamins, phosphate, or a usable nitrogen source, is also an aid to preservation. It has been noted that soft drinks improved by the addition of real fruit juices often became increasingly prone to microbial spoilage.

Table 3 Common methods of achieving microbial stability in soft drinks

Method	*Comment*
Tunnel pasteurization	Sterilizes product and packaging together
In line, plate pasteurization	Sterilizes product only, then requires aseptic or hot filling
Flash pasteurization + preservatives	Flash lowers the microbial load, and preservatives inhibit survivors
Frozen/chill storage	Inhibition or delay of microbial growth

Preservatives are added to soft drinks to kill or prevent the growth of microbes. The preservatives commonly encountered in soft drinks are sorbic acid and benzoic acid. Less frequently found are sulfites (SO_2), parabens, and dimethyldicarbonate (DMDC). Preservative usage and permitted concentrations vary greatly, depending on the legislation in force where soft drinks are produced and consumed. Sorbic and benzoic acids function far better as preservatives at lower pH. Resistance to preservatives has been reported to the greatest extent in *Zygosaccharomyces* spoilage yeasts, but also occurs to a lesser extent in certain molds and bacteria, such as *Gluconobacter* (*Acetomonas*).

Characteristic of Soft-drinks Spoilage

Soft drinks may be spoiled by yeasts, molds, or bacteria. Yeast and mold spoilage predominates, being favored by the low pH and high sugar/assimilable nitrogen ratio. Spoilage of soft drinks may be clear and easily detectable by a number of visual or organoleptic symptoms. However, it is by no means uncommon not to isolate viable microbes from a spoiled product. It appears that spoilage organisms often grow and cause the symptoms of spoilage before dying. This may be due to a lack of nutrients or oxygen, or to the formation of toxic byproducts such as ethanol. Consequentially, it is not always possible to identify the causative agent of spoilage.

Yeast growth in excess of 10^5 cells per milliliter results in a visible cloud or haze. Some spoilage yeasts secrete proteolytic or pectolytic enzymes that can destroy the natural hazes of fruit juices. Spoilage yeasts may be flocculent, forming particulates, whereas others form a surface skin or vellum, notably *Pichia membranaefaciens*. The most significant spoilage yeasts are highly fermentative, producing CO_2 up to high pressure, and consequently distorting and bursting the packaging (Figure 2). Fermentation also results in ethanol production, and yeast spoilage is often associated with a sweet alcoholic taste.

Mold spoilage of soft drinks is usually visual and obvious. Molds given more oxygen via loose seals, large headspace, or oxygen-permeable packaging tend to form surface pellicles and may sporulate. Mold growth in suboptimum conditions, low oxygen or preservatives, tends to form submerged mycelial

masses, often resembling small wispy balls of cotton wool. Mold growth can also eliminate clouds in citrus fruit juices. Taints and musty flavors may be produced.

Bacterial spoilage is usually associated with fruit or vegetable juices and the presence of oxygen. Spoilage is often associated with loss of astringency, souring, slime or ropiness in texture, turbidity, and off-flavors.

Figure 2 Ruptured can of a soft drink caused by yeast spoilage. The can was infected with *Zygosaccharomyces bailii* and incubated for 2 weeks at 25 °C. Cans were visibly swollen within 7 days.

Spoilage Microorganisms of Soft Drinks

Currently, some 800 yeast species, thousands of molds, and vast numbers of bacteria are recognized. The ability of microorganisms to exchange DNA often makes species identification of an organism causing spoilage to be of little value. In the 'forensic approach' to spoilage microbiology, Professor Davenport proposed a simplified taxonomy based on the behavior of microbes, rather than on their species names. Group 1 were the spoilage microoganisms, well suited to proliferate in soft drinks with the potential to cause spoilage from as few as one cell per container. Group 1 spoilage microbes for soft drinks were limited to a number of yeasts, listed in Table 4. All are generally osmotolerant, highly fermentative, vitamin-requiring and resistant to preservatives, such as acetic, sorbic, or benzoic acids. These yeasts are fortunately rare in soft-drink environments and do not form any part of the flora of a well-run soft-drink production facility.

Group 2 microbes, described as spoilage/hygiene, are capable of causing spoilage of soft drinks but only as a result of mistakes occurring during manufacture. This group, examples of which are listed in Table 4, includes yeast and mold species and acid-tolerant bacteria. These can be regarded as opportunistic spoilage organisms, ready to exploit errors such as under-dosing of preservatives, failure of pasteurization, hygiene failures, or ingress of oxygen. Such organisms are often present in soft-drink factories, usually in low numbers and restricted by good hygiene procedures.

Group 3 microbes are hygiene indicators and will not cause spoilage. Most yeasts found in soft drinks production and products are Group 3 organisms (Table 4). Their numbers can be used as a measure of the general hygiene of the facility, and their origin may indicate the origin of the contamination. For

Table 4 Yeasts associated with soft drinks and fruit juices

Group 1	*Group 2*	*Group 3*
Zygosaccharomyces bailii	***Candida parapsilosis***	***Aureobasidium pullulans***
Zygosaccharomyces bisporus	***Debaryomyces hansenii***	***Cryptococcus albidus***
Zygosaccharomyces lentus	***Pichia membranaefaciens***	***Cryptococcus laurentii***
Zygosaccharomyces rouxii	*Saccharomyces exiguus*	***Rhodotorula glutinis***
Saccharomyces exiguus	*Saccharomyces cerevisiae*	***Rhodotorula mucilaginosa***
Saccharomyces cerevisiae	*Candida krusei*	*Candida sake*
Brettanomyces bruxellensis	*Pichia anomala*	*Candida intermedia*
Schizosaccharomyces pombe	*Kloeckera apiculata*	*Candida zeylandoides*
Torulaspora delbrueckii		
Zygosaccharomyces fermentati		
Zygosaccharomyces florentinus		
Zygosaccharomyces microellipsoides		

Group 1 are spoilage yeasts, Group 2 are opportunistic spoilage microbes, and Group 3 are hygiene indicators. The most significant species are in bold. *Saccharomyces exiguus* and *S. cerevisiae* are listed in two groups in respect of their strain variability, abnormal strains causing spoilage.

example, the yeast-like mold *Aureobasidium pullulans*, or red-pigmented yeasts, *Rhodotorula glutinis* or *R. mucilaginosa*, can be used to indicate airborne dust contamination. The presence of such organisms in beverages is relatively common and not a cause for concern. Such organisms are usually present in very low numbers, are harmless to the consumer, and are unable to grow or cause spoilage. It has been estimated that up to a third of all commercial fruit juices contain a few viable yeasts.

Spoilage Yeasts

The most widely reported yeasts in soft drinks are the Group 1 spoilage yeasts, which include *Zygosaccharomyces bailii, Z. rouxii, Z. lentus*, and *Z. bisporus*. These are rarely found in soft drinks or production facilities, but when they do occur, spoilage is usually widespread and devastating. These yeasts share many physiological characteristics, being osmotolerant, preservative-resistant, and highly fermentative, and most are taxonomically closely related.

Zygosaccharomyces bailii (Figure 3) is the most preservative-resistant organism known, able to resist high concentrations of acetic acid and ethanol. Strains of *Z. bailii* can tolerate sorbic and benzoic acids at pH 4.0 at up to 1000 p.p.m. (Figure 4). The European statutory limit for these preservatives is currently 300 p.p.m.! Adaptation to preservatives by prior exposure can increase tolerance by some 50–100%. *Z. bailii* readily forms ascospores, although these are not markedly heat-resistant. *Z. bailii* grows well in sugar syrups and juice concentrates, containing 50–60% sugar, thus allowing easy infection of soft drinks via the raw materials. The infective dose of *Z. bailii* is low; this yeast is reputed to cause spoilage from as little as one cell per container. *Z. bailii* can cause spoilage of fruit juices, cordials and concentrates, and carbonated and still soft drinks. *Z. bailii* requires B-group vitamins and is less likely to spoil products lacking fruit juices or similar vitamin sources.

Zygosaccharomyces bisporus shares most of the characteristics of its close relative *Z. bailii*. *Z. bisporus* is much less frequently encountered than *Z. bailii*. Examination of the characteristics of several strains of *Z. bisporus* show much diversity; some strains being comparable with *Z. bailii* in terms of preservative resistance and osmotolerance, whereas other strains are more sensitive. Overall, *Z. bisporus* strains are less preservative-resistant than *Z. bailii* (Figure 4).

Zygosaccharomyces lentus is a newly discovered species, members of which had previously been mistakenly identified as *Z. bailii*. *Z. lentus* strains are often more preservative-resistant than *Z. bisporus*.

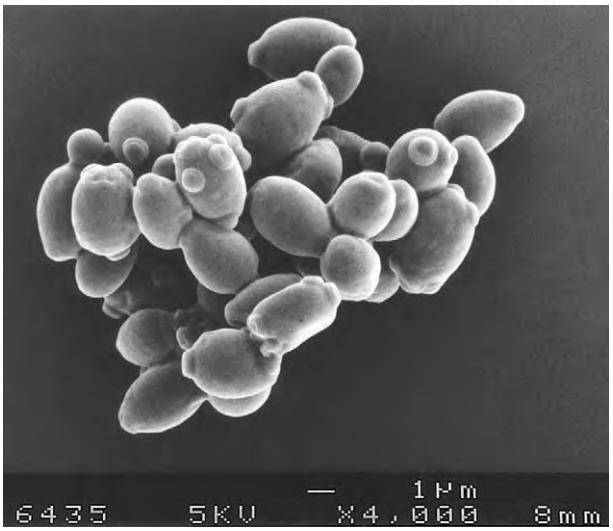

Figure 3 Scanning electron micrograph of the spoilage yeast *Zygosaccharomyces bailii* NCYC 1766. Cells are ovoid, 4 µm in length, with prominent surface bud scars.

All of the *Z. lentus* strains isolated to date are from spoiled foods, predominantly from orange and tomato products. *Z. lentus* strains are unusual in growing very slowly and having a low temperature range. Growth is poor above 25 °C, but these yeasts will grow at 4 °C and cause spoilage of refrigerated soft drinks and fruit juices.

Zygosaccharomyces rouxii is extremely osmotolerant being able to tolerate water activity down to 0.62 in fructose. Consequently, this yeast is probably the most significant spoilage organism in syrups and fruit-juice cordials and concentrates, but also spoils fruit juices and soft drinks. Like the other *Zygosaccharomyces* spoilage yeasts, *Z. rouxii* is highly fermentative, spoilage of concentrates often being detectable by bulging containers. *Z. rouxii* is also reported capable of growth from very low contamination levels. Direct comparisons show that *Z. rouxii* is significantly less preservative-resistant than *Z. bailii* (Figure 4) and shows significantly less resistance to pasteurization than most other yeasts. The rarer honey spoilage yeast, *Z. mellis*, shows very similar characteristics to *Z. rouxii*. Many *Z. mellis* strains have been shown by 26S rDNA sequencing to have been misidentified, in reality, *Z. rouxii* strains.

Saccharomyces exiguus, sometimes known as *Candida holmii* or *Torulopsis holmii*, is also closely related to the central *Zygosaccharomyces* spoilage family. *S. exiguus* strains are vigorous-growing, moderately osmotolerant, and highly fermentative, generally resembling *Saccharomyces cerevisiae*. Some strains of *S. exiguus* are capable of growth in extreme acid conditions and high levels of preservatives.

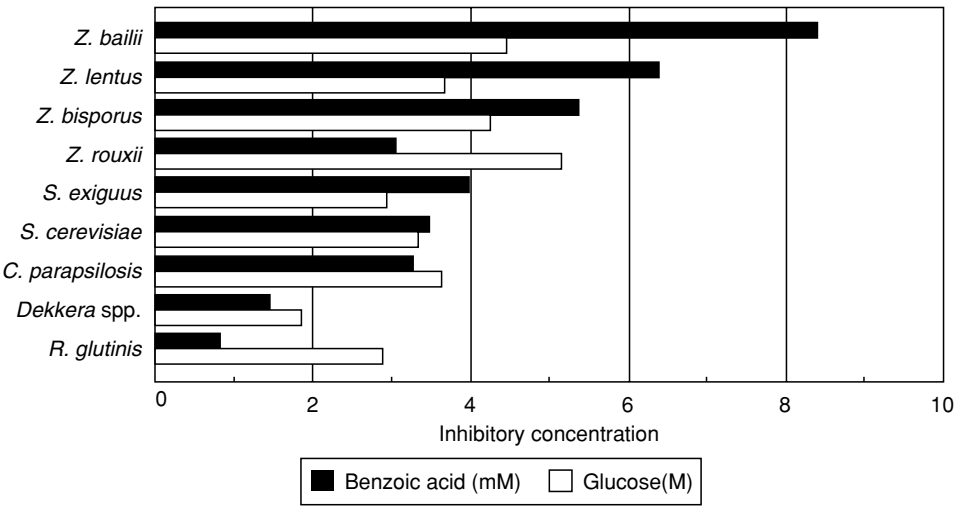

Figure 4 Bar chart showing the relative preservative resistance and osmotolerance of a number of spoilage yeasts (unpublished data from H. Steels, with permission). Inhibitory concentrations were measured in YEPD (yeast extract, peptone, glucose) broth, pH 4.0, at 25 °C. Data are the mean values of 28 strains of *Z. bailli*, 10 strains of *Z. lentus*, six *Z. bisporus*, nine *Z. rouxii*, five *S. exiguus*, 11 *S. cerevisiae*, seven *C. parapsilosis*, five *Dekkera/Brettanomyces* spp., and five *R. glutinis*.

Brettanomyces, and its ascospore-forming teleomorph, *Dekkera*, is a genus containing species noted for spoilage of low nutrient, carbonated beverages such as soda water, tonic, cola, or clear lemon. The most commonly encountered species are *Dekkera bruxellensis* and *D. naardenensis*, causing sediments and characteristic off-flavors and odors. These yeast species are characteristically sensitive to preservatives (Figure 4), high sugar, and heat, but are regarded as spoilage Group 1 yeasts owing their its resistance to CO_2 and spoilage of carbonated beverages.

Other spoilage yeast species are less commonly encountered, including other near-relatives of the *Zygosaccharomyces* spoilage family, *Z. fermentati. Z. florentinus, Z. microellipsoides, Torulaspora delbrueckii*, and the fission yeast *Schizosaccharomyces pombe*. These are all fermentative yeasts with moderate osmotolerance. Their resistance to preservatives is generally moderate to low. (*See* **Yeasts**.)

Spoilage Molds

Molds are, by and large, aerobic multicellular hyphal fungi, but a spectrum of phenotypes exist. Food spoilage molds are generally fast-growing opportunistic organisms. Fungi have a greater tolerance of low pH and low water availability than bacteria and are therefore most closely associated with foods with these characteristics. Their requirement for oxygen and sensitivity to carbon dioxide mean that mold spoilage may be effectively controlled by carbonation. Some molds can produce heat-resistant stages, including sclerotia, chlamydiospores, and ascospores, and are potentially capable of surviving normal pasteurization (Table 5). Although molds produce hyphal growth, they are able to grow well in liquid culture, either growing on the surface or completely submerged. Although molds are generally regarded as obligate aerobes, some do ferment sugars to ethanol and carbon dioxide; those best studied, the dimorphic yeast-like molds such as *Mucor* spp., are also associated with the spoilage of soft drinks. As these molds do not produce exceptionally heat-resistant stages, they should be eliminated by pasteurization, and such spoilage is an indication of hygiene failure. Mold resistance to the common food preservatives is generally reported to be less than spoilage yeasts. However, many molds will degrade sorbic acid to strong-smelling 1,3-pentadiene, making mold spoilage of preserved beverages particularly distinctive.

Many molds have the potential to cause spoilage of soft drinks. Those most commonly encountered include *Aspergillus niger, A. ochraceus, A. fischeri*, and *A. tamarii, Byssoclamys nivea, B. fulva, Paecilomyces variotii, Neosartorya fischeri, Eupenicillium brefeldianum, Phialophora mustea, Taleromyces flavus, T. trachyspermus*, and *Thermoascus aurantiacum*.

Spoilage Bacteria

The ecological conditions of soft drinks limit the growth of bacteria, with formulation pH having the clearest effect on the development of potential spoilage organisms. Bacterial soft-drink spoilage organisms fall into three main categories: spore-formers,

lactic acid bacteria, and acetic acid bacteria. As most soft drinks are pasteurized, acidoduric/philic spore-forming bacterial species are of greatest threat to fruit-juice manufacturers. High-pH fruit or vegetable juices, tomato, apple, pear, or carrot juices have been reported spoiled by *Clostridium* spp. or *Bacillus* spp. including *C. butyricum, C. pasteurianum, Bacillus coagulans, B. licheniformis, B. macerans, B. subtilis*, and *B. polymyxa*, the thermophilic *B. coagulans* being the causative agent of 'flat-souring' in tomato juices.

Alicyclobacillus acidoterrestris is an obligately aerobic spore-forming thermophilic bacteria, associated with soils and acidic fruit juices principally from warm climates. Although not common at present, this organism has the potential to become a major cause of spoilage of fruit-containing soft drinks (Tables 5 and 6). It will grow at pH 2.5, and its spores have been reported to be very resistant or immune to pasteurization ($D_{95\,^\circ C}$ of 2–12 min; $D_{95\,^\circ C}$, time at temperature leaving 10 % survivors in the population). It may grow and produce tarry off-odors, including guaiacol and 2,6-dibromophenol, through the reduction of taint precursors. It does not produce gas, and bacterial haze is often not an important consideration as fruit juice may be naturally cloudy. Potentially, removal of taint precursors, limitation of storage temperature to < 20 °C, for example, prevention of ingress of oxygen or super-pasteurization will eliminate spoilage, though practicalities may limit these solutions.

Unpasteurized fruit juices with pHs higher than about 3.2 may be spoiled by the growth of lactic acid bacteria. *Lactobacillus* or *Leuconostoc* spp. can cause slime, ropiness, and off-flavors in fruit juices, particularly where adapted strains have been allowed to build up in production facilities. Lactic acid bacteria are heat-sensitive and lose viability in chilled juices. (*See* ***Bacillus***: Occurrence; **Lactic Acid Bacteria**.)

Gluconobacter spp. (*Acetomonas*) is the most frequently encountered cause of bacterial spoilage at low pH. Spoilage changes flavor characteristics and may lead to pack swelling and haze. *Gluconobacter* spp. are resistant to preservatives such as sorbic acid, benzoic acid, and DMDC, but are heat-sensitive and absolutely dependent on the presence of free oxygen. Spoilage is a problem only in gas-permeable packaging, such as still soft drinks in plastic beakers (Table 6).

Table 5 Heat resistance of yeasts, molds, mold ascospores, and bacterial spores associated with soft drinks

Microbe	*Form*	*D-values (min)*
Byssochlamys fulva	Ascospores	$D_{80\,^\circ C}$ 300, $D_{90\,^\circ C}$ 90–900
Byssochlamys nivea	Ascospores	$D_{88\,^\circ C}$ 45–48
Neosartorya fischeri	Ascospores	$D_{88\,^\circ C}$ 84, $D_{88\,^\circ C}$ 72–450
Aspergillus flavus	Conidiospores	$D_{55\,^\circ C}$ 186
Talaromyces flavus	Ascospores	$D_{88\,^\circ C}$ 468, $D_{90\,^\circ C}$ 60–420
Talaromyces macrosporus	Ascospores	$D_{88\,^\circ C}$ 420–1320, $D_{90\,^\circ C}$ 132–360
Alicylobacillus acidoterrestris	Spores	$D_{90\,^\circ C}$ 960–1380
Saccharomyces cerevisiae	Ascospores	$D_{55\,^\circ C}$ 6360
Saccharomyces cerevisiae	Vegetative cells	$D_{55\,^\circ C}$ 55
Zygosaccharomyces bailii	Ascospores	$D_{50\,^\circ C}$ 600–2220
Zygosaccharomyces bailii	Vegetative cells	$D_{50\,^\circ C}$ 120–240

Safety and Microbial Hazards in Soft Drinks

The hazards posed by the presence of microorganisms on soft drinks are much lower than for the majority of foods. Owing to the low pH of soft drinks, bacterial spores will not germinate, and vegetative cells progressively die off. Pathogenic bacteria are therefore of little consequence in acidic soft drinks. Fruit juices, notably apple juices prepared from ripe fruit, are generally less acidic than the majority of soft drinks and allow a longer survival of pathogens. Recent, much-publicized cases of illnesses caused by *Escherichia coli* 0157:H7 in unpasteurized apple juice appeared to be caused by animal fecal contamination of the fruit. Pathogens, such as *E. coli* or *Salmonella* spp., die in acidic apple juices, but viability can be maintained for several days and progressively lost over 3–5 weeks, respectively. Occurrences of salmonellosis in fruit juices are rare but finite. Pathogens in fruit juices are easily inactivated by pasteurization or by the addition of preservatives. Soft drinks may also very rarely contain viruses or the parasitic protozoan,

Table 6 Niche habitats formed by different varieties of soft drinks, and spoilage microbes associated with these habitats

Habitat	*Spoilage microbe*	*Spoilage indications*
High carbonation	*Brettanomyces/Dekkera* spp.	Clouds, off-flavors, odors
High preservatives	*Z. bailii, Z. bisporus, Z. lentus*	Excess gas, blown cans
Juices in thin plastic	*Gluconobacter (Acetomonas)*	Off-flavors, haze
Tomato juices	*Bacillus coagulans*	Flat souring
Syrups or concentrates	*Z. rouxii, Z. bailii*	Excess gas, blown cans
Refrigerated juices	*Z. lentus*	Clouds, off-flavors
Heat-treated juices	*Alicyclobacillus acidoterrestris*	Tarry taints, guaiacol
Heat-treated juices	Ascospore-forming molds	Mycelium, off-flavors

Cryptosporidium parvum, infection occurring via contaminated water supplies. Illnesses have been reported, caused by small, round-structured viruses in orange juice or *Cryptosporidium parvum* in apple juices and flavored fruit drinks.

The presence of fermentative yeasts in soft drinks also poses a physical hazard to the consumer and is caused by fermentation to high pressure within packages. Pressures comparable with that in Champagne bottles will cause metal cans and kegs to split or rupture (Figure 2), plastic bottles to distort and effervesce violently when opened, and glass bottles to shatter. Exploding bottles caused by *Zygosaccharomyces*. yeasts are a recognized cause of eye injuries. Molds do not generate gas to the same extent but, in higher pH products, could pose a threat from the formation of mycotoxins. Some concern has been raised regarding formation of patulin in stored apples by *Penicillium expansum*. Apple juices prepared from moldy fruit have been found to contain 1130 $\mu g\,l^{-1}$. Consequently, European and FDA limits have been set for patulin in apple juices.

Dietary Importance

S J Gatenby, Reading Laboratory, Reading, UK

Nutritional Composition

Soft drinks may make a valuable contribution to fluid intake and have become, to some extent, established as part of the daily diet, particularly of young children and adolescents. The nutritional value of a number of readily available soft drinks is shown in **Table 1**. Squashes, crushes, cordials, and carbonated drinks are, however, of little nutritional value (apart from their energy content) as their main ingredients are water and sugar. These soft drinks can be a valuable source of vitamin C, although it is unlikely that they will contain significant quantities unless the vitamin is added. Soft drinks do not contain fat or fiber but may contain nutritionally insignificant traces of protein. (*See* **Ascorbic Acid**: Physiology.)

Energy Content

The energy content of soft drinks varies greatly and is derived exclusively from the sweetening agents, which are principally sugars (**Table 1**). Soft drinks sweetened with mixtures of sugar and intense sweeteners are less caloric than drinks sweetened entirely with sugar, and drinks labeled as being low-calorie are required by UK law to contribute a maximum of 22 kJ (5 kcal) per 100 ml.

Sugar Content

The added sugar content of soft drinks varies from 6 to 10% and is mostly glucose and fructose, with small quantities of sucrose and perhaps maltose (**Table 1**). The sugar content of soft drinks is regulated by the UK 1964 Soft Drinks Regulations (amended 1969, 1970, and 1976). The nutritional value of a soft drink as consumed is dependent upon the dilution factor, which must now be stated on the label of all dilutable drinks. Soft drinks are a major market for intense sweeteners, particularly in the UK where, unlike many other countries, they can be used in conjunction with nutritive sweeteners and are not therefore limited to use in dietetic beverages. There are technical reasons, economic objectives, and health considerations supporting the need for intense sweeteners in soft drinks. No single sweetener is ideally suited to meet all the requirements of soft drinks, but by using them in combination the limitations of one sweetener can be offset by the strengths of another. The sweetening of soft drinks with

artificial sweeteners reduces the energy content and encourages fluid consumption without decreasing the nutrient density of the diet. Those drinks sweetened with aspartame may contain the amino acid phenylalanine in amounts which may be undesirable for individuals with phenylketonuria, a rare genetic disorder or metabolism that requires the patient to follow a special diet. The more liberal use of artificial sweeteners, the establishment of acceptable daily intake levels, and the increased number of sweeteners available has resulted in a wide range of low-calorie beverages which are acceptable to many consumers. Consumers have been advised to insure that they consume a mixture of sweeteners to avoid large intakes of any one type. (*See* **Aspartame; Carbohydrates**: Sensory Properties; **Sweeteners**: Intensive.)

Consumption Patterns

Information on consumption levels of soft drinks within the UK is mostly derived from three sources: the National Food Survey, the Dietary and Nutritional Survey of British Adults, and individual dietary surveys which are reported in the scientific literature. The UK National Food Survey omits foods which are bought for consumption outside the home. Information on soft drinks brought into the home is recorded but this information is not included in the major analysis of the survey data and is reported separately. Together with alcoholic drinks, sweets, and chocolate, for which no information is collected, soft drinks are often bought without the knowledge of the householder and are therefore liable to be underreported. Individual surveys have focused little on soft drink consumption in adults, although there is more information available on children's eating habits in this respect. The consumption of diet and other soft drinks was reported in the Dietary and Nutritional Survey of British Adults (Table 2).

The consumption of soft drinks in all age groups continues to increase and in 1989 was reported to be

Table 2 Consumption (grams per week) of soft drinks by adults by age

Drink	*Age (years)*			
	16–24	*25–34*	*35–49*	*50–65*
Low-calorie	778 (18)	1039 (17)	743 (16)	837 (12)
Other	1689 (82)	1073 (68)	889 (56)	667 (47)

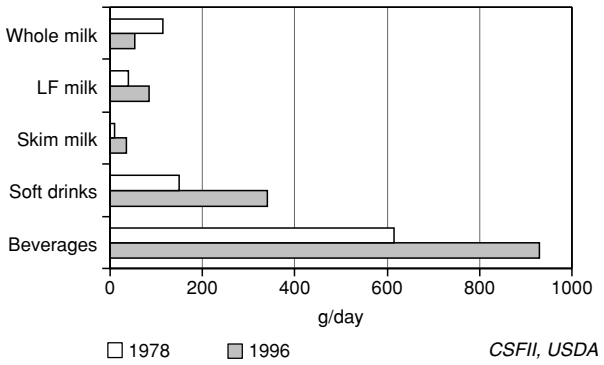

Figure 1 Trends in liquid food and beverage intakes in the US, 1978 and 1996. Data from the US Department of Agriculture, continuing Survey of Food Intake by individuals.

7524 million liters per year, with a total market value of £4.7 billion. This figure excludes the consumption of the increasingly popular fresh fruit juices. Consumption levels as reported in the UK National Food Survey can be seen in Table 3 and Figure 1.

While meal patterns still conform to what could be considered traditional, there is nevertheless a shift towards greater emphasis on snacking, particularly amongst younger age groups. Concern has been voiced regarding the nutritional quality of the diets of schoolchildren and snack eating in particular has been singled out as providing 'empty calories' but little else in the way of nutrients. Soft drinks are very popular amongst children of all age groups and

are frequently consumed between meals. (*See* **Snack Foods**: Dietary Importance.)

Contribution of Soft Drinks to Nutrient Intake in Schoolchildren

As many soft drinks are a source of energy, there is concern that children may obtain a significant proportion of their total daily energy requirement from the sugar contained within soft drinks. However, there is little published evidence to support this. In the scientific literature soft drinks have been reported to provide between 0.7% and 4.8% of total daily energy intake. With the increasing popularity of soft drinks, the wider variety of those available, and powerful advertising, it may be possible that children will reduce the nutrient density of their diet and be nutritionally at risk by consuming large quantities of soft drinks, replacing perhaps more nutrient-dense foods and liquids such as milk. A dietary study of 143 schoolchildren aged 11–12 years examined food consumption and nutrient intake using the 7-day dietary record technique. Soft drinks, confectionery, and table sugar contributed 10% of dietary energy and 40% of the sugar in the diet. Soft drinks were consumed at 1800 g per head each week, providing 4.7% of total energy intake and contributing 21.4% to total sugar intake. These values compare well with values obtained in the survey of British schoolchildren, where the mean consumption of soft drinks was 1775 g per head per week. There was no evidence from the anthropometric data that a high percentage of energy from sugar was associated with obesity. In fact, the average body mass index was lowest in the groups with the highest percentage of sugar intake, hence the putative effect of percentage of energy from sugar on body weight was not demonstrated in this study.

In another study investigating 11–14-year-old Northumbrian children, added sugars contributed on average 15% of dietary energy and 69% of total sugar intake. Soft drinks contributed 3% of energy and 17% of total sugar intake.

It has been estimated that if half the soft drinks consumed were sweetened with artificial sweeteeners alone, sugar consumption would fall by about 10%. Soft drinks are very popular with young children and are universally consumed, with 85–95% of those children surveyed in the UK study consuming these items during the study period. Soft drinks are without doubt one of the most commonly selected snacks amongst schoolchildren and it is reported that children find it difficult to rank fizzy drinks as either healthy or unhealthy and that they make their choice according to taste preference. (*See* **Children**: Nutritional Requirements; **Obesity**: Etiology and Diagnosis.)

In the British study of 15–18-year-olds there was an apparent decline in the consumption of soft drinks with increasing age. Average consumption fell from 200 to 155 g and 220 to 145 g soft drinks per day for female and male subjects, respectively. By adulthood the consumption of soft drinks has fallen markedly (Table 2).

Further studies are required to examine changing dietary patterns and the influence of increased soft drink consumption on total energy intake and nutrient density.

Product for Specific Uses

Diabetic Drinks

There are a number of soft drinks which are sold specifically for use by individuals with diabetes mellitus. By law these must not contain any sugars other than fructose, which is metabolized mainly in the liver, the initial steps in its metabolism being independent of insulin. Some products are sweetened with sugar alcohols (sorbitol, xylitol, mannitol, lactitol) but these offer no advantage over fructose and do not result in a reduced-energy drink. It has been suggested that the daily intake of sugar alcohols should not exceed 25 g as this may result in osmotic diarrhea. There is also an increasing number of low-calorie drinks in which the sugar has been replaced either wholly or in part by an intense sweetener, reducing the energy content significantly. The nature of these drinks enables those on reduced-energy diets to consume them without adding significantly to their energy intake.

The need for dietetic products of this nature is recognized by the provisions of the UK Soft Drinks Regulations (1964, as amended), which exempt low-calorie soft drinks from limitations imposed on the saccharin content of soft drinks in general. The

Table 3 Purchase quantity of soft drinks

Drink	*Quantity purchased (ml (fl. oz) per person per week)*				
	1984	*1987*	*1988*	*1989*	*1990*
Low-calorie	26 (0.91)	58 (2.04)	78 (2.74)	109 (3.85)	129 (4.55)
All soft drinks	844 (29.7)	855 (30.1)	886 (31.2)	1020 (35.9)	1071 (37.7)

Data from *Household Food Consumption and Expenditure* 1990 (with a study of trends over the period 1940–1990), Ministry of Agriculture, Fisheries and Food, UK; *Annual Report of the National Food Survey Committee*. London: HMSO, 1991.

relatively low caloric limits (22 kJ (5 kcal) per 100 ml) imposed on soft drinks compared with other foods make it virtually impossible to include carbohydrate sweeteners in low-calorie soft drinks. (*See* **Saccharin; Sugar Alcohols**.)

Sports Drinks

A range of foods, drinks, and supplements has been launched to fill the requirements of the 'get-fit' craze for consumption before, during, and after exercise. A relatively new phenomenon, these drinks are promoted as being designed to replace water and electrolytes lost through sweating during exercise. Most of the drinks are mixtures of sugar, salt, potassium, and water with a little vitamin C. Some of these drinks claim to be isotonic and some hypotonic. Dehydration does impair performance and therefore anything which decreases dehydration will maintain optimum performance for longer, although rehydration does not improve performance *per se*. In many circumstances water would be an acceptable alternative.

Infant Drinks

Infant drinks, including baby herbal drinks, have been developed to provide a thirst-quenching drink to coincide with the reduced consumption of milk that occurs in the first year of life. Although manufacturers are obliged to recognize that cooled, boiled water is the best refreshment to offer infants, they suggest that many will refuse this and offer their products as an alternative. The infant drinks are lower in sugar than baby fruit juices and unsweetened orange juice and usually provide the recommended daily intake of vitamin C. Potassium citrate is added as an acidity regulator, reducing the intensity of any acid, and infant drinks are of lower osmolality than conventional baby fruit juices. Health educators suggest that after the age of 6 months babies can be offered regular cows' milk or diluted natural fruit juice or water as a refreshment. (*See* **Infants**: Nutritional Requirements.)

Soft Drinks and Health

Dental Caries

Extensive evidence suggests that sugars are the most important dietary factor in the etiology of dental caries. Caries experience is positively related to the amount of nonmilk extrinsic sugars in the diet and the frequency of their consumption. Dental caries is dependent upon bacterial growth on the tooth surface, metabolism of sugars in the mouth by these bacteria, and the formation of acid which attacks the teeth. It is well known that one of the main etiological factors is the length of time sugar is in the mouth. (*See* **Dental Disease**: Role of Diet.)

In younger age groups there has been a shift away from traditional eating patterns of three or four meals per day towards an increasing reliance on snack foods, fast foods, and convenience foods accompanied by a range of sweetened or naturally sweet soft drinks consumed at frequent intervals throughout the day. There is therefore particular concern about the effect of soft drink consumption on dental health. Excessive use of soft drinks has been attacked on two accounts: first, almost all of them are fruit-based or carbonated or both and may therefore be acidic enough to erode the surfaces of the teeth not covered by dental plaque. Second, those which contain fermentable carbohydrate may serve as a source of substrate diffusing into the dental plaque, from which microorganisms inhabiting the plaque can generate acid which, in turn, brings about the destruction process of dental caries.

Carbonated drinks appear to be less cariogenic than pure orange juice and apple juice drinks and erosiveness may be more important than cariogenicity. Many soft drinks do contain sugars and, if allowed to reside in the mouth over long periods of time, as part of a frequent, protracted sugar intake pattern, then it is likely that they will be able to contribute to the caries process in which sugars serve as a substrate for acid formation.

Protective factors such as calcium and phosphorus may help to limit demineralization of teeth. In studies where iced lollies were fortified with calcium and phosphorus, this supplement substantially improved dental properties. Use of intense sweeteners in soft drinks reduces their viscosity and may assist in shortening exposure time.

SORGHUM

L W Rooney, Texas A&M University, TX, USA
S O Serna Saldivar, Instituto Tecnologico y de Estudios Superiores de Monterrey, Monterrey N. L., Mexico

Introduction

In terms of total world production, sorghum (*Sorghum bicolor L* Moench) is ranked fifth among cereals, with 62.7×10^6 tonnes in 1999. Production of sorghum is greatest in the USA, Nigeria, Mexico, India, China, Sudan, Ethiopia, and Argentina, but also occurs in other countries. Most African and Asian countries use sorghum for food, feed, forage, fuel, and building material. In the western hemisphere and Australia, sorghum is used mainly for feed and forage. Speciality types are used for syrup, sugar and alcohol. (*See* **Cereals**: Contribution to the Diet.)

The sorghum plant originated in the northeast quadrant of Africa. It belongs to the Gramineae family, Panicoideae subfamily, and Andropogeneae tribe. It is a warm-season, annual crop, favored by high day and night temperatures and intolerant to low temperatures. Improved types germinate, mature, and yield grain in an average of 120–140 days. Sorghum plants range in height from 0.6 to 6 m and possess an imperfect complete flower that generally self-pollinates. The grain develops on a branched terminal panicle that can be compact or very open. Flowering proceeds from the top of the panicle downward, with each panicle containing 800–3000 caryopses.

An enormous range in morphological diversity exists in the sorghum crop. The World Sorghum Collection in India has more than 29 000 entries. Sorghum is classed as grain sorghum, forage sorghum, grass or Sudan sorghums, and broomcorn. The latter is grown for its long, fibrous panicle branches that are used to manufacture brooms. The grain of sorghum is classed according to pericarp color (white, yellow, or red), presence or absence of a pigmented testa (with or without tannins), pericarp thickness (thin or thick pericarp), endosperm color (white, heteroyellow, or yellow), and endosperm type (normal, heterowaxy, or waxy). These kernel characteristics are genetically controlled. Brown sorghums have a pigmented testa and contain tannins; they may have any color pericarp.

Grain Structure and Physical Properties

The sorghum kernel is considered a naked caryopsis, although some African types retain their glumes after threshing. The kernel weight varies from 3 to 80 mg. The size and shape of the grain vary widely among sorghum races. Commercial sorghum grain has a flattened spherical shape, 4 mm long, 2 mm wide and 2.5 mm thick, with a kernel weight of 25–35 mg. The volumetric weight and grain density range from 708 to 760 kg m^{-3} and from 1.26 to 1.38 g cm^{-3}, respectively.

The sorghum caryopsis is composed of three anatomical parts: pericarp, endosperm, and germ (**Figure 1a**). The relative proportion of these structures varies but in most cases is 6, 84, and 10%, respectively. The pericarp (**Figure 1b**) is the fruit coat and is fused to the sorghum seed. It originates from the ovary wall and is subdivided into three distinctive parts: epicarp, mesocarp, and endocarp. The epicarp is the outermost layer and is generally covered with a waxy film. The mesocarp varies in thickness and can contain starch granules. The endocarp is composed of cross and tube cells and plays a major role during germination. (*See* **Wheat**: Grain Structure of Wheat and Wheat-based Products.)

The true seed consists of the seed coat or testa, endosperm, and germ. The endosperm tissue is triploid, resulting from the fusion of a male gamete with two female polar nuclei. The testa, or seed coat, is derived from the ovule integuments; in brown

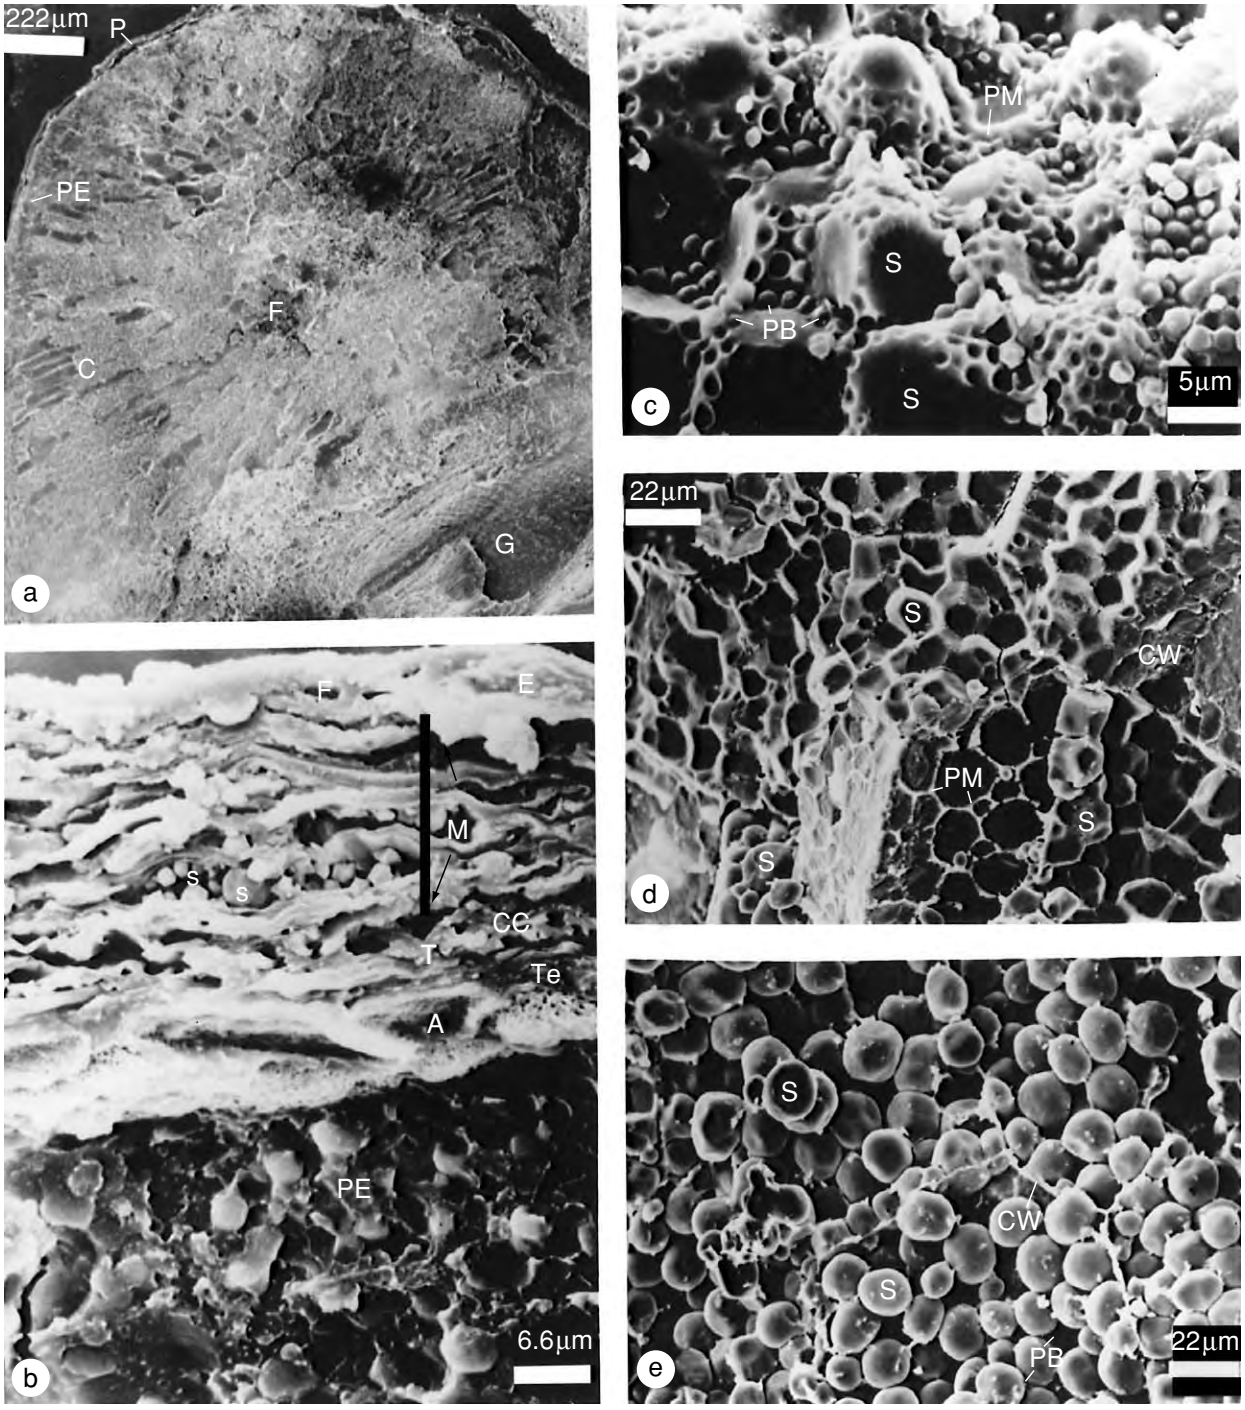

Figure 1 Structure of the mature sorghum kernel viewed with the scanning electron microscope. (a) Cross-section, (b) pericarp, (c) peripheral endosperm, (d) corneous endosperm, and (e) floury endosperm. From Rooney LW and Serna-Saldivar SO (2000).

sorghums, it is thick and contains condensed tannins. The testa is pigmented when the genetics are B_1-B_2-. The endosperm is composed of the aleurone layer, peripheral, corneous, and floury areas. The aleurone consists of a single layer of rectangular cells adjacent to the tube cells or testa. Aleurone cells contain a thick cell wall, large amounts of proteins (protein bodies) and enzymes, ash (phytic acid bodies), and oil bodies (spherosomes). The peripheral endosperm (Figure 1c) adjacent to the aleurone layer is composed

of dense cells containing large quantities of protein and small starch granules. These layers affect the processing and nutrient digestibilities of sorghum. Processing of sorghum by steam flaking, micronizing, popping, and reconstitution is designed to disrupt the endosperm structure to improve the digestibility.

The corneous and floury endosperm cells are composed of starch granules, protein matrix, protein bodies and a thin cell wall rich in β-glucans and hemicellulose. In the corneous endosperm, the protein matrix has a continuous interphase with the starch granules, with protein bodies embedded in the matrix (Figure 1d). The starch granules are shaped polygonally and often contain dents from protein bodies. The appearance is translucent or vitreous. The opaque-floury endosperm is located around the geometric center of the kernel. It has a discontinuous protein phase, air voids, and loosely packaged, round-lenticular starch granules, and is opaque to transmitted light (Figure 1e).

The germ is diploid owing to the sexual union of one male and one female gamete. It is divided into two major parts: the embryonic axis and scutellum. The embryonic axis forms the new plant and is subdivided into a radicle and plumule. The radicle forms primary roots, whereas the plumule forms leaves and stems. The scutellum is the single cotyledon of the sorghum seed. It contains large amounts of oil (spherosomes), protein, enzymes, and minerals, and serves as the connection between the endosperm and germ.

[b]Calculated by difference.
[c]FAO/WHO suggested pattern (g amino acid per 100 g protein): lysine, 5.44; leucine, 7.04; phenylalanine plus tyrosine, 6.08; valine, 4.96; tryptophan, 0.96; methionine plus cysteine, 3.52; threonine, 4.0; isoleucine, 4.0.

Composition

Sorghum grain composition (Table 1) varies significantly, owing to genetic and environmental influences, and is similar to that of maize (*Zea mays* L). Starch (75–79%) is the major component, followed by protein (9.0–14.1%) and oil (2.1–5.0%). The protein content (N × 6.25) of sorghum is more variable and usually 1–2% higher than maize. Approximately 80, 16, and 3% of the protein is in the endosperm, germ, and pericarp, respectively. Sorghum generally contains 1% less oil and significantly more waxes than maize. (*See* **Cereals**: Dietary Importance.)

Sorghum starch is composed of 70–80% amylopectin and 20–30% amylose. Waxy sorghums contain starch with 100% amylopectin; their properties and uses are similar to those of waxy maize. The gelatinization temperature of sorghum starch is slightly higher than that of maize starch. (*See* **Starch**: Structure, Properties, and Determination.)

The main protein fraction in the kernel is the prolamines (kafrins), followed by glutelins (Table 1). The alcohol-soluble prolamine fraction comprises 50% of the protein. These proteins are hydrophobic, rich in proline, aspartic, and glutamic acids, and contain little lysine. They are mainly found in protein bodies and are affected by nitrogen fertilization. Glutelins are high-molecular-weight proteins, mainly located in the protein matrix. The lysine-rich protein fractions – albumins and globulins – predominate in the germ. High-lysine sorghums, such as P-721 and certain Ethiopian types, contain lower levels of kafrins and higher levels of albumins and globulins. The higher-lysine sorghum varieties are soft or dented, and are not produced commercially. (*See* **Protein**: Chemistry.)

Most of the fiber is present in the pericarp and cell walls. Aleurone and endosperm cell walls are associated with ferulic and caffeic acid. Around 85% of the dietary fiber is insoluble and mainly composed of hemicellulose and cellulose. The soluble fraction is rich in pentosans and β-glucans. Sorghum contains approximately 1.3% pentosans, located mainly in the pericarp. Approximately 70% of the pentosans are alkali-soluble, and some 30% are water-soluble. (*See* **Dietary Fiber**: Properties and Sources.)

The germ and the aleurone layer are the main contributors to the lipid fraction. The germ provides about

80% of the oil. The fatty acid composition consists mainly of linoleic (49%), oleic (31%) and palmitic (14.3%) acids. Refined sorghum oil is very similar to maize oil in quality. (*See* **Fatty Acids**: Properties.)

Most of the minerals are concentrated in the pericarp, aleurone, and germ. The ash fraction is rich in phosphorus and potassium and low in calcium and sodium. Most of the phosphorus is bound to phytic acid. The germ and aleurone are rich in fat-soluble and B vitamins. Precursors of vitamin A or carotenes are found only in yellow and heteroyellow endosperm cultivars. (*Refer to* individual vitamins and minerals.)

All sorghums contain phenolic acids, and most contain flavonoids, but only brown sorghums contain condensed tannins. Tannins protect the kernel against preharvest germination and attack by insects, birds, and molds. Brown sorghums always have a pigmented testa (genes B_1-B_2-ss) and some have tannins in the pericarp (B_1-B_2S-). Sorghums without a pigmented testa do not contain any condensed tannins. Birds can and do consume brown sorghums when other food is unavailable. (*See* **Tannins and Polyphenols**.)

Uses of Grain

Milling

Thirty percent of world sorghum production is for human consumption. For production of most traditional foods, sorghum is first dehulled with a wooden mortar and pestle. For decortication, the grain is usually washed, placed in the mortar, and pounded vigorously with the pestle. The abrasive action frees the pericarp from the kernel. The pericarp usually detaches at the mesocarp. Thick pericarp cultivars, with hard endosperm and round kernels, are preferred for decortication. The bran or pericarp is separated from the grain by washing with water or by winnowing the sun-dried grain. Most sorghums are decorticated to remove 10–30% of the original grain weight. Mechanical decortication with rice milling equipment or abrasive disks is becoming more popular. The decorticated kernels are reduced into flour by pounding in the mortar and pestle, with stone mills or by diesel-powered attrition mills. Flour is sieved to obtain fractions with an acceptable particle size for specific products.

Commercial milling of sorghum is practiced in several countries. The sorghum is decorticated using abrasive pearlers, followed by degermination and subsequent sieving, milling, gravity separation, and sieving to produce low-fat grits, meal, and flour. Milling of sorghum with wheat roller mills produces acceptable flour and other products.

Traditional Food Uses

The major categories of traditional foods are as follows: fermented and unfermented flat breads; fermented and unfermented thin and thick porridges; steamed and boiled products; snack foods and alcoholic and nonalcoholic beverages. World-wide, the most popular unfermented flat breads are roti in India and tortillas in Central America. For roti, a portion of the flour is gelatinized, mixed with more flour, and warm water and kneaded into a dough, which is shaped or rolled into a circle and baked on a hot griddle. For tortilla production, whole sorghum is limecooked, steeped overnight, washed, stone-ground into a dough, shaped into thin circles, and baked on a hot griddle. (*See* **Chapatis and Related Products**; **Tortillas**.)

The most popular fermented breads are injera, kisra, and dosa, consumed in Ethiopia, Sudan, and India, respectively. About 80% of the Ethiopian sorghum is used for the production of injera. The sorghum flour is mixed with water and a yeast starter from a previous batch of injera. After fermentation for 24–48 h, the batter is poured onto a greased pan for baking. The resulting product is a flexible, brown pancake containing uniformly distributed fish eyes or air bubbles. Dosa is consumed in India and is produced from a mixture of black gram, sorghum, and rice flour.

Porridges can be fermented or cooked with acid or alkali. Tô is an unfermented stiff porridge, very popular in Mali and Burkina Faso. Decorticated sorghum flour is cooked in plain water or water acidified with tamarind juice or made alkaline with wood ashes (potash). The most popular fermented porridges are ogi and nasha, widely consumed in West and East Africa, respectively. Whole sorghum is soaked in water and allowed to ferment for 2–3 days. The wet grain is crushed in a slurry of water and sieved to remove the bran. The fine particles are allowed to ferment longer. Excess water is decanted and the resulting slurry cooked in water or milk.

For couscous production, sorghum flour is kneaded with enough water to form agglomerates. The particles are forced through a coarse screen and steamed. The cooked product is consumed with a sauce or milk.

Decorticated sorghums are often cooked like rice. Special types of small-seeded, very hard sorghums are used as a substitute for rice.

Two major kinds of alcoholic beverages are produced from malted sorghum. The most common type, called opaque beer, undergoes souring and yeast fermentation and is very popular in southern Africa. The high-solids beer is sour, alcoholic, pinkish and

effervescent. (*See* **Fermented Foods**: Beverages from Sorghum and Millet.)

Industrial Uses

Sorghum grain or sweet sorghum biomass is used for ethanol production. Yields of alcohol (182° proof) per tonne of sorghum grain are comparable with maize (387 vs 372 l). The commercial technology required to ferment sweet sorghum biomass into alcohol has been perfected in Brazil. One tonne of sweet sorghum biomass has the potential to yield 74 l of 200° proof alcohol.

In Southern and West Africa, sorghum malt is used for alcoholic and nonalcoholic beverages, weaning foods, and breakfast foods. Sour-opaque beers are produced commercially in Southern Africa. Opaque beer is produced following the basic steps of the traditional process. Breweries in Mexico, Africa, and Asia use sorghum grits as an adjunct in brewing lager beer. In Nigeria, sorghum and maize are used to produce lager or clear beer without barley malt. Nigerian breweries produce clear beer from a combination of malted sorghum, sorghum, and/or maize grits with commercial enzymes to convert the starch to fermentable sugars because sorghum malt has a low diastatic power. The quality of clear beer is good, but the taste differs from barley malt beer.

Sorghum grits, meal, and flour can be used alone or mixed with wheat flour to produce an array of baked goods. Sorghum does not contain gluten. Thus, the amounts of sorghum flour in the blends depend on the quality of the wheat flour, baking procedure, formulation, and quality of the baked products desired. New food-type sorghums that produce excellent yields of flour with a bland flavor and light color are available. They can be used to extend wheat-based products without affecting flavor. (*See* **Flour**: Dietary Importance.)

Sorghum can be puffed, popped, shredded, and flaked to produce ready-to-eat breakfast cereals. Extrusion of sorghum produces acceptable snacks and precooked products. (*See* **Cereals**: Breakfast Cereals.)

In the Sudan, sorghum is wet-milled to produce starch with properties and uses similar to those of maize starch. Commercial wet milling of sorghum in the USA was discontinued in the 1970s because of poor economics. The enzymatic conversion of starch to liquid glucose syrup is possible.

Nutritional Value

Sorghum is an excellent feed for livestock and companion animals. The feeding value of sorghum for livestock species is generally considered 95% or more of the feeding value of yellow dent maize. Brown sorghums are considered to have 80–85% the feeding value of maize. Sorghum must be properly processed to enhance its digestibility. Popping, steam flaking, and reconstitution are used to prepare sorghum grain in beef cattle feedlots in the USA. Grinding, rolling, crushing, and pelleting are used for poultry and swine feeds.

Sorghum has a proximate composition, amino acid contents, and nutritional value similar to those of maize. However, due to its lower fat content, sorghum usually has a slightly lower gross, digestible, and metabolizable energy. Lysine and threonine are the first and second limiting amino acids. The tryptophan content is higher than that in maize. High-lysine cultivars contain approximately 50% more lysine and promote better weight gains in weaning rats. Fermentation, malting, and other processing methods improve the nutritional value significantly. (*See* **Amino Acids**: Properties and Occurrence.)

Most sorghum hybrids do not contain condensed tannins in contrast to impressions given in some publications. Kernels that contain condensed tannins have a clearly pigmented, thick testa. These sorghums are classed as brown or tannin sorghums. The brown sorghums are grown in some areas where birds and molds are major problems. Birds will consume brown sorghums when other foods are scarce. Animals fed brown sorghum rations eat more feed and produce about the same amount of gain so feed efficiency is reduced significantly.

SOY (SOYA) BEAN OIL

F D Gunstone, Scottish Crop Research Institute, Invergowrie, Dundee, UK

Background

Soybean is the oilseed produced in the largest amounts. The extracted oil is also produced in the largest amounts, though in the next 10–15 years, the supply of palm oil is expected to exceed that of soybean oil. Soybean meal is the dominant oilseed source of high-quality protein for both human and animal use. Other entries in this Encyclopedia deal with the bean and its protein product: this section is concerned with soybean oil. Some advantages and disadvantages have been claimed for this oil. It is widely used on the basis of its advantages, and much effort is devoted to overcoming its alleged disadvantages. The advantages are its high unsaturation, its richness in essential fatty acids, its liquid nature over a wide temperature range, its extensive use as a pourable semisolid oil after partial hydrogenation, and its value as a rich source of phospholipids, antioxidants, and sterols. Its disadvantages include the need to process it to remove phospholipids before use and the presence of linolenic acid, which is considered to promote oxidative instability and to be the cause of the rapid development of off-flavors, which limit shelf-life.

Oil Extraction and Refining

Beans are cleaned, dried to about 10% moisture, dehulled, and flaked before extraction with solvent (isohexane or hexane) by percolation or immersion. Oil/solvent is separated from meal/solvent, and the solvent is removed and recovered for reuse from both fractions. The crude oil is then refined by degumming to remove and recover phospholipids, neutralizing to remove free acids, bleaching to remove undesirable colours, and deodorizing to remove unwanted odor and flavor compounds. These processes, and particularly the last, should be carried out at as low a temperature as possible. Formation of *trans* isomers is negligible below 220 °C, becomes significant between 220 and 240 °C, and rises rapidly with respect to temperature above 240 °C. Some 3–24% of the linolenic present may be isomerized, but linoleic acid is less reactive, and isomerization does not usually exceed 2%.

$$9c12c15c \rightarrow 9t12c15c \text{ and } 9c12c15t \text{ and } 9t12c15t.$$

These processes produce a high-quality bland oil, though for several uses, it may also be necessary to effect some degree of hydrogenation. Very light hydrogenation (brush hydrogenation) is used to reduce the level of linolenic acid to about 3%. This has the advantage of extending the shelf-life of food products containing this material, as linolenic acid is oxidized about twice as quickly as linoleic acid and gives rise to oxidation products with a greater off-taste and off-odor than those resulting from linoleic acid. More extensive hydrogenation is designed to increase the melting point of the oil, so that it can be used to make plastic semisolid fats. This is achieved by raising the levels of acids with melting points above ambient so that the triacylglycerols in which they are present are also solid. These acids are either saturated (stearic)

or monounsaturated acids with *trans* configuration. These changes also have nutritional consequences. The ratio of total dietary *n*-6 (linoleic acid and its metabolites) to total dietary *n*-3 acids (linolenic acid and its metabolites) is considered by many to be too high, with an excess of the former and a deficiency of the latter. This is exacerbated when valuable dietary linolenic acid is reduced through partial hydrogenation. Also, there is now nutritional concern about *trans* acids, and serious attempts are being made to reduce the dietary intake of such acids. (*See* **Vegetable Oils**: Oil Production and Processing.)

Composition of Soybean Oil

The following composition figures for soybean oil refer to the the crude and refined oils, respectively: triacylglycerols (95–97 and >99%), phospholipids (1.5–2.5 and 0.003–0.045%), free fatty acids (0.3–0.7 and <0.05%), plant sterols (0.33 and 0.13%), tocopherols (0.15–0.21 and 0.11–0.18%), iron (1.3 and 0.1–0.3 p.p.m.), and copper (0.03–0.05 and 0.02–0.06 p.p.m.). It is apparent that refining removes most of the phospholipids and free acids but only some of the sterols, tocopherols, and metals. The level of tocopherols remaining in the refined oil is sufficient to provide a measure of oxidative stability. Material removed during the refining process contains several products of commercial value to the food, cosmetics, and pharmaceutical industries. These include the phospholipids (lecithin), tocopherols (vitamin E), and sterols with these industries relying on the supply of each of these.

The following figures for refined soybean oil have been cited as target values: FFA (0.05 max), *trans* acids (1% max), moisture (0.05% max), impurities (nil), peroxide value (max 0.5 mEq O_2 kg^{-1}), phosphorus (max 1 p.p.m.), tocopherols (min 750 p.p.m.), total metal (max 0.1 p.p.m.), PAH (polycyclic aromatic hydrocarbons max 25 p.p.b.), colour 5.25 inches max (1.5R–10Y), cold test (min 48 h per °C), smoke point (min) 220 °C.

Fatty Acid Composition

Typical fatty acid composition data for soybean oil are listed given in Table 1. The oil is rich in linoleic acid (54%, Codex range 50–57%) and oleic acid (24%, Codex range 18–25%) but also contains palmitic (11%, Codex range 10–13%), stearic (4%), and linolenic acids (7%, Codex range 5–10%), with only traces of acids of other chain lengths. Attempts are being pursued both by traditional mutation seed-breeding methods and by genetic engineering to produce soybeans with different fatty acid compositions, including oil rich in lauric acid as an alternative to coconut and palmkernel oils, oil with less palmitic and stearic acid on dietary grounds, oil with more palmitic and/or stearic acid for use in solid (plastic) fats without hydrogenation (which adds cost and produces undesirable *trans* acids), oil with more oleic acid on dietary grounds, and oil with less linolenic acid to enhance the shelf-life without brush hydrogenation. Many such modified oils have been described, and a typical selection is reported in Table 1. Several of these are in an advanced stage of development, and it is likely that these, or materials akin to them, will become available soon. It is expected that they will carry a premium price, but details are not yet known.

Table 1 Fatty acid composition of commodity soybean oil and some modified soybean oils

	16:0	*18:0*	*18:1*	*18:2*	*18:3*
Commodity oil	11	4	24	54	7
High-oleic	11		81	4	4
Low-saturated	4	3	31	59	3
High-saturated	25	4	16	44	10
	24	19	9	38	10
	12	21	63	1	3
Low-linolenic	10	3	44	40	3

Soybean oil can be converted to a semisolid material by partial hydrogenation. For example, soybean oil of iodine value 133 can be converted to fats of iodine value ~80 and mp 30–37 °C depending on the conditions of hydrogenation. These materials contain 18:0 8–12% compared with 4% in the original oil, 18:1 63–72% (23%), 18:2 9–13% (53%), and 18:3 0–0.3% (7.4%). But these numerical changes in fatty acid composition do not fully convey the changes that have taken place for the partially hydrogenated oils contain 27–40% of *trans* acids, which will be mainly 18:1 with the *trans* double bond ranging from Δ6 to Δ16 but mainly Δ8 to Δ13. The *trans* acids have higher melting points than their *cis* isomers and thus contribute to the hardening process. (*See* **Fats**: Classification; **Fatty Acids**: Properties.)

Triacylglycerol Composition

Although most oils are traded and used according to their fatty acid composition, it is known that some properties are related to triacylglycerol composition. The following data are taken from a paper describing triacylglycerol composition for soybean oil and for several modified oils, but only the former is discussed here. The original paper must be consulted for other details.

Ignoring the minor components, the soybean oil under study had a fatty composition of palmitic (10.2%), stearic (4.1%), oleic (23.4%), linoleic (52.8%), linolenic (8.3%), and other acids (1.2%)

and was analyzed by appropriate methods to give 'individual' molecular species and also the distribution of fatty acids at the *sn*-1, 2, and 3 positions.

In terms of molecular species it is to be expected that in view of the high level of linoleic acid, the dominant triacylglycerol molecules will contain at least two linoleic chains, thus: LLLn (7.9%), LLL (17.6%), LLO (15.3%). LLSt (4.2%), and LLP (10.2%), making a total for this group of 55.2%. Other triacylglycerols include LnLnL (3.1%), LnLO (4.8%), LnLP (3.7%), LOO (6.3%), LOP (6.9%), PLL (3.1%), OOO (3.3%), LOSt (3.7%), OOP (3.4%), PLSt (3.1), others (3.4%) where Ln=linolenic, L=linoleic, O=oleic. St=stearic, and P=palmitic. These three-letter symbols indicate only the acids present, and not their position on the glycerol backbone, so that, for example, LLO represents three different isomers (LLO, LOL, and OLL), and LOP represents the sum of six isomers. These results were obtained by reverse-phase HPLC.

The stereospecific analysis of the soybean oil gives the results indicated in Table 2. As would be expected, the *sn*-2 position has enhanced levels of oleic and linolenic acid and lower levels of palmitic and stearic acid. The results for linolenic acid are somewhat unexpected, since all unsaturated acids are usually enhanced in the *sn*-2 position. The two sets of results for the *sn*-2 position agree reasonably well, except for oleic and linolenic acid, when allowance is made for the difficulties of these analytical procedures.

Other Components

The AOCS publication on 'Physical and Chemical Characteristics of Oils, Fats and Waxes' reports that crude soybean oil contains 1.8–4.1 mg per kilogram of sterols, which are mainly campesterol (16–24%), stigmasterol (16–19%), and β-sitosterol (52–58%). Tocopherol levels are given as 601–3363 mg kg^{-1} and include the α (9–352), β (0–36), γ (89–2307), and δ (154–932) forms. (*See* **Tocopherols**: Properties and Determination; **Vitamins**: Overview.)

Table 2 Stereospecific distribution of fatty acids in soybean oil

	Oil	*sn-1*	*sn-2*	*sn-3*	*sn-2*[a]
16:0	10.2	18.2	1.9	12.0	3.7

minors	1.2				

[a]Results obtained by pancreatic lipase hydrolysis; other results obtained by the method involving naphthylurethanes of diacylglycerols. The original paper includes more detail and similar data for modified soybean oils (Reske J, Siebrecht J and Hazebroek J (1997) Triacylglycerol composition and structure in genetically modified sunflower and soybean oils. *Journal of the American Oil Chemists' Society* 74: 989–998).

Physical Properties

The same publication lists the following physical and chemical properties properties: specific gravity at 20/20° 0.919–0.925, refractive index at 40 °C 1.466–1.470, iodine value 124–139, saponification value 189–195, unsaponifiable not above 1.5%.

Major Food Uses

Oils and fats are significant components of the diet contributing 30–40% of caloric intake. They are consumed in many different forms as: spreading or yellow fats (butter, margarine, industrial margarine, low-fat spreads), frying fats, salad oils, and mayonnaise, and as an essential component of baked goods. Refined soybean oil, before or after hydrogenation, is used in these. As indicated later (Table 3), its contribution is very high in the USA but somewhat lower in other countries. In many cases, blends of two or more oils are required to achieve the desired properties. When considering the relative nutritional merits of these preparations, it is important to note the extent to which the various components have been hydrogenated, that is to know the level of *trans* acids that they contain.

Mayonnaise must contain at least 65% oil and salad dressings at least 30%, though products with lower levels of fat are also produced. These products are generally refrigerated, so it is important that the oil does not crystallize and break the emulsion. It is therefore usual to use soybean oil that has been hydrogenated to IV 110–115 to reduce the level of linolenic acid and then winterized to remove components that would crystallize under refrigeration. Oils used for mayonnaise or salad dressings must remain clear when cooled in ice water (0 °C) for 5.5 h. Soybean oil treated as above remains clear, even after 24 h.

Table 3 Disappearance (million tonnes) of selected oils in USA, EU-15, China, India, and Japan in 1999/2000

	sbo	*sun*	*rape*	*palm*	*pko*	*coco*

China	2.87	0.25	4.52	1.37	0.02	0.05
India	1.55	0.82	1.94	3.38	0.02	0.44
Japan	0.69	0.01	0.93	0.36	0.05	0.06

sbo, soybean oil; sun, sunflower oil; pko, palmkernel oil; coco, coconut oil. Source: *Oil World Annual* (2000) Hamburg: ISTA Mielke.

Frying oils, particularly for the preparation of fried goods that will be stored, should not contain linolenic as this will shorten the shelf-life. For such products, it is usual to use a partially hydrogenated oil, and the hydrogenated–winterized oil developed for mayonnaise is often used for frying purposes also. For fast-food purposes, where long-term storage is not necessary, this additional processing of the oil is less important.

Margarines have to meet certain physical specifications, particularly in respect of their appearance and melting behavior between refrigerator (4 °C) and mouth temperature (37 °C) as well as nutritional guidelines. A variety of binary and ternary mixtures of soybean oil and of soybean oils hydrogenated to various iodine values have been used. The hydrogenated oils contain *trans* acids, and attempts are being made to reduce the level of these by developing procedures of hydrogenation that give less *trans* acids or by blending nonhydrogenated oil with 'hardstock,' which may be a fully hydrogenated oil or palm stearin. These products are improved by interesterification of the blended oils. (*See* **Margarine**: Types and Properties.)

Industrial margarines used in the baking industry need specific functionality. This requirement may take precedence over nutritional factors since labeling of baked goods does not include the content of *trans* fatty acids, and blends used for this purpose frequently contain hydrogenated soybean oils.

Shortenings or baking fats used for biscuits, biscuit fillings, and various kinds of pastry and bread have to vary in their fat composition depending on their end use and generally consist of blends of two or more hard and soft fats, some or all of which may be hydrogenated. Soybean oil and hydrogenated soybean oil can be components of these blends.

Market Data

Soybeans are used as beans in some animal feeds, but for the most part, they are crushed and extracted, either in the country of origin or after export to another country. Production of soybean oil is therefore not confined to those countries where the beans grow. Extraction of soybeans gives ~18% of oil, and the balance is seed meal, which is also an important commodity of world trade. The main countries that produce, export, import, and use soybean oil (for food or nonfood purposes) are shown in Table 4. The figures cited are millions of tonnes for the year 1999/2000. In respect of production, USA, Brazil, Argentina, and China grow and extract their own beans, though China is also a large importer of beans for local crushing. The other countries listed in Table 4 crush imported beans. Exports from some of the producing countries/regions go to a wide range of geographical locations, of which only the larger importing countries/regions are listed. Soybean oil is used in virtually every country in the world. The major consumers include the producing countries, except that Argentina has only a small population so that only limited quantities of oil are consumed locally.

As the major grower of soybeans, the major producer of soybean oil, and the major consumer of the oil, the USA is a special case. The following information is taken from SoyStats published by The United Soybean Board (America). Edible oil consumed in the USA is almost entirely soybean oil, as is apparent from the following figures for 1999: total oil 6.93 million tonnes, including soybean (5.73), corn (0.23), rapeseed (0.22), cottonseed (0.18), lard (0.13), other (0.31). Thus, soybean oil represents 82.6% of US consumption, and no other oil exceeds 3.3%. The oil is consumed in a refined state, but much of it is hydrogenated to a greater or lesser extent before use. With brush hydrogenation, the level of linolenic acid is reduced to around 3%, but otherwise, the oil is hardly changed. With more extensive hydrogenation, linoleic and linolenic acids decline in level, and saturated acids and *trans* monoene acids increase. Soybean oil is consumed in the USA mainly in salad and cooking oils (~47%), for baking and frying (~36%), and in margarine production (~12%).

Table 4 Production, exports, imports, and consumption (million tonnes) in 1999/2000 by country/region

	Total	*Major countries/regions*
Production	25.21	USA 8.15, Brazil 4.24, Argentina 3.10, EU-15 2.87, China 2.20, Japan 0.69. Taiwan 0.41
Exports	7.15	EU-15 1.00, Argentina 3.00, Brazil 1.49, USA 0.58
Imports	7.21	Iran 0.82, China 0.80, India 0.74, Bangladesh 0.47, Pakistan 0.28, former USSR 0.24, Venezuela 0.25, Morocco 0.23
Consumption (food and nonfood use)	25.02	USA 7.42, Brazil 2.88, China 2.87, EU-15 1.88, India 1.55, Mexico 0.71, Japan 0.69, Iran 0.67, Taiwan 0.47, Bangladesh 0.46, South Korea 0.33, former USSR 0.33, Pakistan 0.32, Venezuela 0.29, Canada 0.29, Mexico 0.26

SOY (SOYA) BEANS

Contents

The Crop

H E Snyder, University of Arkansas, Fayetteville, AR, USA

Production

The soya bean originated in the Far East and has provided food for that part of the world for thousands of years, but only during the past few decades have soya beans become an important food crop in the West. **Table 1** shows how the production of soya beans has increased since 1940. The newly recognized value of the soya bean is in both the extracted oil and the residual high-protein meal. The oil is widely used as a food in margarines, shortenings, and salad oils. The meal is valuable for its high-protein content as an animal feed, particularly for poultry and swine.

Table 1 Soya bean production ($\times 10^6$ t) by major countries during the past 50 years

	1940	*1950*	*1960*	*1970*	*1980*	*1990*
USA	2.1	7.8	16.3	30.7	48.7	52.4
Brazil				2.1	15.5	20.0
China	9.7	4.9[a]	7.0	9.7	7.9	10.8
Argentina					3.4	10.5
World	11.9	17.8	28.1	45.2	81.2	107.1

[a]Data for 1948.

The USA, Brazil, China, and Argentina produce 87% of the world's soya beans. China has been a major producer for a long time, but the USA reached that status only in the 1940s, and Brazil and Argentina only since the 1970s.

In comparison with grain production, annual soya bean production of about 100×10^6 t is not large. World production of coarse grains (maize, sorghum, etc.) is about 800×10^6 t, while rice and wheat amount to about 450×10^6t each. Soya beans per unit weight are worth about twice as much as grains. (*See* **Cereals:** Contribution to the Diet.)

Soya beans are the predominant oilseed in the world. About half of the world oilseed production comes from soya beans, and this is more than the combined production of the next four oilseeds: cottonseed, peanut, sunflower, and rapeseed (canola). Oilseeds vary widely in total oil content; the annual vegetable oil production therefore differs from oilseed production. **Table 2** shows vegetable oil production for the world during the 1980s. Palm oil comes from palm fruit and is not classified as an oilseed, but palm oil is produced in the largest quantities next to soya

Table 2 World vegetable oil production ($\times 10^6$ t)

	1980	*1982*	*1984*	*1986*	*1988*
Soya bean	12.8	13.8	13.4	14.8	15.0

bean oil. Most of the vegetable oils are increasing in production to keep up with world demand, but cottonseed, coconut, and olive oil production are relatively stable. (*See* **Ground Nut Oil; Palm Oil.**)

The increased use of vegetable oils for foods parallels the growth of soya bean production. In the 1920s, animal fats were predominant in human diets, but since the 1940s, vegetable oils have steadily replaced animal fats. The particular vegetable oil that is used depends on the country. Soya bean oil makes up about 75% of vegetable oil use for food in the USA. Peanut oil is the oil of choice in India, and rapeseed oil is important in Canada.

Soya beans are annual legumes and were used at first in the USA as a hay crop. Since legumes are nitrogen-fixing plants, the hay crop could be used in rotation with corn to replenish soil nitrogen. With increased use of nitrogen fertilizers, the value of soya beans for their nitrogen fixation decreased.

Most of the spectacular recent increase in production in the USA and South America (Table 1) is due to increased area devoted to growing soya beans. There has been a slow but definite increase in yield per unit area, with an approximate doubling since 1940 to 2 t ha^{-1} in 1990 in the USA.

The problems that producers face in trying to increase yields of soya beans are the same as with any agronomic crop. Pests such as birds and rodents may eat planted seeds; diseases may slow down the growth of roots, stems, or leaves; insects can cause damage as well as transmit diseases; weeds compete for moisture, soil nutrients, and sunlight.

The flowers of soya beans are small and inconspicuous, making it difficult to produce hybrid seed. Under normal conditions, soya beans are self-fertilizing. The time of flowering is triggered by lengthening nights, and different soya cultivars (cultivated varieties) respond to different night lengths. Thus, it is important to select the proper cultivar for the latitude in which it will be grown. If a cultivar from southern latitudes is grown farther north, it will not flower until late in the season and may freeze before the seed matures. Conversely, northern cultivars grown in southern latitudes may flower before the plant has reached full growth, thus greatly reducing yield.

Morphology

Soya beans can range in weight from about 100 to 300 mg each, with diameters of 4–8 mm. They are roughly spherical in shape when dry and swell to a definite bean or kidney shape when wet. The morphological features of the whole bean (Figure 1) are the hilum (point of attachment to the pod), the micropyle (a small opening through which the germ tube grew), and the chalaza (a small groove opposite the hilum from the micropyle).

The seed coat makes up about 9% of the weight of soya beans and tightly encloses the two cotyledons and embryo. The seed coat is not easily separable from the intact dry seed, but if the seed is broken or if it imbibes water, the seed coat separates readily. The morphological features noted above (hilum, micropyle, and chalaza) are part of the seed coat, which

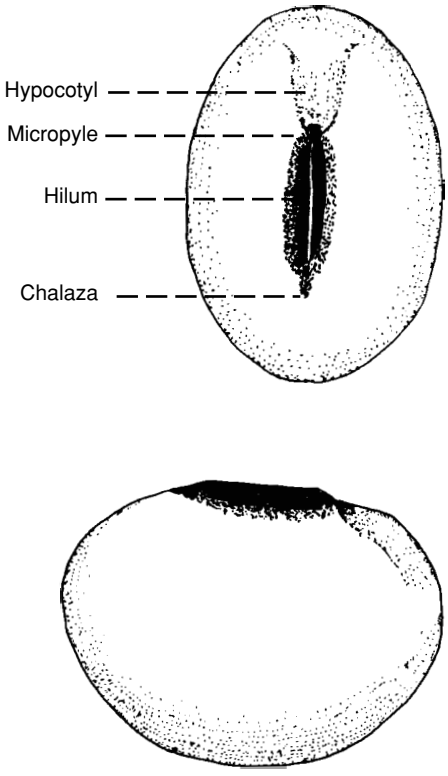

Figure 1 Morphological features of whole, mature soya beans. The features shown are associated with the seed coat or hull. Reproduced from Soya Beans: The Crop, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

may be yellow, green, brown, or black, but the cotyledons are green or yellow. United States grading standards discriminate against brown and black soya beans. Since very little oil is present in the seed coat, it is removed before oil extraction and may or may not be added back to the defatted meal used as animal feed.

Several layers of cells make up the seed coat, and cells of a distinctive type, termed hourglass cells because of their shape, are readily distinguishable by light microscopy. The hourglass cells can be used as qualitative markers to determine whether or not soya bean meal has been added to other foods.

If soya beans are soaked in cold water, a few, perhaps 1%, fail to imbibe water and are called 'hard seeded.' The failure to imbibe water is a property of the seed coat being completely intact and is probably due to the outermost waxy layer, termed the cuticle.

The two cotyledons make up 90% of the soya bean. The cotyledon cells are packed with protein bodies and lipid bodies, the two principal organelles (Figure 2). Early in the maturity of the cotyledons, starch granules are prominent, but they decrease to less than 1% of weight as beans mature.

Protein bodies are 2–20 μm in diameter and contain principally the glycinin and conglycinin storage proteins. Protein bodies are osmotically fragile but can be isolated by using high-osmotic-strength buffers at pH 5. In addition, heating (soaking soya beans for a few minutes in boiling water) causes protein bodies to be heat-fixed and not to disperse in water.

Lipid bodies (0.2–0.5 μm) are much smaller than protein bodies and are the sites of oil storage. Centrifugation of broken cotyledon cells separates lipid bodies as a floating layer, but because of their phospholipid-protein membrane, the smallest lipid bodies sediment in a centrifugal field.

The hypocotyl of the soya bean has a different composition to that of the cotyledon (less oil and more carbohydrate), but since it makes up only about 2.5% of the weight of the bean, the different composition has little influence. The hypocotyl is processed into oil and meal along with the cotyledons after the seed coat is removed.

Composition

As a first approximation, soya beans contain 20% lipid, 40% protein, 35% carbohydrate, and 5% ash on a dry-weight basis. Considerable variability exists in these numbers, depending on the cultivar and the growing conditions. In the northwestern part of the soya bean production area in the USA, protein content of soya beans is generally lower than in other production areas. Protein content is known to be inversely related to yield and to lipid content.

Lipids

The crude oil extracted from soybeans contains about 96% triglycerides. The fatty acid composition of the triglycerides is approximately 11% palmitic (C16), 4% stearic (C18), 25% oleic (C18:1), 51% linoleic (C18:2), and 8% linolenic (C18:3), with other minor fatty acids also present. The fatty acid composition is not fixed and can be changed by breeding new cultivars. (*See* **Fatty Acids**: Properties.)

Minor components in the crude oil include the plant pigments lutein (3,3′ dihydroxy α-carotene) and chlorophyl. Also present are phospholipids, free fatty acids, triglyceride hydroperoxides, sterols, saponins, squalene, tocopherols (vitamin E), and flavor compounds. During refining of the crude oil, phospholipids, free fatty acids, pigments, and flavor compounds are removed to produce an oil that contains more than 99% triglyceride. (*See* **Chlorophyl**; **Colorants (Colourants)**: Properties and Determination of

Natural Pigments; **Flavor (Flavour) Compounds**: Structures and Characteristics; **Phospholipids**: Properties and Occurrence; **Triglycerides**: Structures and Properties.)

Protein

Soya proteins have been separated in the ultracentrifuge and characterized as 2*s*, 7*s*, 11*s*, and 15*s* fractions (*s* is a sedimentation constant, and larger numbers indicate larger proteins). The 2*s* fraction contains low-molecular-weight proteins, including the Bowman–Birk and Kunitz trypsin inhibitors that inhibit growth in young animals. Heating of soya bean meal is necessary to denature trypsin inhibitors and allow full utilization of the protein. (*See* **Protein**: Chemistry.)

The 7*s* fraction includes a storage protein, β-conglycinin, with a molecular weight (M) of about 180 000. β-Conglycinin is a trimer with α, α', and β subunits, which, in different combinations, give six distinct β-conglycinins. Also present in the 7*s* fraction are hemagglutinins (lectins) and lipoxygenases. Hemagglutinins are glycoproteins that can cause agglutination of red blood cells and can be toxic, but are probably heat-denatured along with trypsin inhibitors and have no toxic effects when fed. Several lipoxygenases have been characterized that catalyze the removal of hydrogen and addition of molecular oxygen to linoleic and linolenic fatty acids to yield hydroperoxides. The hydroperoxides can break down to yield off-flavor compounds associated with oxidative rancidity. (*See* **Oxidation of Food Components**.)

The 11*s* fraction is glycinin, a hexamer (M, 360 000). Each of the six subunits consists of acidic polypeptides (M, 32 000–36 000) and basic polypeptides (M, 19 000–20 000). The 15*s* fraction is a dimer of glycinin.

Associated with protein in soya beans is phytin, the calcium and magnesium salt of hexaphosphoryl inositol. Phytin strongly chelates divalent cations and has been implicated in decreased availability of iron in diets with soya protein. (*See* **Phytic Acid**: Properties and Determination.)

Carbohydrate

Insoluble carbohydrate includes the pectin, cellulose, and hemicellulose that are associated with cell walls in soya bean cotyledons. This is also the dietary fiber component, which is increasingly recognized as an important part of the human diet. The fiber is more prevalent in soya bean seed coats (hulls) than in cotyledons. (*See* **Carbohydrates**: Classification and Properties; **Cellulose**; **Hemicelluloses**.)

The soluble carbohydrate in soya beans is about 10% by weight of the dry bean and includes about 5% sucrose, about 4% stachyose, and about 1% raffinose. Raffinose is a trisaccharide, and stachyose is a tetrasaccharide, neither of which can be digested by humans. As a result, microbial fermentation of these sugars in the intestine produces gas (flatus), which leads to gastrointestinal distress.

Handling and Storage

As soya beans are harvested and moved from the field into storage, conditions have to be controlled to minimize deterioration. The moisture content of the beans should be 14% or lower to prevent microbial growth. Also, the cleanliness of the beans is important to avoid insect or other contaminants, which may provide moisture and be a focus for microbial growth. If deterioration does start, bacterial or mold growth will generate higher temperatures and moisture so that the process becomes autocatalytic. The best control procedure in storage is to have temperature sensors spread throughout, and quickly mix beans that show generation of hot spots. (*See* **Spoilage**: Bacterial Spoilage; Molds in Spoilage.)

Much of the crop from the USA and Argentina is exported as beans. As the beans are transported by truck, train, barge and ship, and they are transferred into and out of storage, they tend to break, and the pieces are known as splits. Splits are a factor in grading, and the oil extracted from splits tends to have greater amounts of free fatty acids and phospholipids than oil from intact beans.

Much of Brazil's crop is crushed in the country, and oil and meal are exported. In handling oil, it is necessary to minimize exposure to oxygen of the air during transfer. Any outlet spouts should be below the surface to prevent air incorporation in the oil, and blanketing the surface with nitrogen is a good protective measure. Storage tanks must be kept clean. This is particularly important for the tanks in ship's holds or for tankers, both of which may carry many different liquid cargoes. Cross-contamination between cargoes is avoided by careful cleaning of the tanks.

Grading

In the USA, there are four numerical grades and sample grades for those beans that have the lowest quality. The factors used for grading are test weight, splits, heat damage, foreign material, and color. These are similar criteria to those used for grains, and the grading systems in other countries rely on the same criteria, although the actual grades and maximum limits may differ. The economically valuable constituents, protein and oil, are not part of the grading system.

Until recently, there have been difficulties in measuring protein and oil quickly and accurately enough to be part of the grading system. Infrared spectrophotometers now perform excellent analyses for protein, oil, and moisture of either whole or ground samples. Consequently, there is a renewed interest in using the protein and oil content of soya beans to provide premiums or discounts in pricing. Aside from the analysis problem, other problems exist in keeping high-oil or high-protein beans segregated as they move through marketing channels.

Processing for the Food Industry

H E Snyder, University of Arkansas, Fayetteville, AR, USA
L A Wilson, Iowa State University, Ames, IA, USA

Background

Soya beans are seldom simply cooked and eaten. They are traditionally processed into soyafoods or into food ingredients. This article covers soyfood processing and the initial separation of soybeans into oil and meal by solvent extraction and then the further processing of oil and meal. Oil needs to be refined to remove minor components and is then processed to make products such as margarines, shortenings, and salad dressings. The protein-rich meal is mainly used as animal feed but can be processed into food ingredients such as flours, concentrates, and isolates. The protein products may also be textured in various ways to simulate meats or cheeses.

Oil Separation

The first step in processing most soya beans is to separate the oil, either by solvent extraction or by expelling. The processing companies that do the separation are called crushers, and each of the 100 or so crushers in the USA processes on average about 1000 tonnes of soya beans daily. (*See* **Vegetable Oils**: Oil Production and Processing.)

Preparation

Before solvent extraction, soya beans are cleaned and cracked into several pieces (meats). The hulls are removed by aspiration, and the meats are conditioned by warming and by adding moisture. Conditioning is necessary to make a cohesive flake. The conditioned meats are put through smooth rollers that make flakes of approximately 0.025 cm thickness. Making flakes is advantageous for uniform penetration of solvent in deep beds (minimal channeling) and for disruption of the soya bean tissue so that solvent can penetrate and dissolve the oil.

A recent development is to put the flakes through a cooking extruder (expander) to yield collets. The collets are pieces of the 'rope' exiting the outlet of the expander. This processing gives a porous but still high-density collet that extracts more readily than flakes. Also, the collet holds less solvent that the flake, thereby minimizing the energy needed for removing the solvent.

Solvents

The solvent of choice is commercial hexane, a petroleum fraction with a boiling range of 65–70 °C. Commercial hexane is a mixture of *n*-hexane, cyclohexane, and methylpentanes. It has low viscosity and a low heat of vaporization. The main disadvantages of hexane are its flammability and the safety precautions needed for safe handling.

Chlorinated hydrocarbons are equally good solvents for soya bean triglycerides, but the use of trichloethylene led to toxic soya bean meal during the 1940s, and this has discouraged further use of these solvents.

Ethanol and isopropyl alcohol are effective triglyceride solvents when hot, and cooling can be used to separate the dissolved triglyceride from the solvent. Isoflavones are also extracted by alcohol. However, alcohol solvents are not being used in commercial extractions.

Extraction

The full-fat flakes (or collets) are loaded into the extractor to make beds over which the solvent flows. Extractors may have deep (1.2 m) or shallow (0.6 m) beds, and are always arranged so that solvent flows countercurrent to the movement of the beds. Thus, the fully extracted flakes are contacted by fresh hexane entering the extractor, and full-fat flakes are contacted by the full miscella (solution of crude oil in hexane) just before it leaves the extractor. The temperature of extraction is about 60 °C to speed up diffusion of solvent and to lower the miscella viscosity, both of which enhance the extraction of oil. Solvent extraction is capable of reducing the residual oil in the soya flakes to less than 1%.

Removal of Solvent

Upon completion of extraction, the solvent has to be removed from both the oil and flakes. The full-fat miscella contains 25–30% oil, and solvent is removed by two stages of rising-film vacuum evaporators followed by a third-stage stripping column. At the end of this process, the crude oil contains about 1000 p.p.m. of hexane, which corresponds to a flash point for the oil of 121 °C.

The flakes are treated in a desolventizer-toaster by direct contact with steam first to remove the hexane and second to heat treat the flakes for trypsin inhibitor destruction. After leaving the desolventizer-toaster, the flakes are cooled and ground to a meal for use as a high-protein feed ingredient. The protein content is 44% with hulls added or 47.5–49% protein without hulls.

If flakes are to be used to produce soya bean protein isolates or soluble soya bean concentrates, the solvent has to be removed with minimal heat to maintain protein solubility. Flash desolventizers are available in which superheated hexane is used as the heat-transfer medium to evaporate hexane. The flakes are kept dry and, with this system, protein solubility is preserved.

Expelling

The original methods for recovering oil from oil seeds were designed to exert pressure on the seeds and express the oil. The modern technique for exerting pressure is an expeller: a motor-driven auger rotating within a cage of narrowly spaced metal bars. As the oil seed flakes move through the expeller, pressure exerted by the auger forces oil out through the bars, while the defatted flakes are pushed by the auger to the opening at the end. Considerable heat is generated by expellers, and often the protein meal is of a lower quality than the solvent-extracted meal because of excess heat. Also, the residual oil in expeller meal is 3–4%. Nevertheless, expellers are widely used when it is necessary to handle a variety of oil seed in one facility. Expellers can handle as much as 50–80 tonnes of oil seeds per day. The soya bean preparation for expelling is similar to that for solvent extraction. Recent interest in extruding or expressing has increased the number of small operations that can produce 'crude' oil and reduced-fat flour.

Soya Oil Refining

After extraction and removal of solvent, the crude soya bean oil needs to be refined to convert it to edible products. (*See* **Vegetable Oils**: Oil Production and Processing.)

Degumming

The crude oil contains about 1–3% phospholipids, known in the industry as gums. The phospholipids act in conjunction with tocopherols as antioxidants, but they will also precipitate out of the oil, making a sludge that is difficult to remove from storage tanks, road tankers, or ship holds. Therefore, crude oil is often degummed by the crusher before shipping or storing.

The degumming process involves adding 1–3% water to hydrate the phospholipids, followed by centrifuging to remove the hydrated material. The phospholipids are removed in the water phase and either recovered to be sold as a food ingredient, lecithin, or added to the meal portion to be sold as animal feed. Phospholipids remaining in the oil are said to be nonhydratable, and are largely calcium and magnesium salts of phosphatidic acid. An acid treatment of the crude oil makes these phospholipids removable by water washing. About half of the soya bean oil in the USA is degummed before going to the refiner.

Alkali Refining

The purpose of alkali refining is to remove free fatty acids from the crude oil (if the oil has not already been

degummed, phosopholipids are also removed by alkali refining). Free fatty acids are undesirable because they lower the temperature at which the oil begins to smoke and flash (ignite) when heated, as in frying. The fatty acid content of crude soya bean oil is 0–0.7%, and alkali refining yields oil with < 0.05% free fatty acids.

The process washes the oil with a 12% sodium hydroxide solution followed by centrifugation. Fatty acids are converted to sodium soaps and separate with the water phase. Invariably, some oil is lost with water phase (neutral oil loss), and the greater the amount of free fatty acids, the greater the neutral oil loss. After washing with dilute alkali, the oil is washed once with water to remove residual soaps and vacuum-dried to a moisture content of 0.1%.

The fatty acids may be recovered by acidifying and centrifuging the water phase. Fatty acids can be used for soap manufacture but are often added to the soya bean meal to serve as additional feed energy.

Bleaching

Crude soya bean oil is darker in color than desired by consumers, and bleaching is used to lighten the color. Bleaching is achieved by the addition of bleaching earth (adsorbent clays usually acid-treated) to the hot oil under vacuum. The main pigments in soya bean oil are carotenoids and chlorophyll, and these are adsorbed on bleaching earths, which are separated from the oil by filtration.

In addition to removal of pigments, the bleaching process adsorbs oxidation products and the prooxidant metals, iron and copper. Thus, bleaching plays an important role in stabilizing the oil regarding oxidation as well as lightening the color.

Hydrogenation

Soya bean oil is highly unsaturated and, to make products such as shortening and margarines, hydrogen is added to double bonds in the triglycerides to increase their melting points. Hydrogenation is also used to saturate partially double bonds in soya bean oil, so that the oxidative stability is increased. (*See* **Vegetable Oils**: Oil Production and Processing.)

Hydrogenation is usually done in batches (although continuous equipment is available), and the requirements are a nickel catalyst, hydrogen gas under pressure, vigorous agitation, and soya bean oil at 120–200 °C. The temperature, pressure, degree of agitation, and amount of catalyst are variables that affect the rate of hydrogenation and the degree of selectivity. Selectivity refers to the increase in hydrogenation rate of linolenic acid to linoleic acid to avoid off-flavor generation from oxidation of linolenic acid.

During hydrogenation, isomerization of fatty acids takes place to give double bonds in new positions and to shift double bonds from *cis* to *trans*. This process reduces the amount of ω-3 fatty acids (linolenic). Melting point increases result both from saturation of double bonds and from isomerization of *cis* to *trans* double bonds.

Deodorization

The development of hydrogenation and deodorization in the early 1900s made it possible to substitute vegetable oils for animal fats in human diets. Hydrogenation controlled the texture, and deodorization controlled the flavor of vegetable oils.

Deodorization is steam distillation at a high temperature under a vacuum. By this process, unwanted flavors are removed, and some bleaching of remaining carotenoid pigments occurs. The distillation temperatures range from 204 to 275 °C at 6 mmHg vacuum. Under these conditions, not only flavor compounds but free fatty acids and about half of the tocopherols are distilled out of the soya bean oil.

If the oil to be deodorized is sufficiently devoid of phospholipids (less than 5 p.p.m. phospholipid phosphorus), free fatty acids can be removed by distillation rather than by alkali refining. Such removal is known as physical refining. The phospholipids must be present in low concentrations because they brown severely at high temperatures.

The distillate remaining from deodorization is a valuable byproduct because of the relatively large content of tocopherols (vitamin E). Batch, semicontinuous, and continuous equipment is available for deodorization.

Soya Oil Products

After sufficient refining, soya bean oil is used to produce shortening, margarines, salad dressings, and cooking oils of various types. (*See* **Dressings and Mayonnaise**: The Products and Their Manufacture; **Fats**: Uses in the Food Industry; **Margarine**: Methods of Manufacture.)

For plastic products such as shortenings and margarines, the texture is achieved by a mixture of triglyceride crystals plus oil. To avoid a large crystal size and grainy texture, it is necessary to have a mixture of fatty acids. For soya oil products, this means adding oils that contribute palmitic acid to achieve small crystals. In addition to the familiar plastic shortenings produced for home use, dry shortenings are manufactured for incorporation into various bakery mixes,

and liquid shortenings are used for ease of metering in automated baking processes.

For margarines, the solids content at various temperatures (solid fat index) is an important quality criterion. If the margarine is to be used in the home, manufacturers want a product that spreads easily at refrigerator temperatures and melts completely in the mouth (body temperature). These texture characteristics are achieved by blending hard and soft fats and oil. The crystal formation for both shortenings and margarines is achieved by cooling mixtures rapidly while mixing in scraped-surface heat exchangers.

Cooking oils based on soya oil are usually partially hydrogenated to minimize the linolenic acid content and to minimize oxidative rancidity in the hot oil.

Soya Bean Protein Products

Although an estimated 90% of the soya bean defatted protein meal goes to animal feed, a variety of food products and ingredients are produced from the remainder. These include soya bean flours, ranging from full fat to defatted, soya bean protein concentrates, soya bean protein isolates, and various textured products simulating meats, seafoods, and cheeses.

Soya Bean Flours

By grinding defatted soya bean flakes to flours (or grits, if the particle size is larger), a product is produced that is used in the baking industry for its moisture sorption capability. Soya bean flours and grits are also used in meat emulsions for the emulsifying ability in addition to moisture sorption. (*See* **Emulsifiers**: Uses in Processed Foods.)

Full-fat flours are produced by grinding dehulled soya beans. The unheated flours have active lipoxygenase and are used to bleach wheat flours used in the baking industry. The oxidative action of lipoxygenase both bleaches the carotenoids in wheat flour and oxidizes the proteins to improve machinability. Full-fat flours can be heat-treated to produce enzyme inactive flours where less 'beany' flavors with more cereal/nutty flavors are desired.

A range of soya bean flours between defatted and full fat can also be produced by adding soya bean oil and lecithin in varying amounts to defatted flours. These products are used mainly in the baking industry.

If the soya bean flours are used in substantial concentration in food products, soy beany flavors can become a problem. The presence of indigestible oligosaccharides, raffinose and stachyose, that cause flatus can also be a problem. To avoid the flavors, heated soyflours and lipoxygenase-null soybeans have been developed. Reduction of the oligosaccharides has been accomplished by the development of soya bean protein concentrates. (*See* **Soy (Soya) Beans**: Processing for the Food Industry.)

Soya Bean Protein Concentrates

The processing of defatted soya bean flakes into concentrates requires the protein to be rendered insoluble and extracting the soluble sugars (sucrose, raffinose, and stachyose) with water. The protein can be made insoluble by heat treatment, by aqueous ethanol treatment, or by adjusting the pH to the isolectric point of 4.5. The water extraction leaves complex carbohydrates and protein, and the protein concentration has to be 70% to be classified as a concentrate. The use of water extraction retains more of the isoflavones than traditional ethanol extract concentrates. Both types of concentrates are currently in the market place.

In some food applications (a high-protein drink, for example), soluble protein may be needed, and this can be achieved by using a pH to render the protein insoluble followed by pH increase after extracting the sugars. Protein solubility is measured by the nitrogen solubility index (NSI) or protein dispersability index. The indices give the percentage protein remaining in solution or suspension after centrifugation. (*See* **Protein**: Chemistry.)

Soya bean protein concentrates are used in the baking and meat industries for their moisture sorption and emulsifying properties.

Soya Bean Protein Isolates

For those food applications in which only soya bean protein is suitable, soya bean isolates are available. Isolates contain 90% soya bean protein and are prepared from defatted flakes with a high NSI. The protein is dissolved with dilute alkali, separated from the remaining cellular material, and precipitated by adjusting the pH to 4.5. The protein can be recovered as spray-dried isolectric protein (no pH adjustment and low solubility) or as soluble proteinate after raising the pH. About one-third of the original flake is recovered as protein isolate.

Soya bean protein isolates can be used for moisture sorption and emulsification in baked goods and meat emulsions. They can also provide textural improvement through gelation and adhesion properties or serve as primary nutrients in infant formulae.

Soya bean flours, concentrates, and isolates may modify texture in foods by increasing viscosity, by holding moisture or fat, or by adhesion and cohesion.

Furthermore, texture in foods can be modified by changing the texture of the soya bean materials.

Texturing

Numerous ingenious methods have been patented to add chewy textures into flours, concentrates, and isolates. The most commonly used procedures are extrusion and spinning.

Extrusion is used mainly with flours and concentrates and is a method of both heating and forming. The extruder is a screw or auger rotating within a jacketed barrel. As the flour or concentrate is moved through the auger, it is heated by friction and/or by steam jacketing. High pressures are developed in the nose of the barrel just before the exit. As the material is forced through the exit port, it is shaped and puffed due to the sudden drop in pressure.

Spinning applies only to soya bean isolates. A concentrated solution of isolate is prepared and forced through spinnerets (platinum plates with small holes) into an acid bath. The protein precipitates in the acid as a continuous fiber, and the spun fibers can be wound together into a bigger 'tow.'

With both extruded and spun soya bean products, flavors, colors, fats, etc., can be added to simulate meats or seafoods.

Soyfood Manufacture

Traditional soybean foods are classified into two groups: nonfermented foods, including regular, deep-fried, frozen-dried, roasted tofu, soybean protein film (yuba), and soybean sprouts; and fermented soybean foods such as miso, soy sauce (shoyu), and fermented whole soybeans (natto) and Tempeh.

Soymilk

Soymilk is a very popular beverage with the Chinese, but considerably less so with the Japanese and Western populations. However, soymilk production has increased in the USA due to lipoxygenase-null soya beans and improved processing methods that remove or limit the 'beany' flavor of the milk. The health benefit of soy protein to reduce cholesterol (heart disease) has also caused an increase in soymilk sales (and soya used in foods) as the US FDA now allows a health claim if the food contains at least 6.25 g of soy protein with low levels of cholesterol, saturated fat, and total fat. Soymilk is very important to tofu producers because it is the intermediate product in the manufacture of tofu.

Many Japanese, like their Western counterparts, find the odor of soymilk undesirable. This odor is formed by the oxidation of specific unsaturated fatty acids by the enzyme lipoxygenase during seed grinding. Understanding how off-flavors and undesirable flavors interact with soy proteins and similar seed constituents may lead to improved processing systems. Breeding programs at Purdue University (West Lafayette, IN), Iowa State University (Ames, IA), and the Japanese Ministry of Agriculture, Forestry, and Fisheries (Tsukuba, Japan) have developed lipoxygenase-null varieties.

Additionally, odor formation may be circumvented by heat inactivation of the enzyme before the beans are ground (significantly lowering yields), or by masking the flavor with additives. (*See* **Soy (Soya) Beans: Properties and Analysis**; **Soy (Soya) Milk.**)

Soymilk is traditionally made by soaking soybeans in water overnight, then grinding the beans with water added during grinding. Alternatively, full fat flakes, grits, or flour can be used to produce the soymilk slurry. The resulting slurry is boiled and stirred for 1–30 min (depending on the temperature). This heating step improves the nutritional value of the milk (by inactivating trypsin inhibitors) and improves the flavor (by inactivating lipoxygenase and volatizing some of the off-flavor compounds that result during grinding). Heating also increases the shelf-life of the milk by reducing its microbial load. The heated slurry is then filtered through a cloth or nylon bag to separate the undispersible fiber residue (okara) from the soymilk. The resulting soymilk may then be flavored, if desired. It may also be pasteurized, homogenized, or sterilized before being bottled, aseptically packaged, or retorted.

Typically, high-protein, clear or yellow hilum, large-seeded soybeans are preferred for soymilk production. Two hundred grams of soybeans will yield about 1 l of soymilk. Soymilk can be made more shelf-stable by spray-drying or roller-drying it into a dry powder (as is done with cows' milk). Spray-dried soymilk can be instant in beverages, confections, and meat fillers.

Although soymilk has a composition similar to cow's milk, the oil-to-protein ratio is lower. For this reason, reconstituted soymilk is often supplemented with oil. In addition, soymilk may be supplemented with sugar to enhance its palatability. These soymilk beverages often contain fruit juice, cocoa, flavors (artificial or natural), stabilizers, and other ingredients to enhance customer acceptance by masking soy flavors.

Tofu

Tofu has been produced in Japan for more than 2000 years. It was introduced from China along with the agronomic introduction of soybeans. The shelf-life of tofu can be quite variable, ranging from 1 to 5 days

for fresh tofu, 3 weeks to 1 month for pasteurized tofu in the package, and 6 months to 2 years for tofu processed aseptically. The initial microbial load and storage temperature largely govern the shelf-life. Some products (such as silken tofu) are more difficult to transport because they are susceptible to temperature abuse and physical damage.

Large-scale factories in Japan consume 2–3 tonnes of soybeans per day. These large manufacturers have developed integrated production and marketing systems. From the factory to the supermarket showcase, superior product quality is ensured by sophisticated, timely distribution using refrigerated transport and display systems. Likewise, in Japan, some supermarket chains are now producing their own tofu in-house, where it is kept in refrigerated display cases. Aseptically packaged tofu gained popularity in the USA because it has a longer shelf-life and can be stored and transported easily.

Different types of tofu can be made from the soymilk by altering the starting materials (beans, full fat flakes, etc.), solids content, temperature of coagulation, type of coagulant, breaking of the curds, and pressing. Firm tofu (called momen in Japan) is more cheese-like in texture, whereas Kinugoshi (silken or soft) tofu has a much more homogenous, delicate texture, is softer, and has a smoother feeling than regular momen tofu. Reduced fat, grilled, backed, and flavored tofus can be made by altering the starting material or by grilling, baking, and flavoring. Packed tofu differs from other forms because it is processed within its sealed retail container. Aseptically packaged tofus are packaged tofu products made from all ingredients commercially sterilized before aseptic packaging. Deep-fried tofu includes three main types: namage (single-fried tofu), aburage, and gan-modoki (double-fried tofus). Kori tofu is a frozen, dehydrated tofu. Upon rehydration, its texture is very different from the original tofu in that it is more meat-like in texture, and it acts as a sponge in soups, etc.

Yuba

Yuba is a soy protein film produced from the surface of cooling soymilk. Some consumers use fresh film for cooking, but others prefer dried yuba. It is packaged in sheet form, small rolls, or pieces of various shapes and sizes, and it can be used in a variety of food applications.

Texturized Soy Protein Foods

Texturized soy protein products, made by texturizing whole soybeans, soy flour, concentrates, or isolates with single and twin-screw extruders are used to make meat analogs and snacks.

Fermented Soyfoods

Fermented soyfoods usually contain salt and the byproduct of a desirable fermentation. They have a relatively long shelf-life compared with fresh soy products like traditionally prepared momen tofu.

Miso

Miso is made in Japan by mixing cooked soybeans with rice koji (fermented rice started culture) and salt water. This material is then fermented for several months. There are several miso products that differ in the type of koji starter (a high ratio of rice to soybeans results in a more lightly colored and sweeter miso) used for the fermentation. Miso is used in soups, as a spice, and in coatings for vegetables and meat products.

Soya Sauce (Shoyu)

Soy sauce (shoyu) manufacturing was modernized much earlier than other soy foods. Defatted soya flakes are used instead of whole soyabeans because the soybean oil separates and collects on the surface of the sauce. Both fermentation and acid hydrolysis are used to produce different types of soy sauce that are now commonly available around the world.

Natto

Natto is cooked whole soybean product fermented with *Bacillus natto*. Small soybeans are often preferred for natto production. The soybeans are fermented until a white, sticky glutamic acid polymer is formed, which gives the natto a distinctive flavor and sticky and stringy characteristics.

Tempeh

Tempeh is a fermented whole soybean product that originated in Indonesia but is equally popular in Malaysia. Tempeh is usually cooked before it is eaten. Preparation usually involves frying, deep-fat frying, or baking the product. It is also added to soups and fast foods, and is used as a meat replacement in main dishes.

Properties and Analysis

E G Hammond, P A Murphy and L A Johnson, Iowa State University, Ames, IA, USA

Background

Soya beans vary widely in their appearance and composition. The main constituents of soya beans, in descending order, are protein, oil, complex carbohydrates, oligosaccharides, simple sugars, and minerals. Phytochemicals in soybeans have gained prominence in the last 10 years, especially isoflavones, saponins, and phenolic acids, because of their potential health-protective effects. Soya isoflavones in particular have been associated with a variety of other improved physiological states, including reduced cholesterol levels, anticarcinogenicity, and improved bone health.

Most legumes contain 20–25% protein, but soya beans typically contain 30–45% protein (moisture-free basis), and average 35.35% at 13% moisture. Levels as high as 55% protein (moisture-free basis) have been observed. The oil content typically ranges from 15 to 24% and averages 19.16% on a 13% moisture basis. The composition varies with growing area; for example, soya beans from northern and midwestern areas of the USA typically contain 1.5–2% less protein and 0.2% more oil than beans grown in southern states. One Iowa soybean processor has begun offering premiums for soybeans containing higher-than-normal oil contents.

The total crude fiber content of soya beans is about 4.4% at 13% moisture. These materials are predominantly cellulose, hemicellulose, and pectin. The outer hull, typically 8% by weight of the bean, is especially rich in crude fiber (35%). Fiber is hard to digest and contributes little to the nutrition of swine and poultry, the primary markets for soya bean meal.

The total sugar content of soya beans is 4.9–9.5% at 13% moisture. Of the total sugar content, about 60% is sucrose, 10% raffinose, and 30% stachyose. Raffinose and stachyose are oligosaccharides, causing flatulence (intestinal gas) in humans and reduced feed efficiency in livestock.

Isoflavone content of soya beans varies from 800 to 4000 $\mu g\,g^{-1}$ on an aglycon basis. Soya contains 12 isoflavones, namely genistein, daidzein and glycitein, as β-glucosides, 6″-*O*-malonylglucosides, 6″-O-acetylglucosides and aglycons. Soya saponin concentrations vary in a similar manner to isoflavones ranging from 2 to 12 $\mu mol\,g^{-1}$.

Because of the variety of glucoside forms of saponins and isoflavones, their concentrations should be expressed in micromoles. The isoflavones and saponins fractionate with the seed protein and are not lipid-soluble. As soya beans are fractionated into food ingredients, the forms of the isoflavones and saponins are rearranged depending on the extent of heat processing and the method of protein fractionation.

Generally soya bean meal is sold on a 44% protein basis and 48% when soya beans are dehulled (Hi-Pro meal). The average price of soybeans during the 1997–98 crop year was $6.47 per bushel (0.259 kg). Oil sells for about twice the value of meal. Typical selling prices for soya bean oil were 25.7 cents per pound (0.566 kg) and meal (44% protein) for $197 per ton or 9.9 cents per pound (0.566 kg) during 1998. The 2000 crop year prices were considerably lower.

Recent developments in breeding and genetic modification of soya beans have achieved: new fatty acid compositions, e.g., $<2\%$ linolenic acid and $>80\%$ oleic acid to improve oxidative stability; removal of all lipoxygenase isozymes to improve the flavor of soya protein ingredients; elimination of oligosaccharides to eliminate intestinal gas; altered protein and amino acid composition to improve functional and nutritional properties; and inserted

vaccines for human and animal health. While genetic engineering holds great promise for the future (healthier foods, reduced environmental impacts, increased yield, and lower input costs), consumers have begun to question the safety of this new technology.

Proteins

Glycinin and β-conglycinin constitute 65–80% of the protein fraction or 25–35% of the seed weight. Glycinin is classified as a legumin, characterized by molecular weights of 300–400 kDa and sedimentation coefficients of 11S ± 1S. β-Conglycinin is a vicilin, which is in the range of 150–250 kDa, is glycosylated, and has sedimentation coefficients of 7S ± 0.5S. In soya beans, the major proteins, glycinin and β-conglycinin, are frequently described by their respective sedimentation values, 11S and 7S, but such fractions are often impure. The 7S fraction of soya protein contains, in addition to β-conglycinin, lectins, lipoxygenase, and β-amylase.

β-Conglycinin is a trimer and/or hexamer in solution and probably occurs in both forms in the seed. Two similar peptides, α and α′ (57 kDa), and a glycosylated β peptide (42 kDa) are assembled in the mature protein in a nonrandom set of seven forms, $\alpha'\beta_2$, $\alpha\beta_2$, $\alpha\alpha'\beta$, $\alpha_2\beta$, $\alpha_2\alpha'$, α_3, and β_3 with molecular weights of 125–171 kDa. The α and α′ subunits have 1–2 mol of cysteine per mole of peptide, while the β peptide has no cysteine.

Glycinin is a hexamer, although in older literature, it is referred to as a dodecamer. It is composed of six nonrandomly paired acidic and basic peptides. The acidic peptides have molecular weights of 44, 37, and 10 kDa; the basic peptides are 20 kDa. The acidic–basic (AB) pairs have been identified in the experimental line, CX635-1-1-1, and are shown in Table 1. Seven acidic and eight basic peptides have been identified in 18 cultivars. There appear to be sulfur-rich and sulfur-poor AB pairs.

Soya beans contain two main classes of protease inhibitors or trypsin inhibitors (TI), although there appear to be many isogenic variants. The two principal classes are the Kunitz inhibitor with a molecular weight of 21 500 and the Bowman–Birk inhibitor, with a molecular weight of 8000. The Kunitz inhibitor acts only on trypsin, while the Bowman–Birk protein inhibits both trypsin and chymotrypsin. Moist heat treatment denatures about 90% of the TI activity with the residual being heat-stable. TI affects animals of guinea-pig size and smaller but has little effect on larger animals, except for weanling pigs. Recently, the Bowman–Birk TI has been demonstrated to be an anticarcinogen and is currently in Phase II cancer trials. There are reports that TIs exert a carcinogenic effect on rodents. There has been interest in recovering and purifying soya bean protease inhibitors to treat AIDS patients.

The United States Food and Drug Administration has approved a health claim for soya protein that, as part of a heart-healthy diet, 25 g per day of soya protein will contribute to improved cardiovascular health. (*See* **Trypsin Inhibitors**; **Protein**: Chemistry.)

Lipid

Soya bean lipids contain about 2–5% phospholipids, depending on the growing conditions, and 1.6% unsaponifiables. The balance is chiefly triacylglycerols.

Oleic (18:1), linoleic (18:2), palmitic (16:0), stearic (18:0), and linolenic (18:3) acids are present in soya-bean oil, along with traces (less than 1%) of myristic (14:0), palmitoleic (16:1), heptadecanoic (17:0), eicosenoic (20:1), arachidic (20:0), behenic (22:0), and erucic (22:1) acids. The range of acyl groups present in soya bean oil has been extended by mutation breeding and selection to the values reported in Table 2.

The acyl groups are distributed asymmetrically in the triacylglycerols with all the saturates on the *sn*-1 and -3 positions and linoleate concentrated on the *sn*-2 position. Generally, the *sn*-1 contains more palmitate and stearate than *sn*-3, and the oleate is enriched on *sn*-3. Phospholipids contain the same acyl groups found in the triacylglycerols, but the

Table 1 Glycinin acidic–basic complexes from CX635-1-1-1

Acidic–basic complex	*S-amino acids*	*Molecular weight*

From Nielsen NC (1985) Structure of soy proteins. In: Altschul AM and Wilcke HL (eds) *New Protein Foods Vol. 5. Seed Storage Proteins*, pp. 27–64. New York: Academic Press.

Table 2 Range of acyl group percentages produced in soya bean lipids by mutation breeding and genetic engineering, and the composition of a typical unselected variety

	Range	*Typical value*
Palmitate	3.5–30	10
Stearate	2.5–32	4
Oleate	8.0–85	26
Linoleate	2.0–60	52
Linolenate	1.8–13	8

concentration of palmitate is generally higher and that of oleate lower. Phosphatidyl choline (50%), ethanolamine (26%), and inositol (18%) are the chief phospholipid components along with lower concentrations of phosphatidic acid and phosphatidyl serine.

The unsaponifiables contain sterols, hydrocarbons, and tocopherols. The chief sterols (3.5 mg pergram of oil) are β-sitosterol, campesterol, and stigmasterol. The tocopherols (about 1.25 mg per gram of oil) are typically more than 70% gamma with smaller amounts of delta and alpha. (*See* **Fats**: Classification; **Fatty Acids**: Properties.)

Methods to Measure Composition

Proximate analyses for moisture, protein, crude free fat, crude fiber, ash, and total carbohydrate have been adopted by the American Oil Chemists' Society, the American Association of Cereal Chemists, and the Association of Official Analytical Chemists. All composition values for soya beans are reported either on a moisture-free basis or at 13% moisture.

Several methods are acceptable for moisture determination, but the most widely used procedure involves measuring the weight loss when drying the ground sample for 3 h at 130 °C. In South America a Karl Fischer titration is frequently used.

Protein is estimated from Kjeldahl nitrogen. The nitrogen content is multiplied by a factor of 6.25 to convert to protein values despite the major soya protein, glycinin containing only 17.5% nitrogen (equivalent to a N conversion factor of 5.7).

Oil content is determined as crude fat by continuously extracting dried ground samples with petroleum ether for 5 h. Total fat, which includes bound fat as well as free fat, requires acid hydrolysis of the sample prior to extraction. In recent years, the use of near-infrared reflectance and near-infrared transmittance has become widespread for rapid estimation of grain composition, especially moisture, protein, and oil. These spectrophotometers must be calibrated against the standard wet chemical methods described above. Moisture is also routinely measured by electrical capacitance.

Crude fiber is measured as the weight loss on incineration of the oven-dried residue remaining after digestion of the sample with boiling dilute sulfuric acid followed by boiling dilute sodium hydroxide.

Ash is primarily composed of noncombustible minerals and is determined by heating the ground sample in a muffle furnace for 2 h at 600 °C. Soya beans contain about 4.7% ash at 13% moisture. Total carbohydrate is often estimated as the difference after subtracting other constituents. This method does not discriminate between oligosaccharides and other sugars, and it often gives inflated values. Sugars can be extracted with hot aqueous ethanol and quantified by gas or liquid chromatography.

Acyl group composition of soybean lipids generally is determined by gas chromatography. Lipid classes are separated by thin-layer or liquid chromatograms.

Qualitative and quantitative analyses of the individual proteins have been performed by immunoelectrophoresis and/or sodium dodecyl sulfate polyacrylamide electrophoresis.

Isoflavones are assayed by reverse-phase high-performance liquid chromatography (RP-HPLC) of 80% acetonitrile extracts and absorbance detection at 250–260 nm. Methanol and ethanol tend to underextract some isoflavone forms. Saponin analysis is typically by RP-HPLC with absorbance detection at 290 and 205 nm, depending on the form, although older methods used silica-based thin-layer chromatography. The major impediment to accuracy has been the lack of suitable standards, although most of the isoflavone forms are now available. (*See* **Analysis of Food**; **Chromatography**: High-Performance Liquid Chromatography; Gas Chromatography.)

Grading Standards

Each exporting country has unique standards, but the grade standards established by the Federal Grain Inspection Service (FGIS) for the USA listed in Table 3

Table 3 Official grades and grade requirements of the Federal Grain Inspection Service, United States Department of Agriculture

Grade	*Minimum test weight kg/L (lbs/bushel)*	*Maximum limits*				
		Damaged kernels		*Foreign material (%)*	*Splits (%)*	*Soyabeans of other colors (%)*
		Heat-damaged (%)	*Total (%)*			
US No. 1	0·721 (56·0)	0.2	2.0	1.0	10.0	1.0
US No. 2	0·695 (54·0)	0.5	3.0	2.0	20.0	2.0
US No. 3	0·669 (52·0)	1.0	5.0	3.0	30.0	5.0
US No. 4	0·631 (49·0)	3.0	8.0	5.0	40.0	10.0
US sample grade						

are typical. Soya beans are divided into two classes based on color: yellow soya beans and mixed soya beans. Each class is divided into four numerical grades and a US sample grade. Special grades (e.g., garlicky, infested) are provided to emphasize special qualities affecting the value, and are added to, and made part of, the grade designation. Six factors are considered in assessing a grade designation: test weight, heat damage, total damage, foreign material, splits, and soya beans of other colors. Although protein and oil contents are not part of the official grading standards, they may be specified in some markets. Near-infrared transmission is used for rapid estimation of moisture, protein, and oil contents.

Test weight is determined on a 1·36 L sample before removing foreign material using an Official Test Weight Apparatus. Foreign material is determined by sieving. Splits are determined by sieving a portion of the grain after removing foreign material. Damaged kernels are determined by hand-picking after removal of foreign material.

Dietary Importance

A M Fehily, Tinuviel Software, Warrington, UK

Background

The soya bean (*Glycine max*) is a native of China, where it has been part of the diet for several thousand years. It has also been important in Japan and Korea for almost as long. These beans are used to produce foods that are important components of the diet in the Far East, e.g., fermented soya products such as tofu, miso, tempeh, and soy sauce. More recently, soya beans have become widely used in the Western diet, being used to produce a range of ingredients: soya flour and soya protein, which are used to make foodstuffs such as bread, other cereal products, meat products, and vegetarian alternatives; soya oil, which is widely used as a vegetable oil both in domestic cooking and by the food industry and is also used in the manufacture of spreadable fats; soya lecithin, which is used as an emulsifier in many foods; and soya milk, a vegan alternative to cow's milk. Soya is also used to produce infant formulas for those infants who are intolerant to lactose or cows' milk protein.

Soya can provide a valuable contribution to nutrient intakes and may also have a number of potential health benefits. This article discusses the composition of soya beans, the role of soya in the diet, and its potential health benefits.

Composition

Soya beans contain a wide range of nutrients. They contain some 'antinutrients' and also contain other components, e.g., isoflavones, which may have beneficial effects on health.

Nutrients

Soya beans contain protein, fat, carbohydrate, vitamins, minerals, and fiber.

Protein Soya beans are a good source of protein, containing 14 g per 100 g. This is more than that in most other vegetables and more than that in most other legumes (typically 5–9 g per 100 g), the exception being peanuts, which contain 26 g of protein per 100 g. In terms of protein quality, soya contains substantial amounts of most essential amino acids. When compared with a reference protein (egg), soya protein, in common with other legumes, is deficient in sulfur-containing amino acids (the essential amino acid methionine and the nonessential amino acid cystine) and has a higher content of lysine. Combining legumes with cereals provides a meal with a high protein quality, as cereals have adequate amounts of sulfur-containing amino acids but are deficient in lysine. (*See* **Protein**: Food Sources.)

Carbohydrate Soya beans contain 5 g of carbohydrate per 100 g. This is lower than that of many other legumes. Of the total carbohydrate, 37% is starch, 41% is sugars, and 22% is oligosaccharides. The sugars present are sucrose, fructose, and glucose. (*See* **Carbohydrates**: Classification and Properties.)

Fat Soya beans contain 7 g of fat per 100 g. This is more than that in other legumes, most of which are low in fat. The exception to this is peanuts, which contain 46 g of fat per 100 g. The fatty acid composition of soya has a high ratio of unsaturates to saturates. Of the fatty acids, 16% are saturates, 24% are monounsaturates, and 60% are polyunsaturates. The polyunsaturated fatty acids present are the essential fatty acids linoleic acid (18:2*n*-6) and α-linolenic acid (18:3*n*-3). (*See* **Fats**: Classification.)

Minerals Soya beans contain significant amounts of several minerals: calcium, iron, magnesium, potassium, phosphorus, and zinc (see Table 1). One hundred grams of soya beans provide about 12% of the daily reference nutrient intake (UK) for calcium, 20% of that for iron, 23% of that for magnesium, 15% of that for potassium, 45% of that for phosphorus, and 13% of that for zinc (see Figure 1).

Vitamins Soya beans contain a number of water-soluble vitamins: thiamin, riboflavin, niacin, vitamin B_6 and folate (see Table 1). One hundred grams of soya beans provide about 15% of the daily reference nutrient intake (UK) for thiamin, 8% of that for riboflavin, 21% of that for niacin, 19% of that for vitamin B_6 and 27% of that for folate (see Figure 1). Soya beans also contain vitamin E: 1 mg per 100 g. (*See* **Vitamins**: Overview.)

Fiber Soya beans provide a valuable source of fiber in the diet: 6 g of nonstarch polysaccharides (NSP) per 100 g. Of this, 44% is soluble fiber, and 56% is insoluble fiber. One hundred grams of soya beans provide

Table 1 Vitamin and mineral composition of soya beans

	Amount per 100 g as consumed
Sodium	1 mg
Potassium	510 mg
Calcium	83 mg
Magnesium	63 mg
Phosphorus	250 mg
Iron	3.0 mg
Copper	0.32 mg
Zinc	0.9 mg
Manganese	0.7 mg
Selenium	5 μg

33% of the daily dietary reference value (UK) for fiber. (*See* **Dietary Fiber**: Properties and Sources.)

Antinutrients

Raw soya beans contain a number of substances that may have detrimental effects on digestion and other metabolic processes (lectins, goitrogens, and digestive enzyme inhibitors). These substances are, however, inactivated by appropriate cooking of the beans or, in the case of goitrogens, counteracted by adequate iodine intake. (*See* **Plant Antinutritional Factors**: Characteristics.)

Lectins Lectins, also known as hemagglutinins, are present in raw soya beans and in other legumes. They are, however, heat-labile and are inactivated when the beans are properly cooked. In experimental animals, these polymeric proteins have been shown to cause damage to red blood cells and intestinal mucosa, and thereby impaired nutrient utilization and loss of body weight. In humans, these compounds can result in nausea, vomiting, diarrhea, and abdominal pain.

Goitrogens Enlargement of the thyroid gland has been shown to occur in rats fed soya bean meal. The goitrogenic agent in soya beans is unknown. However, the effect is counteracted by adequate iodine intake.

Digestive enzyme inhibitors Raw soya beans contain certain proteins (protease inhibitors) that react with digestive enzymes (trypsin, chymotrypsin, or salivary and pancreatic α-amylase), thereby interfering with the digestion of protein and starch. In humans, raw soya or isolated protease inhibitors increases levels of cholecystokinin (CCK) and pancreatic secretion. It is thought that chronic pancreatic stimulation may lead to pancreatic hypertrophy, hyperplasia, and possibly cancer. In rats, raw soya has been shown to increase the risk of pancreatic cancer. However, protease inhibitors present in raw soya are inactivated by heat and are therefore not a problem in cooked beans. For example, in countries such as Japan, where soya foods are widely consumed, the incidence of pancreatic cancer is similar to, or less than, that for Western countries, where soya forms a relatively small component of the total diet.

Phytic acid Phytic acid is present in soya beans and also in other fiber-containing foods. It has been suggested to reduce the absorption of calcium, iron, zinc, and vitamin D from the diet. However, these effects have been observed in *in vitro* experiments and not in *in vivo* studies, even at fiber intakes at the upper limit of the normal human consumption range. In addition, levels of micronutrients tend to be higher in fiber-rich foods than in fiber-poor foods. Thus, adverse effects of phytic acid on nutrient absorption are likely to be unimportant at the levels of fiber normally consumed in the human diet. (*See* **Phytic Acid**: Nutritional Impact.)

Isoflavones

Soya beans contain isoflavones, a group of compounds that are structurally similar to estradiol (phytoestrogens). Soya beans contain high amounts of the isoflavones genistein and daidzein (see **Figure 2**) and smaller amounts of glycitein, primarily in the form of glycosides: genistin, daidzin, and glycitin (total isoflavone content of 180 mg per 100 g). The glycosides are hydrolyzed in the gut by a bacterial enzyme, glucose being removed to produce the aglycone forms (genistein, daidzein, and glycitein). Daidzein and genistein have been shown to have a weak estrogenic activity and are able to bind with a low affinity to estrogen receptors, the affinity being greater for β-receptors than for α-receptors. Compared with 17β-estradiol, daidzein and genistein have been reported to have much less potency in producing estrogenic effects, by about 1000-fold or more.

In the 1940s, it was reported that phytoestrogens may exert adverse effects on uterine and ovarian function. This was because sheep grazing on pastures containing a particular type of clover (*Trifolium* sp.) rich in formononetin, which is converted to daidzein in the rumen, developed a widespread infertility. An infertility syndrome has also been described in captive cheetah, as a result of soya bean use, the syndrome

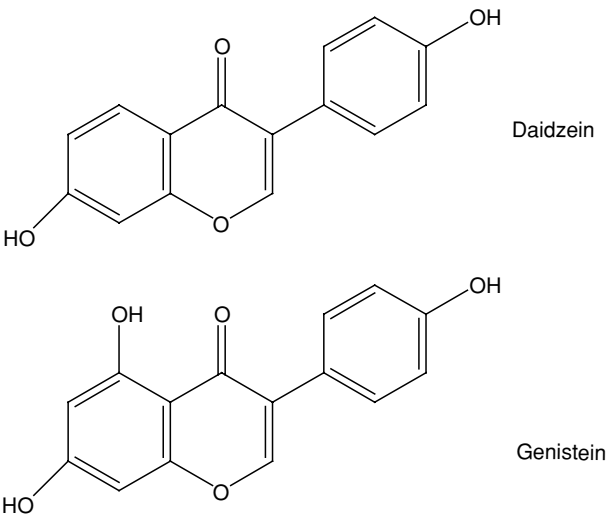

Figure 2 Chemical structure of the main isoflavones present in soya (daidzein and genistein).

being reversed by removal of soya from the food. No adverse effects of soya beans on human fertility have been reported.

More recently, it has been recognized that isoflavones may act either as weak estrogens or as antiestrogens, competing for estradiol at the receptor complex, yet failing to stimulate a full estrogenic response after binding to the nucleus. This fact has stimulated much research into whether isoflavones may have a protective role in hormone-related diseases such as breast cancer.

Role of Soya in the Diet

Soya has been a staple in the diet of many Far Eastern countries for centuries, e.g., foods such as tofu, tempeh, and miso. In Western countries such as the USA and UK, the amount of soya consumed is much less than in countries such as Japan. In Western countries, these traditional soya foods are not very widely consumed but are sometimes used as an alternative to meat. Soya beans are, however, extremely versatile, providing a wide range of ingredients that can be used in foods for most meal occasions, e.g., soya flour, soya protein, soya oil, soy sauce, and soya lecithin. For this reason, consumption of foods containing soya has increased in Western countries over the last 50 years. Nevertheless, soya still forms only a small part of the total diet. It is noteworthy that of the soya beans grown world-wide, only about 10% of the total is used in foods for humans, the majority being used as feed for animals.

Soya beans can be an important component of a normal healthy diet, as they are low in saturates, provide a source of fiber, and contain a wide range of other nutrients. Soya beans are also the main source of phytoestrogens in the diet. In addition, soya beans may have a number of potential health benefits, and these are discussed in the following sections.

For vegetarians, and particularly for vegans who eat no animal products, soya beans play a very important role in the diet. They provide a valuable source of protein that can be of high quality if soya beans are combined with cereals, since the amino acid compositions are complementary. They also provide an important source of iron. Low iron intake can lead to iron-deficiency anemia. Ensuring adequate iron status can be difficult for vegetarians as, in general, iron from vegetable sources is less well absorbed than that from animal sources. However, soya beans provide a source of iron that can be absorbed as well as that in meat.

For infants intolerant to cows' milk protein or to lactose, soya-based infant formulae can be an invaluable alternative to cows' milk-based formulae. For older children and adults who are allergic to cows' milk or intolerant to lactose, drinks and other foods made from soya can be very important components of the diet, helping to ensure that nutrient intakes are adequate for the maintenance of health.

In common with other legumes, soya beans are also of agricultural importance, as they increase the nitrogen content of the soil. Although green plants cannot utilize nitrogen in the atmosphere, there are several species of bacteria, fungi, and blue–green algae that are able to transform nitrogen in the air into a form that can be used by plants. An important genus of nitrogen-fixing bacteria is *Rhizobium*, which forms nodules in the roots of legumes. These bacteria live symbiotically with the legumes, the bacteria obtaining food from the green plant, and the legumes obtaining abundant usable nitrogen compounds from the bacteria.

Soya and Coronary Heart Disease

Coronary heart disease (CHD) is a major cause of death in many countries. For example, in the UK, CHD accounts for about 30% of male deaths and 23% of female deaths.

The level of cholesterol in the blood is a major risk factor for CHD. Soya protein substituted for animal protein in the diet results in reductions in total plasma cholesterol (by 9% on average), low-density lipoprotein cholesterol (LDL-C) (by 13% on average) and triacylglycerols (by 11% on average). High-density lipoprotein cholesterol (HDL-C) is unchanged or may be slightly increased. The amount of reduction in blood lipids tends to be greater among those with the highest plasma cholesterol levels at baseline.

A great deal of research has been done to identify the component(s) of soya protein responsible for its effect on blood lipids. Studies using a mixture of amino acids that duplicates the amino acid profile of soya protein have found that this does not have the same effect on blood lipids as the intact protein. However, studies of soya protein with isoflavones intact have shown that this has a lipid-lowering effect, whereas soya protein with isoflavones removed has no significant effect. It has been suggested, therefore, that the isoflavones present in soya protein are largely responsible for the lipid-lowering effect of soya protein. The benefits of isoflavones present in soya protein on cholesterol lowering have been suggested to be mediated through upregulation of LDL-receptor activity. Nevertheless, studies of isolated and purified isoflavones have failed to show that these have a lipid-lowering effect.

Soya may reduce the risk of CHD through several mechanisms in addition to its ability to lower blood

lipids. For example, soya isoflavones are known to act as antioxidants and have been suggested to reduce oxidative damage to LDL-C. A decrease in oxidized LDL particles, which are considered atherogenic, may reduce the risk of atherosclerosis.

A study of young cynomolgus monkeys showed that the size of atherosclerotic lesions was 70% less in those fed on a diet containing soya protein with isoflavones present compared with those fed on a diet containing soya protein with isoflavones removed. This suggests that isoflavones may inhibit atherogenesis. In another study of surgically postmenopausal cynomolgus monkeys, soya protein with isoflavones intact was found to reduce the progression of atherosclerosis. The magnitude of the effect was reported to be comparable with that of postmenopausal estrogen therapy.

Soya bean isoflavones, in particular genistein, impact beneficially on vascular reactivity. Genistein has also been shown, *in vitro*, to have a number of other effects whereby the development of atherogenesis may be delayed: inhibition of the migration and proliferation of smooth muscle cells; inhibition of platelet activation and aggregation; and reduction in platelet serotonin uptake.

In 1999, in response to the available evidence on the benefits of soya protein, the USA Food and Drug Administration (FDA) announced that it would allow food manufacturers to label products containing 6.25 g of soya protein per serving as helping to reduce risk of heart disease, as part of a balanced diet low in fat and saturates.

Soya and Cancer

Cancer is a major cause of morbidity and mortality. For example, in the UK, about one in three people will develop cancer at some time during their life, and cancer accounts for about one in four of all deaths. There are marked differences in death rates from several types of cancer between Asian countries and many Western countries. The differences are more striking for hormone-dependent cancers of the prostate, breast, and colon/rectum. For example, the risk of dying from prostate cancer among Japanese men is only one-fifth that of men in the USA, and Japanese women have a breast cancer mortality rate that is only one-quarter of that of women in the USA.

Countries where mortality from prostate and breast cancers is low have considerably higher intakes of soya than those countries where mortality from these cancers is high. In animal models, studies investigating the effects of soya beans on prostate cancer or breast cancer have shown reduced tumorigenesis. In humans, however, evidence is inconclusive. Epidemiological studies of prostate cancer conducted in Japan and in Japanese migrants to Hawaii have shown no significant effect of soya consumption. However, a recent study in the USA reported that men who drank one cup of soya milk per day had a risk of developing prostate cancer that was 70% lower than that of controls. For breast cancer, although some studies have shown that soya can help prevent breast cancer, others have found no significant effect. An increase in menstrual cycle length has been observed in some studies, in response to soya bean consumption, although no change was observed in others. Such an effect is of potential relevance to the hypothesis that soya may be protective against breast cancer, because some data indicate that longer cycles, which are typical of Asian women, are associated with a reduced risk of breast cancer.

For colorectal cancer, data are also inconclusive: some studies showed no significant effect, some reported a protective effect of soya, and others observed an increased risk with soya consumption. For cancers at other sites, data tend to show that increased soya bean consumption may be protective against lung and stomach cancer. Much more research is needed to confirm whether soya has a protective effect against cancer in humans. (*See* **Cancer**: Diet in Cancer Prevention.)

Isoflavones appear to be the components of soya that would be most likely to account for any protective action of soya against cancer, especially in inhibiting the initiation stage of carcinogenesis. Genistein has been shown to suppress the growth of a wide range of cancer cells. It inhibits certain enzymes that could affect the onset of cancer or the growth of tumors: tyrosine protein kinase, mitogen-activated protein (MAP) kinase and ribosomal S6 kinase. Genistein also inhibits the DNA repair enzyme topoisomerase II and acts as an antioxidant, thus potentially preventing oxidative DNA damage. It increases *in vitro* concentrations of transforming growth factor β, which is thought to inhibit the growth of cancer cells. In addition, genistein has also been shown to inhibit angiogenesis, the formation of new blood vessels, an abnormal event that occurs as part of the growth and expansion of malignant tumors. However, many of these effects have been shown with very high concentrations of genistein and not in cells treated with levels likely to be achieved in plasma of human subjects eating soya foods.

Soya and Bone Health

Osteoporosis is a clinical condition in which there is a reduced amount of bone per unit volume and an

increased susceptibility to fractures, particularly fractures of the vertebrae, distal forearm (Colles fracture), and hip. Of these, hip fracture is the most severe, since patients require a lengthy hospital stay, there is a high mortality rate (about 20% within 6 months of the fracture), and of those who survive, many suffer permanent disability and dependency. Osteoporosis is a major health problem in many Western countries, but not in Asian countries. A number of factors are known to increase the risk of osteoporosis, including insufficient dietary calcium, low physical activity, and lack of estrogen.

In women, bone mass reduces at a rapid rate in the first few years after the menopause, owing to the reduction in estrogen. Hormone-replacement therapy (HRT) is well known to reduce bone loss in postmenopausal women. However, HRT is not appropriate for all women. Since soya may have estrogenic effects, it has been hypothesized that it may provide an alternative to HRT.

Soya protein containing isoflavones has been reported to reduce bone loss due to estrogen deficiency in ovariectomized rats. Soya bean isoflavones have also been shown to have a protective effect on bone loss in ovariectomized rats, suggesting that the beneficial effect of soya protein is due to isoflavones. The effect of isoflavones on bone loss in rats has been reported to be similar to that for estrogen. The bone-sparing effect of soya protein isoflavones has been suggested to be due to a reduction in bone resorption and/or to an increased osteoblast activity (increasing bone formation).

In humans, most but not all studies indicate that soya protein containing isoflavones favorably affects bone turnover and bone mineral density in the lumbar spine of perimenopausal and postmenopausal women. Treatment with ipriflavone, a synthetic isoflavone, has also been reported to have bone-conserving effects in postmenopausal women with a low bone mass, thus confirming that the beneficial effect of soya protein is likely to be due to isoflavones.

In addition to the effect of soya protein on bone mineral density, it has also been suggested that soya protein, when substituted for animal protein, may indirectly enhance bone strength. Another effect of soya protein is that it helps to conserve calcium by reducing urinary calcium excretion. This is due to the lower sulfur amino acid content of soya protein.

Soya protein therefore appears to have modest beneficial effects on bone density. However, studies to date have been short term and have involved only small numbers of subjects. In addition, no study has investigated whether soya protein containing isoflavones has an effect on fracture risk.

Soya and Menopausal Symptoms

Hot flushes (also known as hot flashes) are a common symptom among menopausal women in Western societies but are reported to be much less common in Japan. Whether this difference is due to the higher consumption of soya in Japan is not clear. HRT generally alleviates hot flushes and other menopausal symptoms such as vaginitis. There is much research interest in the possibility that soya may provide an alternative to HRT in this regard.

Evidence of benefit of soya in menopausal women is conflicting. Some researchers have reported an improvement in the frequency of hot flushes in women taking soya protein daily. Others have reported no effect of soya protein on the number of hot flushes experienced but found a reduction in the severity of symptoms. Others have reported a reduction in both the incidence and severity of hot flushes with soya protein or an isoflavone extract compared with a control group. Others have reported no difference in either the frequency or severity of hot flushes in the intervention group compared with the control group.

Two studies have investigated the effects of phytoestrogen supplements on vaginal cytology and found an increase in cell proliferation (an indication of estrogenic activity) and reversal of menopausal atrophy. Others have reported no significant effect.

There are difficulties in interpreting the results of these studies. This is because there are differences in the amounts of soya protein and isoflavones used and differences in the duration of the studies. Interpretation is also complicated by the fact that the reported frequency and severity of symptoms tend to decrease in the control group as well as the intervention group. Thus, much more research needs to be done before soya protein can be proposed as a potential alternative to HRT for the control of menopausal symptoms.

SOY (SOYA) CHEESES

T Ono, Iwate University, Morioka, Iwate, Japan

Introduction

Soy cheeses (soya cheeses) are a curd made from soymilk (soybean milk) and its processed foods. The soybean curd is a popular food used in daily meals in eastern Asia. It is usually called tofu in English. Tofu is made in a similar process to making cheese from milk. The soymilk is curdled by adding coagulants ($CaSO_4$, $MgCl_2$, glucono-delta-lacton (GDL)). Curds are then pressed into cakes of various types. There are three types of tofu: soft tofu, medium-soft tofu, and firm or extra-firm tofu. Soft tofu is not pressed and is eaten as it is. Medium-soft tofu is the most popular in everyday use. Firm tofu is used in processed foods which are fried, grilled, fermented, and dried. Tofu derivatives are also familiar in eastern Asia.

Tofu has a long history of 2000 years and has held an important position in the eating habits as popular foodstuffs in eastern Asia. The composition and nutrient contents of tofu are similar to those of cheese made from milk. Soybean products, however, contain phytoestrogens, such as isofravones, which may lead to a low incidence of estrogen-related cancers and low prevalence of climacteric syndrome and osteoporosis. The rate of these diseases is lower in Asian peoples who consume a lot of soybean products.

Soy cheeses (tofu and its derivatives) are now spreading throughout the world as healthy foods and a low-cost supply of nutrients.

History of Tofu

It is believed that tofu was invented by Lui An, King of Hui Nang (178–122 BC) of the western Han dynasty (202 BC–8) in China. A wall relief showing tofu making was found in Dahuting tomb no. 1 (Mi, Henan) in the eastern Han era (25–220). It became popular among the public in the Song (960–1271). The technology for making tofu was spread to neighboring countries (Japan, Korea, Vietnam) in the early stage of the Tang dynasty (618–907). The Chinese character dou-fu means soybean curd; dou (to) means soybean and fu means a soft elastic object, although the object is a solid. Doufu was first written in the early stages of the Song dynasty (960–1271). Perhaps the idea for the name derives from nyu-fu (yogurt); nyu means milk. This nyu-fu was written in historical documents of the Tang dynasty (618–907).

In Japan, the oldest literature about tofu is found in the record of Kasuga-shrine in 1183. When tofu was introduced into Japan in the Nara period (761–793), it was called okabe, and the old cookbook referred to it as kabe (wall) or shirakabe (white wall). Tofu became a common food in the eating habits of Japanese people in the Edo era (seventeenth century) and cookbooks on its use were published one after another.

The soy curd is called doufu in China, tahu in Indonesia, tofu in Japan, tobu in Korea, tau fu and tau kuan in Malaysia, tokwa in the Philippines, and tau pho and tau hu in Vietnam. The Chinese character (dou-fu) was spread to eastern Asia through trading with China at 1000 years ago, and called by the pronunciation of each country. The name tofu has now entered into the English language. Tofu is gradually becoming a popular food for health and as a low-cost supply of proteins in the American continent, Europe, and Africa.

Manufacturing Process

Soybeans are soaked in water overnight, then drained. The beans are ground as a small quantity of water is poured over them. The resultant mash is adjusted by adding 10 times the amount of water as there are

soybeans for medium-soft and firm tofu, or seven times the quantity of water for soft tofu. The slurry is allowed to boil gently for about 5 min by steaming or heating and is then filtered. Alternatively, after the slurry is filtered, the filtrate (raw soymilk) is then heated (in the Chinese old style). The heated filtrate is soymilk and the residue is okara. A small amount of either calcium sulfate or magnesium chloride is introduced to coagulate the soymilk. The use of the calcium salt (gypsum) is in the original Chinese style and using magnesium chloride (bittern) from sea salt is the Japanese style. After the milk has curdled (above 80 °C), a part of the whey is squeezed to make medium-soft and firm tofu. The curds are ladled into a rectangular forming container lined with cheesecloth. A lid is placed on the container, and the curds are pressed at 70–80 °C to make a block and to squeeze the whey. The water content of medium-soft tofu and firm tofu is about 85% and 75–80%, respectively. The tofu block is sometimes soaked into a tub of cold water to replace the whey with water. On the other hand, to make soft tofu, the soymilk is curdled in the container and is packed without pressing. Soft tofu (packaged tofu) is also made from a packaged soymilk containing GDL by heating above 90 °C for 1 h. GDL changes to gluconic acid by heating and pH decreases to 5.8. Soymilk coagulates by decreasing pH.

Bean Curd (Tofu)

The types of soft tofu products include silken, doufang (China), oboro (Japan) and packaged. Doufang (meaning bean flower) and oboro (meaning hazy) are eaten like yogurt as they are. Silken and packaged are packaged, have a longer shelf-life, and are used in salads and various cooked foods. Types of medium-soft tofu include momen (meaning cotton cloth) tofu (Figure 1), which is used in various cooked foods. It is the most popular type of tofu in eastern Asia. Firm tofu (pressed/firm curd (Figure 1) and curd sheet) is used as processed foods which are fried, grilled, fermented, dried, and so on. These tofus are available in grocery stores and supermarkets.

Tofu is like a dairy product in that it must be refrigerated and has a short shelf-life (1–7 days). Packaged tofu (silken) is often ultrapasteurized and so has a very long shelf-life (1–2 months). These tofus are always offered as fresh.

Processed Foods (Derivatives of Tofu)

Tofu Cheese (Cheese Alternative)

Firm tofu is scrambled and mixed with casein, soybean oil, modified food starch, salt, citric acid, sodium citrate, natural flavor, vitamins and minerals, and the mixture is heated and molded. It is sold as a cheese alternative containing no cholesterol and no lactose. There are Cheddar, Mozzarella, garlic and herb, and other types.

Fried Bean Curd (Aburage)

Firm tofu is cut into boards or cubes and deep-fried. A board-shape one is then swollen with air, and becomes something like the skin of fried chicken. It

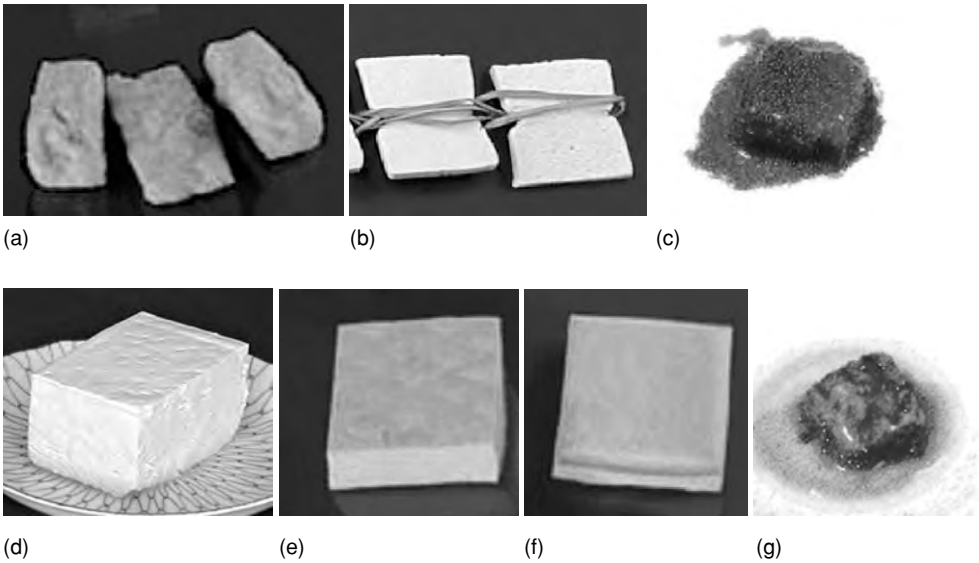

Figure 1 (see color plate 127) Photographs of various tofu and its derivatives. a, fried tofu; b, dried frozen tofu; c, furu; d, momen tofu; e, firm tofu; f, dried tofu; g, choutofu.

is often used for wrapping boiled rice or other foods. Cube and block types (Figure 1) are eaten like fried tofu.

Grilled Bean Curd (Yaki-Tofu)

The top and bottom surfaces of a rectangular firm tofu are roasted till a part is scorched. This process gives it durability against damage in cooking.

Ganmodoki

Firm tofu is scrambled, mixed with vegetables and seasonings, molded into a disk shape and deep-fried. Sometimes beans and seaweeds are mixed. These are eaten intact or after roasting and cooking.

Dried Bean Curd

Firm tofu is pickled and dried. This is an amber hard block (Figure 1) and has a very long shelf-life (6 months). When cooked, it is cut into a chip shape.

Dried Frozen Tofu (Kohri-Tofu)

Firm tofu is cut into rectangular boards, frozen between −3 and −5 °C for 1–7 days, thawed, and dried. The tofu becomes a porous plate (Figure 1) in this process and has a very long shelf-life (1 year). This porous texture is made by tofu proteins denaturing during freezing. When cooked, its texture is different from tofu and it is like a sponge with many fine holes. It is able to contain large quantities of soup in cooking.

Smoked Bean Curd

Firm tofu is dipped into soy sauce, smoked, and aged for 1–2 weeks at a low temperature. Its texture is like smoked cream cheese. It is excellent as a side dish with alcohol.

Tofu-Kamaboko

Firm tofu is scrambled, packed into a semicylindrical shape, and steamed. Sometimes beans and vegetables are mixed in. It is flavored with sugar and salt.

Bean Curd Stick

Curd sheet is cut into stick shapes and deep-fried. This is used for Chinese cooking.

Fermented Tofu (Furu, Choutofu, Tofuyoh)

There is an original fermented tofu in each district, particularly in China. It is similar to fermented cheese, like blue and Brie cheese.

Furu (Figure 1)

Firm tofu is cut into small cubes and these are inoculated over their surfaces with appropriate molds (*Actinomucor elegans*, *Mucor hiemalis*, *M. silvaticus*, *Rhizopus chinensis*, and the like). The molded cubes are salted in brine containing alcohol (red or white), moldy rice (*Monascus purpureus, M. anka*, and the like) and spices (hot pepper, star anise, bay laurel, sesame oil, and rose essence), then packed and aged for 1–6 months. It has a creamy, salty, hot taste and a strong flavor. There are many synonyms for furu: sufu, doufuru, fooyue, fuju, and toefuru. Furu is the standardized name in China. Furu is broadly divided into three categories by color: red, white, and yellow. It is eaten with rice gruel or mantou (steamed bread) at a morning meal, and cooked with meat or vegetables as a seasoning in China.

Choutofu (Figure 1)

The making process is similar to that of furu. However, the moldy rice is not added to the brine and bacterial fermentation occurs in the brine. The brining period is about 1 month. Choutofu is a kind of furu, but is differentiated from other furu in China. It is usually fried before serving and eaten as a relish.

Tofuyoh

Tofuyoh is like furu, and is produced in Okinawa, Japan. Cubes of firm tofu are fermented in brine of moldy rice and awamori (rice liquor). The mold inoculation is neglected when making tofuyoh, and red moldy rice (*Monascucs*) and yellow moldy rice (*Aspergillus*) are added to the brining solution. It is eaten as a relish with liquor.

Bean Curd Skin (Yuba)

Fresh yuba is the layer of skin that is formed by simmering soymilk at near boiling point. After drying, the film becomes yuba. Therefore, it is not a tofu derivative but rather a product of soymilk. It can be eaten as a snack, or used in cooking. Yuba is used in traditional cooking in Japan.

Composition and Nutrients

The composition of medium-soft tofu (momen-tofu), being the most popular, is shown in Table 1, together with that of cheese (Edam) for comparison. The equivalent value of momen-tofu is also shown to compare with cheese composition. The content of protein, lipid, and carbohydrate is similar in both. The calories in 100 g are also similar. As concerns minerals, the sodium content of tofu is 13 times lower than that of cheese, while the potassium content is 10 times higher. These mineral proportions reduce high pressure in blood vessels and may reduce the risk of a cerebral hemorrhage. The iron content of

tofu is 13 times higher than that of cheese. It is effective for healing anemia. Tofu is rich in vitamins D, K, and the B group.

The composition of the main tofu derivatives is shown in Table 2. The lipid content increases in deep-fried products. Each content changes proportionally with water content, except for that of fried products.

The lipid content of tofu is 20% less than that of cheese, and less in saturated fat and cholesterol. It is important to eat less saturated fat and cholesterol to reduce the risk of heart disease. Tofu and its derivatives may play a role in keeping the heart healthy. (*See* **Cholesterol**: Factors Determining Blood Cholesterol Levels.)

Asian people have a low incidence of estrogen-related cancers and a low prevalence of climacteric syndrome and osteoporosis. It is suggested that the cause is due to consumption of a lot of soybean products containing phytoestrogens, such as isofravones. Tofu comprises 40–60 mg isofravones 100 g^{-1}. It is reported that people in Japan and Shanghai consume 20–30 mg of isoflavones per day on average.

Tofu comprises 50% protein and 35% fat in a dry-matter base. The fat in the curd is very stable against ooze and oxidation by cooking and storing. Therefore, the tofu curd must support a stable fixation of lipids. Soymilk for tofu has astringent and soybean flavors and is not suited for drinking unless it is already part of your culture. But these flavors are restrained in tofu and many people can eat tofu. These characters can be explained by the mechanism of curd formation.

Table 1 The compositions of tofu and cheese

Contents	*Tofu (momen)*	*(Equivalent)*	*Cheese (Edam)*
Water (kcal/100g)	86.8	(41)	41.0

Mechanism of Curd Formation

Tofu curd is made from soymilk. Therefore we need information about soymilk before we can understand curd formation. The following is known about soymilk. Soymilk is a turbid solution like cows' milk and contains particulates (40–100 nm) and soluble proteins and oil globule fractions. The particulate protein has a higher binding ability with calcium than soluble protein. The oil globules contain almost all lipids in soymilk, and exist as a globule (200–400 nm) like oil body, as shown in a scanning electron micrograph (Figure 2). The globules disperse in a stable form, packed with oil body protein and soy proteins. The oil globules also have a higher binding ability with calcium than the soluble protein. It is found that in a mixed solution of oil globules and particulate proteins, both fractions aggregate at the same concentration of coagulants, such as $CaCl_2$. Therefore, these results show that a mechanism of curd formation can be illustrated by the behavior of protein particles, oil globules, and soluble proteins when the coagulants are added into soymilk, as shown in Figure 3. At first, protein particles (80 nm) combine with the oil globule (350 nm) by adding magnesium or calcium ions, and then the bound globules aggregate with each other while bringing round water. The curd becomes firm,

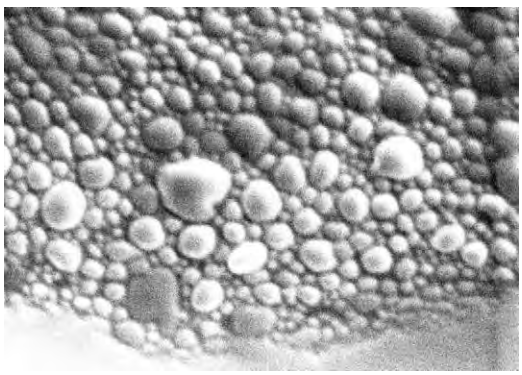

Figure 2 Scanning electron micrograph of oil globules in soymilk.

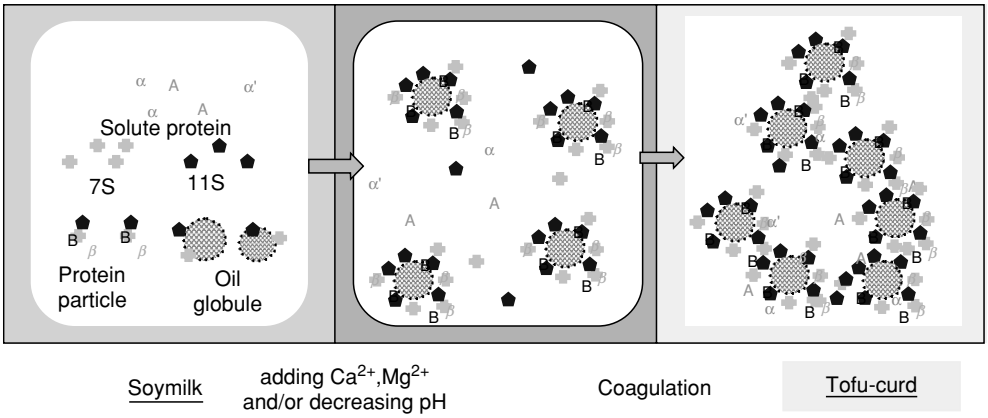

Figure 3 (see color plate 128) Formation of tofu-curd from soymilk (speculation). Oil globule is packed with triple layers of the proteins; oil-body's (oleosin), particulate and solute proteins.

as combining soluble proteins with the pH decrease caused by calcium binding. This assumes that the oil is packed with triple layers of proteins, that is, oil body protein, protein particles, and soluble proteins. Therefore, the oil in the curd is very stable against ooze and oxidation during cooking and storing. The astringent and soybean flavors are also packed in the oil with triple layers of proteins. When we eat tofu and its derivatives, there is no oily and astringent flavor.

The protein particles bind at first on to the oil globule and become a trigger for curd formation. Therefore, the protein particulate content in soymilk is important when making tofu. The particulate content is influenced by the various species and genetic variants of soybean. It is known that the soymilk from glycinin-rich (major soybean protein) soybean contains more particles and the curd shows greater braking stress. The combination of protein particles with oil globules decides the quality of tofu. (*See* **Protein**: Functional Properties.)

SOY (SOYA) MILK

T Odo, Iwate University, Morioka, Iwate, Japan

Background

Soymilk (soya milk) is a milky liquid made from the soybean. Its composition and nutrient and contents are similar to those of dairy milk. Soymilk has been a traditional breakfast drink for centuries throughout South-east Asia. It is made from soaked soybeans by grinding, heating, and filtering. There are three types of soymilk: regular (traditional), reconstituted (modern), and derivatives. Regular soymilk is prepared from whole soybeans by the aforementioned method. Reconstituted soymilk is made from soybeans by a new processing method and adjusted by adding soybean meal, vegetable oils, and seasonings. Derivatives of soymilk are made from regular or reconstituted soymilk and include drinks, yogurt, soy cheese (tofu), and so on. There are two manufacturing processes for regular (traditional) and reconstituted (modern) soymilk. The traditional process involves a heating process after grinding soaked soybeans. To Chinese people, both in China and overseas, traditional (Chinese-style) soymilk is an everyday regular drink, just like cows' milk is in the West. There are many soymilk producers in Hong Kong, Singapore, Malaysia, Thailand, Taiwan, and China. However, some people are uncomfortable with the natural bean (or raw grass)-like flavor of soymilk. In modern processing, grinding and heating are carried out, reducing the bean-like flavor, and thus increasing the popularity for this type of soymilk for many in Eastern Asia, including Korea and Japan. Soybean products contain phytoestrogens, such as isoflavones, which may reduce the incidence of estrogen-related cancers and prevalence of climacteric syndrome and osteoporosis. The rate of these diseases is lower in Asian people consuming a diet high in soybean products. Soy products are now spreading across the world as healthy foods and as a low-cost source of nutrients.

History of Soymilk

A stone mill for soaked soybeans, found at Huainam in China, is thought to have been made in the Western Han dynasty (202 BC–AD 8). A wall relief showing milling of soaked soybeans was found in Dahuting tomb No. 1 (Mi, Henan) from the Eastern Han era (AD 25–220). These remains indicate that soymilk was originally produced in China over 2000 years ago. Tofu made from soymilk became popular in the Song dynasty (AD 960–1271). The technology for tofu manufacture eventually spread to neighboring countries (Japan, Korea, Vietnam, etc.) in the early years of the Tang dynasty (AD 618–907). Traditional soymilk is called 'Doujiang' in China ('dou-jian' means soybean-serous; 'dou' means soybean, and 'jiang' means a serous liquid). Chinese people went abroad and lived overseas from the song era (AD 960–1271), and in the nineteenth century, many emigrated to South-east Asia in particular (Singapore, Malaysia, Thailand, and so on). Some people are uncomfortable with the natural bean flavor of soymilk, and so soymilk has not become popular in some countries. A new processing method (modern style) for soymilk was developed in the USA in the twentieth century. In this method, grinding and heating are carried out simultaneously. The bean flavor is reduced, thus increasing its popularity. Modern-style soymilk gradually spread to north-eastern countries (northern China, Korea, and Japan). There are many soymilk producers in East Asia, just as there are many dairy producers in Western countries. Nowadays, modern-style soymilk has become a very popular beverage across the world.

Manufacturing Process

There are three types of soymilk: traditional, modern style, and derivatives.

1. Traditional (Chinese-style) soymilk (regular soymilk): Soy beans are washed with water and soaked overnight in cold water. The soaked soybeans are then ground, with a small amount of water being poured over them. The resultant mash is adjusted by adding 10 times more water than soybeans. The slurry is filtered and then boiled gently for 30–60 min. The boil filtrate is traditional (Chinese-style) soymilk (bean-flavored soymilk).
2. Modern-style soymilk (reconstituted soymilk): There are three methods for producing modern-style soymilk: the Cornell, USDA, and Illinois methods, after the organizations involved in the development, i.e., the University of Cornell, United States Department of Agriculture, and University of Illinois, respectively. In these methods, enzymes of the soybean are inactivated by heating before being dissolved in water, because the bean flavor develops by enzymatic reactions. There are several modified

methods for producing modern-style soymilk. These are as follows:

a. Cornell method: Soybeans are soaked in 0.05 N NaOH at 50–65 °C for 2 h and washed with water. The washed beans are ground as hot water (80–100 °C) is poured over them. The resultant, mash is filtered, and the filtrate is digested to soymilk by adding water, emulsifier, sugar, and seasonings, and then homogenized.
b. USDA method: Dry soybeans are dehulled and then mashed at a high temperature with an extruder. The resultant soybean powder is mixed with water, emulsifier, oils, and seasonings, and vigorously homogenized. This method has no filtration process, and whole soybeans (minus their hull) are used for soymilks.
c. Illinois method: Cleaned soybeans are selected by removing dirt, and cracked, damaged, and discolored soybeans. The soybeans are blanched for 5 min in boiling water containing 0.25% baking soda, and blanched again for 5 min in boiling water containing 0.05% baking soda. The blanched soybeans are then ground with hot water (near boiling), and the resulting mash is adjusted to soymilk with water, emulsifier, oils, and seasonings, and then vigorously homogenized. This method has no filtration process, and whole soybeans are used for soymilk. There is also a variation of this method in which the ground mush is filtered and adjusted to soymilk.
d. Other methods: Dried soybeans are dehulled and ground as hot water is poured over them. Alternatively, cleaned soybeans can be soaked and ground with hot water. The resultant mashes are then filtered. The filtrate is adjusted to soymilk by adding water, oils, and seasonings, and then homogenized. Another method uses lipoxygenase-deficient mutant soybeans for soymilk processing. The soymilk from this soybean has no bean flavor, even using the traditional method.

3. Soymilk derivatives
   a. Soymilk soft drinks: Soymilk soft drinks are made from a mixture of reconstituted soymilk and fruit or vegetable juice, coffee, cocoa, or cows' milk. Emulsifier and seasonings are also added and homogenized. The product is then ultrapasteurized and packed in aseptic Tetra brick or retort standing pouches.
   b. Soy yogurt: Soy yogurt is made from reconstituted soymilk by using a starter culture (*L. acidophilus, St. thermophilus*, etc.) and flavors. Soymilk is mixed with sugar, glucono-delta-lacton (GDL), starter, flavors, and seasonings. The mixture is then poured into cups and fermented for 1–2 days. Soy yogurt is sold in chilled lines.
   c. Soy cheese (tofu and its derivatives): Soy cheese (tofu and its derivatives) is made from traditional soymilk. The soymilk is curdled by adding coagulants ($CaSO_4$, $MgCl_2$, GDL). The curds are then pressed into cakes of various types. There are four types of tofu: soft, medium, firm, and extra firm. These are discussed in detail later.

Products

Traditional (Chinese-style) Soymilk (Regular Soymilk)

Regular soymilk has a mellow, bean-like flavor, and is acceptable to the Chinese people. Tofu curd can be made from this soymilk. This soymilk is used for cooking in North-east Asia and is used as a traditional breakfast drink in South-east Asia.

Modern-style Soymilk (Reconstituted Soymilk)

There are two types of reconstituted soymilk. One has only a slight bean-like flavor and is prepared from soaked soybeans by grinding together with hot water. People who often eat soy products prefer the slight bean-like flavor of soymilk. The bean-like flavor is an important factor. Some flavors are often added (masking) to reduce the bean-like flavor in soymilk. This type of soymilk is drunk in North-east Asia. Another type of reconstituted soymilk is the Western-style soymilk (characterized by an off-bean-like flavor) produced by modern methods (Cornell, USDA, and Illinois). This white soymilk has a dairy-like taste and is often ultrapasteurized. It is packed into aseptic Tetra brik packs or retort standing pouches and is distributed and sold without the need for refrigeration. This type of soymilk is becoming a very popular beverage in North America and Europe.

Composition and Nutrients

Table 1 lists the compositions of traditional soymilk, bovine milk, and human milk. The protein content of soymilk is slightly higher than that of bovine and human milks, the lipid and carbohydrate contents are 30% lower, and the calories per 100 g are 30% lower. Therefore, the constituents of soymilk can be adjusted to be the same as those of bovine milk. In terms of minerals, the calcium content of soymilk is 50% lower than that of human male, whereas the potassium content is twice as high. The iron content of soymilk is 12 times higher than that of bovine and human milk, and so it is effective in treating anemia.

Table 1 Compositions of soymilk, bovine milk, and human milk

Contents	*Soymilk*	*Bovine milk*	*Human milk*
Water (g/100 g)	90.8	88.7	88.0
Calories (g/100 g)	192	247	272
Protein (g/100 g)	3.6	2.9	1.1
Lipid (g/100 g)	2.0	3.2	3.5
Carbohydrates (g/100 g)	2.9	4.5	7.2
Ash (g/100 g)	0.5	0.7	0.2
Calcium (mg/100 g)	15	100	27
Sodium (mg/100 g)	2	50	15
Potassium (mg/100 g)	90	150	48
Phosphorus (mg/100 g)	49	90	14
Iron (mg/100 g)	1.2	0.1	0.1
Thiamine (B_1) (mg/100 g)	0.03	0.03	0.01
Riboflavin (B_2) (mg/100 g)	0.02	0.15	0.03
Niacin (mg/100 g)	0.05	0.1	0.2

Soymilk contains small amounts of the the lipid-soluble vitamins (A, D, and E) but slightly lower levels of the vitamin B groups (B_1, B_2, niacin) than the other types of milk. (*See* **Protein**: Food Sources; Quality; **Vitamins**: Overview.)

Soymilk contains less saturated fat and cholesterol than bovine and human milk. Nutritionists recommend that less saturated fat and cholesterol be consumed so as to reduce the risk of heart disease. It has been reported that a soy protein intake of about 25 g per day (roughly the equivalent of four glasses of soymilk per day) reduces the risk of coronary heart disease and lowers blood cholesterol levels. Evidence for these two claims is so compelling that since October 1999, the US Food and Drug Administration (FDA) has allowed manufacturers of soy products to cite these claims on the packaging and in advertising. Soymilk may play a more important role in keeping the heart healthy than bovine milk.

Soymilk does not contain any lactose, and it is an ideal milk for lactose-intolerant people. Its popularity is now increasing in North America and Europe. Asians have a low incidence of estrogen-related cancers and a low prevalence of climacteric syndrome and osteoporosis, and it has been suggested that this is because they consume a large number of soybean products, which are high in phytoestrogens such as isoflavones. Soymilk contains 40–60 mg of isoflavones per 100 g. It has been reported that consumers in Japan and Shanghai consume 20–30 mg per day on average. (*See* **Lactose**.)

Structure of Soymilk

Soy milk is a milky liquid and contains mainly protein, lipid, and glucide. bovine milk is also an milky liquid because it contains micellar proteins (100 nm mean diameter) and Lippitt globules of (5 μm mean diameter). Soymilk is known to contain a particular protein (18 nm mean diameter) and oil globules (350 nm mean diameter). Half of the protein in soymilk exists in a particular form, and half is in soluble form. The glucide in soymilk consists of sugar and oligosaccharides, which are soluble in solution. The colloidal solution forms a curd like bovine milk. Soymilk can be made to curdle by adding coagulants to make soy cheese (tofu).

SPECTROSCOPY

Contents

Overview

R H Wilson, Institute of Food Research, Colney Lane, Norwich, UK

Background

The term 'spectroscopy' encompasses a range of techniques for acquiring information on atomic and molecular structure. In all cases there is absorption or emission of electromagnetic radiation, but the basic processes by which this occurs vary considerably, as does the nature of the information that can be obtained. This article provides a broad overview of the important processes that give rise to the most important of the chemical analytical spectroscopies in food and nutrition.

The Electromagnetic Spectrum

When light interacts with matter it may stimulate transitions between quantized energy levels. Light is considered to travel in discrete packets (quanta) of energy called photons. The exact type of transition stimulated depends upon the energy (E) of the photon which in turn is related to the frequency (υ) by:

$$E = h\upsilon \qquad (1)$$

where h is Planck's constant.

The energy of the quanta is highest at the γ-ray end (10^6 eV) and lowest at the radiofrequency end (10^{-8} eV) of the electromagnetic spectrum. The full electromagnetic spectrum is shown in **Figure 1**. In this discussion a more detailed examination will concentrate on the region between the ultraviolet and the radiofrequency end of the spectrum, as this is where most routine chemical spectroscopy is carried out. Spectroscopy is usually concerned with the measurement of a specific spectrum, which is a measure of energy absorbed or emitted as a function of wavelength (or frequency) across a limited region. The objective is to use the spectrum to obtain information on molecular structure or for quantitative analysis. The types of transition that are normally stimulated range from electronic to vibrational through rotational to the low-energy nuclear transitions that are examined in nuclear magnetic resonance (NMR). There are also high-energy nuclear transitions that can be stimulated by γ-radiation and are used for Mössbauer spectroscopy, but this will not be considered in this article.

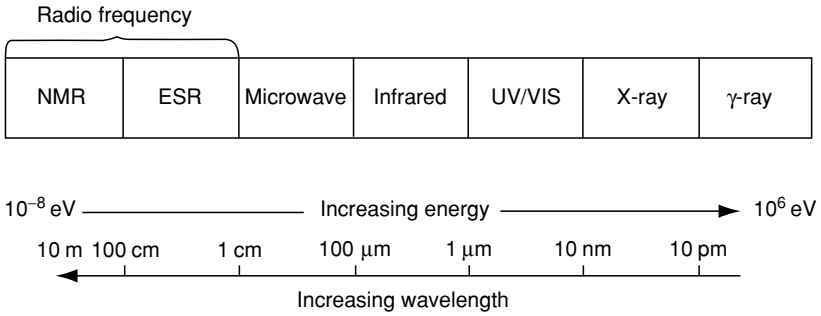

Figure 1 The electromagnetic spectrum. NMR, nuclear magnetic resonance; ESR, electron spin resonance; UV/VIS, ultraviolet and visible. Reproduced from Spectroscopy: Overview, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Since the energy required to stimulate an electronic transition is greater than that for a vibrational transition, which in turn is greater than for rotational transition, it is found that more than one transition is usually stimulated so that, for example, pure vibrational spectra are not seen and are nearly always complicated by rotational transitions.

The normal way for interaction of the radiation to occur is through one of four processes: (1) absorption, (2) emission, (3) elastic scatttering, although there is not net energy absorption, and (4) inelastic scattering. These mechanisms are described in more detail under the appropriate headings as the spectroscopies are discussed in more detail. The first to be discussed are ultraviolet and visible (UV/VIS) spectroscopies, both of which involve electronic transitions.

Electronic Transitions

In UV/VIS spectroscopies, absorption of radiation is the result of the excitation of bonding electrons. The types of bonds that give rise to absorption are known as chromophores and in the UV the electrons of the chromophore are either directly used in bond formation or are nonbonding or unshared outer electrons of an electronegative atom, such as oxygen, nitrogen, or sulfur. The general mechanism in a chromophore such as C═C, in which orbitals are used for bonding, involves the promotion of an electron in a bonding π orbital into a nonbonding π^* orbital (a so-called $\pi-\pi^*$ transition), which typically requires about 7 eV, corresponding to a wavelength of 180 nm. It is also possible for a nonbonding electron to be promoted to a π^* (an $n-\pi^*$ transition). These two are the most common transitions, although similar ones exist for single (σ) bonds ($n-\sigma^*$ or $\sigma-\sigma^*$). However, because the latter required much higher energies, they are seen in the vacuum-UV and are harder to observe. The frequencies of the absorption can be influenced by solvents and by delocalization in conjugated systems.

Transition-metal ions absorb in the UV/VIS region and the transitions responsible involve 4f and 5d electrons. Alternatively, in some inorganic complexes the process of charge-transfer absorption occurs.

Most UV/VIS spectroscopy involves absorption processes and normally a spectrophotometer is used to measure a spectrum. The major components are a source, a dispersing system, and a detector. Normally, light from a suitable source is passed to a prism or grating where it is dispersed into its component frequencies. The dispersing element may be rotated so that each frequency is passed in turn through a narrow slit. This light may be divided so that half passes through a channel containing the sample and half through a reference channel. The emerging beams can be directed in ratios at a detector and the absorbance of the sample as a function of frequency (or wavelength), i.e., the spectrum, can be plotted.

It should be noted that UV/VIS spectra do not consist of discrete lines. The reason is that the high energy of the UV/VIS region can be transferred into the vibrational and rotational substates so that both types of transition are simultaneously stimulated. In Figure 2 the energy level diagram for a chromophore is shown. E_0 and E_1 represent the ground and excited electronic energy levels of a molecule. Each electronic level has associated with it various vibrational sublevels, $\nu_{0,1}$ $\nu_{0,2}$, etc., which in turn have rotational sublevels. An electron may be promoted from the E_0 to E_1 electronic state but may go from the $\nu_{0,0}$ to $\nu_{1,0}$ or $\nu_{1,1}$ state; i.e., there is a simultaneous vibrational transition. The range of vibration subtransitions possible, combined with rotational transitions, means that there is no discrete frequency at which transition occurs.

Furthermore, if an electron is promoted from the $\nu_{0,0}$ state of E_0 to the $\nu_{1,1}$ state of E_1 it may lose energy by collision, for example, and may become lowered into the $\nu_{1,0}$ state. During relaxation to the ground electronic state a photon is emitted of

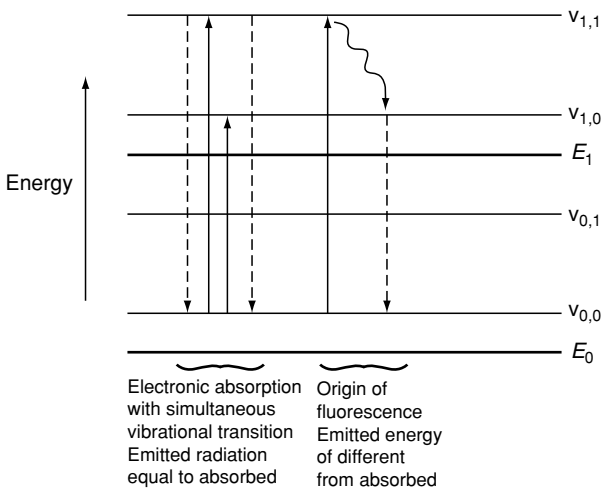

Figure 2 Energy levels for a chromophore, showing electronic and vibrational levels. Reproduced from Spectroscopy: Overview, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

different energy from that absorbed, and this process is called fluorescence.

Vibrational Spectroscopy

The transitions between the vibrational energy levels are the basis of infrared and Raman spectroscopies. The infrared region is divided into the near, middle (or mid) and far infrared. This division is on the basis of instrumental factors as well as the types of vibration that occur in each region. It is easiest to consider first the middle infrared, which is usually considered to lie between 2.5 and 25 μm in wavelength. It is common practice, however, for vibrational spectroscopists to use the unit wavenumber (reciprocal of the wavelength in centimeters) rather than wavelength; this has units of cm^{-1}, which is a frequency term. The middle infrared then stretches from 4000 to 400 cm^{-1}.

The bond between two atoms can be considered to be rather like a spring that has a certain strength of force constant (k). The bond, or spring, can be stretched and caused to oscillate. It will do so at some natural frequency, f, that depends upon k and the masses of the atoms according to Hooke's law:

$$f = (1/2\pi)\sqrt{k/\mu} \qquad (2)$$

where μ is the reduced mass given, defined as:

$$\mu = (m_1 m_2)/(m_1 + m_2) \qquad (3)$$

m_1 and m_2 being the masses of the individual atoms constituting the bond. Equation (2) shows that a particular bond will give rise to a characteristic frequency that depends upon the masses of the atoms and the strength of the bond. Therefore, a C═O bond, which has a greater force constant than a C—O bond, will have a vibrational frequency which is larger. In practice, different functional groups give rise to characteristic vibrational frequencies. This is the major use for vibrational spectroscopy; it is a highly useful probe for the identification of functional groups and for structural determination. It has greater selectivity than UV/VIS in this respect.

Equation (2) is derived from classical physics, but of course the actual process is quantized and (2) should be written as:

$$F = (h/2\pi)\sqrt{k/\mu} \qquad (4)$$

where h is Planck's constant.

In the main, an infrared spectrum is generated by absorption using a similar arrangement to that used for UV/VIS but with different source, detector, and dispersing optics. The process is illustrated in Figure 3. The energy level diagram shows the ground ($v_{0,0}$) and excited ($v_{1,0}$) vibrational states. Also shown are the various rotational substates (J' and J''). Excitation can occur from $v_{0,0}$ ($J''=0$) to $v_{1,0}$ ($J'=0$), corresponding to the band center of the absorption band. However, excitation from the $J''=1$ to $J'=1$ rotational substates (i.e., $\Delta J=0$) will produce a slightly different frequency as the rotational sublevels are not equally spaced. It is also possible for ΔJ to be ± 1, giving rise now to a complicated absorption

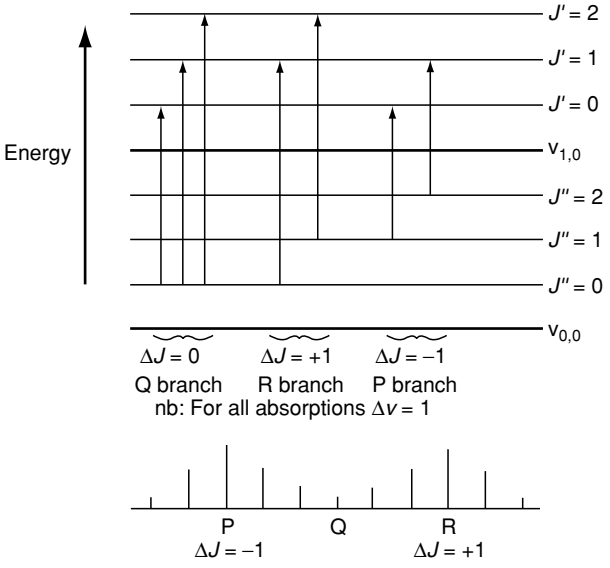

Figure 3 Energy levels for infrared transitions, showing vibrational and rotational levels. Reproduced from Spectroscopy: Overview, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

band comprising of a central absorption (Q branch) with equally spaced lines either side called the P branch ($\Delta J = -1$), and the R branch ($\Delta J = +1$). This structure is only seen as such in the gas phase. In solid or solution state the result is that a broad absorption rather than a sharp line is seen. However, no absorption will be seen at all unless the selection rule is applied. This states that for absorption to occur there must be a change in dipole moment during the vibration. Consequently, homonuclear bonds do not absorb.

At normal room temperature most molecules will be in the ground vibrational state. However, as the temperature is increased, a more significant population will develop in the excited state. As a result transitions from the ν_1 to ν_0 state can occur with the emission of a photon. This is the process of infrared emission which is, albeit rare, an alternative to absorption spectroscopy. In this case the (heated) sample acts as the infrared source.

Infrared spectroscopy has, until recently, been of little use for industrial, biological, and food use owing to the difficulties of sample handling and the time of data acquisition. However, the recent development of Fourier transform methods involving the replacement of the dispersing element with an interferometer has benefits of increased speed, throughput, and frequency reproducibility. Coupled with new methods of sample presentation, this has led to a reawakening of interest in the middle infrared.

The absorptions in the middle infrared are known as the fundamentals. However, various overtones and combinations of the fundamentals can arise. For example, a molecule with two fundamentals at frequencies ν_1 and ν_2 may give overtones at $2\nu_1$, $3\nu_1$, $4\nu_1$, or $2\nu_2$, etc., or combinations at, say, $\nu_1 + \nu_2$ or $2\nu_1 + \nu_2$. In practice, not all fundamentals give rise to overtones, usually only bonds in which a heavy atom such as N or O is coupled to hydrogen. The overtone and combinations constitute the near infrared ($2.5-0.7\,\mu$m) which, despite the apparent complexity of the spectra, has found considerable application to food problems.

Raman Spectroscopy

If a sample is illuminated with monochromatic visible light, it is found that much of the light is scattered and that the scattered light is of the same frequency as the illuminating light. This is elastic or Raleigh scattering. However, analysis shows that a small amount ($< 10^{-6}$) of the incident radiation is scattered with a different frequency. A series of lines is found with frequencies less than the incident light. A weaker series is found with higher frequencies. When the former set of lines are presented as a spectrum of intensity versus frequency shift, the result is something similar to an infrared spectrum with the shift scale from about 4000 to 20 cm^{-1}. This effect is the Raman effect and the spectrum is called the Raman spectrum. The lines comprising the spectrum are called Stokes lines. Those of higher frequency than the exciting line are called anti-Stokes lines and consist of the same peaks with the same shift, but there may be different intensity ratios.

The electrical field of the incident radiation interacts with the electrons in the sample and causes periodic polarization and depolarization so that energy is momentarily absorbed in a distorted, polarized state or virtual state. Most molecules relax by the emission of energy of the same frequency to that absorbed. In a few cases some of the energy will be dissipated amongst the vibrational energy levels, causing vibrational excitation and giving rise to the Raman spectrum. Even fewer molecules will not be in the ground vibrational state before excitation but in the virtual state may relax and the emitted photon will be of higher energy than that incident, leading to the anti-Stokes lines. In contrast to infrared spectroscopy, the selection rule for absorption is that, during vibration of the bond, there must be a change in the electronic polarizability. There is thus a distinct difference in the two spectra and vibrations that may be weak or absent from infrared spectra, e.g., C—C are present and perhaps strong in the Raman. The two spectroscopies are thus complementary and together provide a complete picture of the vibrational states of a molecule.

Far Infrared/Microwave

To complete the picture, at lower energy there is the far infrared ($400-10\,\text{cm}^{-1}$), which has major applications in inorganic chemistry as bonds between metals and organic ligands appear here as well as skeletal vibrations of molecular backbones. This region is of limited application in food and nutritional studies.

In the microwave region, at even lower energy, pure rotational spectra can be produced. However, they will not be addressed here as this is also of limited application.

At the radiofrequency end of the spectrum is NMR spectroscopy which involves transitions between magnetic quantum levels of atomic nuclei. Nuclei have properties of spin and magnetic moment. Splitting of the energy levels can be induced by placement in a magnetic field and transitions can be induced by the application of radiofrequency radiation. Today, this is usually achieved by irradiating the sample exposed to a high magnetic field with a pulse of broadband radiation. After excitation the nuclei reemit

energy at their resonance frequencies and the observed signal is a combination of these frequencies, and this decays with time. A spectrum can be produced by Fourier transformation of this decaying signal. The usefulness of the technique lies in the fact that the resonance frequency of a given nucleus depends upon its chemical environment. However, the range of NMR experiments possible is very large indeed and it is a very powerful method for structural analysis.

In the food industry the use of NMR spectra as such is increasing but relaxation time measurements are still more important, particularly in the determination of solid/liquid ratios. The relaxation rate from the excited state depends on environmental factors and molecular mobility.

Absorption Laws

In UV, near infrared, and mid-infrared adsorption spectroscopy, the fundamental law governing adsorption is the Beer–Lambert relationship. For a sample illuminated by radiation of intensity I_0 the amount transmitted, I, is given by:

$$I = I_0 e^{-\varepsilon c l} \tag{5}$$

where c is the concentration of absorbing species, l is the pathlength through which the light passes, and ε is the molar absorptivity.

For quantitative analysis, spectra are usually presented in absorbance units, where absorbance, A, is defined as

$$A = -\log(I/I_0) = \varepsilon c l \tag{6}$$

so that A is directly proportional to the concentration at constant pathlength.

Practically, optical spectroscopy requires that ε be determined for any absorbing species. This is achieved by calibration and their absorbance is measured. Solutions of the sample to be determined are prepared at known concentration and their absorbances are measured. When the latter are plotted against the concentration, a linear plot results of slope ε. Unknown concentrations can be calculated by measuring absorbance and interpolating from the calibration curve.

Deviations from the Beer–Lambert relationship can occur if too wide a range of concentration is chosen so that solute–solute interactions occur, or where there is chemical interaction between components.

A particular problem that exists in the near and mid-infrared is where significant overlap of absorbance peaks occurs. Clearly, the absorbance at a given wavelength may then depend upon more than one concentration, so that:

$$A = \varepsilon_1 c_1 = \varepsilon_2 c_2 + \varepsilon_3 c_3 \ldots \tag{7}$$

Hence, more complicated solutions to the Beer–Lambert relationship may be required for multicomponent analysis. Such methods include p and k matrix, partial least-squares, or principal components regression.

In NMR single-pulse experiments the signal observed is directly proportional to the number of nuclei, provided sufficient time is allowed between pulses for the reestablishment of equilibrium. Under such circumstances the NMR experiment is quantitative and requires no calibration. Double-resonance experiments can, however, lead to enhanced signals for certain nuclei (nuclear Overhauser effect) so that some form of calibration is necessary. In relaxation measurements the magnetization decay can be broken down into components from fast (solid) and slow (liquid) components, the relative magnitude of each reflecting the relative concentrations.

Practical details and applications of the most relevant spectroscopies in food analysis can be found in following chapters.

Infrared and Raman

B Schrader, Essen, Germany
S Keller, Hamburg, Germany

Principles

A molecule can be identified uniquely by its vibrational spectrum, since this depends on every structural feature. The vibrational spectrum consists of the frequencies and intensities of the vibrations

observed by infrared and Raman spectroscopy. Both are nondestructive methods. This means that the samples can be investigated afterwards by other methods. The intensity of the bands in the infrared and Raman spectra gives complementary information about the nature of the vibrating bonds. Therefore, it is advisable to evaluate both the infrared and Raman spectra in order to obtain the maximum amount of analytical information.

Now, the advantages of both methods, IR and Raman spectroscopy, can be employed by powerful spectrometers, thus making vibrational spectroscopy a very useful tool in food analysis. State-of the-art instruments for vibrational spectroscopy are equipped with interferometers coupled to computers for the transformation of interferograms into spectra, so-called Fourier transform infrared (FTIR), Fourier transform near-infrared (FTNIR), or FT Raman spectrometers. Compared with grating instruments, interferometers have several advantages, in particular the fact that the radiant flux analyzed is larger by about two orders of magnitude. Interferometers therefore permit reliable routine analyses of small samples and of low concentrations.

Basic Theory

In Figure 1, the theory necessary to understand infrared and Raman spectroscopy is outlined. Every molecule can be considered as being built up from atoms with a definite mass, connected by chemical bonds behaving like elastic springs (Figure 1a). The frequency, $\tilde{\nu}$, is usually measured in wavelengths per centimeter, called the wavenumber (cm^{-1}). For a diatomic molecule of two bound atoms, the frequency of the vibration is proportional to the square root of the force constant (f), – which is approximately proportional to the bond order – and the sum of the reciprocal masses.

For larger molecules, the vibrations of the fragments couple and produce complicated 'fingerprint' patterns. However, most of the structural units keep their typical frequency range. Thus, X—H bonds, with X any element, show their typical vibrations between 4000 and 2500 cm^{-1} (Figure 1b), followed by groups with triple bonds or cumulated double bonds in the range 2500–1800 cm^{-1}. Groups with 'double' bonds show their characteristic vibrations between 1800 and 1500 cm^{-1}, and groups

with single bonds vibrate below 1500 cm^{-1}. Stretching vibrations change bond lengths, and deformation vibrations change bond angles. They occur at approximately half the stretching frequency.

According to quantum mechanics, vibrations are excited by energy quanta, $h\nu_s$, where h is Planck's constant, and ν_s is the vibrational frequency. Radiation quanta in the infrared range, 2.5–1000 μm, equivalent to 4000–10 cm^{-1}, can be absorbed by the molecule and excite it from the vibrational ground state (v=0) to the vibrational excited state (v=1). Thus, absorption bands are produced in the infrared spectrum (Figure 2a).

If the molecules are irradiated with quanta of the near-infrared range, 0.8–2.5 μm, equivalent to 12 500–4000 cm^{-1}, the overtones and combination bands of the infrared spectrum, especially, of the CH, NH, and OH bonds are excited, giving rise to the near-infrared spectrum.

Near infrared

When the molecules are irradiated with quanta of large energy, $h\nu_0$ (by monochromatic, usually laser, radiation from the ultraviolet, visible or near infrared region), a scattering process may occur, by which vibrations with energy $h\nu_s$ are excited and quanta of lower energy, $h\nu_R = h\nu_0 - h\nu_s$, are emitted simultaneously. These constitute the so-called Raman spectrum (Figure 2b). The quantum yield of Raman scattering is quite low (10^{-12}), this means that Raman spectra are of a low intensity. If there are samples with absorption bands that can be excited by the quanta $h\nu_0$, then fluorescence may occur, a strong emission spectrum with broad bands (Figure 2c). Since the quantum yield for this process is nearly 1, Raman spectra can be completely concealed, even when the concentration of the fluorescing impurities is very low. Until 1986, Raman spectroscopy with excitation in the visible region was only rarely applied to food analysis, since the spectra were heavily masked by the fluorescence spectra of some natural compounds: cells can only live with the help of an enzymatic machinery with absorption bands in the visible range of the spectrum – consequently, it shows fluorescence and is photochemically endangered. Raman spectra of most food products therefore cannot be investigated with 'classical' excitation in the visible range. However, when Raman spectra are excited in the near-infrared range, e.g., with 1064 nm, the energy of the quanta, $h\nu_0$, is too small (only about half of the quanta at 488 nm) to excite fluorescence (Figure 2c). Excitation with the Nd:YAG laser at 1064 nm marks an optimum for non-destructive recording of the Raman spectra of living cells and all kinds of food.

The intensities of the vibrations revealed by the infrared spectrum are proportional to the square of the change of the molecular dipole moment, μ, during the vibration, described by the 'normal coordinate,' q. The intensity of the Raman spectrum is proportional to the square of the change of the molecular polarizability, α, during the vibration:

$$\text{Infrared intensity} \sim \left(\frac{\partial\mu}{\partial q}\right)^2.$$

$$\text{Raman intensity} \sim \left(\frac{\partial\alpha}{\partial q}\right)^2.$$

The polarizability characterizes the elastic deformation of the charge distribution of a molecule by an electric field. Therefore, infrared spectra usually show strong bands for vibrations of polar groups. Raman spectra, however, show strong bands for vibrations of nonpolar and multiple bonds as well

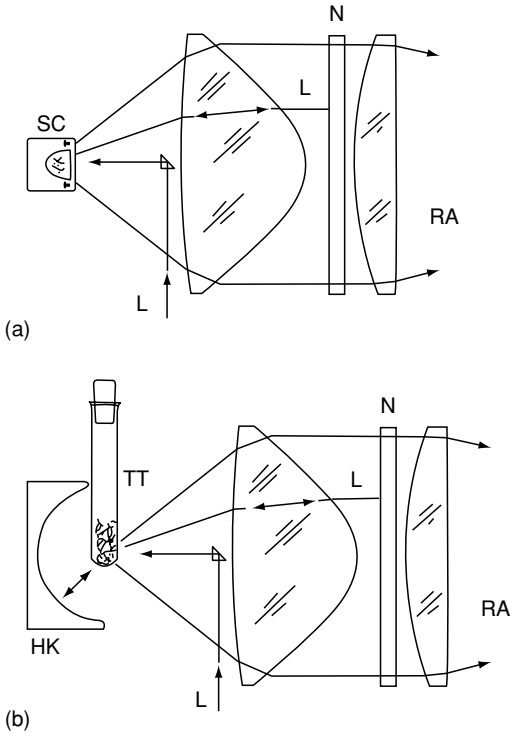

Figure 4 Entrance optics for an NIR-FT-Raman spectrometer: (a) SC sample cup with CaF_2 window and a VITON O-ring, L beam of a Nd:YAG laser; (b) the sample in a small test tube, TT, in the center of a hemispherical mirror HK. The exciting radiation, diffusely scattered by the sample is reflected by the notch filter N; together with HK this multiple reflection arrangement enhances the intensity of the observed Raman spectrum and integrates the spectra of the whole sample.

as for symmetric vibrations of collections of similar bonds, as in ring systems.

Typical Features of Infrared and Raman Spectra

In Table 1, typical properties of the methods of vibration spectroscopy are collected. In several aspects, Raman spectroscopy has several advantages compared with infrared spectroscopy: it needs only very simple or no preparation, uses nonproblematic sample containers, and needs only one spectrometric set-up for the whole spectrum. In particular, the intensity of the bands is proportional to the concentration. Unfortunately, Raman spectrometers are at present more expensive than the infrared instruments. The properties of the near-infrared spectrometry are also listed, for comparison.

Table 2 lists the assignment of the bands that can be observed using both methods. Vibrations of polar groups are more intense in the infrared spectrum, whereas multiple bonds and symmetric

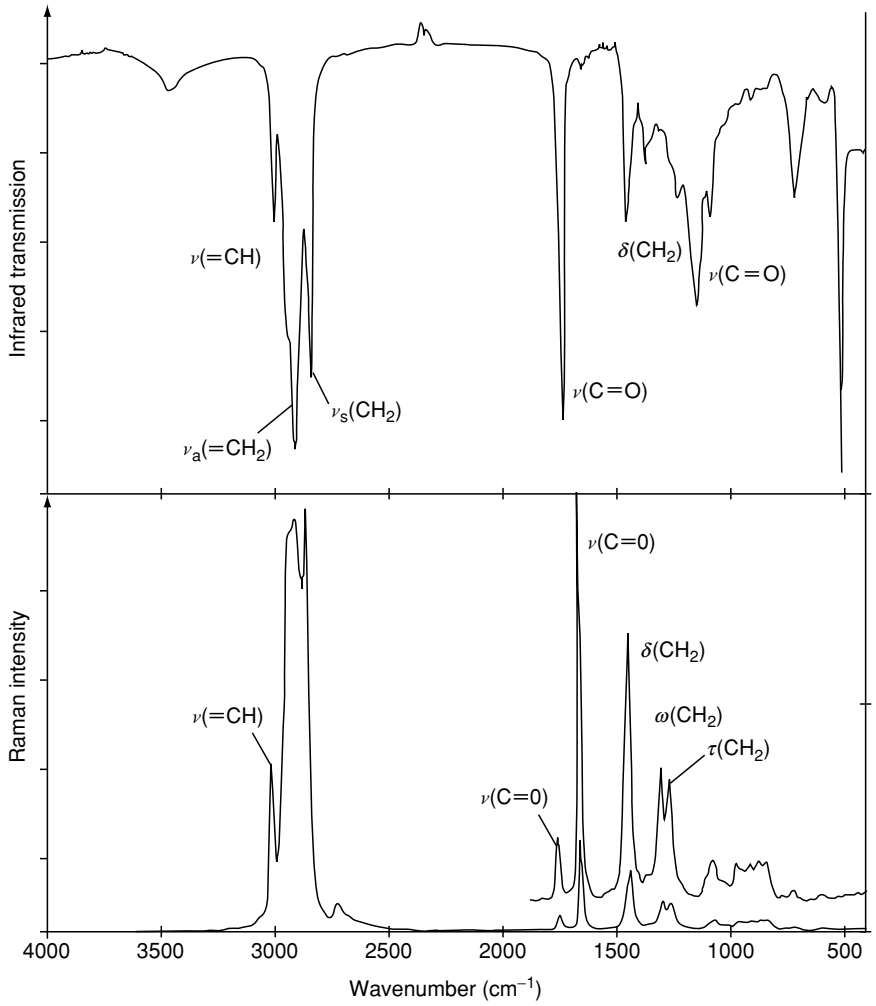

Figure 6 Infrared and Raman spectra of safflower oil. ν, δ, ω and τ mark stretching, deformation, wagging and twisting vibrations. Note the high intensity of the ν (C = C) in the Raman spectrum.

vibrations are usually more intense in the Raman spectrum. Therefore, it is often useful to evaluate both spectra.

Every molecule is a vibrating unit. If it contains n atoms, it has $3n - 6$ 'normal vibrations.' Together, they represent a unique fingerprint, allowing the identification of the molecule. For example, Figure 3 shows the infrared spectra (above) and the Raman spectra (below) of eight important food components.

The spectra of the cystine molecule (Figure 3a) shows many bands with the same frequencies in the infrared and the Raman spectrum. However, the intensities clearly demonstrate the nature of the groups responsible: vibrations of polar groups are strong in the infrared. The bands due to the COOH and NH_2 groups with participation of zwitterionic COO^- and NH_3^+ groups are strong and broad in the infrared spectrum at 3000 and 1600–1400 cm^{-1}, but they are weak in the Raman spectrum. Conversely, the stretching vibrations of the CH_2 group at 2917 and 2969 cm^{-1} and especially the S—S stretching vibration at 499 cm^{-1} are very strong in the Raman spectrum.

In Figure 3b, the spectra of linolenic acid methyl ester are shown. The ester C═O group (1743 cm^{-1}) produces a strong infrared and a weak Raman band; the C═C group (1654 cm^{-1}), however, shows a very strong Raman and a very weak infrared band. These are useful for the determination of the unsaturated fatty acids in fats (see below).

The spectra of retinol, vitamin A (Figure 3c) show the typical vibrations of the conjugated C═C bonds at 1586, 1193, and 1155 cm^{-1}, strong in the Raman and weak in the infrared spectrum.

In Figure 3d and 3e, the spectra of caffeine and vitamins B_1 show many strong and sharp bands, typical for nonflexible ring systems.

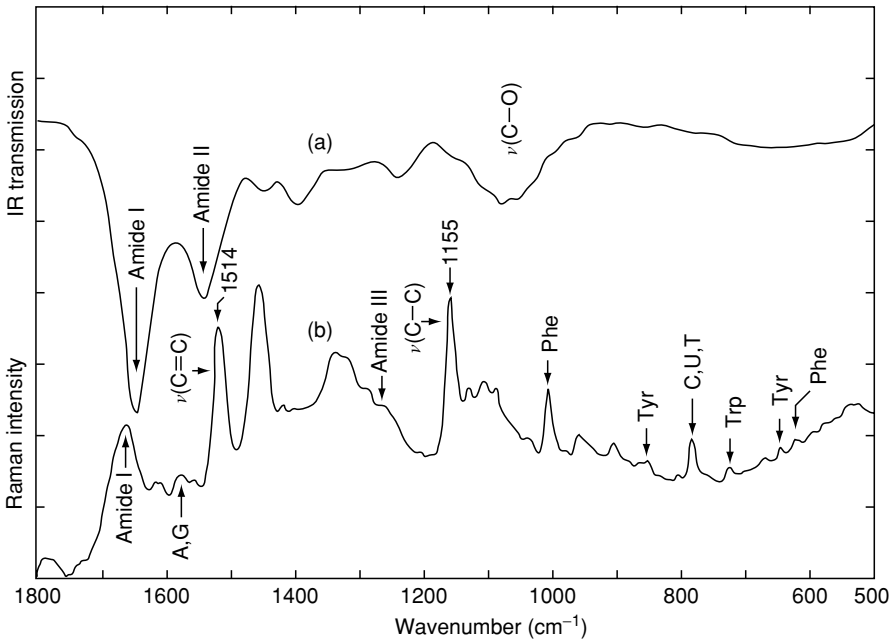

Figure 7 (a) Infrared and (b) Raman spectrum of *Micrococcus roseus*. C, cytidine; U, uridine; T, thymidine; A, adenosine; G, guanosine.

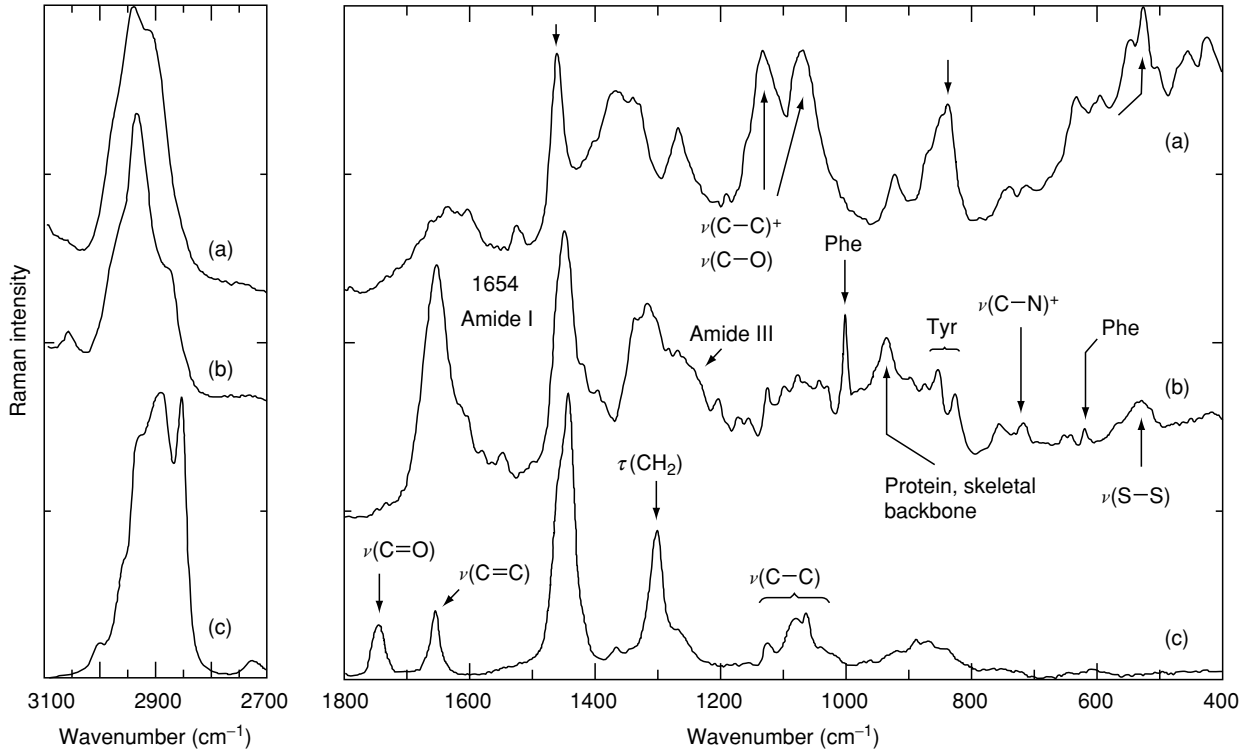

Figure 8 Raman spectra of typical components of food: (a) banana (carbohydrate); (b) turkey breast (protein); (c) butter (lipid).

Figure 3f, g, and h show the spectra of carbohydrates: vitamin C, glucose, and sucrose. All show strong bands in the range 1200–1000 cm^{-1}, due to the C—O groups. Hydrogen-bonded O—H groups show bands around 3400, and 'free' OH bonds above 3500 cm^{-1}.

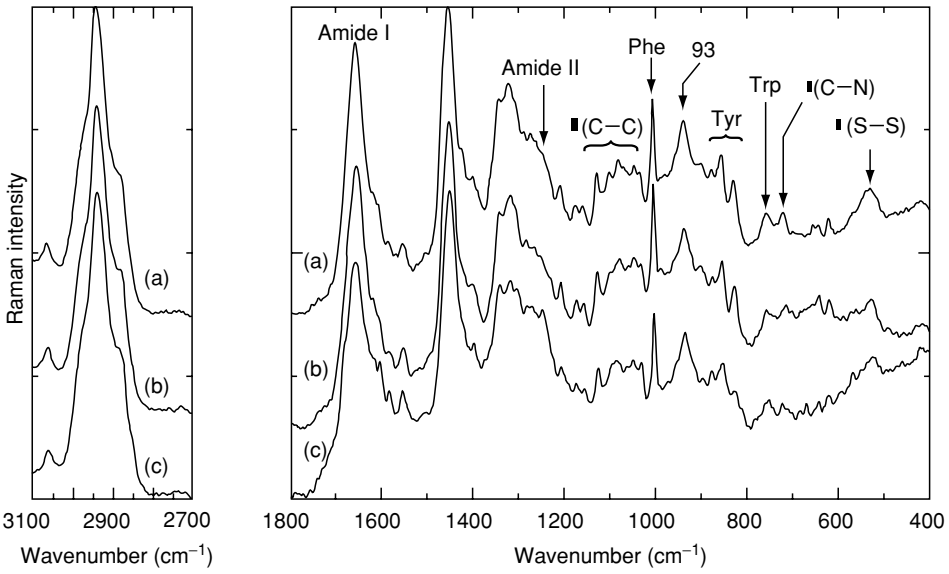

Figure 9 Raman spectra of fresh meat of (a) turkey, (b) pork, and (c) beef.

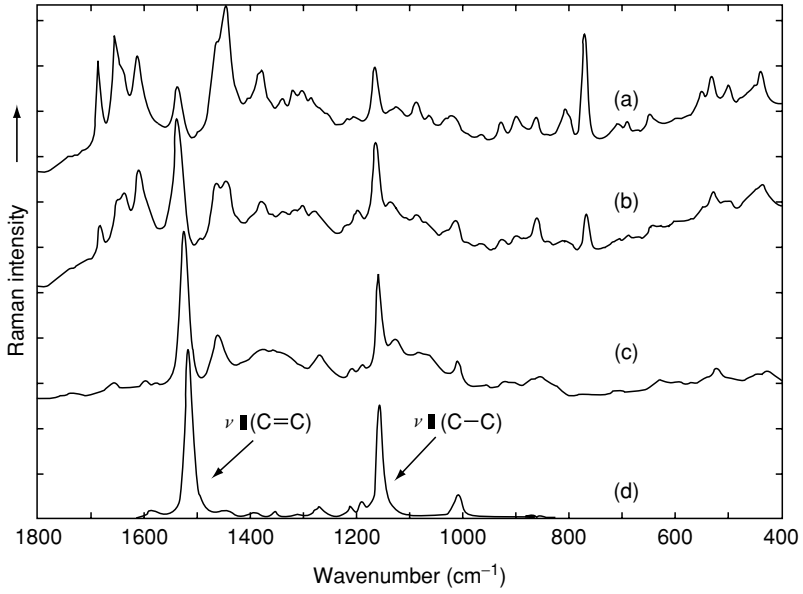

Figure 10 Raman spectra of food components containing carotinoids: (a) peel of untreated orange; (b) peel of orange, treated with wax and fungicides; (c) carrot; (d) β-carotene.

Identification is made easy by comparison of the observed spectra with those in atlases of Raman and infrared spectra of organic and inorganic compounds and by collections of digitized spectra supplied by the instrument manufacturers.

Quantitative Analyses

The basic relation for quantitative analyses by infrared absorption spectroscopy is the Beer–Lambert law:

$$\Phi = \Phi_0\ 10^{-\varepsilon c l} = \Phi_0\ 10^{-A}.$$

Here, Φ_0 is the radiant power illuminating the sample, and Φ is the transmitted power. The transmittance of the sample, $\tau = \Phi/\Phi_0$, is usually recorded, ε is the molar absorption coefficient, c is the concentration and l is the absorbing path length. Most instruments allow quantitative analyses by recording the absorbance, A, which is proportional to the concentration.

The intensity of Raman lines is proportional to the concentration over several orders of magnitude. Non-linearities due to intermolecular interactions can be taken into account by calibration curves determined under conditions similar to those of the practical application. Depending on the circumstances, 'intensities' are measured at the maximum of a band or by integration of the band contour. The analysis of spectra is supported by the use of sophisticated multicomponent analysis, e.g., cluster analysis or neuronal networks.

Special Techniques

Infrared Spectroscopy

For infrared spectroscopy, the common technique uses sample cells with a lamella of a liquid sample of a path length between 5 and 20 μm or a solution of about 100–500 μm, the transmittance of which is measured as a function of the wavenumber. The lamella is supported by infrared-transparent windows, mostly of (hygroscopic(!)) potassium bromide (KBr). However, solid samples need special preparation. They can be mixed with KBr powder and pressed into disks, or they can be ground together with an infrared-transparent oil.

The so-called 'attenuated total reflection' (ATR) or 'frustrated multiple internal reflection' (FMIR) technique is especially useful for food analyses by infrared spectroscopy. An infrared beam coming from a material with a large refractive index is totally reflected at a surface adjacent to a sample having a smaller refractive index. Under the conditions of total reflection the beam emerges into the adjacent medium as 'evanescent wave', thus being partially absorbed by infrared active vibrations. The ATR technique can be used for samples which are difficult to prepare such as meat, cheese, vegetables or dressings. Especially as 'circle cell' this technique is specially designed for continuous analyses of flowing liquids such as alcoholic beverages, syrups or milk products.

Powdered materials can be investigated by the 'diffuse reflection' method. By making use of multiple reflections of the infrared beam by the powder, components in even very low concentrations may be detected. Analysis of samples on thin-layer chromatography (TLC) plates is possible directly after extraction. (*See* **Chromatography**: Thin-layer Chromatography.)

Investigation of volatile components is possible by coupling of an infrared spectrometer to a gas chromatograph either by making use of internally reflecting glass capillaries as sample cells or by condensing the fractions on a cooled infrared-transparent support. Aroma components are determined in this way by headspace analyses. Trace analyses of toxic components in gases, e.g., in human breath, employ cells with mirror systems (White cells) allowing large effective path lengths by multiple pass of the beam. (*See* **Chromatography**: Gas Chromatography.)

Infrared microscopes are now available, which employ the properties of reflecting objectives having no chromatic aberration. The samples can therefore be adjusted in the beam by inspection with visible light, and afterwards, the infrared spectra in either transmission or reflection can be run from exactly the same spot. The spatial resolution of infrared microscopes is limited by the wavelengths of the radiation employed and is of the order of 50 μm.

Raman Spectroscopy

The new FT Raman spectrometers usually observe the spectra of samples with a 180° geometry. This means that the exciting radiation is directed on to the sample perpendicularly to its surface. The Raman radiation emerging from the surface is collected with

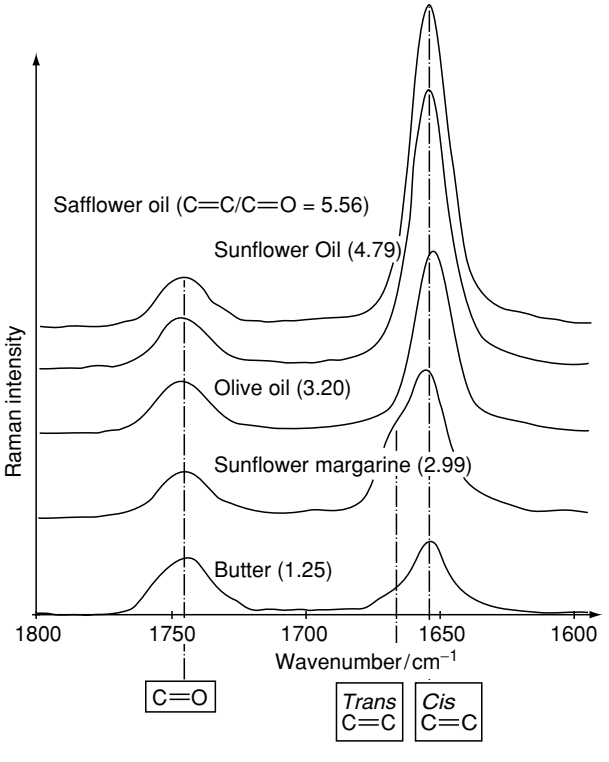

Figure 11 Raman spectra of different fats: (a) safflower oil; (b) sunflower oil; (c) olive oil; (d) sunflower margarine; (e) butter. All spectra are normalized to the intensity of the C=O vibration at 1746 cm^{-1}. The *trans*-C=C is at 1662, and *cis*-C=C at 1653 cm^{-1}. Intensity ratio of *cis*-C=C to C=O for (a) 5.56, (b) 4.79, (c) 3.20, (d) 2.99 and (e) 1.25.

a lens system with a large aperture. The samples are analyzed in cells, allowing multiple reflection (Figure 4). The amount of sample is about 100 mg, but 1 mg of a liquid or solid sample in a melting-point tube is often sufficient; much less is needed when a Raman microscope is applied.

The Raman spectra were usually recorded with the Bruker FT-Raman spectrometer (IFS 66 with FRA 106) and a resolution of 4 cm^{-1}, 350 mW of laser power at 1064 nm with unfocused beam, and a recording time of 15 min.

Fiber-optical systems are especially useful for food analyses by Raman spectroscopy. They connect the spectrometer with a remote sample. Optical fibers may have a very high transmittance in the near-infrared range (about 80% per kilometer), and therefore an analysis of remote process streams of powders or fluids is possible, even of the content of reactors.

A microscope for recording of FT-Raman spectra of small particles or inclusion is commercially available as an accessory to the instruments. It is coupled by fiber optics to the spectrometer, which may be placed at some distance. Raman spectra of tissues, microorganisms and fibers, often complementary to infrared microscopy, can be investigated. One advantage of Raman microscopy is its greater spatial resolution of the order of 5 μm.

Selected Applications

Figure 5 shows the infrared and Raman spectra of bovine serum albumin. The typical vibrations of the amide groups of proteins can be seen in the infrared as well as in the Raman spectra (Table 2). (*See* **Amino Acids**: Determination.)

Figure 6 shows the spectra of safflower oil. As mentioned in the discussion of Figure 3b, the esters of unsaturated fatty acids show complementary intensities of the C═O and the C═C stretching vibrations in the IR and Raman spectra. (*See* **Fatty Acids**: Analysis.)

Microorganisms can be characterized by Raman as well as infrared spectroscopy. Employing multivariate statistical analysis of the second derivative of the spectra, different strains of bacteria can be classified. With FTIR and especially near infrared FT Raman microscopes the identification of bacteria, viruses, fungi, and even mammalian cells is possible (Figure 7).

As already discussed with Table 1 for several applications, Raman spectroscopy is better than infrared spectroscopy. This is partially due to the fact that the water content of food shows a very strong absorption in the infrared range and also, since, for Raman spectroscopy, only minimal sample preparation is necessary. Therefore, the examples discussed below concentrate on NIR-FT-Raman spectra.

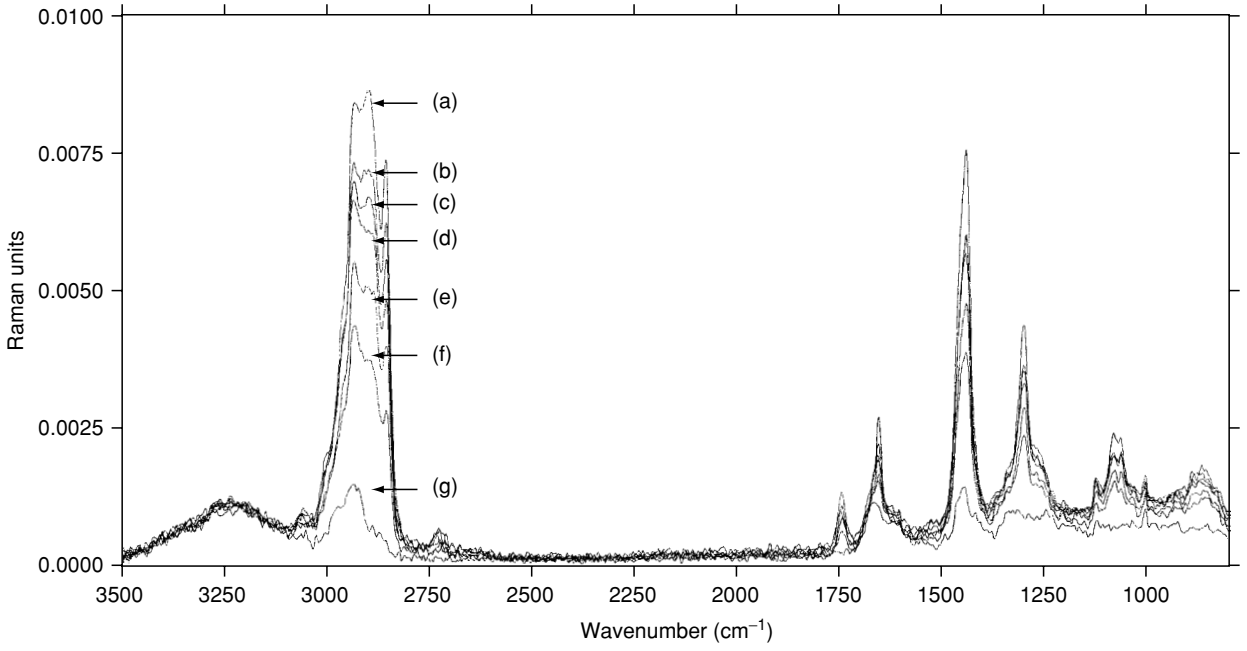

Figure 12 Raman spectra of cheeses with different concentration of fat in solid matter (%): (a) Wörrishofer (60), (b) Pikantje (48), (c) Gouda (48), (d) Edam I (40), (e) Edam II (40), (f) Westlite (30), and (g) Harzer Roller (*c.* 3). Spectra are not processed.

Figure 8 represents typical spectra of important food components: carbohydrates (banana), proteins (turkey breast), and lipids (butter).

Carbohydrates are poor Raman scatterers, revealing vibrations at 2902 and 2941 cm^{-1}, based on their large quantity of methine groups. The spectral range from 1200 to 800 cm^{-1} is dominated by stretching vibrations resulting from the carbon skeleton strongly coupled with C—O bonding.

Protein spectra demonstrate a stretching vibration at 2939 cm^{-1}. The amide I-band, amide III-band, and the vibrations originating from the protein backbone, allow an analysis of the secondary protein structure (see Table 2). The Raman spectra show specific vibrations of amino acids with ring systems: phenylalanine; 1607, 1003, 621 cm^{-1}; tyrosine 1611, 854, 829 cm^{-1}; tryptophan; 1556, 1424, 1356, 1009, 873, 755 cm^{-1}. The very strong S—S vibration in the Raman spectrum between 540 and 520 cm^{-1} in cystine is shown in Figure 3a. Cysteine shows a strong S—H vibration at 2543 cm^{-1}.

Lipids are dominated by strong stretching vibrations of the methylene group at 2850 and 2884 cm^{-1}, indicating a large quantity of coupled methylene groups. Several typical spectral features are: the vibration of the ester group at 1744 cm^{-1}, an intense bending vibration at 1440 cm^{-1}, a twisting vibration at 1299 cm^{-1}, and vibrations of the carbon chain between 1150 and 800 cm^{-1}. If unsaturated fatty acids are present, the spectra show an additional band, a sensitive marker of conjugation, ranging from 1655 cm^{-1} (C═C, cisoid form) to 1670 cm^{-1} (C═C, transoid form) (Figure 9).

Fresh meat can be distinguished by general differences of the spectra (Figure 10).

Carotenes show strong vibrations in the Raman spectrum at about 1150 and 1500 cm^{-1}, due to the C═C and the C—C vibrations of the whole chain. Since the absorption bands of carotenes are not far from the position of the exciting line, the observed Raman spectrum show a 'pre-resonance' enhancement. They allow the detection of carotenes, even in low concentrations in plant and animal cells.

As demonstrated in Figure 11, the Raman spectra of fats, when the spectra are normalized to the intensity of the C═O vibration, show the relative amount of unsaturation. The spectra demonstrate the high number of *cis*-substituted double bonds in safflower and sunflower oil but demonstrate that the fat hardening for preparing sunflower margarine reduces the concentration of the *cis* bonds and enhances the *trans*-substituted double bonds.

Figure 12 shows spectra of cheeses with different concentration of fat in solid matter, recorded using the original samples. The bands due to the fat and protein content reduce their intensity with a lower concentration, whereas the band at 3200 cm^{-1}, due to water, is nearly constant.

Typical noodle spectra reveal the spectral feature of starch (amylose and amylopectin) (Figure 13 and 14). The intense band at 479 cm^{-1} is assigned to a C—O bending mode. The vibrations at 845 $\pm$ 5 cm^{-1}

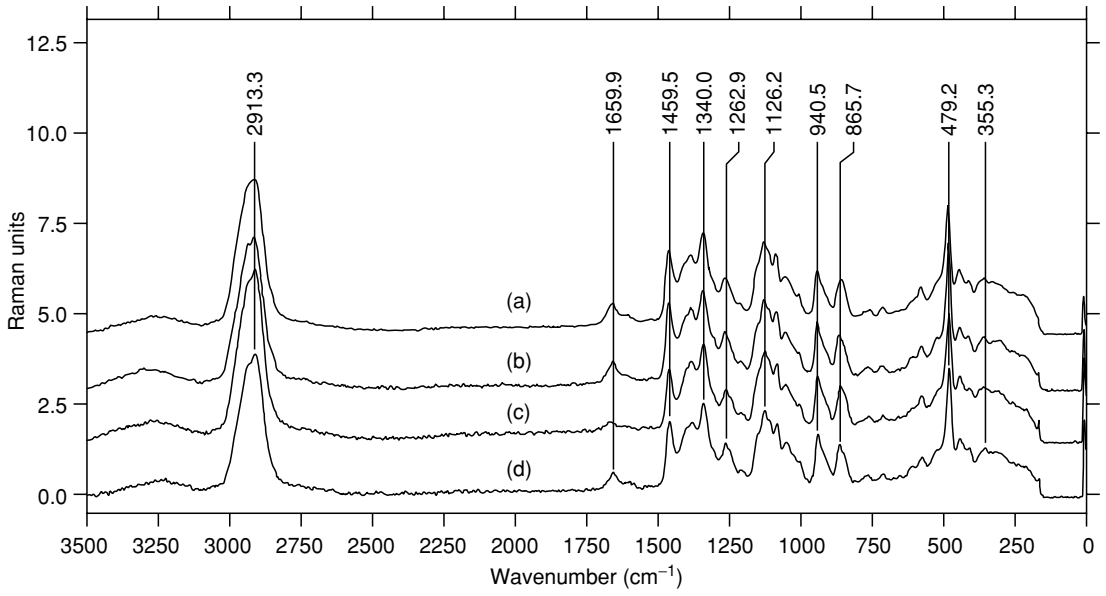

Figure 13 Raman spectra of noodles: (a) Spätzle; (b) Gold-Ei Landnudeln (durum wheat semolina, whole eggs 15%); (c) Bamboo Garden Chinese Rice Noodles; (d) Reine Hartweizen-Schnittnudeln (100 % durum wheat semolina, no egg). All spectra are normalized to the carbohydrate band at 1162 cm^{-1}.

(α-anomers) and at $900 \pm 10\,cm^{-1}$ (β-anomers) are marker bands indicating the type of configuration at the anomeric C_1 position. However, the spectra structure correlations show that the band at $900\,cm^{-1}$ is not attributed exclusively to the β-anomeric configuration. The variation in protein content can be monitored by the band at $1660\,cm^{-1}$ (amide I) in relation to the band at $1459\,cm^{-1}$ (δ(C—H)).

The spectra of noodles are an example of a nondestructive investigation of packaged food. There are only small reductions of the intensity of all bands visible. Food, even in glass containers, can be investigated by Raman spectroscopy.

Finally, Figure 15 gives examples of food containing fat, carbohydrates and protein in different relative concentration with the typical bands already

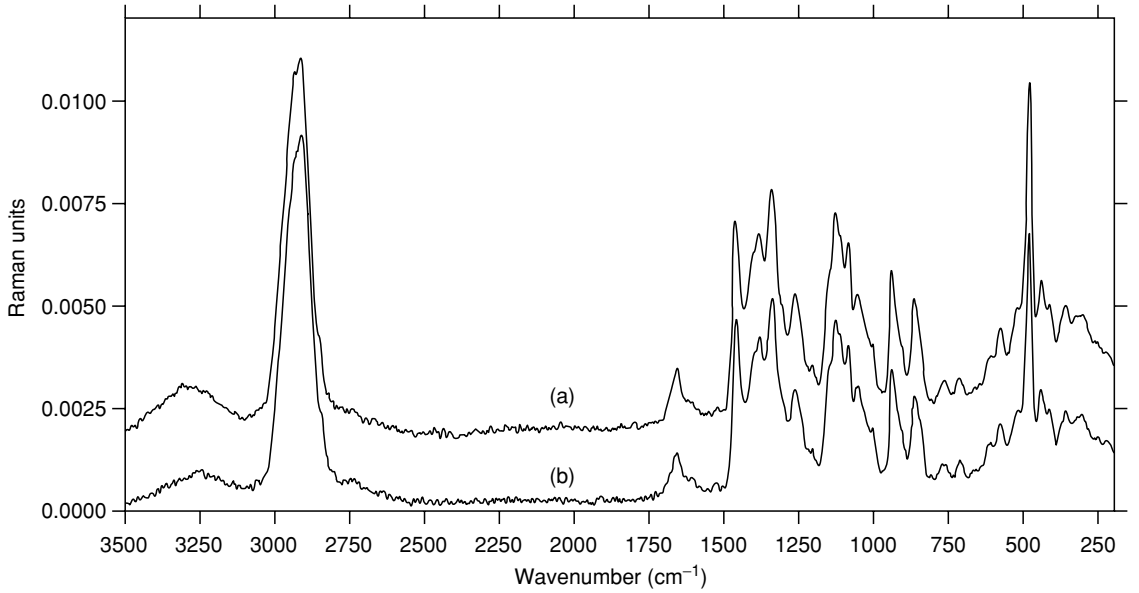

Figure 14 Raman spectra of noodles as in Figure 10b: (a) in test tube; (b) directly through the original plastic bag.

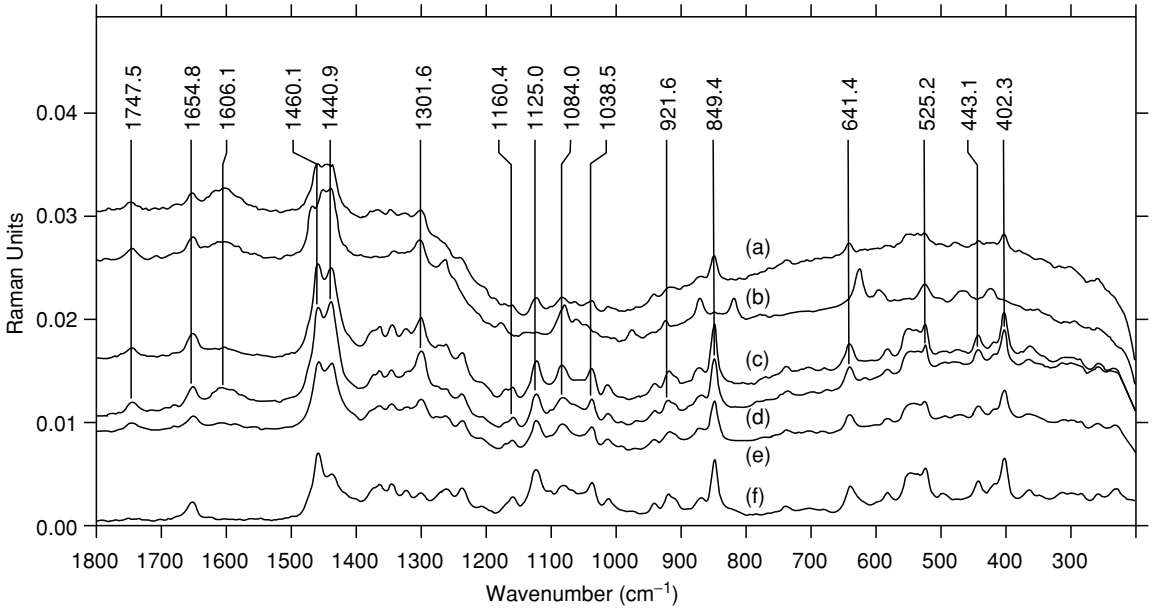

Figure 15 Raman spectra of chocolates and marzipan: (a) Schwarze Herrenschokolade (Chocolate puro extrafino), 60% cocoa; (b) chocolate for diabetics, $\geq$50% cocoa; (c) nougat chocolate, 42% cocoa; (d) superior semibitter chocolate, $\geq$55% cocoa; (e) milk chocolate, $\geq$30% cocoa; (d) marzipan.

discussed. Of special interest is chocolate for diabetics (Figure 15b with the typical bands of sucrose with very low intensity).

Near-infrared

R L Wehling, University of Nebraska, Lincoln, NE, USA

Background

Near infrared (NIR) spectroscopy is a technique that is widely used throughout the food-processing industry for both quantitative and qualitative analysis. Typically, NIR spectroscopy measures a food's absorption of electromagnetic energy over a wavelength range of 800–2500 nm (12 500–4000 cm^{-1}). For most foods, this results in spectra with broad, overlapping absorptions that involve C—H, O—H, or N—H bonds. Since at least one of these functional groups is found in many of the major components of foods, information about a wide range of constituents and quality attributes can be extracted from NIR spectra.

Near infrared spectroscopy began in 1800 with an experiment by Herschel. When he used a prism to create a spectrum from white light and placed a thermometer at a point just beyond the red region of the spectrum, he noted an increase in temperature. This was the first observation of the effects of NIR radiation. Between 1920 and 1945, many of the absorption bands observed in the NIR spectra of organic compounds were assigned to specific chemical functional groups. By the 1940s, NIR spectroscopy was being used in the chemical industry for applications such as the determination of water in organic liquids.

Modern NIR spectroscopy applied to foods and agricultural commodities established its foundations in the 1960s and 1970s. Karl Norris and colleagues at the Beltsville, MD laboratory of the United States Department of Agriculture (USDA) developed successful methods for obtaining NIR reflectance spectra from solid biological samples such as leaves, fruit, or cereal grains. In their work developing a rapid method for moisture determination, they also coupled NIR spectroscopy with computer-based multivariate statistical techniques that helped to eliminate interference from absorptions of other constituents (protein, fat, carbohydrate) on the moisture determination. Ultimately, the use of such correlational techniques allowed the measurement of these other constituents, as well.

The first commercial NIR instruments specifically designed for analysis of foods and agricultural

commodities were introduced in the early 1970s. These instruments were dedicated primarily to the determination of moisture, protein, and oil in grains such as wheat, barley, and soybeans. In the intervening years, rapid advances in optics, digital electronics, and computer technology have greatly improved the reliability of the technique, as well as making it possible to analyze a much larger range of constituents in a wide array of products.

Origins of Spectra

A molecule can absorb infrared radiation if it vibrates in such a way that its charge distribution, and therefore its electric dipole moment, changes during the vibration. A vibrating molecule, or molecular functional group, can absorb radiant energy to move from the lowest (ground) state to its first excited state. The frequency of radiation that will make this occur will be identical to the initial frequency of vibration, and is referred to as the fundamental absorption. Typically, fundamental absorptions have frequencies that fall in the midinfrared region of the electromagnetic spectrum ($4000–650\,cm^{-1}$, wavelength = 2.5–15 μm). Molecules can also absorb radiation to move to a higher (second or third) excited state, such that the frequency of the radiation absorbed is two or three times that of the fundamental frequency. Such absorptions are referred to as 'overtones,' and the intensities of these absorptions are much lower than the corresponding fundamental, since these transitions are less favored. Combination bands can also occur if two or more different vibrations interact to give bands with frequencies that are sums of their fundamental frequencies. Combination and overtone bands typically have frequencies that fall in the NIR spectral region.

Both the overtone and combination bands observed in the NIR tend to be weak in intensity. However, this is actually an advantage, since absorption bands that have sufficient intensity to be observed in the NIR region arise primarily from functional groups that have a hydrogen attached to a carbon, nitrogen, or oxygen atom. These are common functional groups in the major constituents of food, including water, proteins, lipids, and carbohydrates. The NIR absorption bands associated with a number of important food constituents are listed in Table 1. The NIR absorption bands of many foods frequently overlap, yielding spectra that are quite complex. This can be illustrated by observing the spectra of the starch and zein (protein) components isolated from corn (maize) shown in Figure 1. The protein fraction exhibits absorption bands centered at about 2050 and 2180 nm, whereas starch has a strong absorption band centered at 2100 nm. Note, however, that there is significant overlap of the starch band into the regions where protein absorbs. Because of such overlaps, quantitative analysis of most foods requires measurements to be made at multiple wavelengths in order to relate the amount of a constituent present to the spectral measurement.

Principles of Diffuse Reflectance Measurements

One of the advantages of NIR spectroscopy is its ability to take measurements directly on solid food

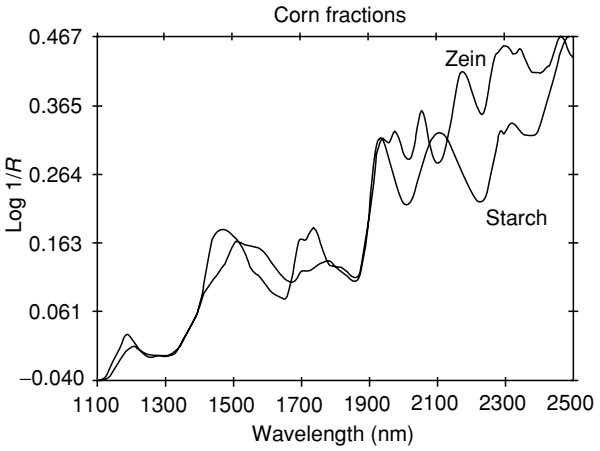

Figure 1 Near infrared reflectance spectra of the starch and zein (protein) components of corn (maize).

Table 1 Absorption bands for important food constituents

Constituent	*Absorber*	*Wavelength (nm)*
Protein, peptides	Amide I, II, and III combinations	2050–2180
	—N—H stretch first overtone	1520–1570
Carbohydrate	C—O, O—H stretching combination	2060–2150
Lipid	Methylene —CH stretch + deformation combination	2300–2350
	$—CH_2$ and $—CH_3$ C—H stretch first overtone	1690–1765
Water	—O—H stretch first overtone	1400–1450
	O—H stretch + O—H deformation combination	1920–1950

samples with little or no sample preparation. This is typically accomplished by measuring the diffusely reflected radiation as a beam of NIR energy is directed on to the sample. When radiation strikes a solid or granular material, part of the radiation is reflected from the sample surface. This mirrorlike reflectance is referred to as specular reflectance, and gives little useful information about the sample. Most of this specularly reflected radiation is directed back toward the energy source. Another portion of the radiation will penetrate through the sample surface and be reflected off several sample particles before it exits the sample. This is referred to as 'diffuse reflectance,' and the diffusely reflected radiation will emerge from the surface of the sample at various angles through 180°. Each time the radiation interacts with a sample particle, the chemical constituents in the sample can absorb a portion of the radiation. Therefore, the diffusely reflected radiation contains information about the composition of the sample, indicated by the amount of energy absorbed at specific wavelengths. It should be noted that the size and shape of the sample particles can affect the amount of radiation that penetrates and escapes from the sample surface.

In NIR spectroscopy, the intensity of the diffuse reflectance from the sample is quantitatively measured at each wavelength of interest. The intensity of radiation reflected from the sample is compared with the intensity reflected from a nonabsorbing reference, such as a ceramic or fluorocarbon material. Reflectance (R) is calculated by the following formula:

$$R = I/I_0,$$

where: I = the intensity of radiation reflected from the sample at a given wavelength and I_0 = the intensity of radiation reflected from the reference at the same wavelength. Reflectance data are expressed most commonly as $\log(1/R)$, an expression analogous to absorbance in transmission spectroscopy. Various mathematical transformations, such as derivatization and scatter correction, can also be applied to the spectra. Such treatments may help to remove spectral differences that can occur due to variations in sample particle size.

Transmission measurements can also be made in the NIR region, and this is often the method of choice for liquid samples. A liquid can be placed in a quartz cuvette, and the absorbance measured at the wavelengths of interest. Transmission measurements can also be taken from solid samples, but generally only in the 800–1100 nm range. In this wavelength region, the absorption bands are higher overtones that are very weak, allowing the radiation to penetrate through several millimeters of a solid sample. The use of transmission measurements can minimize errors that could occur with reflectance measurements taken from samples having heterogeneous surfaces.

Instrumentation

The radiation source in most NIR spectrometers is a tungsten–halogen lamp with a quartz envelope, similar to a projector lamp. Such lamps emit large amounts of energy in both the NIR and visible regions. Wavelength selection in many NIR instruments is accomplished with a grating monochromator. These may be scanning monochromator instruments where a grating is used to disperse the radiation by wavelength, and is then rotated to impinge a single wavelength, or, more appropriately, a narrow band of wavelengths, on to a sample at any given time. With this arrangement, it may take several seconds to collect a spectrum from a sample over the entire NIR region. Some rapid scanning instruments impinge light covering the entire NIR region on to the sample, with the reflected or transmitted light then directed on to a fixed grating that disperses the light by wavelength, and also focuses it on to a multichannel array detector that measures all wavelengths at once. These instruments allow a spectrum to be collected from a sample in less than 1 s.

Instruments dedicated to specific applications often use optical filters to select from 6–20 discrete wavelengths that can be impinged on a sample. The filters are selected to obtain wavelengths that are known to be absorbed by the sample constituents. The instrument inserts filters one at a time into the light beam to direct individual wavelengths (or narrow bands of wavelengths) of radiation on to the sample.

Recently, commercial NIR instruments based on interferometry and using Fourier transform (FT) mathematics have become available. In these FT instruments, the radiation is not dispersed as with a grating monochromator, but rather all wavelengths arrive at the detector simultaneously, and a Fourier transform mathematical treatment is used to convert the results into a typical NIR spectrum. Because all wavelengths are measured simultaneously with an FT-NIR instrument, these instruments can acquire spectra very rapidly with a very high signal-to-noise ratio. Also, such instruments have very high resolution, indicating that they can discriminate differences in reflectance or absorbance occurring between very small wavelength (or wavenumber) intervals. While this may not be much of an advantage for food and agricultural materials whose absorption bands are very broad, it can be important when working with mixtures of pure chemicals that have narrow absorption bands, such as in the pharmaceutical industry. More complete descriptions of

interferometric principles and Fourier transform mathematics can be found in the Further Reading section.

Semiconductor detectors are most commonly used to measure the NIR radiation reflected from or transmitted through a sample. Silicon detectors are used primarily in the 800–1100 nm range, whereas lead sulfide (PbS) detectors are used for wavelengths from 1100 to 2500 nm. Solid-state detectors with a more rapid response, such as indium–gallium arsenide (InGaAs), are being used more frequently in FT and rapid scan dispersive instruments because of their rapid response to changes in light intensity, but they are limited to a maximum wavelength of around 1700 nm.

When taking diffuse reflectance measurements, arrangement of the sample and detectors is extremely important. Most commonly, solid or granular food samples are packed tightly into a cell against a quartz window. Quartz does not absorb in the NIR region, and packing the samples against a window helps to provide a smooth, uniform surface from which reflection can occur. For diffuse reflectance measurements, it is important that the specular reflectance not be measured. In some instruments, this is accomplished by positioning the detectors at a 45° angle with respect to the incoming infrared beam, such that the mirrorlike radiation reflected back toward the infrared source is not measured. Other instruments use an integrating sphere, which is a gold-coated metallic sphere with two holes cut on opposite sides of the sphere, one positioned directly over the sample, and the other through which the radiation beam is introduced. The detectors are mounted inside the sphere. The sphere collects the diffusely reflected radiation coming at various angles from the sample and focuses it on to the detectors. The specular component exits from the sphere through the same port by which the incident radiation beam enters and strikes the sample.

Recent advances in fiber optic technology allow NIR energy to be transmitted through a fiber optic cable some distance from the monochromator or interferometer. This allows either reflectance or transmission measurements to be made remotely from the instrument. Various commercial sampling probes are available that can be inserted directly into bulk granular materials, or can be inserted in a pipe carrying a flowing liquid.

Quantitative and Qualitative Analysis Using NIR

Because of the overlapping nature of NIR absorption bands arising from various food constituents, it is usually necessary to take measurements at two or more wavelengths to quantitate a food component reliably. Most commonly, some type of multivariate regression technique is used to develop mathematical models, or calibrations, that relate NIR spectral measurements to the amount of a particular constituent in a food. The most widely used regression techniques include multiple linear regression (MLR), partial least squares (PLS) regression, and principal-components regression (PCR).

The first step in calibrating an NIR instrument for quantitative analysis is to select a set of calibration, or training, samples. The samples should be representative of the products that will be analyzed, contain the constituent of interest at levels covering the range that is expected to be encountered, and have a relatively uniform distribution of concentrations across that range. The calibration samples are analyzed by the classical analytical method normally used for that constituent, and spectral data are also obtained on each sample using the NIR instrument at all available wavelengths. All data are stored in computer memory.

When multiple linear regression is applied for calibration development, it is used to select the optimum wavelengths for measurement, along with an intercept and associated coefficients for each wavelength, such that an equation with the following form is developed:

$$\%\ \text{constituent} = z + a\log(1/R_{\lambda 1}) + b\log(1/R_{\lambda 2}) + c\log(1/R_{\lambda 3}) + \ldots$$

Derivatized or other transformed spectral measurements can be used in lieu of the raw log $(1/R)$ values. Wavelengths are selected based on statistical significance by using a step forward or reverse stepwise regression procedure, or by using a computer algorithm that tests regressions using all possible combinations of two, three, or four wavelengths to determine the combination that provides the best results. Most calibrations will use between two and six wavelengths, and one should always check to make sure that the wavelengths chosen on the basis of statistical significance also make sense from a spectroscopic standpoint. The use of too many wavelengths can result in 'overfitting' of the data, decreasing the predictive capability of the technique. Calibration results are evaluated by comparing the multiple correlation coefficients, Fs of regression, and standard errors for the various equations developed. It is desirable to maximize the correlation coefficient (generally, R should be > 0.9) and minimize the standard error.

PLS and PCR regression techniques can make use of the entire NIR spectrum, rather than a few selected wavelengths, to predict sample composition. PLS and PCR both use data reduction techniques to extract

from a large number of variables (i.e., reflectance or absorbance measurements at many wavelengths) a much smaller number of new variables that account for most of the variability in the samples. These new variables then can be used to develop a regression equation to predict the amount of a constituent in samples of a food. When using PLS and PCR methods, it is not necessary to eliminate spectral information, as it is when measurements at only a limited number of wavelengths are used. PLS and PCR methods have been found to yield improved results for some analyses when compared with the MLR technique.

Artificial neural networks (ANN) have also recently been used to predict composition from NIR spectra. Neural networks may have some advantages over the linear regression techniques for dealing with highly complex samples, samples from diverse geographic regions, or samples where the relationships between composition and spectral properties do not change in a linear manner.

No matter which calibration technique is used, the models developed should always be tested by using the instrument to predict the composition of a set of test samples that are independent of the calibration set, and comparing the results obtained with those from the classical analytical method.

NIR spectroscopy can also be used for qualitative analysis, classifying a sample into one of two or more groups, rather than providing quantitative measurements. Discriminant analysis techniques can be used to compare the NIR spectrum of an unknown sample with the spectra of samples from different groups. The unknown sample is then classified into the group to which its spectrum is most similar. This technique has been used most widely in the chemical and pharmaceutical industries for raw material identification, but it is beginning to be used more widely for food applications.

Advantages and Limitations of NIR Spectroscopy

NIR spectroscopy provides a number of advantages over traditional wet chemical methods of analysis. Foremost, once an instrument has been calibrated, samples can be analyzed very rapidly, usually in less than 1 min. Also, sample preparation is minimal, and in some cases unnecessary. The technique requires no chemical reagents, so no hazardous wastes are generated. The need for weighing of samples is eliminated as well, thereby eliminating a traditional laboratory bottleneck.

NIR instruments are available that can be used in a production plant environment either in an at-line mode or as on-line monitors. Again, once an instrument has been calibrated, it can be used routinely by production personnel without extensive training. The ability of this technology to provide real-time process control has tremendous potential.

Limitations of the technology include the need for a specific calibration for each product to be analyzed. This is generally not a problem in a production environment where only a few products are likely to be manufactured. However, this limits the usefulness of the technique for situations such as contract laboratories, where a few of many different types of samples may need to be tested each day. Also, early instruments required frequent recalibration. For example, when measuring protein in wheat, it was usually necessary to recalibrate an instrument when grain from a new crop year arrived. However, the use of large calibration sets containing samples from wide geographic areas and time frames, more stable instruments, and more robust calibration techniques such as PLS has made the need for frequent recalibration much less. In fact, recent results have shown that surprisingly diverse sample types can be analyzed with a single calibration model. Research conducted by Kays *et al*. at the USDA Russell Research Center in Athens, GA found that dietary fiber could be measured successfully in products as diverse as snack crackers, granola bars, sugar-coated cornflakes and cookies, all with a single calibration.

Another limitation for users with low sample throughput is the capital cost of commercial NIR instruments. Instrument cost can vary widely, depending on the level of sophistication and automation needed. However, capital expenditures can often be recovered rapidly through labor and reagent

Table 2 Applications of NIR spectroscopy in food analysis

Product	*Constituents measured*
Cereal grains and flours	Moisture, protein, starch, oil, dietary fiber
Oilseeds, flours, meals	Moisture, oil, protein, fiber
Bread	Moisture, protein, fat, fiber
Cereal breakfast foods	Moisture, dietary fiber, sugar
Pasta	Moisture
Cheese	Moisture, fat, protein
Butter	Moisture, fat
Milk and whey powders	Moisture, fat, protein, lactose
Red meat, poultry, fish	Moisture, fat, protein
Processed meats	Moisture, fat, protein
Dehydrated eggs	Moisture, fat, protein
Fresh fruits and vegetables	Total sugar, soluble solids
Dehydrated fruits	Moisture, total sugar, fiber
Potato chips	Moisture, fat
Beer	Alcohol
Corn sweeteners	Sugar

savings, and by minimizing the production of out-of-specification product.

Applications

Applications of NIR spectroscopy to food analysis have greatly expanded since its first use for measuring protein and moisture in wheat and barley. An in-depth discussion of specific applications is beyond the scope of this chapter; however, a number of representative applications are listed in Table 2. A number of NIR procedures have been adopted as approved methods of analysis by the American Association of Cereal Chemists. Typically, if a substance or constituent absorbs in the NIR region, and is present at a level of a few tenths of a per cent or greater, it has potential for being measured by this technique.

In addition to performing compositional analyses of foods and ingredients, NIR has also been used to measure specific chemical constituents in foods that affect their end-use qualities, for directly predicting processing characteristics of commodities that are related to chemical composition, and for monitoring changes that occur during processing. Examples of such applications include determining the amylose content in rice, an important determinant of rice starch quality; predicting corn-processing quality for dry and wet milling; estimating the baking quality of hard wheat; monitoring the degree of cook during extrusion processing; and monitoring the coagulation of milk during cheese-making. In some of these cases, correlations between NIR measurements and measurements from the conventional technique may be < 0.9, but the NIR technique is still good enough for purposes of screening out very good and very poor materials.

Examples of qualitative applications of NIR spectroscopy include the classification of milk powders based on the level of heat treatment, the classification of wheat as hard red spring or hard red winter, the detection of internally infesting insects inside kernels of stored wheat, and the identification of orange juice samples from different sources.

Fluorescence

L Munck, Royal Veterinary and Agricultural University, Frederiksberg, Denmark

Introduction

Fluorescence (the name originates from the fluorescent mineral fluorspar) refers to cold light emission (luminescence) by electron transfer in the singlet state when molecules are excited by photons. The afterglow lasts less than 10^{-9} s and it is independent of temperature, in contrast to phosphorescence, which is light from the triplet state defined as an afterglow lasting longer than 10^{-6} s, and which is temperature-dependent.

Thus, the fluorescence phenomenon is a form of energy transfer mediated in each case by a specific electronic arrangement, which upon absorbing excitation light of a specific wavelength transforms this energy to another rather specific emission peak, always at a longer wavelength. With suitable filters and mirrors in the fluorescence microscope, fluorescent components are visualized against a black background after filtering out the shorter-wavelength light used for excitation. Similarly, the grating monochromator of a spectrofluorometer enables a sample to be illuminated with light of a specific excitation wavelength. The light emitted at 90° to the incident light passes through another grating that allows only the specific emitted light of interest to pass through to reach the photodetector. Just as in the microscope, absence of fluorescence gives a black background, so in the spectrofluorometer the absence of fluorescence

gives total darkness, i.e., no emitted light. This leads to one of the main problems in fluorescence analysis – how to calibrate against zero light and a zero-signal baseline. This, together with differences in equipment design, confers individual characteristics on spectrofluorometers to a much greater extent than with spectrophotometers. Spectrofluorometers are up to 1000 times more sensitive than most spectrophotometers, but while this may confer considerable advantages, it may also cause additional problems, e.g., with fluorescent impurities. Moreover, the fluorescence phenomenon is sensitive to environmental conditions, such as temperature, viscosity, pH, and interacting substances, which can diminish the intensity of fluorescence by quenching.

Due to the unique structure of the fluorescence emission landscape from a sample, new data techniques may deconvolute the excitation and emission spectra of the pure underlying fluorophores as a form of mathematical chromatography. With chemometric methods, whole fluorescence spectra may be calibrated, e.g., to predict oxidation in vegetable oils, thus complementing current predictive near infrared and infrared spectroscopic screening methods with methods which are both more sensitive and specific.

Fluorescence analysis can be used to follow separation processes of plant and animal chemical components and tissues in food production because of naturally present fluorescence markers (autofluorescence or primary fluorescence). Thus, through primary fluorescence, and without using chemical reagents, we can study the refinement process of sugar, the health of chloroplasts in plants, respiration enzymes in microorganisms and fish meat, and one state of lipid oxidation in meat. The value of fluorescence techniques resides in the fact that specific changes in food components during processing can be followed in the fluorescence microscope and then these changes can be quantified using homogenized samples, and even with a turbid suspension, in a spectrofluorometer. Specific fluorochromes, prepared by organic synthesis or tagged on to specific immunoglobulins, can also be added with different affinities for chemical structures and enzymes (Table 1) and thus biochemical changes in foods can be followed. These are termed secondary fluorescence techniques. Here again we can combine the structural visualization in the fluorescence microscope with direct spectroscopic measurements of the fluorescence intensity.

Physics and Chemistry

In general, the vast majority of intensely fluorescent organic compounds (fluorophors) are aromatic in nature, such as benzene and naphthalene. Some nonaromatic but highly conjugated compounds, such as β-carotene and vitamin A, are also fluorescent. In exploiting secondary fluorescence, nonfluorescent derivatives such as fluorescein dibutyrate (FDB: Figure 1) and calcofluor white Mr2 new (Table 1) are used, which can be rendered strongly fluorescent by enzymic modification or by binding, respectively. (*See* **Carotenoids**: Occurrence, Properties, and Determination; **Polycyclic Aromatic Hydrocarbons**; **Retinol**: Properties and Determination.)

Any fluorescent molecule has two characteristic spectra (Figure 2): the excitation spectrum (the

Table 1 Examples of the use of fluorochromes

Compound	*Excitation wavelength (nm)*	*Emission wavelength (nm)*	*Application*
Acridine orange	470	530–650	Starch, nuclei, pectin, microorganisms, DNA, RNA, acidic nuclear proteins
Aniline blue	420–490	520	Cell wall, (1,3)-β-D glucans, callose
Auramine	400–440	470	Bacteria, cutin
Benzoylarginyl-β-naphthylamide	338	410	Protease activity (trypsin)
Calcofluor white CFW	350	435	Cellulose, chitin, collagen, elastine creatine, bacteria, fungal mycelium/spores
Calcofluor white Mr2 new	360	415	β-D-Glucans in cell walls from, e.g., barley, oats, and wheat
Dansyl fluoride	495	525	Primary amines, A-T bases of DNA
Fluorescein dibutyrate	495	525	Esterase/lipase activity
Fluorescein isothiocyanate (FITC)	490	520	Used as a marker of immunoproteins; in yeast viability test and in cell culture
Phenylalanyl-β-naphthylamide peptides	335	410	Amino peptidase assay
Resorufin butyrate	540	560	Cellulase

The conditions under which the fluorochromes are used largely determine their specificity and fluorescence properties. See Guilbault GG (ed.) (1990) *Practical Fluorescence – Theory, Methods and Techniques*. New York: Marcel Dekker and Francisco A (1989). In Munck L (ed.) *Fluorescence Analysis in Foods*, pp. 266–276. Harlow: Longman.

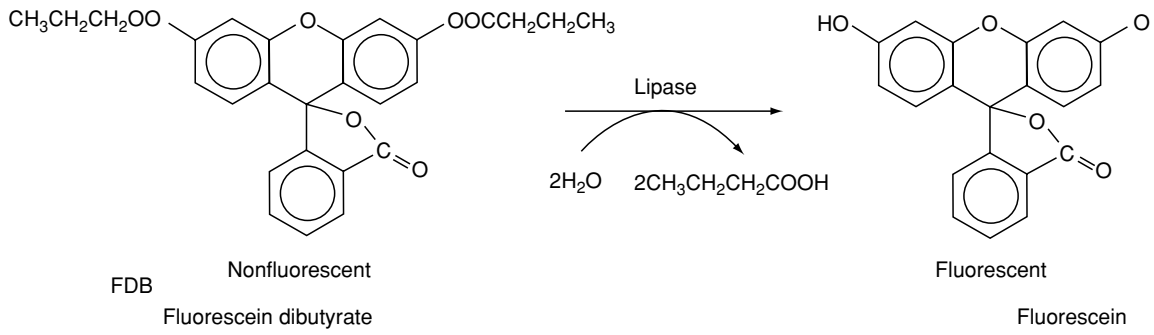

Figure 1 Use of secondary fluorescence. Fluorescein dibutyrate used to detect lipase (esterase) activity by enzymic cleavage to the yellow fluorescent substance fluorescein (excitation 495 nm, emission 525 nm). Reproduced from Spectroscopy: Fluorescence, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

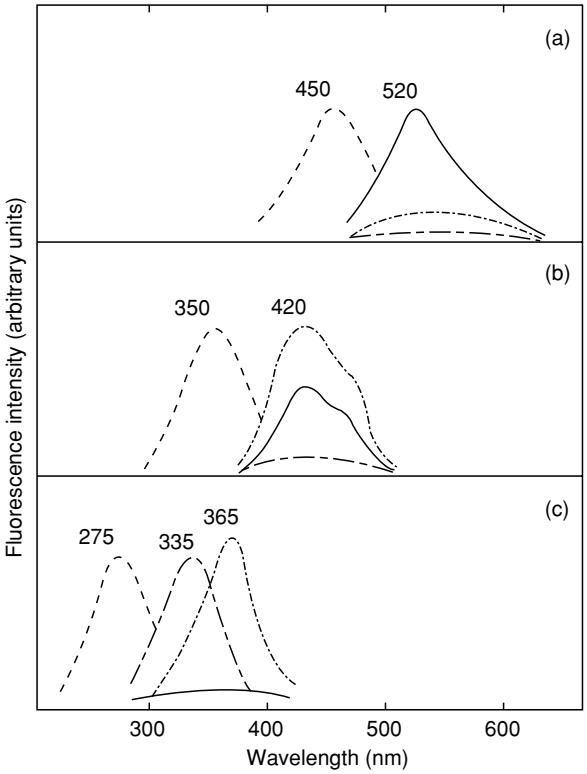

Figure 2 Excitation and emission spectra in the detection of the botanical components of wheat by their primary fluorescence. Excitation (- - -) for (a) pericarp; (b) aleurone; (c) endosperm. Emission spectra of manually dissected pericarp (——), aleurone (–·–), and endosperm (- –) obtained at maximum excitation wavelength for these components: (a) 450 nm; (b) 350 nm; (c) 275 nm. The primary fluorescence probably originates from carotenoids (a), ferulic acid (b), and tryptophan (c). Measurements were made on suspensions of ball-milled flour in glycerin. Reproduced from Jensen SAA, Munck L and Martens H (1982) The botanical constituents of wheat and wheat milling fractions. I. Qualification by fluorescence. *Cereal Chemistry* 59: 477–484, with permission.

relative efficiency of different wavelengths in causing fluorescence) and the emission spectrum (the relative intensity of radiation which is emitted at various wavelengths at a given, e.g., maximal, excitation wavelength). Theoretically, the shape of the excitation spectrum of a fluorescent substance, discounting instrumental artifacts, is identical with that of the absorption spectrum as measured by spectrophotometry. The longest-wavelength peak should be chosen for excitation of the sample, thereby minimizing photodecomposition of the fluorophore by ultraviolet (UV) light. Rayleigh and Tyndal scattering can be observed in the emission spectrum at the same wavelength as the excitation wavelength, and also at twice this value (second-order grating effect) in a grating spectrofluorometer.

The basic equation defining the relationship of fluorescence of a substance to its concentration is:

$$F = \Phi I_0(1 - e^{-\varepsilon bc})$$

For very dilute solutions, this equation is reduced to Beer's law in spectrophotometry:

$$F = K\Phi I_0 \varepsilon bc$$

where Φ is the quantum efficiency of yield (number of quanta emitted divided by number or quanta absorbed), I_0 is the incident radiant power, ε is the molar absorptivity, b is the path length of the measurement cell, and c is the molar concentration of the fluorophore. K designates an arbitrary constant with no unit.

The sensitivity of fluorescence is large because a signal over a zero background is measured. Its specificity is high because, although all compounds absorb radiation, only a few emit, and those that do can be differentiated on the basis that they very seldom have the same excitation and emission maxima. The main disadvantage of fluorescence is that the output is strongly dependent on temperature although the afterglow time is independent. It is also dependent on pH, ionic strength, and viscosity, making it necessary to standardize analysis conditions rigorously. Fluorescence is affected by quenching, which reduces

fluorescence by a competing deactivation process that might be enhanced by oxygen, impurities (e.g., dichromate and iodide), high temperature and high concentrations of the fluorophore.

Concentration quenching may be substantial in transmission mode (inner-cell effect), whereas it is negligible in front-face (reflectance) fluorescence with solid samples.

Instrumentation and Sample Preparation

Light Sources

Spectra for two conventional light sources for microscopy (HBO, mercury lamp; XBO, xenon lamp) and spectrofluorometry (XBO) are presented in Figure 3. Xenon lamps for spectrofluorometry need a certain burning time in order to obtain a constant spectral output, and they have a limited lifetime of 200–1000 h. When working with the information from complete spectra, lamp spectral stability is crucial, and spectral instability cannot be totally compensated for across complete spectra by using the rhodamine standard in a ratio spectrofluorometer, as explained below. Recently, monochromatic laser techniques have increased light intensity and wavelength precision, but at high cost. The aim of increased light intensity is often counteracted by photodecomposition of the fluorophore which necessitates short illumination periods.

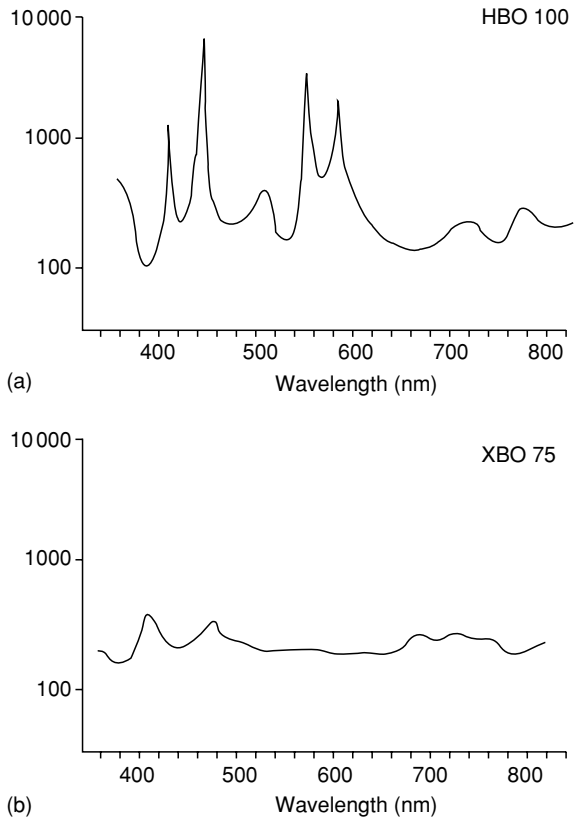

Figure 3 Light sources. Examples of spectral outputs typical of common illuminators in fluorescence microscopy and spectrofluorometry. (a) Mercury lamps (e.g., HBO series), mostly used in microscopy, generate very intense peaks at certain wavelengths (e.g., 365 nm (not shown), 450, 435, and 546 nm), while (b) xenon (e.g., XBO series) lamps produce a more uniform spectrum at lower intensity, and these are used in both fluorescence microscopy and spectrofluorometry. Reproduced from Fulcher RG, Irwing DW and Francisco A de (1989) Fluorescence microscopy: Applications in food analysis. In: Munck L (ed.) *Fluorescence Analysis in Foods*, pp. 59–109. Harlow: Longman.

Fluorescence Microscopy

Ideally a minimum of preparation should be used so that the material can be examined in as near a native state as possible. A suitable technique is cryosectioning at freezing temperatures (−20 °C) with and without additives to prevent ice crystal formation. Simpler, but also effective, is hand-sectioning with a razor blade at room temperature. The sections or macerated material are transferred to a microscope slide, stained, and covered with a cover slip. Permanent preparations need fixation of samples, e.g., with glutaraldehyde, followed by embedding in a resin such as glycol methacrylate (GMA), which is especially suitable for fluorescence, including immunofluorescence; sections are then cut with a glass-knife microtome and stained appropriately. GMA is easy to handle at room temperature and need not (and cannot) be removed from tissues prior to staining. Tissue sections do not require hydration or dehydration prior to staining. GMA fluoresces minimally; the polymerized block is much harder than paraffin and it can thus be sectioned more thinly.

The most frequently used fluorescence microscopy technique is epiillumination (reflectance), which is most light-efficient owing to its specific filter/optics arrangement (Figure 4), but the older transmission mode (diaillumination) can also be used. There is an inverse relationship between the number and volume of glass pieces in an objective lens and its usefulness in fluorescence techniques because a more sophisticated optical construction compromises effective light transmission. It is difficult to find light-efficient, low-magnification objectives for fluorescence work because of their low numerical aperture. Modern sensitive films and video cameras can compensate for the limiting factor of low light intensity in fluorescence microscopy.

Successful fluorescence microscopy is critically dependent on the use of filters that have transmittance characteristics such that they can excite maximum fluorescence in a specimen (excitation filter)

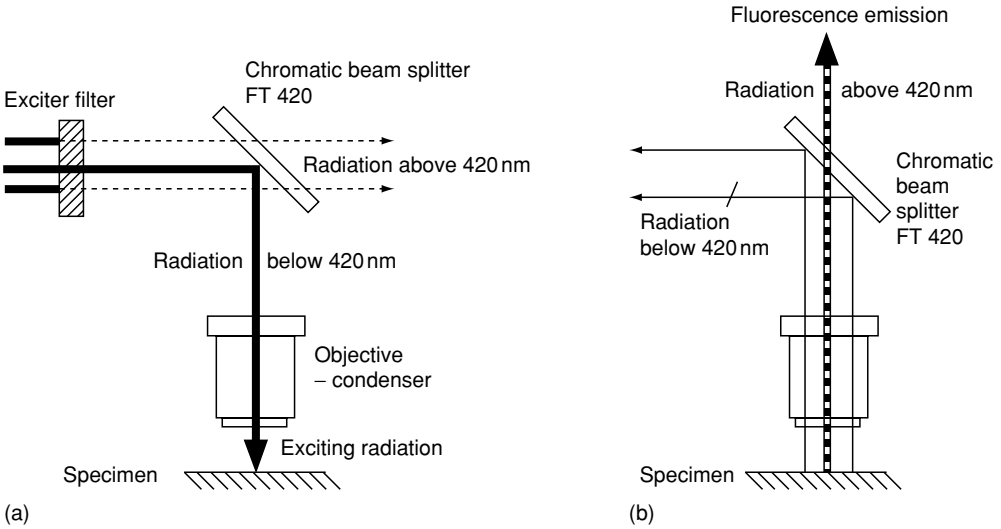

Figure 4 Diagrammatic representation of a typical fluorescence microscope epiillumination system equipped with a filter combination, as shown in **Figure 5(a)**. (a) Broad-spectrum illumination first passes through a colored glass filter that transmits maximally at 365 nm. Upon striking the chromatic beam splitter in this example all wavelengths below 420 nm are reflected to the top surface of the specimen through the objective, causing it to fluoresce at a longer wavelength. Both the excitation (by reflection) and fluorescent wavelength are generated at the specimen surface and are again collected by the objective (b). However, only fluorescent wavelengths longer than 420 nm are now transmitted to the detector (e.g., the eye) by the beam splitter, which acts as a barrier filter. In most instruments, an additional barrier filter is placed between the beam splitter and the detector to define further the range of fluorescence wavelengths to be examined. Reproduced from Fulcher RG, Irwing DW and Francisco A de (1989) Fluorescence microscopy: Applications in food analysis. In: Munck L (ed.) *Fluorescence Analysis in Foods*. Harlow: Longman, with permission.

and subsequently filter out all but the fluorescent wavelengths (barrier filter) from the final image (Figure 5). Fluorescence microscopes can be combined with sophisticated monochromators and detectors which can extend into the short-wave UV region (220 nm) with the use of quartz objectives.

An attractive refinement of the fluorescence microscopy is the laser confocal microscope (such as the Leica Lasertechnik TCS NT confocal microscope). A laser beam is scanned over a fixed specimen, restricting illumination and detection to the same small volume. Detection, via a computer-controlled video system that controls the scanning function, is limited to what is in focus, allowing the study of crude samples in three dimensions and eliminating glare. Up to four lasers can be attached to the microscope from UV to near infrared. The specimens studied are usually stained by fluorochromes responsive to the specific wavelength of the laser.

Spectrofluorometry

Recent research has shown that spectrofluorometers may be used in combination with computers and suitable software to predict important quality factors in foods analogous with the established near infrared spectroscopic techniques. (*See* **Spectroscopy**: Near-infared.)

Applications are, for example, to monitor formation of colored substances (Maillard compounds) in sugar processes, oxidation products in frying oils, and purity of pectins. However, the application of these techniques in industry has been delayed due to lack of suitable instruments which are able to measure a sample area large enough to obtain correct sampling of the often nonhomogeneous food products.

Sample holders delivered with the instrument are for front-surface (reflected) or transmitted light and employ quartz cuvettes. Fluorescence of insoluble particles such as wheat flour can be studied after fine ball-milling and suspension (about 1 mg ml^{-1}) in fluorescence-free glycerin/water which slows down sedimentation.

A typical laboratory spectrofluorometer with a measurement area of only 1×9 mm is shown in Figure 6. It is a convenient tool for obtaining complete excitation and emission spectra of homogeneous fluorescent samples, for identification and quantification through data processing, and for measuring fluorescence at a defined pair of excitation and emission wavelengths. For some applications in which maximum excitation and emission wavelengths are known, a simple and inexpensive filter fluorometer is superior to a spectrofluorometer because the superior accuracy in wavelength definition obtainable with

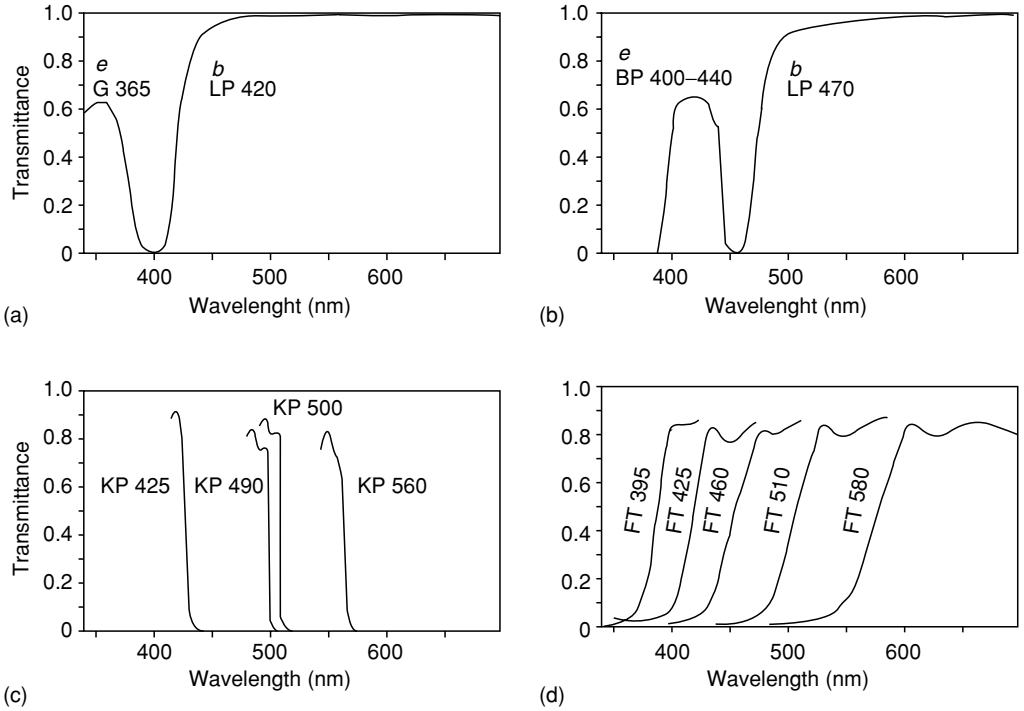

Figure 5 (a, b) Filters. Typical spectral transmission curves of paired exciter (*e*) and barrier (*b*) filters designed to optimize fluorescence by an HBO illumination. G 365 is a colored glass filter while the other filters displayed in the figure are interference filters coated by vacuum evaporation of metallic oxides. The latter can be specified more flexibly, but are also more expensive. A bandpass filter (BP 400–440) shows sharp cut-offs on each side of the curve (b). Short-pass (KP) interference filters (c) are used as exciting filters. They suppress long-wavelength light, and show a steep cut-off at the high limit of transmittance. Barrier filters may also be of the BP type but are mostly long-pass (LP) filters (d) showing steep cut-offs at the lower limit of transmittance and uniform transmittance throughout the rest of the visible range, making it possible to detect a range of emission wavelengths with the same barrier filter. Filters are examined in a high-quality spectrophotometer. Reproduced from Fulcher RG, Irwing DW and Francisco A de (1989) Fluorescence microscopy: Applications in food analysis. In: Munck L (ed.) *Fluorescence Analysis in Foods*. Harlow: Longman, with permission.

the latter instrument may be compromised by the greater amount of light that can pass through the filters of a filter fluorometer. Fluorescence thin-layer chromatography (TLC) scanners, which are specialized (epi)spectrofluorometers, are often convenient for studying, for example, bones in fish fillets and connective tissue in minced meat. Filter and spectrofluorometry may be exploited to provide highly sensitive detection of specific substances in high-pressure liquid chromatography (HPLC) and flow-injection analysis (FIA). (*See* **Chromatography**: Thin-layer Chromatography; High-performance Liquid Chromatography.)

Applications

Monitoring Structure and Function in Food Systems

In many applications, the evaluation of structural (physical) properties of a food material accompanies determination of its (bio)chemical characteristics. In the case of wheat grain, it becomes readily apparent that the bran tissues (pericarp and aleurone; Figure 7:2:1 and 3) have yellow and blue fluorescence, respectively, at specific excitation wavelengths. A method can then be developed to quantify fluorescence on the basis of excitation and emission spectra obtained with suspensions of finely milled hand-dissected samples of the pure botanical tissue components (Figure 2). An additional finding will be that the floury endosperm part of the seed autofluoresces in the UV region, which cannot be detected by the eye in the fluorescence microscope. This information could be used tentatively to monitor the fractionation process in a wheat mill by spectrofluorometry much more accurately than with the present ash and color analyses. It is also possible, for example, to optimize the milling process to obtain an increased content of the vitamin- and mineral-rich bran component, aleurone, in the flour, while still obtaining a relatively white bread with good baking volume despite a high ash content.

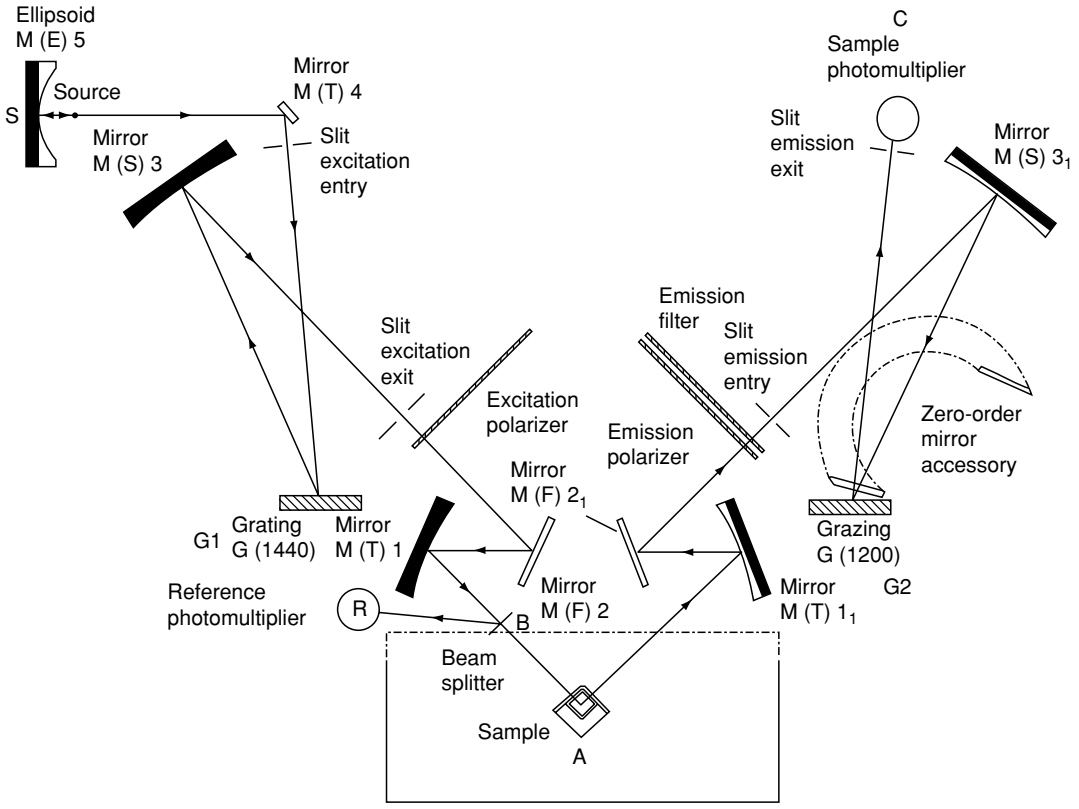

Figure 6 Fluorescence spectrophotometer (Perkin Elmer LS-50). The source (S) is a pulse xenon flashtube (less than 0·02 s for a complete pulse). Light from S is reflected by a mirror through a slit to the diffraction grating (G1) which has 1440 lines per millimeter. The resulting narrow-wavelength band is transferred via another system of mirrors and slit to the sample (A). The effective wavelength of the excitation beam is determined by the setting of the grating, the angle of which is controlled by means of a stepping motor. A very small proportion of the excitation light is reflected by a beam splitter (B) to a reference photomultiplier. To correct for the response of the reference multiplier, a rhodamine correction curve is stored within the software in the instrument computer. Light emitted by the sample is transferred via slits and mirrors to a second diffraction grating (G2), which has 1200 lines per millimeter and is controlled by another stepping motor, and on to the sample photo multiplier (C). A microprocessor controls the xenon tube, grating stepping motors, slit apertures, and photo multipliers. The digitized signal is accumulated for about 0·08 s, i.e., four flashes of the source. The sample accumulation is divided by the corrected reference accumulation to obtain a ratio that is unaffected by variation in source intensity. Output is given by the microprocessor on a data screen and a recorder. The computer is programmed so as to allow calibration spectra to be subtracted from sample spectra to generate difference spectra. The wavelengths of the instrument can be calibrated by the characteristic fluorescence spectrum of benzene vapors, for example, or from fluorescent standards cast into plastic blocks furnished by the instrument manufacturers. It is important in some applications to be able to record accurately several of the internal settings of the instrument, including spectral correction and different scanning modes, and this can be done with a high-specification spectrofluorometer. The practicable wavelength ranges for the standard version of the instrument are about 230–600 nm for excitation and about 250–650 nm for emission. Reproduced from Spectroscopy: Fluorescence, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

The problem of calibrating and handling such complex fluorescence information will be discussed below. Likewise, autofluorescence of animal tissue components and parasites, detected in the fluorescence microscope and defined in the spectrofluorometer, can be exploited in digital video techniques coupled to image analyzers and robots, e.g., to facilitate automatic butchering operations and cutting out bones from cod fillets (Figure 7:3A–D). In the laboratory, naturally fluorescent compounds such as vitamin E components can be separated and detected in an HPLC system coupled to a fluorometer. In commercial-scale fermentation processes, the fluorescing reduced forms (NADH and NADPH) of the respiratory coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) can be used online to follow the rate of the fermentation process. (*See* **Tocopherols:** Properties and Determination.)

Similarly, a food chemist in need of a certain assay, e.g., to monitor the breakdown of mixed-linkage β-glucan in the malting and brewing industry or to

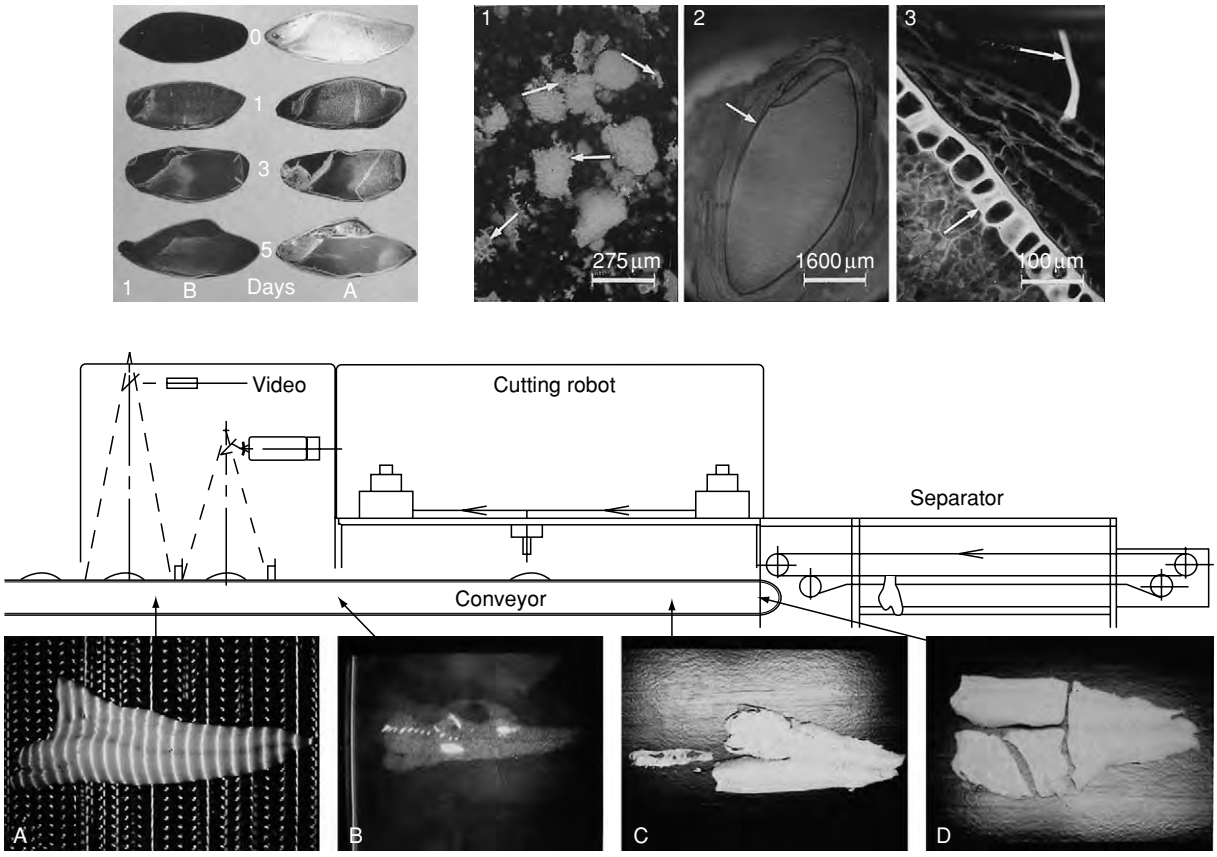

Figure 7 (see color plate 129) Examples of fluorescence microscopy and imaging reproduced from articles referred to below in Munck L. (ed.) (1989) Fluorescence Analysis in Foods, Harlow: Longman. pp. 289. 7:1. Cryostat sections of 0, 1-, 3- and 5-day malted barley viewed through a 4× microscope objective. The sections were stained by (A) Calcofluor/Fast green photographed at 400 nm excitation/418 nm emission in order to show the patterns of cell wall (β-D-glucan) breakdown and by (B) FITC-labelled antibodies against α-amylase viewed with BP 455-490 nm exciter/LWP515 nm emission filter. Sections are identical pairwise – first stained with method B followed by A. It is seen that α-amylase is spread from the germ (the structure on the left of each section) and from the aleurone layer enclosing the starchy endosperm. The enzyme invades only the endosperm areas where cell walls are absent. (Compare B with A on each day of malting.) From Munck L. Practical experiences in the development of fluorescence analyses in an applied food research laboratory, ibid. p. 1-32. 7:2:1-3. represent a wheat and barley material with natural and added fluorochromes. 7:2:1. A view of ground whole wheat flattened slightly with cover glass, excited at 365 nm with a barrier filter from 420 nm. Bran fragments are readily detected by the natural bright blue fluorescence characteristic of the aleurone layer (arrows). See also **Figure 2b**. 7:2:2. A low-power view of a longitudinally halved barley kernel treated with a multiple fluorescent stain (Safranin, Basic Fuchsin, Alcian Blue) to show several grain components simultaneously. The starchy endosperm (central region of the kernel) fluoresces bright yellow due to starch-safranin interaction under 450-490 nm excitation, while the outer bran layers are deep red as a result of Basic Fuchsin interaction with lignified and other phenolic-enriched structures such as cell walls (arrows). In this case, safranin is used to detect starch, while the other stains are added as counterstains to surpress non-starch specific fluorescence. 7:2:3. As in 7:2:2, but showing the bran tissues at higher magnification and 365 nm excitation. In this case, the procedure clearly differentiates between I. ferulic acid-enriched aleurone cell walls (lower left) detected due to their natural fluorescence (as in 7:2:1), II. surface trichomes (arrows) which do not bind significant amounts of the red fuchsin stain and III. the pericarp cell walls (right diagonal) which are intensely stained deep red. Starch does not fluoresce significantly at these wavelengths. From Fulcher RG, Irwing DW and de Francisco A. Fluorescence microscopy: Applications in food analysis, ibid. 59-109. 7:3:A-D. Operation of an automatic Fish Fillet Deboning Line based on fluorescent technology. Skinned cod fillets are fed onto a steel conveyor while moving at one m/s. The video detector (see drawing above the photographs) detects a fillet (A). The detector consists of two cameras and two light sources for visible and UV light for fluorescence, respectively. The visual light is projected in stripes (A) in order to detect (I) the boundaries of the filet and (II) the topography of the fillet for later partition (D) into desired weight portions. The video UV fluorescence system detects the naturally fluorescent bones (ex. max 340/em. max 390) seen on a TV monitor (B). The information from the two cameras is directed to a computer which directs a water jet nozzle (diameter 0.1 mm, pressure 300 bar) robot with an operating space of 1 m. The cutting of the fillet bones (C) and further partition of the fillet (D) is performed while the steel conveyor is moving and completed within the time span of one second. Bones and fillet pieces are separated and graded in the separator unit drawn above. This principle may also be used to remove bones from chicken breast fillets. From Jensen SAa, Reenberg S and Munck L. Fluorescence analysis in fish and meat technology, ibid. 171–180.

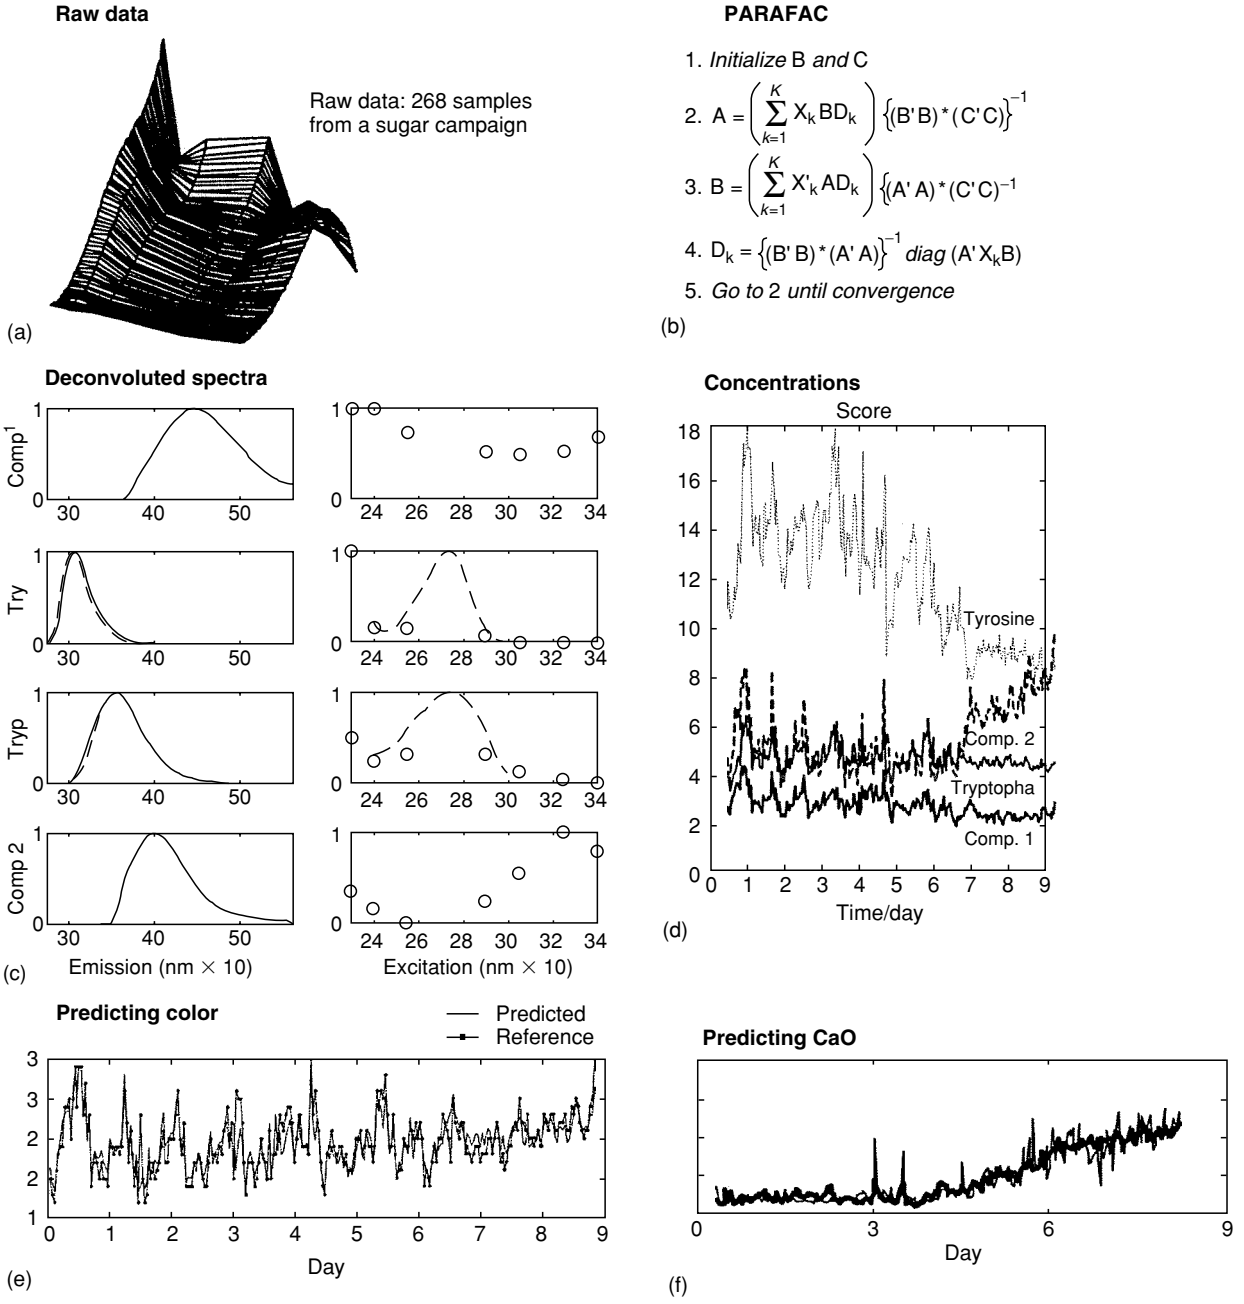

Figure 8 An example of mathematical chromatography is multiway modeling of fluorescence landscapes of sugar into the pure excitation and emission spectra of the underlying fluorophores. A total of 268 samples of sugar have been dissolved in water and measured spectrofluorometrically, spanning the sugar campaign with three samples representing three 8-h periods per 24 h. Each such measurement gives a characteristic landscape of a sample (a). By using the so-called parallel factor analysis (PARAFAC) model (b), it is possible to describe these landscapes by the variation in four estimated fluorophores (c). Thus, at any time the sugar landscape of any sugar sample can be described by having different amounts expressed in scores of these four fluorophores, defined by their estimated excitation and emission spectra. The former is described less accurately than the latter due to sampling (20 nm). The amounts of the four fluorophores in the 268 samples thoughout the season are shown in (d). Furthermore, it is possible to qualify which chemical analytes these four fluorophores represent, just as in ordinary chemical chromatography. In this case, two of the analytes have been identified as the uncolored amino acids tyrosine and tryptophan which have the potential for color formation through reaction with reducing sugars. (Estimated and true emission spectra are shown.) The other two fluorophores represent colored fluorescent high-molecular Maillard products. These interpretations have been checked with high-performance liquid chromatography. Thus, a chemical understanding of the fluctuations during the campaign is provided. In (e) and (f) it is demonstrated that this spectrofluorometric chemically based variation can be used for creating cheap online screening analyses for prediction of, e.g., important process variables such as CaO in sugar juice or quality parameters such as color in sugar by using a multiple linear regression model based on scores of the four fluorophores.

screen for lipases in oat products, may select from potentially useful fluorochomes (Table 1) to solve the analytical problems by employing secondary fluorescence techniques: for example, calcofluor white Mr2 new and fluorescein dibutyrate can be used to determine mixed-linkage β-glucan and esterase/lipase contents, respectively, of cereal grains. In the case of the calcofluor/β-glucan assay, two official European brewing convention methods, one visual – malt modification analysis (Figure 7:1A) – and one chemical – FIA for mixed-linkage β-glucan in wort and beer – have been developed. These methods have helped to strengthen the insight of brewing chemists into the strong relationship between the physical cell wall structure of barley and malt and the chemistry of wort and beer related to viscosity and filterability due to the influence of β-glucans. Mg-ANS (1-aniline-8-naphthalene sulfonic acid) can be used to detect dead cells in pitching brewer's yeast, and fluorescein isothiocyanate (FITC)-immunofluorescent visual and chemical methods can also be applied successfully, for example, to monitor the distribution of α-amylase activity in malting barley seeds (Figure 7:1B). A range of components such as aleurone, starch, β-glucans, protein bodies, fat globules, protein, and crystalline inclusions can be convincingly demonstrated by employing a range of fluorochromes and treatments one at a time or in combination as demonstrated in an example with wheat in Figure 7:2:2 and 3. Several of these methods can also be used quantitatively to determine components in homogenized samples by spectrofluorometry.

Fluorescence Spectrofluorometry for Prediction of Food Quality Calibrated with Chemometrics

Due to its specificity and sensitivity, spectrofluorometric analysis allows a unique characterization of a fluorescent food sample, thus complementing near infrared spectrophotometry. Fluorescence measurement with fluorochromes *in vitro*, e.g., to detect lipase (esterase) activity with fluorescein dibutyrate at 495 nm excitation and 525 nm emission (Figure 1) is a rather straightforward analysis using the equations given above. However, spectra from complex fluorescence systems, such as that from wheat flour (Figure 2), need advanced data analysis techniques (chemometrics) similar to those developed for protein analysis of seeds by near infrared spectroscopy. These use complete spectra, and involve principal component analysis for discrimination between normal and deviating samples and partial least-squares analysis (PLS) for calibration to chemical analyses for prediction. Precise calibration of the spectrofluorometer that is stable from day to day is obligatory here, if data from whole spectra are to be utilized. Spectrofluorometric data in the form of excitation/emission landscapes are ideally resolved by multiway chemometric algorithms such as parallel factor analysis (PARAFAC: Figure 8) which in the fluorescence example from process control in a beet sugar factory covers three dimensions: excitation, emission, and sample. In a PLS evaluation of a complex fluorescence landscape the latent factors, or loadings, are difficult to interpret due to orthogonality. In contrast, PARAFAC loadings are interpretable and expressed in the form of estimates of the underlying excitation and emission spectra of the corresponding fluorophores. If stable computerized instruments with enlarged measurement area for fluorescence monitoring (mathematical chromatography) of inhomogeneous samples in the food industry can be developed, the chemometric software already developed will be able to create a measurement system with unique potential with regard to sensitivity and specificity to measure those quality characteristics which depend on fluorophores.

Atomic Emission and Absorption

N Ulrich, University of Hannover, Hannover, Germany

Summary

Atomic spectrometry is suitable for the determination of trace concentrations of most elements. The principle is the absorption or emission of light of certain wavelengths after the atomization and excitation of the sample. The wavelength gives qualitative information about the element, whereas the intensity of the emission or the quotient of the intensity before and after the absorption is proportional to the concentration of the analyte. Several spectral and non-spectral interferences must be considered.

Background

Atomic emission and absorption spectrometry are used for the qualitative and quantitative determination of chemical elements, mainly metals and semimetals in a huge variety of different matrices. Both techniques are based on the interaction of atoms and electromagnetic energy. Kirchhoff and Bunsen grounded the atomic spectrometry in the middle of the nineteenth century. They observed that free, gaseous atoms of an element can absorb or emit radiation of discrete and specific wavelengths. In atomic spectrometry, wavelengths between 170 and 800 nm are investigated.

The Atomizing Process – Important for Both Techniques

Prior to the excitation or absorption step, free atoms of the elements must be formed. In classic techniques, the samples are introduced into the system as aerosols, e.g., solutions of sodium chloride. These aerosols are desolvated and evaporated rapidly by adding thermal energy to form microparticles. By interactions with the environment in the flame or the plasma, free atoms are formed that are capable of absorbing light of specific wavelengths (atomic absorption) or, if excited by thermal energy, can emit light of specific wavelengths (atomic emission). The wavelength is equal for both processes. **Figure 1** shows the atomization process for aerosols using sodium chloride (NaCl) as an example.

Excitation and Relaxation of Valence Electrons

After the atomization, the excitation of the electrons (absorption) and relaxation (emission) take place. Only the valence electrons are capable of the radiation used in atomic spectrometry. In their basic form, these electrons are in certain energy levels, representing the ground state for an atom of a given element. The electrons can absorb energy and form energy-enriched, excited states. Two forms of excitation are of importance for atomic spectrometry:

1. Thermal excitation: The electrons can be excited by thermal energy. At temperatures of 2000–3000 °C, most of the atoms are in the ground state, following the Boltzmann distribution. More states can be populated at higher temperatures, e.g., in the Ar-plasma of an inductively coupled plasma (ICP). The relaxation takes place as electromagnetic radiation, which is measured in atomic emission spectrometry (AES).
2. Electromagnetic excitation: The electrons can absorb light of a certain wavelength according to Einstein's law of absorption and emission, which is measured in atomic absorption spectrometry (AAS). The wavelength depends on the energy difference between the ground and excited electronic state of the atom. The relaxation may take place as thermal or electromagnetic radiation.

There are many emission lines in different series starting from the ground state or an excited state, but

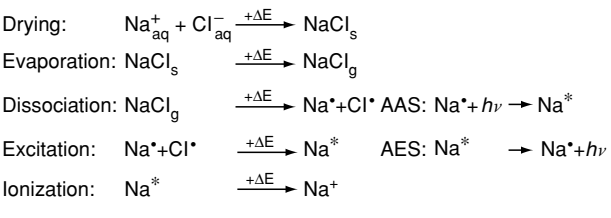

Figure 1 Processes in the atomizer of an atomic spectrometer.

not every emission line is also a detectable absorption line in AAS. The intensity of the absorbance line depends on the population of that state (,) which absorbs the light. In most cases, only the ground state is populated to such an extent that intensive radiation is emitted.

Atomic Emission Spectrometry

In AES, the atoms are excited by thermal energy and emit light of specific wavelengths. The frequency of the light is proportional to the energy difference of both states. For optical emission spectrometry, the wavelengths are in the ultraviolet/visible region. This light is measured and can be correlated by the wavelength to the element (qualitative information) and by the intensity to the concentration (quantitative information).

The intensity of the emitted light depends on the number of atoms in the excited state. This number will be larger for higher temperatures given by the Boltzmann distribution. At temperatures below 2500 °C, only transitions between the ground state and one of the first excited states are possible for most of the elements. The alkali metals can be excited in sufficient rates at temperatures of *c*. 2000 °C. The concentration of the analyte in the sample is directly proportional to the intensity of the emitted light.

Principal Components of an Atomic Emission Spectrometer

The main components of an atomic emission spectrometer are the sample introduction device, which is often a pneumatic nebulizer system, the atomization and excitation source, one or more monochromators, and a detector, mostly a photomultiplier. The principal set-up of an AES is shown in Figure 2. AES can be used as single element method or as a simultaneous measurement device, as detailed below.

Atomizing and Excitation Techniques

There are many techniques for atomizing and exciting samples, like bow and spark excitation or glow discharge excitation. The two most important methods are flame photometry, which is suitable primarily for alkaline and some earth alkaline elements, and ICP, which is used widely as an energy source in atomic emission spectrometry.

Flame Photometry (Atomic Emission Spectrometry)

Flame photometry was established by Bunsen. It is called photometry, although it is an emission technique. The correlation between the intensity and concentration is linear, and the Lambert–Beer law cannot be applied. The atoms are excited in a flame, and the intensity of the emitted light is measured.

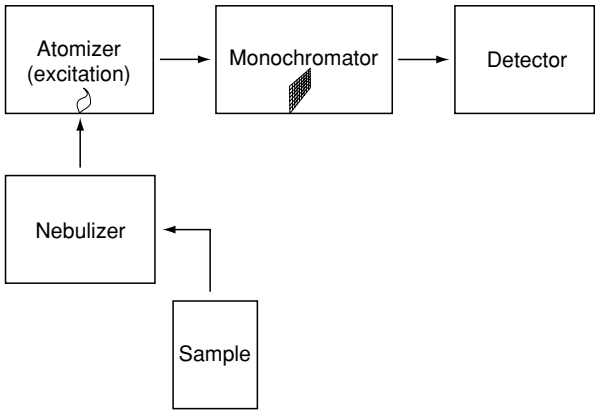

Figure 2 Principal set-up of an AES apparatus.

The apparatus of FAES contains a nebulizer system, a burner, suitable for different gases like nitrous oxide or methane, a monochromator, which is important for the quality of the measurement, and a detector. Often, flame atomization absorption spectrometry systems with the lamps turned off are used as the FAES device.

Applications and analytical performance In the early years, FAES was used for all metals. However, the exciting efficiency of the flames was poor, and the detection limits were quite high. Today, FAES is mainly used for the determination of alkali metals in solutions. The sensitivity for these elements, especially Na and K, can be better than for the FAAS. Typical detection limits are $0.01\,\mathrm{mg\,l^{-1}}$ (Na) and $0.1\,\mathrm{mg\,l^{-1}}$ (K) in liquid biological samples. For other elements, AES with plasma excitation, atomic absorption spectrometry, or mass spectrometry is used nowadays.

Problems and interferences Spectrometric determinations are relative methods, so calibration is necessary. Differences between the samples and the standard solutions can lead to systematic errors, called interferences. In spectrometry, there are two types of interferences. The spectral interferences are problems caused by unspecific radiation or absorption, whereas nonspectral interferences affect the concentration of the analyte in the atomizer and exciting zone.

Spectral interferences in flames include the spectral lines of matrix compounds and the high continuous background of the flame, emitting light of all wavelengths. In relatively cold flames (2000 °C), emission

spectra with few lines are observed. However, excesses of one element, e.g., 1000-fold excess of Na for Li determination can lead to an overlapping of the signals. In addition, Ca and Sr can lead to interferences.

Nonspectral interferences can be classified as chemical interferences, transport interferences, ionization interferences, and self-absorption. If stable compounds of the analyte and matrix components are formed, these will hinder or even completely suppress the atomization and excitation. Organic substances can alter the flame temperature, which is important for the FAES, and can emit continuous background radiation. In addition, the analytes can react with the flame gases, e.g., Ca can form CaO with oxygen.

Transport interferences occur when the amount of sample introduced into the atomizer changes over time. The main reason is a difference in viscosity between water solution and organic solvents. In addition, larger concentrations of salts and matrix compounds can disturb the nebulizing process.

Ionization interferences occur, when part of the analyte is ionized within the flame. It only takes place to a small extent, but causes a reduction of the population in the excited state. One problem with a high concentration of the analyte is self-absorption. Because emission and absorption take place at the same wavelength, analyte atoms can absorb light, which is emitted by other analytes. This leads to a significant curving of the calibration graph.

Inductively Coupled Plasma–Atomic Emission Spectrometry (ICP-AES)

The inductively coupled plasma was introduced into atomic emission spectrometry by Greenfield in 1964. ICP-AES is today one of the most widely used techniques for trace metal and semimetal determination in a huge variety of different samples.

An argon plasma with a gas consumption of *c.* 17 l min^{-1} is used as atomizer. The gas is delivered through three concentric quartz tubes (the torch), which are surrounded by an induction coil. This coil is operated at a frequency of 27.1 MHz and a power of 1000–2000 W. Gas temperatures of 6000–8000 °C are observed in the plasma, which, in combination with the relative long residence time of the analytes in the plasma, lead to an effective energy transfer on to the analytes. Even refractive metals and oxides can be atomized to a great extent. The spectra obtained are often complicated and contain many lines, especially for the transition metals. The plasma can be observed either axially or radially.

One of the main advantages with respect to AAS is the ability of multielement determinations, because sequential and simultaneous set-ups can be used. Analytical wavelengths range from 170 to 800 nm. For sequential investigations, the monochromator, often of the Czerny–Turner type, is tuned for each element. Several monochromators of unchangeable wavelengths are fixed in the detector, mostly forming a Rowland circle, for simultaneous measurements.

Applications and analytical performance The ICP-AES is suitable for a wide range of elements, because the high temperatures provide very good atomizing conditions. All metals and semimetals and even some of the nonmetals (e.g., sulfur, phosphorus, and iodine) can be detected. The simultaneous spectrometers are limited to six to 30 elements, depending on the number of monochromators in the detector. Quantitative results for these elements can be obtained in *c.* 1 min. Typical detection limits range from 0.01 $\mu g\,l^{-1}$ for Ca, Mn, Mg, and Mo to 20 $\mu g\,l^{-1}$ for As, Bi, and Sn. The dynamic range reaches usually over five to six decades, so that matrix compounds and trace elements often can be detected in one analysis.

Gaseous, liquid, and solid samples can be detected using ICP-AES. Liquids can be nebulized with any of the standard nebulizers. Flow injection and on-line coupling to chromatographic devices are other options. Gases, e.g., metal hydrides, can be brought directly into the plasma. The dry plasma and the nearly complete sample introduction lead to a significant enhancement of the detection limits. For solid samples, mostly slurry techniques with particles less than 2 μm in diameter are used.

Problems and interferences The drawbacks of ICP-AES are the high costs of the apparatus and maintenance, and the high spectroscopic background of the plasma.

In addition, there are numerous interferences observed in the spectra. Spectral interferences arise from the plasma itself, which is an intensive source of unspecific radiation and argon emission lines. Both depend on the temperature and the composition of the plasma gas and vary, e.g., with the introduction of water from the sample. Further, there are emission lines of hydrogen, nitrogen, and oxygen. Different molecular species are formed in the plasma, e.g., N_2^+, OH, NH, or NO, which show a large number of rotation and vibration bands.

Nearly all elements in the sample emit characteristic spectral lines not only from the ground state but from several excited states, because the high temperatures in the plasma lead to a remarkable population of numerous states. These interferences can be resolved to some extent by the use of high-efficiency

monochromators, but many lines are too close together for separation.

Chemical interference is not important in most cases. Transport interference can occur, as described for FAES.

Other Plasma Sources for Atomization

Microwave-induced plasmas (MIP) are formed by microwaves (frequency 2.45 GHz, power 50–200 W). This plasma is mainly used as a detector for gas chromatography. Mostly, He is used as the plasma gas, providing very high electron temperatures and excitation energies, e.g., for the nonmetals.

Several other plasma sources have been applied for AES. Glow discharges, sparks, and bows are mostly used for metallic samples. In addition, capacity coupled plasmas can be utilized to excite metal atoms.

Atomic Absorption Spectrometry

This technique is based on the selective absorption of light by the gaseous free atoms. The absorbance is the logarithm of the quotient of the radiation intensity before the absorption, I_0, and after the absorption, I. According to the Lambert–Beer law, it is directly proportional to the concentration of the absorbing atoms in the atomizer, c, the length of the atomizer, d, and the absorption coefficient, a.

$$A = 1^{\circ}\mathrm{g}\frac{I_0}{I} = adc. \qquad (1)$$

The coefficient, a, depends on the element and the wavelength, γ, and can be related to the Einstein transition probability of an absorption process, B and the Planck constant, h.

$$a = B\frac{h}{\lambda}. \qquad (2)$$

Principal Components of an Atomic Absorption Spectrometer

The main component of an analytical absorption spectrometer is the light source, providing monochromatic light for the absorption process. Two types of light sources are mostly used. Hollow-cathode lamps contain a cathode of the analyte element and an anode, and are filled with a noble gas. There is a glow discharge between the cathode and the anode, in which positive gas ions are formed, which sputter element atoms of the cathode at relatively low temperatures. These lamps emit mostly lines excited from the ground state and show only slight line broadening. The other type of lamps are electrodeless discharge lamps that contain the element in a small quartz tube filled with a noble gas. A high-frequency field (*c*. 27 MHz) leads to a plasma within the tube, in which the element is excited and emits specific light. The advantages are the better stability of the lamp, especially for elements like antimony, mercury and tin, and the higher intensity. A problem is the formation of ions, which reduce the effective concentration of the excited atoms. Both lamp types generate narrow emission lines and are available for all elements that can be determined by AAS. AAS is mostly a single element or sequential analytical technique, because a specific light source is used for each analyte.

The light beam is sent through the atomized sample and then via a monochromator to the detection system similar to that of AES. Pneumatic nebulizers are used as well for AAS. In addition, slurry and solid samples have been investigated. The atomizer in the light path can be of different types. The principal set-up of an AAS is shown in Figure 3.

Atomizing Techniques for Atomic Absorption Spectrometry

The purpose of the atomizer is the reproducible formation of gaseous atoms of the analyte in the ground state. There are three main atomizing techniques in atomic absorption spectrometry. The classical method is flame atomization. Electrothermal atomization provides better detection limits for most elements, and chemical vapor atomization is well suited for gaseous samples like the metal and semimetal hydrides and gaseous mercury.

Flame Atomic Absorption Spectrometry

In FAAS, the liquid sample is introduced as an aerosol in a flame with temperatures between 2000 and 3000 °C. The flame should have a low self-absorption at the analyte wavelength and be a low source of

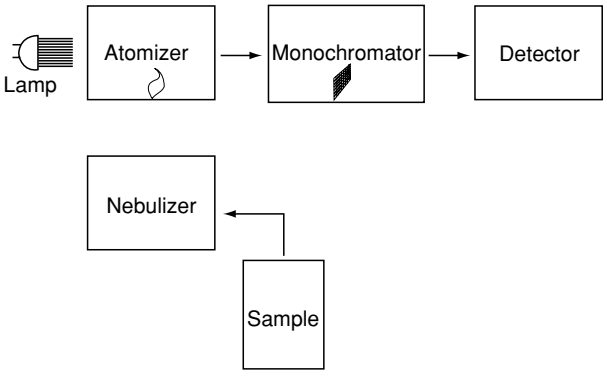

Figure 3 Principal set-up of an AAS apparatus.

white light to provide adequate signal-to-noise ratios. In addition, the residence time of the analyte atoms in the flame should be sufficient for the absorbing process, and therefore, lower flow rates for the flame gases should be used.

The most important is the acetylene/air flame, which is rather transparent over a broad region of wavelengths and, at temperatures of *c*. 2500 °C, is suitable for most analytes. Higher temperatures are needed for some elements like Be, Ca, Ti, V, Mo, and the rare earths, so acetylene/nitrous oxide flames with temperatures of *c*. 3000 °C are used. Other flame types include hydrogen/air and methane/air.

Applications and Analytical Performance

FAAS is suitable for samples with analyte concentrations of mg l^{-1} to the higher μg l^{-1}. The sensitivity is often given as a characteristic concentration, c_0, which depends on the parameter of the instrument (e.g., the geometry of the atomizer) and the element. Linear calibration functions are obtained up to 100 c_0, and the precision is frequently better than 0.5%.

FAAS can be used to determine the macronutrient elements in human body fluids and other biological matrices. Whereas sodium and potassium are mainly investigated by flame photometry, calcium and magnesium are analyzed by FAAS by direct measurement after dilution.

Problems and Interferences

The matrix in the samples can influence the drying, crystal formation, atomization, and distribution of elements in the flame. Mostly, the kinetic of the atomization is changed by analyte compounds with high boiling points. The energy of the flame can lead to an ionization of certain elements like the alkali or earth alkali metals and to curved calibration functions. The addition of electron donators like Cs shifts the equilibrium to the atoms and provides a better linearity of the calibration. Chemical reactions and spectral effects are less important for the FAAS, because of the dilution of the analytes and the matrix by the flame gases. Problems can arise from organic solvents and high salt concentrations, which alter the viscosity of the solution.

Electrothermal Atomic Absorption Spectrometry (ETAAS)

One major problem of the FAAS is the residence time in the atomizer. In order to improve this time, the ETAAS has been invented by L'vov in the middle of the twentieth century and is now one of the most widely applied techniques for trace and ultratrace metal determinations.

In the ETAAS, the atomizer is a small quartz tube mounted between two electrodes. Samples containing a few microliters of liquid or micrograms of solid are injected through a small hole on top of the tube. The oven is heated electrically following a temperature program:

1. The drying step, in which the water or the solvent is evaporated.
2. The sample preparation step, in which matrix components are evaporated or altered.
3. The atomization step, in which the analytes are atomized at constant temperatures, 1500–2500 °C, depending on the analyte.
4. The cleaning step, in which the temperature is brought to a maximum, and the graphite furnace is cleaned.

In order to improve the sensitivity of the ETAAS and to inhibit the formation of carbides by elements like Mo, V, and Ti, the furnace can be coated by different materials including Os and Pd. In contrast to the continuous signal of the FAAS, in ETAAS, a transient signal, mostly a heavy tailing peak, is obtained.

Analytical Performance

The ETAAS has several advantages in respect to the FAAS. Slurry and solid samples can be used without dissolution, and the analytes can be separated from the matrix using a program of different temperatures. The method provides a high sensitivity and very low sample consumption, because nearly the whole sample is introduced into the atomizer. Drawbacks are the complicated apparatus and handling, the low sample throughput, and the large number of interferences. The ETAAS is now widely used for the determination of trace elements in biological samples.

The detection limits of the ETAAS are from 0.5 μg l^{-1} for elements like V and Li to 0.005 μg l^{-1} for elements like K, Cd, and Zn (10–1000-fold better than for the FAAS). The absolute sensitivity depends on the dimensions and geometry of the quartz tube and further experimental parameters. It is given as characteristic mass, m_0. The precision is *c*. 1% standard deviation at 10 m_0, and the linear range ends by *c*. 100 m_0, similar to the FAAS.

Problems and Interferences

In the ETAAS, numerous spectral interferences have been determined. These interferences are based on the insufficient separation of the analytes and matrix. The radiation from the light source can be absorbed unspecifically by atoms and molecules, leading to overlapping atomic and molecular bands or can be scattered on particles like undissociated metal salts

in the light beam. At high atomizing temperatures, sublimating graphite particles can lead to problems.

The background depends strongly on the matrix, so that background correction is much more important than for FAAS. Modern apparatus use either a deuterium lamp or the Zeeman effect for correction of the data. The standard addition method should be used for complex matrices.

Chemical Vapor Atomic Absorption Spectrometry (CVAAS)

CVAAS is used for the determination of gaseous metal and semimetal compounds. It is an important detector for the speciation of hydride-forming elements. There are two sectors of the CVAAS: the cold vapor technique, which is only suitable for mercury, and the hydride generation process, which can be applied to Se, Te, As, Sb, Bi, Sn, and Pb. In the latter case, the elements are reduced to the corresponding hydrides mostly with sodium tetrahydridoborate in acidic solution. A quartz furnace is used as the atomization unit, which is typically heated electrically to 900–1000 °C. The samples are introduced as gases to nearly 100% by an inert carrier gas stream. The residence time in the atomizer depends on this gas stream.

Mercury compounds can be reduced by sodium tetrahydridoborate to elemental mercury, which can be introduced by inert gas into the atomizer nearly without heating. The quartz furnace is used at 120 °C in order to inhibit the condensation of mercury and to reduce the scattering on water particles in the oven.

Analytical Performance

The absolute performance of the hydride generation is *c*. 100-fold less than the ETAAS, but the larger sample volumes (up to 100 ml in one batch reactor) lead to an increase in the detection ability usually at a factor of 10. The determination of 0.01 μg per liter of arsenic or selenium is possible. In addition, the oxidation states and organic species of the hydride formers can be detected separately, so that more information about the species distribution of these elements in different matrices can be gathered. In addition, the matrix is nearly completely separated from the analytes. The drawbacks are the complicated experimental set-up, relatively long analysis times, the instability of the formed hydrides, and the high risk of contaminations by the addition of high excesses of solid and difficult-to-clean reagents (e.g., sodium tetrahydridoborate, sodium hydroxide).

The CVAAS for the mercury determination provides very good detection limits (0.001 μg l^{-1}). Even enrichment is possible by using gold foils for amalgam formation.

Problems and Interferences

In the CVAAS, the separation of the analytes of the matrix is nearly complete for nonhydride formers. However, the hydride-forming elements can strongly interfere with the reduction of one another (e.g., As interfering with the reduction of Sb). In addition, the reduction process can be inhibited by oxidants or complexing agents in the matrix or even by some transition metals. The platinum group elements adsorb large amounts of hydrogen, so that the effective reduction ability of the solution is lowered. Standard addition for calibration is therefore strongly recommended.

The volume of the sample must be constant. Foam formation can influence the degassing of the analytes, especially in biological matrices. This should be suppressed.

Conclusion

Atomic spectrometry is suitable for trace concentrations of most elements. The principle is the absorption and emission of light of a certain wavelength after atomization of the sample. The wavelength provides qualitative information about the element, whereas the intensity of the emission (AES) or the quotient of the intensity before and after the absorption (AAS) is proportional to the concentration of the analyte. Several spectral and nonspectral interferences must be considered.

Nuclear Magnetic Resonance

A M Gil, University of Aveiro, Aveiro, Portugal

Introduction

The nuclear magnetic resonance (NMR) phenomenon was discovered at Stanford University in 1945 by Bloch, Hansen, and Packard, who detected a proton signal from water and at Harvard University by Purcell, Torrey, and Pound, who observed a signal from the protons of paraffin wax. Bloch and Purcell were jointly awarded the Nobel Prize for physics in 1952 for this discovery.

The observation of an NMR signal from a nucleus requires that the nuclear spin (I) is described by $I \neq 0$. For instance, ^{12}C and ^{13}C have respectively $I = 0$ and $I = 1/2$, hence only ^{13}C is observable by NMR. Associated with the nuclear spin, there is a nuclear magnetic moment (μ), which will interact with an applied magnetic field B_0. This interaction causes the magnetic moment of a nucleus of spin I to take $2I + 1$ possible orientations, each corresponding to an energy level. In the case of $I = 1/2$ (e.g., ^{1}H, ^{13}C, ^{31}P, ^{15}N), two energy levels separated by $\Delta E = h\gamma B_0/2\pi$ are generated, where γ is the nuclear magnetogyric ratio. However, the exact value of ΔE absorbed by a nucleus is also very sensitive to its surrounding molecular environment; hence, by registering the absorbed energy, NMR probes molecular structure and molecular dynamics. Chemical shifts (δ), scalar coupling constants (J) and relaxation times (T_1, T_2) are NMR parameters which carry both structural and dynamic molecular information.

One of the earliest applications of NMR in food science dates from 1957 and concerned the measurement of moisture in foods. However, it is only from the early 1980s that a consistent and widespread growth in the use of NMR in food science has been observed. This resulted from: (1) the increasing sophistication and relative ease of use of NMR instrumentation; (2) the increasing need of the food industry to understand and innovate its products and processes; and (3) the increasing pressure for new methods to enforce legislation and control quality. Many applications have grown in parallel to applications in the biological and biomedical fields, in which the noninvasiveness of the technique is a requirement. In foods, such requirement stems not from ethical considerations but from the need to preserve and examine food structure.

The first review of applications of NMR in food science dates from 1993; the first international conference on the subject was held in 1992 and has been followed by meetings every 2 years since then.

The NMR Techniques for Food Analysis

Foods are generally very complex systems both chemically (containing an enormous variety of compounds differing in nature, size, and quantity) and physically (often being multiphase systems). The choice of NMR method depends primarily on the chemical and physical complexity of the food. For liquid foods like juices, wine, and oil, the method of choice is usually liquid-state high-resolution one-dimensional (1D) and two-dimensional (2D) NMR spectroscopy. Total correlation spectroscopy (TOCSY), heteronuclear correlation spectroscopy (e.g., $^{13}C/^{1}H$ or $^{15}N/^{1}H$) and J-resolved spectroscopy are 2D experiments which give, respectively, information on homonuclear couplings, heteronuclear couplings, and J-values/multiplicity. This information enables chemical identification and structural determination to be carried out, provided the spectra are free from serious signal overlap. In recent years, automated methods have been developed to allow the handling of high numbers of samples with little or no user intervention. Hyphenated techniques have also recently been developed, to handle the high chemical complexity of many foods. These couple NMR with liquid chromatography (LC) and mass spectrometry (MS) in the forms of LC-NMR and LC-NMR/MS.

If the above NMR techniques are applied to solid or semisolid foods, spectra with very broad lines will result, from which structural information can be very difficult to extract. Solid-like foods call for specific methods which enable resolved spectra to be obtained. Magic angle spinning (MAS) aids the observation of dilute nuclei, e.g., ^{13}C, ^{15}N, when coupled with cross-polarization (CP) and high-power decoupling. The CPMAS experiment selects the nuclei present in the solid phase of the food.

Conversely, direct excitation methods select the nuclei in the mobile phase of the food, therefore both CPMAS and direct excitation methods can give complementary information on multiphase foods. But for solid and heterogeneous foods, magnetic resonance imaging (MRI) has been one of the most recent and popular methods. In this technique, the frequency of the NMR signal is dependent on position and, therefore, putting together the information arising from different parts of the sample gives rise to a 2D or 3D representation. The contrast in such image may result from changes in spin density (related to concentration), relaxation times, or diffusion coefficients. A recent novel idea is the attempt to correlate molecular properties, viewed by NMR, with macroscopic properties, e.g., rheological behavior. The method of Rheo-NMR aims precisely at achieving this correlation and its use for foods is now at its infancy. The method registers NMR information (either using imaging or spectroscopy) while stress (shear or extensional) is applied to the sample.

Water in Foods

Water profoundly affects many aspects of food quality: texture, microbiological safety, nutritional status, and digestibility. NMR has been used to probe water activity and water translational mobility in foods. Water relaxation times provide information on the amount and mobility of water. Of the three NMR-active nuclei available in water (^{1}H, ^{2}H in HOD, and ^{17}O in $H_2{}^{17}O$), ^{17}O is the more direct probe since it is not affected by the chemical exchange of protons between solute and water. The different degrees of 'water binding' to solute or biopolymer molecules have been measured in systems as varied as caseinate solutions, potato and wheat starch suspensions, and gelatin gels. Glass transitions in food ingredients like casein, gluten, amylopectin, protein/sugar, and polysaccharide/sugar mixtures are strongly dependent on water activity/content and have important consequences in product quality. Again, the understanding of molecular mobility of water and of the solute, by NMR relaxation, has enabled structural models to be proposed. For instance, relaxation data have suggested a model of a maltose glass in which water molecules undergo rapid rotational and translational motion inside more rigid 'cages' or 'channels' formed by maltose molecules. (*See* **Water**: Structures, Properties, and Determination.)

The effect of food microstructure on water relaxation is important since a distribution of relaxation times occurs and may be used to determine pore size distributions in the food. Many studies have involved model systems like water-saturated porous rocks, sandstones, chalks, and cement pastes. Some studies of actual food materials have been done, trying to handle the additional complexity due to the chemical nature of food components.

At a macroscopic scale, water located in different types of tissue is characterized by different relaxation properties and diffusion coefficients, which result from distinct cell types and sizes. Water is distributed among different subcellular compartments such as vacuoles, starch granules, and the cytoplasm, and again each compartment is characterized by a certain distribution of water relaxation times. These NMR measurements may be used to give information about cell morphology and membrane water permeabilities. Applied to fruits and vegetables, this approach is useful to determine water/air/ice distribution, related to overall quality changes, as the food is ripened, dried, rehydrated, frozen, and stored.

The dependence of relaxation properties on tissue type is the origin of contrast in relaxation or diffusion-weighted MRI of intact fruits and vegetables. MRI has long established its value and potential in food science, not only enabling the qualitative imaging of 'static' food structure but also, and more importantly, following mass and heat transport in foods, noninvasively, and in real time during processing or storage. MRI may be used for temperature mapping of foods, after a suitable calibration of the relaxation times or diffusion coefficients against temperature. The temperature profile of a whole food may be used to deduce thermal diffusivity and surface heat transfer coefficients. Subzero temperature MRI is very useful for the detection of freezing effects, detection of unfrozen water, measurement of freezing times, and of freeze-drying kinetics. MRI is also used to monitor changes at food surfaces, an important application since the efficiency of many processing operations (e.g., baking, drying) depends on the magnitude of heat and moisture transfer rates at the food surface.

Besides providing the moisture and temperature profile of a food, MRI is sensitive to several other quality factors: lipid distribution, solute concentration, pH, solid–liquid ratios, protein and polysaccharide aggregation. Table 1 gives some examples of the applicability of MRI in foods, and a more comprehensive list can be found in the specialized manuals indicated at the end of this text.

Food Biopolymers

Proteins

Both liquid-state and solid-state NMR methods have been of value to elucidate aspects of structure and

behavior of food proteins, such as the milk proteins casein and α-lactalbumin and many cereal proteins. Whereas the wide range of liquid-state NMR methods has been applied to small proteins like α-lactalbumin, seed and storage proteins generally have higher molecular weight and higher heterogeneity and are often insoluble, which renders the usual high-resolution methods rather ineffective. Hence, ^{1}H and ^{13}C solid-state NMR methods have been valuable in characterizing the structure and behavior of large cereal proteins of wheat, barley, maize, and sorghum. These proteins have important functional and nutritional properties which require an understanding at the molecular level, in order to enable suitable quality control. The Rheo-NMR method has already proved promising in the attempt to correlate the molecular structure of hydrated gluten (wheat protein) with its characteristic viscoelasticity. Multinuclear NMR (^{25}Mg, ^{31}P, ^{43}Ca) has also been used to study ion-binding proteins, e.g., β-casein and α-lactalbumin, in order to determine the characteristics of the binding site and of metal competitivity under physiological conditions (*See* **Protein**: Chemistry.)

Table 1 Some examples of magnetic resonance imaging (MRI) applications in foods

Food	*Study*
Apple	Water relaxation in parenchyma tissue; drying; bruising; deterioration during storage
Potato	Water relaxation at subzero temperatures; freeze-drying; drying
Carrot, potato	MRI temperature mapping
Peach	Freezing; bruising
Extruded pasta	Rehydration, radial imaging
Cod	Freezing (texture changes)
Peanut butter/bread	Fat transport
Milk	Cream separation
Food gels	Temperature mapping; spatial heterogeneity; drying
Cereal seeds	Maltose and water distribution during germination
Tomato	Water distribution during ripening
Foams	Water drainage
Biscuits	Water and fat distribution during baking
Meat/fish	Fat and water distribution

Polysaccharides

The interest of the food scientist in polysaccharides includes the issues of dietary components (starch, plant cell wall polysaccharides) and functional ingredients like gelling, thickening, and stabilizing agents. Naturally, high-resolution NMR is a powerful technique for carbohydrate analysis in solution, whereas CPMAS and related solid-state techniques have been applied to solid polysaccharides, in gels and in heterogeneous samples. In solution, NMR can not only provide a measurement of overall composition and detailed conformational structure, but also be sensitive to fine details such as degree of esterification, degree and type of substitution, residue sequence, and average block length. Table 2 shows some examples of studies of several food polysaccharides in solution (*See* **Carbohydrates**: Classification and Properties.)

The knowledge of the physical properties of complex carbohydrates is extremely useful for food scientists. Such information is available in several databases, including an NMR database. Processes like gelation, crystallization, starch gelatinization, and retrogradation are extremely important in determining the quality of a polysaccharide-containing food. Cellulose and starch provide excellent examples of solid polysaccharides from which extensive structural information may be obtained by solid-state NMR. ^{13}C CPMAS NMR clearly distinguishes the A (from cereals) and B (from tubers) starch polymorphs and can also measure the proportions of crystalline and amorphous components. Starch

Table 2 Examples of food polysaccharides characterized by high-resolution nuclear magnetic resolution (NMR)

Polysaccharide		*Study*
Pectins	^{1}H and ^{13}C NMR	Degree of esterification; characterization of monomer sequences and average chain lengths; galacturonic acid content; conformational analysis
Guar, locust bean gum	^{1}H and ^{13}C NMR	Detection of substituted mannose residues; characterization of monomer sequences

Amylopectins	^{1}H and ^{13}C NMR	Ratio of α(1-4) and α(1-6) linkages
Wheat arabinoxylans	^{1}H and ^{13}C NMR	Degree and type of substituted xylose rings; correlation between structure and gelling capacity/thermal stability
Agarose, κ, ι, λ, β-carrageenans	^{1}H, ^{13}C, ^{87}Rb, ^{23}Na, ^{39}K, ^{133}Cs NMR	Study of coil–helix transitions;strength of metal binding
Xanthan	^{1}H and ^{13}C NMR	Acetate and pyruvate contents; study of coil–helix transition
Gellan gum	^{1}H and ^{13}C NMR	Structural determination
Starch	^{1}H and ^{13}C NMR	Amylose content; degree of amylopectin branching; interaction with metals

gelatinization occurs upon heating up to 70 °C, causing starch granules to absorb water and burst, leading to the formation of a gel. On subsequent cooling, starch crystallization or retrogradation occurs. Retrogradation is the main cause for bread staling and, therefore, it has attracted a lot of interest from the food scientific community. A variety of ^{13}C CPMAS, ^{1}H MAS, and relaxation times measurements have been coupled to follow and understand both the gelatinization and the retrogradation processes, including the understanding of the role of each component, amylose and amylopectin, in the process. ^{31}P NMR can also be used to view phosphate groups which are found in starch molecules, believed to contribute to the clarity and viscosity of starch pastes.

Many gelling processes of a variety of food carbohydrates (starch maltodextrins, carrageenans, xanthan, pectins, scleroglucan, konjac glucomannan, methyl and hydroxymethyl cellulose) have been characterized, generally by ^{13}C, ^{1}H, and in specific cases by ^{127}I, ^{23}Na, ^{87}Rb, ^{133}Cs NMR. Such studies give information as varied as solid-to-liquid ratios, identification of different water populations, degrees of metal binding, characteristics of coil–helix transitions, and degree of aggregation. Plant cell wall polysaccharides, e.g., pectins, are a major source of fiber and determine the texture of plant foods. Much NMR work has been applied to acquire knowledge of the structure, composition, and function of these polymers, both in their natural environment – the plant – and as food additives.

Analysis and Authentication of Foods by NMR

The high cost of NMR spectrometers and the relatively low sensitivity of the technique compared to competing methods has prevented the adoption of the technique as a routine analytical tool in industry. A very important exception to this is the low-resolution 'benchtop' NMR spectrometers which have found numerous uses in food industry as well as in other industries. However analytical applications of high-resolution NMR to lipids, sugars, and many other compounds still remain nonroutine. In the last few years, high-resolution NMR has been coupled to LC and to MS techniques, making way for a new generation of hyphenated techniques with great potential in rapidity, sensitivity, and precision. But, one high-resolution NMR technique has alone justified the costs of sophisticated equipment enabling the achievement of information of a unique nature: the site-specific natural isotope fractionation NMR (SNIF-NMR) technique.

Low-resolution Pulsed NMR

Low-resolution NMR methods involve the extraction of information directly from the magnetization decay, and not from the NMR spectrum. Usually the nucleus observed is ^{1}H but others may be used, e.g., ^{2}H, ^{13}C, ^{31}P. The rates of transverse magnetization decay (or T_2 relaxation rates) following a 90° pulse are very different for solid and liquid phases and a typical determination which has been extensively explored is the determination of solid fat content (SFC) of semisolid fats, not requiring any sample preparation. Absolute measurements of oil or moisture content are based on the same principle but require sample weighing and a calibration of the method with an independent method. When species with similar relaxation times are present, e.g., oil and water in some oil-seeds, the Carr–Purcell–Meiboom–Gill (CPMG) experiment is used and appropriate software used to obtain relaxation times and relative proportions of the components of interest. These low-resolution methods are noninvasive, involve short measuring times (a few seconds), and require little sample preparation. They are therefore ideally suited for quality control of large numbers of samples and this has led to their extensive industrial use, supported by the development of dedicated, low-cost benchtop instruments. Existing online applications include determination of oil and moisture contents in seeds, determination of SFC of fats, use of relaxation times to follow cake cooking, nondestructive detection of fruit quality (as sugar content), and the determination of phospholipid content in peas.

High-resolution NMR and Hyphenated Techniques

The applications of high-resolution NMR in food science have been reviewed in 1996 and, since then, the use of 2D NMR for structural analysis of complex natural products, including minor food components, has become widespread. The qualitative applications are numerous and many quantitative determinations have been explored.

One of the recognized applications of ^{1}H, ^{13}C, and ^{31}P high-resolution NMR has been the study of lipid structure and composition. The quantitative determination of lipids by NMR has been carried out extensively. For example, for palm oil, composed of triacylglycerol mainly of palmitic (P), oleic (O) and linoleic (L) acids, the mole fractions of P, O, and L may be obtained from integration of particular signals in the ^{13}C NMR spectrum and their positional distribution may be determined. Applications have included determination of saturated and unsaturated fatty acids in edible oils and spreads, differentiation of different grades of olive oils, detection of synthetic

oils in mixtures of virgin olive oil, determination of ω-3 acids in fish samples, the study of the oxidative deterioration of several oils, and the effects of storage and thermal stressing, structural determination of pigment compounds and antioxidants in oils. Interestingly, the determination of oil in intact seeds has been made possible by high-resolution MAS NMR, and sunflower and rapeseeds are examples.

Quantitative ^{13}C NMR has been applied to many other systems, e.g., quantification of disaccharides in honey and quantification of sugars and sugar derivatives in wine. However, ^{1}H high-resolution NMR has gradually proved its usefulness too. Up to the early 1990s ^{1}H NMR had received little attention as a tool for food analysis, mainly because of the great complexity of the spectra and reduced spectral dispersion, as well as the need for efficient suppression of the very high water signal. In recent years, water suppression efficiency has improved largely and the use of higher field instruments (> 400 MHz) has caused a renewed interest for the analysis of complex food mixtures like fruit juices (Figure 1), coffee, and wine by ^{1}H NMR. Indeed, at higher fields a wealth of signals may be detected in all regions of such spectra, besides the main solute signals (sucrose, glucose, fructose, citrate, etc.). Such spectra often show great spectral complexity and signal overlap, even in 2D (Figure 2) and, in some cases, multivariate analysis has proved useful for spectral interpretation. It is in the disentanglement of the information present in high-field ^{1}H NMR spectra that hyphenated techniques play a determinant role. Methods such as LC-NMR or LC-NMR/MS enable NMR, LC, and MS data to be collected for the same sample in relatively short experimental times (min–1 h). The usual set-up of such experiments is represented in Figure 3. These techniques present a valuable aid in cases of metabolites which, because of their low abundance or particular chemical nature, cannot be identified using solely 2D NMR techniques. Along with NMR parameters, the coupled techniques add information about absolute or relative retention times and molecular mass. These developments show the potential for rapid detection and characterization of minor compounds in foods, many with important roles in aroma/flavor chemistry or with potential interesting properties such as antioxidant or preservative properties.

Site-Specific Natural Isotope Fractionation Nuclear Magnetic Resonance

SNIF-NMR is certainly a success story in the use of NMR for the practical needs of the food industry. The technique has been developed based on the fact that the percentage of heavy isotopes occurring for a given element (hydrogen, carbon, oxygen) in natural products is not a fixed quantity but depends on the history of the sample, e.g., geographical, climatic, and biochemical factors. The differences arise

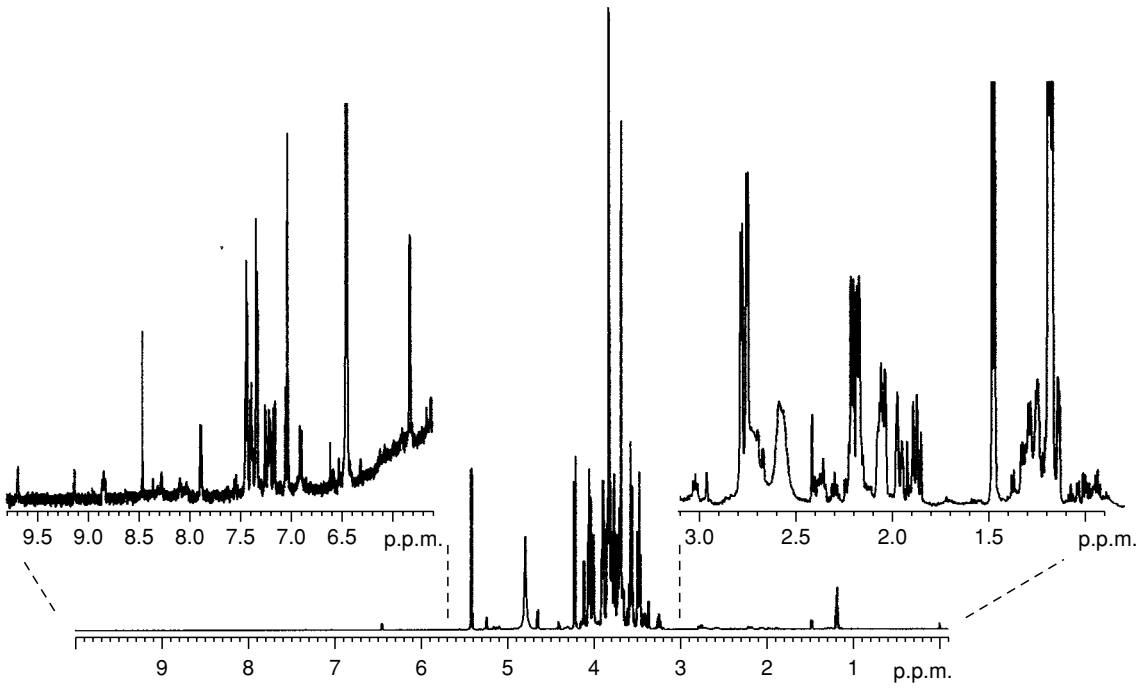

Figure 1 ^{1}H nuclear magnetic resonance (NMR) spectrum of mango juice, at 600 MHz; 64 scans.

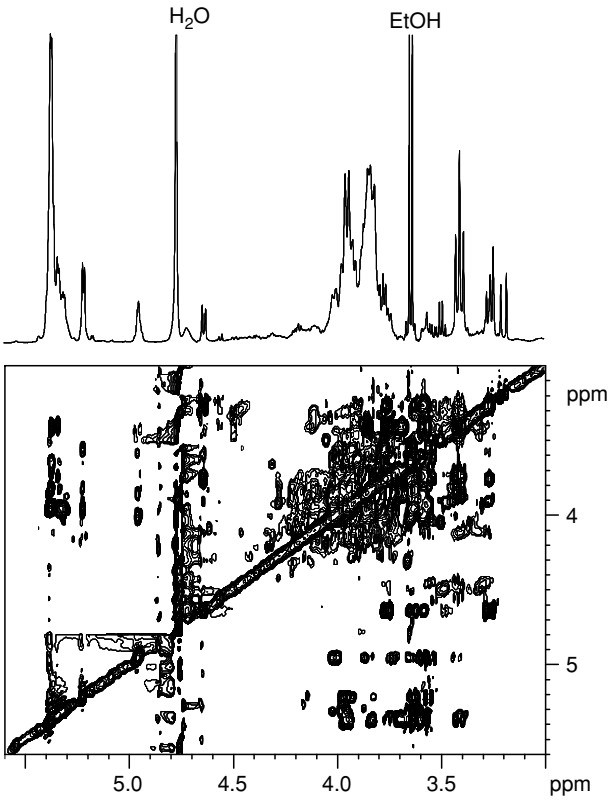

Figure 2 Total correlation spectroscopy (TOCSY) spectrum of a beer sample, at 500 MHz.

from distinct isotopic composition of the starting materials (e.g., rainwater at different latitudes) and from fractionation effects occurring during bioconversions. Measurement of isotope ratios by MS is widely used for assessment of the authenticity of foods but this technique gives an average isotope ratio and no information on the intramolecular distribution of the isotopes. SNIF-NMR uses ^{2}H NMR to measure the deuterium-to-hydrogen isotope ratios at specific sites (i) in the molecule, $(D/H)_i$. The analysis and characterization of wines and other alcoholic drinks were among the first applications of SNIF-NMR. Such samples are examined as distillates with about 95% ethanol. The proton-decoupled ^{2}H NMR spectrum of an ethanolic distillate consists of four resonances: from CH_2DCH_2OH (1), CH_3CHDOH (2), CH_3CH_2OD (3) and HDO (the latter two collapse into one single resonance under conditions of fast exchange). From the intensities (or areas) of the peaks of 1 and 2 it is possible to obtain the ratio $(D/H)_2/(D/H)_1$ which varies for alcohols from different sources, reflecting the occurrence of strong site-specific fractionation effects. $(D/H)_3$ is related to $(D/H)_{water}$ and may be obtained through the measurement of $(D/H)_{water}$ by NMR or by MS. Furthermore, absolute D/H ratios may be obtained using a working standard with a known isotope ratio.

Ethanols from different plants (sugar cane, corn, wheat, barley, apple, grape, sugar beet, and potato) have been distinguished using differences in the $(D/H)_1$ ratio. These results have been used to detect the origin of raw materials used to make commercial spirits (whiskey, vodka, gin, rum, and fruit brandies). The characterization of wines has involved additional systematic experiments to relate the (D/H) ratios of the starting materials (starting water and glucose) with those of the end products, ethanol and water. By showing the connection between isotope ratios of starting and end products, it has been shown that the ratios for ethanol and water can be used as 'fingerprints' in the characterization of wines. SNIF-NMR parameters in tandem with statistical analysis have performed remarkably in distinguishing wines of different origins, according to varieties, geographical origins, and year of production. Distinction in terms of country of origin reflects differences in temperature and rainfall figures. SNIF-NMR became the most efficient technique to detect enrichment of wines with exogenous sugars and watering of wines. Other applications relate to the determination of origin of flavors and fragrances (natural or synthetic),

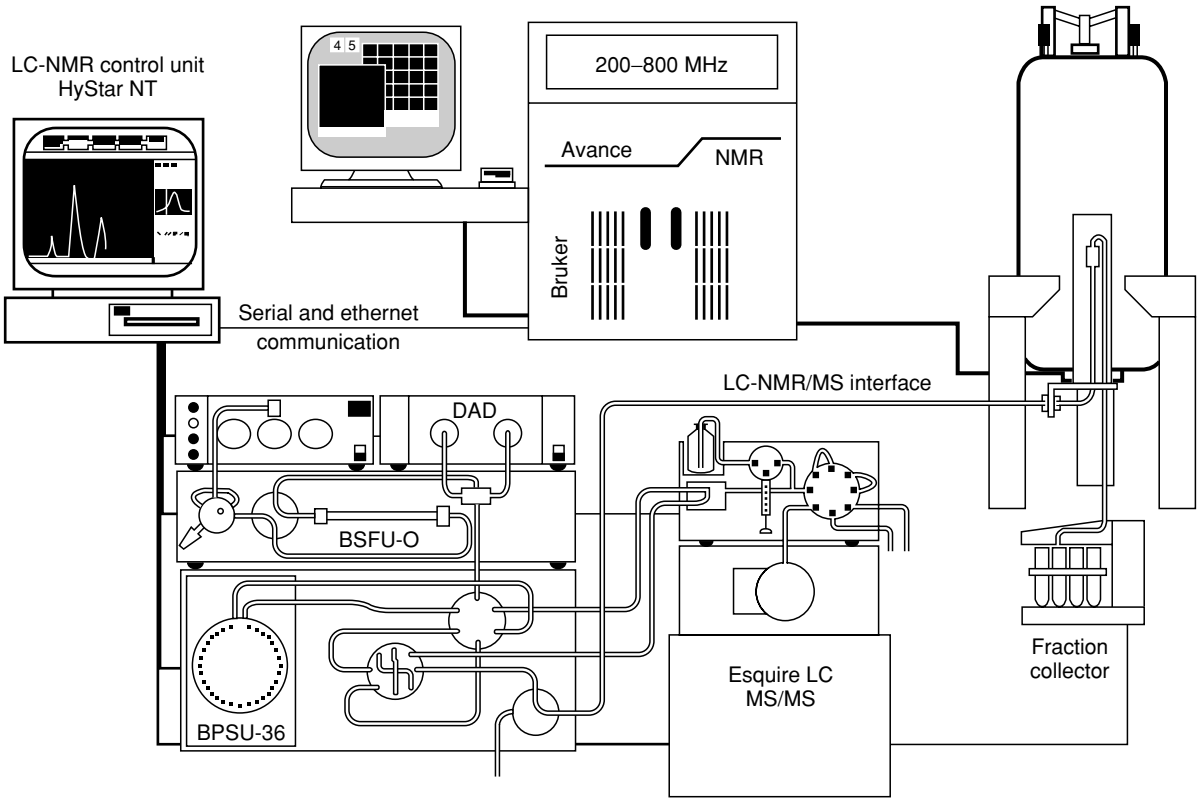

Figure 3 Set-up for the LC-NMR/MS technique. Courtesy of Bruker BioSpin, Germany.

vinegars, fruit juices and jams (detection of beet sugar addition), almond and cinnamon oils (detection of synthetic benzaldehyde).

Other Foods

Many additional studies have been devoted to other foods, e.g., milk, meat, spices and phytochemicals, tea, coffee, wine, fruits, and vegetables. These studies often involve an interplay of high-resolution NMR, solid-state NMR, and imaging methods. Additional applications to those already mentioned are as varied as predicting sugar content in intact fruits, analyzing pesticide residues in vegetables, determining the fluorine and aluminum contents in intact tea leaves, and analysis of the insoluble deposits in bottled wine. A comprehensive description of the enormous variety of studies of foods by NMR may be found in many reviews, some of which are indicated below. It was the aim of this text to give the reader a flavor of the versatility of NMR spectroscopy, adaptable to different physical states and to the chemical complexities of foods. Its applications now extend in new directions, such as online applications and the study of nutritional issues. Scientific growth is continuing in this field and, increasingly, industrialists and scientists are coming together to share practical problems and scientific knowledge.

Visible Spectroscopy and Colorimetry

T Chiba, Iwate Prefectural University, Takizawa, Japan

Background

Visible spectroscopy and colorimetry are forms of spectroscopic analytical methods. They are based on the measurement of the absorption of visible light and can provide qualitative and quantitative information about a sample.

Visible light consists of electromagnetic radiation in range wavelengths from 380 to 780 nm, to which the human eye is sensitive. In this part of the spectrum, radiation with different wavelengths gives rise to light with different colors, while a mixture of light from these wavelengths forms white light. The color of a substance depends on the wavelength of light it absorbs. Thus, when a sample is exposed to white light, certain wavelengths are absorbed, and the remaining wavelengths are transmitted to the eye. The color perceived by the eye is determined only by the wavelength transmitted. In simple terms, the color seen is the complementary color to the color(s) absorbed (**Table 1**). The intensity of color relates to the amount of light absorbed by a substance. The wavelength and efficiency of absorption by a substance depend on the structure of the substance and its environment, making it possible to measure the presence or concentration of the substance.

Identification or determination of a substance based on its color is probably one of the oldest methods of examination in analytical chemistry. Earlier work was entirely empirical and led to qualitative or semiquantitative estimation rather than quantitative determination. The hues and intensity of colors were measured by visually comparing the color of a sample with that of several permanent color standards, which may have been samples containing the same substance at known concentrations or colored glass. These methods, with the human eye as a detector, inherently include a subjective perception of color and are dependent on the reproducibility of the observer's eye. Moreover, even the best observer has difficulty comparing the intensity of two colors with slightly different hues.

The development of detectors of radiation together with the general advance of instrumentation has resulted in improvements in measurement techniques. Photometric techniques with a high level of sensitivity and reliability are available. With these techniques, an instrument called a photometer is used as a photoelectric detector instead of the human eye and converts the intensity of light to an electrical current. Recent photometers are spectrophotometers capable of splitting the incident light into different wavelengths and measuring the intensity of that radiation. Spectrophotometric measurements are an important tool for field testing, industrial applications, and research departments. The term colorimetry describes the measurement by the human eye, and colorimetric methods have been largely replaced by spectrophotometric methods.

Table 1 Colors of light

Absorbed wavelength (nm)	*Absorbed color*	*Transmitted color (complement)*
400–435	Violet	Yellow–green
435–480	Blue	Yellow
480–490	Blue–green	Orange
490–500	Green–blue	Red
500–560	Green	Purple
560–580	Yellow–green	Violet
580–595	Yellow	Blue
595–620	Orange	Blue–green
620–750	Red	Green–blue

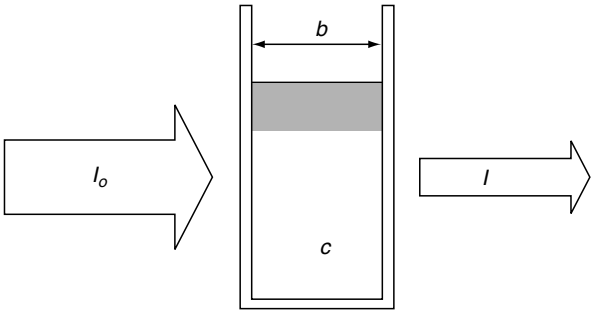

Figure 1 Absorption of radiation by a sample. I_o, intensity of incident light; I, intensity of transmitted light; b, path length of a sample; c, concentration of a sample.

Colorimetric methods (visual methods) are still utilized for fieldwork and simple determinations such as monitoring the pH and chlorine levels of swimming pools. The apparatus required for these methods is simple and inexpensive. The sensitivity and precision are often satisfactory for particular determinations.

Principles

Beer–Lambert Law

Electromagnetic radiation can be characterized as a wave with frequency, v, and wavelength, λ. This wave has energy, E, is proportional to its frequency and is given by the equation:

$$E = hv = hc/\lambda,$$

where h is Plank's constant, and c is the velocity of light. If such a wave of radiation encounters a substance, and the energy is absorbed, a molecule of the substance is promoted to an excited state. The absorption of visible light generally excites electrons of a molecule from a ground electronic state to an excited electronic state.

The amount of light absorbed by a substance in a solution is quantitatively related to its concentration. This relationship is expressed in two fundamental laws: the Bouguer–Lambert law, which is also known as Lambert's law, relates the amount of light absorbed to the length of the path it travels through a medium containing an absorbing substance; Beer's law relates light absorption to the concentration of the absorbing substance. These two laws are combined as the Beer–Lambert law, or simply called Beer's law, and are written as the equations (Figure 1):

$$\log_{10}(I_0/I) = -\log_{10} T = abc = A$$

or

$$I_0/I = 1/T = 10^{abc},$$

where I_0 is the intensity of incident light, I is the intensity of transmitted light, T is the transmittance, b is the path length through an absorbing solution, c is the concentration of the absorbing substance, and A is the absorbance (extinction or optical density in older literature).

The constant a, which is called the absorptivity or the extinction coefficient, specifies a characteristic property of the absorbing substance and is a function of its wavelength. Its units depend on the units of concentration and length of the path employed. When c is expressed in moles per liter, and b is expressed in centimeters, the constant is known as the molar absorptivity, formerly called the molar absorption or molar extinction coefficient. The molar absorptivity is used as a physical constant for absorbing species under standard conditions. It is in liters per mole per centimeter ($\mathrm{l\,mol^{-1}\,cm^{-1}}$) and is given a symbol, ε.

These expressions show that there is a linear relationship between the absorbance and the concentration of a given solution, if the length of the path and the wavelength of light are kept constant. By measuring the transmittance or absorbance, the concentration of a substance in a solution can be calculated.

Deviation from the Beer–Lambert Law and Errors in Determination of Concentration

The Beer–Lambert law is not necessarily obeyed because the law applies strictly to instances when incident radiation is monochromatic, and when the absorbing centers act independently of one another regardless of the number and kind. In practice, there is usually a deviation from a linear relationship between the concentration and absorbance as with a concentrated solution (> 0.01 M) of most substances. These deviations occur as the result of chemical and instrumental factors. Chemical factors can be caused by chemical equilibria with the solution, intermolecular

interaction, reagent and chromophore stability, and impurities that fluoresce or absorb at the absorption wavelength of incident light. Instrumental factors are associated with instrumental limitations determined by the quality of the instrument's optical, mechanical, and electrical systems. These deviations can produce errors in application of the law for practical purposes, but this problem can be overcome by preparing calibration curves that show the experimental relationship between absorbance and simple concentration used for preparing a calibration curve, provided this relationship is always followed under analytical conditions.

There are also several sources of error in measuring transmittance and absorbance. These sources of error include a faulty readout from a detector, incorrect wavelength settings, improper handling of cells, and faulty sample preparation. Any measurement of transmittance or absorbance is more or less subject to error.

The magnitude of instrumental errors, in relation to the real value of the concentration, changes with the transmittance measured. The relative error is high at both very high and very low values of transmittance and lowest over the transmittance range of 20–65%. It is advisable to work in the transmittance range 10–90% (absorbance 1.0–0.1) to prevent large errors.

Methods of Operation and Instrumentation

It may be suitable to use a classification where the two methods are distinguished by the means of detecting light: the visual method, as judged by the human eye, and the spectrophotometric method, as detected by a photoelectric detector.

Visual Method

This method is a visual comparison of samples with standards of known concentration observed in ambient light by the human eye. Therefore, a successful result requires that the sample be the same color as the standard, with only the intensity of the color differing.

Dilution method (duplication method) This is performed by matching color intensity by adding water or a preferred diluent to a darker solution until the two match in terms of color intensity. A standard and a sample solution are placed in a colorless glass tube of equal thickness with a flat bottom, called a Nessler tube. Light from a source passes through each tube and is compared. The more concentrated solution is progressively diluted until the light emerging from both tubes is equal in intensity when viewed crosswise and protected from side illumination. At this point, the concentrations of the two solutions are equal, and the contents of the solutions are related to each other by volume.

Series-of-standards method A sample solution is compared with a series of standards consisting of colored glasses or solutions of known concentration prepared in the same way as the sample solution. Nessler tubes or test tubes are used. A series of tubes of the standard exhibiting a regular gradient of color are placed in a rack. The tube of a sample solution is compared side by side with the standard until a match is found or until the concentration is determined to lie between that of two standards.

Spectrophotometric Method

This is a more sophisticated method and uses a spectrophotometer, which is an instrument for measuring the intensity of light of various wavelengths transmitted by a sample. The intensity of light is determined by photoelectric detectors, which convert radiation energy to electrical energy and can eliminate the need for subjective measurement by the human eye. This method has a number of advantages over visual methods: the limit of detection is lowered by measuring the absorption of a solution at the maximal wavelength; it is possible to avoid or minimize the effect of foreign colored substances by working at a suitable wavelength; a greater precision can be obtained with spectrophotometric methods than with visual methods.

A spectrophotometer consists essentially of (1) a light source; (2) a monochromator for furnishing monochromatic light; (3) one or more sample containers; (4) a detector for measuring the intensity of transmitted light; and (5) a signal processing and readout device (Figure 2).

A common light source is a tungsten filament lamp. This lamp produces continuous and intense radiation in the range of 320–3000 nm and is adequate for measurement over the visible region. Devices used as monochromators include diffraction gratings and glass prisms. A diffraction grating is a superior form of general device, giving a constant and narrow radiation bandwidth. Various types of optical filters may be used as a monochromator, although they provide only a limited wavelength while a different filter is necessary for each wavelength required. Such an instrument is known as a filter photometer. Sample containers are usually called cells or cuvets. They must be transparent in the visible region. General cells are commonly rectangular in shape with a path length of 10.0 mm and are made of optical-quality

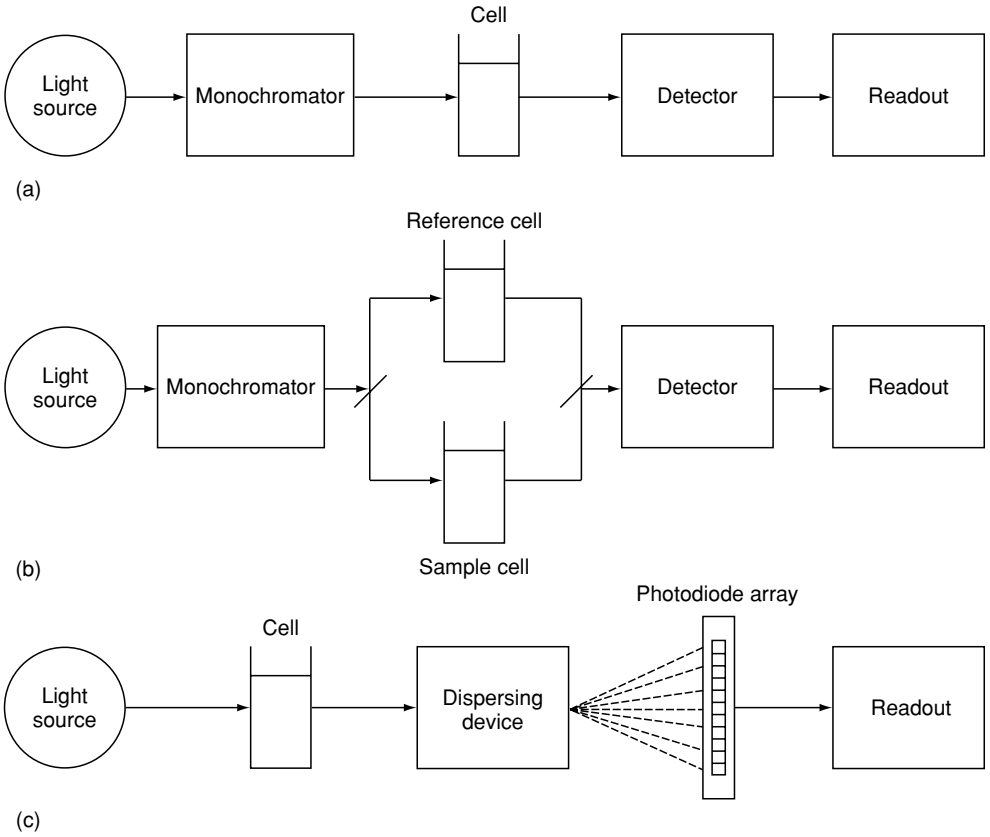

Figure 2 Designs of various types of instruments for visible spectroscopy: (a) single-beam instrument; (b) double-beam instrument; and (c) multichannel instrument with a photodiode array detector.

glass or plastic. There are several types of cells available from commercial sources: a microcell for small volumes of solutions, a stoppered cell for volatile solutions, and a flow cell for measuring the absorbance of flowing solutions. The most common detectors are photomultiplier tubes or phototubes. Photodiode arrays, which are solid-state detectors, are also used in newer spectrophotometers. The electrical current produced in these detectors is amplified and plotted on a recorder or displayed on the spectrophotometer as either absorbance or percentage transmittance.

Measurements are made by inserting a cell containing a sample into the light path of the spectrophotometer. The concentration of a substance can be determined either from a calibration curve or from a calculation based on the Beer–Lambert law through the use of an instrumental readout.

Commerical spectrophotometers are classified into two broad categories, single- and double-beam systems, depending on their optics. The individual components of the system have the same function.

A basic spectrophotometer is a single-beam instrument, which has only one light path for radiation (Figure 2a). This instrument is simple and inexpensive, but is somewhat troublesome to measure with because a sample and a reference (or a reagent blank) must be placed alternatively in the light path, and for measurement at different wavelengths, set-up procedures are required at each wavelength. It is well suited for quantitative measurements at a single wavelength.

The double-beam system provides two equivalent paths, both originating with the same light source (Figure 2b). One of them travels through a sample cell, and the other passes through a reference cell. The two beams are measured separately, either by two matched detectors or by rapidly alternating use of the same detector. The ratio of the intensity of the two beams can be obtained by this system. Thus, the double-beam instrument automatically compensates for absorbance by the reference, as well as for any variation of source intensity with time and wavelength. This instrument provides more accurate quantitative measurement of transmittance or absorbance than a single-beam instrument. There are also spectrophotometers equipped with an automatic drive for scanning the wavelength. An automatic recording

of absorbance as a function of wavelength permits an absorption curve (an absorption spectrum) to be obtained. The spectrum is useful for the qualitative identification of a substance and selecting a suitable wavelength for quantitative analysis. It may also reveal the presence of impurities that are interfering in determination.

A conventional spectrophotometer simultaneously measures transmittance or absorbance only at a single selected wavelength. However, a modern spectrophotometer is a multichannel instrument, which can monitor any selected wavelength range in the visible region. This spectrophotometer is usually a single-beam system with a photodiode array as a detector (Figure 2c). The photodiode array is designed with a linear array that has a series of photodiodes arranged side by side. Each photodiode responds to visible light. If dispersed light in its component wavelength is focused on the surface of the array, the individual photodiode measures the intensity of radiation from a particular section of the spectrum. The data from photodiodes are then accumulated and processed by a computer. This instrument allows the immediate and continuous recording of an entire spectrum without mechanical wavelength scanning. This feature is very useful for the analysis of mixtures of absorbing species and kinetic studies.

Spectrophotometers with a flow cell are often used as detectors in analytical systems and subsequently have extended the application of visual spectroscopy. When linked with a turnable type of sampler and a recorder, they expedite manual procedures and read large batches quickly. By directly observing eluate from a chromatographic column with this detector or, if the substance to be measured is colorless, after a color-developing reaction, several constituents can be concurrently determined by high-performance liquid chromatography. The photodiode array spectrophotometer is an effective detector for this purpose, since it can obtain essentially continuous spectra of the eluate and produce an absorption spectrum for any point on the chromatogram.

There are several types of automated analyzers equipped with spectrophotometric detectors in which analytical procedures are entirely automated to handle large numbers of analyses and routine work, especially for clinical specimens.

A modern spectrophotometer, incorporating a computer for instrument control, data collection, and data processing, provides derivative determinations using derivative absorption spectra and dual-wavelength, absorption difference methods by simultaneous measurements at two different wavelengths. These methods lead to analytical approaches that increase both the sensitivity and selectivity.

New absorptiometric techniques, photoacoustic and thermal-lens spectroscopy, now allow trace amounts of light absorption to be measured. Photoacoustic spectroscopy is based on the detection of thermal modulations from a light-absorbing sample as pressure waves in gas surrounding a sample. Thermal-lens spectroscopy utilizes a thermal-lens effect where, when a laser beam is introduced into a sample, local heating along the beam leads to a change in the refractive index in the vicinity of the beam. These highly sensitive techniques can accurately detect an extremely small absorption, even lower than 0.001, by increasing the laser's power.

Analytical Applications

A visible spectroscopic method is one of the most powerful and widely used procedures for quantitative analysis. There are many applications for inorganic, organic, biochemical, and food constituents. However, qualitative applications of this method are restricted, since the spectra of most substances in the visible region are simple and consist of one or a few broad peaks with no fine structure. Usually, this method is combined with a more useful quantitative technique like nuclear magnetic resonance or mass spectrometry.

Derivatization

Naturally colored substances can be directly analyzed, while most other substances, which are colorless or weakly colored, must be converted to an intensely colored derivative. The reaction for color formation may include enzymatic conversion or chemical modification of a substance to produce colored products and a complex formation between a substance and a color-forming reagent. Color-forming reagents have been developed and are now available for analysis of many substances including inorganic and organic constituents.

Specific Examples

Protein (Folin–Lowry method) This is widely used for the measurement of protein and consists of two steps: the reaction of a protein with copper ions in an alkaline solution and the reduction of a Folin–Ciocalteu reagent by copper-treated protein containing tyrosine and tryptophan residues.

A carbonate-copper solution (0.1 ml) is added to a sample solution (0.2 ml) in a test tube containing 5–100 μg of protein. The carbonate–copper solution is prepared by combining 2% sodium carbonate in 0.1 N sodium hydroxide (50.0 ml) and 0.5% hydrated copper sulfate in a 1% potassium tartrate

solution (1.0 ml). The sample solution is mixed vigorously and allowed to stand for 10 min at room temperature. Folin–Ciocalteu reagent (0.1 ml) (commercially available) is added and mixed. After 30 min, the absorbance of the sample solution is measured at 750 nm. The protein content is calculated from a standard curve prepared from bovine serum or egg white albumin.

Glucose (glucose oxidase method) This procedure, taking advantage of the specificity of glucose oxidase, is based upon the conversion of glucose to gluconic acid and hydrogen peroxide by glucose oxidase and the subsequent oxidation of *o*-dianisidine to its oxidized form, measurable at 420 nm, by hydrogen peroxide with peroxidase.

A sample solution (0.5 ml), containing 0–50 μg of glucose, is mixed with glucose oxidase reagent (3.0 ml) in a test tube and incubated in a water bath at 37 °C for 60 min. The glucose oxidase reagent is prepared by creating a mixture of glucose oxidase (125 000units), horse-radish peroxidase (0.5 mg), and 1% *o*-dianisidine in 95% ethanol (0.5 ml) to 100 ml with 0.5 M sodium phosphate buffer, pH 7.0, and, if necessary, filtering the solution. After incubation, the absorbance at 420 nm is measured against a blank. The sample content is then calculated from a standard curve.

Iron (di(2-pyridyl)-*N*,*N*-di[(8-quinolyl)-amino]-methane method) Di(2-Pyridyl)-*N*,*N*-di[(8-quinolyl)amino]methane (DPQAM) is a selective chelating reagent for iron(II), and under suitable conditions, the green 1:2 metal ligand chelate formed can be used to determine iron in an aqueous solution and, by solvent extraction, in the presence of large amounts of foreign metal ions.

An aliquot of the sample solution (10–150 ml), containing 2.5–25 μg of iron(II) and iron(III), is placed in a separating funnel. A 5% ascorbic acid solution (1.0 ml) and 0.84 M acetic acid buffer, pH 4.7 (5.0 ml), are added and extracted with one 10-ml aliquot of 0.1% DPQAM in chloroform. The mixture is then shaken vigorously and transferred into a 25-ml flask containing anhydrous sodium sulfate. The absorbance of the chloroform extract is measured against distilled water at 693 nm, and the calibration graph is prepared using standard solutions of iron (II) treated in the same way.

SPICES AND FLAVORING (FLAVOURING) CROPS

Contents

Use of Spices in the Food Industry

L A Wilson, Iowa State University, Ames, IA, USA

Introduction

Spices and herbs are valuable commodities that have played a major role in world civilization; wars were fought, governments and their economies altered, cultures enriched, legends created, and new worlds discovered. Many of the great chronologers and explorers – Hippocrates, Theophrastus, Marco Polo, Christopher Columbus, Vasco da Gama, Ferdinand Magellan – were associated with the use or trade of spices. Throughout history, the most powerful and richest countries were those countries that controlled the spice trade. Mankind has used spices and herbs to mask spoiled meat and body odor, preserve the remains of their dead, heal afflictions of the flesh and mind, and add enjoyment to their food.

Spices and herbs have historically been used to improved color (turmeric, saffron, paprika, chillies) and flavor (cinnamon, cloves, cumin, rosemary, sage, pepper) and, in some cases, improve the shelf-life (antioxidant and antimicrobial activity) of foods. Without spices, our diet would be bland, boring, and unappetizing. The aromatic and pungent principles that make spices so valuable are contained in their essential oils and oleoresins. (*See* **Antioxidants:** Natural Antioxidants.)

Classification

The definition of spices, herbs, and condiments has created considerable debate over the years. The International Standards Organization (ISO) defines spices and condiments as the natural vegetative products or mixture thereof, without extraneous matter, that are used for flavorings, seasonings, and imparting aroma to food. Spices and condiments are usually grown in tropical semitropical climates and comprise one portion of the plant. Spices are the whole or ground seeds, fruits, bark, or roots of a plant (Table 1). Herbs are generally defined as the leafy parts of a soft-stemmed plant whose main stem dies down to the roots and regrows each year (Table 1). Herbs are generally found in the more temperate regions of the world. Herbs generally contain a lower percentage of volatile (essential) oil than spices (Table 2). The US Food and Drug Administration (FDA) further specifies that paprika, saffron, and turmeric are colors, and that they must be labeled with their common names on food labels. While the legal definition of spices and herbs may vary between countries and trade organizations, this article will use the term spice to describe both spices and herbs collectively.

Economics

Since spices are an agricultural commodity, their prices are influenced by climatic and political conditions. Wars and national disasters also limit the exporting of spices.

While more than seventy recognized spices are used to season food, approximately 30% of the total international trade is accounted for by black and white pepper. Cloves, cardamon, cinnamon, nutmeg, and pepper represent about 70% of the world spice trade.

In 2000, the USA consumed approximately 1 billion pounds (453 600 tonnes) of spice per year. Per capita consumption increased to 3.7 pounds (1.7 kg). The average consumption has increased by over 50% from a decade ago due in part to the increased consumption of spices used to make foods less bland (e.g., capsicums, oregano, basil). Imported spices represent more than 70 herbs and spices grown and processed worldwide under a variety of environmental conditions. Black, white, and red peppers, mustard seed, capsicum, cassia, paprika, coriander,

Table 1 Geographic origin of common spices and herbs and plant parts used

Name	*Latin name*	*Plant part*	*Country of origin*
Allspice	*Pimenta dioica* L. (formerly *Pimenta officinalis*)	Unripe berry	Jamaica, Guatemala, Mexico, Honduras,
Anise seed	*Pimpinella anisum* L.	Seed	Spain, Egypt, Turkey
Basil	*Ocimun basilicum* L.	Leaves	France, Egypt, USA
Bay leaves	*Laurus nobilis* L.	Leaves	Turkey, Greece
Capsicum peppers	*Capsicum frutescens* L.	Includes red pepper, chilli pepper and sweet bell peppers	Hottest varieties: Africa, China Milder varieties: China, Japan, the Middle East, India, USA, Mexico Chilli pepper: California, New Mexico, Mexico
Caraway seed	*Carum carvi* L.	Fruit	Native to: Europe, Asia, North Africa Primarily exported from the Netherlands
Cardamon	*Elettaria cardamomum*	Fruit	India, Ceylon
Celery seed	*Apium graveolens* L.	Fruit	France, India, USA
Cinnamon	*Cinnamomum zeylanicum* Nees, *Cinnamomum cassia*	Bark	Indonesia (Korintyi), China
Cloves	*Eugenia caryophyllata* Thunb	Unopened flower buds	Madagascar and Brazil
Coriander seed	*Coriandrum sativum*	Ripe fruit. Leaves known as cilantro	Coriander: Morocco, Romania
Cumin	*Cuminum cyminum* L.	Fruit	Middle East, India, Turkey
Dill	*Anethum graveolens* L.	Dillweed, seeds	Egypt, India, USA
Fennel seed	*Foeniculum vulgare* Mill.	Dried fruit	India, Egypt, Turkey
Fenugreek	*Trigonella foenumgraecum* L.	Pod	India, Morocco
Ginger	*Zingiber officinale*	Rhizomes	China, India, Jamaica
Marjoram	*Majorana hortensis*, Moench	Leaves	France, Egypt, Europe, South America, USA
Mustard seed	*Brassica hirta*	Seeds	Canada, Northern plains of USA
Nutmeg and mace	*Myristica fragrans*, Houtt	Seed. Mace is a lacey netlike orange covering over the seed	Indonesia, East Indian Islands of Grenada and Trinidad
Oregano	*Origanum vulgare* L.	Leaves	Greece, Turkey, Mexico
Parsley	*Petroselinum crispum* L.	Curly leaf variety	California
Paprika	*Capsicum annum* L.	Ground fruit pods	California, Spain, Hungary
Pepper	*Piper nigrum* L.	Berries, Green (immature), White (ripe with black hull removed), Black.	Malabar Coast of India, Lampong district of Sumatra in Indonesia and Brazil
Rosemary	*Rosmarinus officinalis*	Leaves	Former Yugoslavia, France, Spain, Portugal
Saffron	*Crocus sativus* L.	Dried stigmas of the flower	Spain
Sage	*Salvia officinalis* L.	Leaves	Former Yugoslavia (Dalmatia), Albania, Turkey
Savory	*Satureja hortensis* L.	Leaves	Former Yugoslavia, France
Tarragon	*Artemisia dracunculus* L.	Leaves	California, France
Thyme	*Thymus vulgaris* L.	Leaves	Spain
Turmeric	*Curcuma longa* L.	Rhizomes	India (alleppey)

ginger, and oregano accounted for approximately 75% of the weight and 63% of the dollar value of these imported spices. The USA domestically produces 35–40% of its spice needs, including onions, shallots, chives, garlic, parsley, dill, basil, tarragon, mustard seed, mild and chilli peppers, cayenne (capsicum), spearmint, and peppermint leaves each year.

In the marketplace, similar spices from different geographical locations do not necessarily demand the same prices. European oregano (Greek and Turkish) demands a higher price than Mexican oregano.

Spices obtained from different plant parts have different volatile characteristics owing to differences in spices, environmental conditions, geographical origin, and processing. Milling also significantly influences the characteristic volatile oil content, composition, aroma, flavor, and color.

Spice Quality

Spice quality typically includes its degree of excellence and uniformity, as measured against specific

Table 2 Volatile oil content (% v/w)

Spice or herb	*Volatile oil content (% v/w)*
Anise	1.5–3.5
Allspice	2–4.5
Basil	0.1–1.1
Bay leaves	1.5–2.5
Caraway	1.5–3.5
Cardamon	3–8
Cassia (cinnamon)	0.5–4.0
Celery seed	1.5–3
Cloves	15–20
Coriander	0.1–1.5
Cumin	1.5–5
Dill seed	2–5
Fennel seed	1–3
Ginger	1.5–3
Mace	5–25
Marjoram	0.7–3
Nutmeg	5–16
Oregano	2.0–4.4
Pepper, black	0.6–5.0
Pepper, white	1.0–3.0
Rosemary	0.5–2.0
Saffron	< 1
Sage	1.5–2.5
Tarragon	0.2–1.5
Thyme	0.8–2.0

standards and specification (sensory properties, cleanliness, and safety). The quality attributes of spices can be divided into specifications concerning microbiological quality and safety, filth/contamination, foreign material, granulation, color, flavor, total ash and acid-soluble ash, moisture level, and volatile oil content. Specific tests (American Spice Trade Association (ASTA) color, Scoville heat units, curcumin content, piperine content, phenolic content) may also be used for certain spices. These specifications are set by the processor on the basis of international, federal, and trade standards.

Microbiology

A large percentage of the spices supplied to the world are produced in countries where sanitary conditions and hygienic handling and storage of spices are poor. Bacteria, insects, and bird and rodent droppings are common sources of contamination. Often, spices are laid out in fields or in backyard areas around houses to dry where they are subject to a high degree of contamination from animals and humans alike. It is not uncommon to find standard plate counts on black pepper of up to 10 million per gram. Spices with high microbial counts include allspice, caraway, celery seed, cumin, pepper, paprika, and onion powder. Standard plate count, yeast mold, coliform (*Escherichia coli*), and *Salmonella* tests are typically used to evaluate the microbiological quality of raw and processed spices. It is not uncommon to find metal wires and scrapings, dirt, sand, glass, bird feather, whole insects, and insect fragments in raw spices. Therefore, ISO, ASTA, and the US FDA have set cleanliness specifications (or guidelines) that all imported spices should meet. These are usually referred to as Defect Action Levels (DALs) and ASTA Cleanliness Specifications. Both of these specifications are designed to take into account that spices are a natural agricultural commodity that cannot be totally free of insects and foreign material. These numbers reflect the maximum amount of material that can be found under good manufacturing practices. Heavy and light filth testing procedures are used to evaluate the amount of filth and foreign material present in the spice (whole and ground spices). Total ash after ignition of the spice is a measure of metal, sand, rocks, and minerals naturally occurring in the spice. Acid-insoluble ash is the residue remaining after the total ash has been treated with hydrochloric acid, leaving only the sand. (*See* **Contamination of Food**.)

Moisture

High moisture levels in a dried spice are indicative of improper storage. High moisture levels lead to microbiological growth of molds and bacteria. Both degrade the quality of the spice and may lead to the presence of toxins (such as aflatoxin). Moisture testing is usually determined by vacuum oven drying for capsicums and dehydrated vegetables with low volatile oils. Toluene distillation of spices is used to determine the moisture of spices with high volatile oil contents (the procedure minimizes the loss of volatile oils that would contribute to a higher moisture determination). (*See* **Mycotoxins**: Occurrence and Determination; **Water Activity**: Effect on Food Stability.)

Volatile Oil

The terms volatile oil and essential oil are synonymous and are used interchangeably in the flavoring industry. These oils volatize at low temperatures and are the main contributors to the aroma and flavor of spices. Volatile oils are a complex mixture of organic compounds, hydrocarbons (terpenes, sesquiterpenes), oxygenated compounds (alcohols, esters, aldehydes, ketones), aromatic benzenoids, and compounds containing nitrogen or sulfur, present in droplets of cell sap and in glandular hairs. In plants, essential oils are functional enigmas; some may act as insect attractants and so aid in pollination, whereas others may protect plant tissue against parasites and animal depredation. For example, oregano and thyme essential

oils have been shown to inhibit molds and foodborne-illness bacteria. (*See* **Essential Oils**: Properties and Uses.)

The percentage of volatile oil in spices usually ranges from 0.5 to 3.0%, with the seed spices typically having higher values than the herbs (Table 2). The volatile oil content of spices is influenced by crop year, origin, milling technique, age, and extraction technique. Owing to these variations, a standard method and a minimum level of volatile oil are specified for the determination of volatile oils. ASTA Method 5 Modified Clevenger Trap Method) is typically used to steam-distill off the volatile oils from the spices and collect them to be measured.

The percentage of volatile oil has long been the method of choice for defining spice quality, but the validity and sensitivity of this method are questionable, as research has shown that consumers and analytical methods are able to detect differences not identified by the percentage of volatile oil. The steam distillation process often produces conditions that may distort volatile oil composition. The composition of the oil can be more important than the total amount of oil present in the spice. On-column cryogenic focused gas chromatography of the spice headspace and/or heat gas-chromatography injections of the volatile oil can be used as a supplemental technique for the determination of spice flavor quality. (*See* **Chromatography**: Gas Chromatography.) Electronic nose technology is also being used as quality-control instrument to differentiate different spices based on their volatile patterns. Typically, one to 32 sensors, of different types, are exposed to the headspace over the spice. If the volatiles bind with a sensor, they change its electrical resistance, which can be measured. The patterns produced from this measurement can be related to spices from different geographical locations and aroma quality. Many of these units have neural networks, which can be trained (using sensory or chemical data) to recognize these differences.

The relative heat of red peppers is measured by Scoville heat units. This procedure uses five trained taste panelists to determine the threshold hotness of ethanol extracts of red pepper: the higher the number, the hotter the red pepper. Unfortunately, the variation in Scoville numbers between laboratories can be as high as 50%. Newer instrumental methods using high-performance liquid chromatography have been developed to determine the amount of specific capsaicinoids present to try to reduce the variation found with taste panels. (*See* **Chromatography**: High-performance Liquid Chromatography.)

Solvent extraction methods are typically used to determine the color of paprika (carotenoid pigments) and turmeric (curcumin content). These procedures utilize acetone to extract the color pigments, which are then measured spectrophotometrically. The results are then expressed as ASTA color units. (*See* **Spectroscopy**: Overview.)

Spice Processing

Spices are treated as an agricultural commodity and shipped in bags, bales, or totes. Upon arrival, they must meet the cleanliness specifications of that country. Processors first check the whole spice for cleanliness by pulling a representative sample from multiple containers and determining the amount of foreign material (stones, metal, hairs, excreta, glass, insects) and microbiological load. If a product is found to have these items present in excess of the DALs, the spices must be cleaned or treated. Infestations due to insects and high microbial loads can be reduced by ethylene oxide, propylene oxide or irradiation treatment. Steam sterilization procedures are also used by a few spice companies, especially in Europe, to reduce microbiological loads. Wet steam sterilization requires drying of the spice after treatment. The use of ethylene oxide in sealed chambers usually reduces the microbiological load by 90%. However, ethylene oxide has been classified as a carcinogen, and the FDA has set a maximum residue tolerance of 50 p.p.m. in spice. Owing to the undesirable toxicological effects of ethylene and propylene oxide, alternative methods for sterilizing spices are being investigated. Irradiation of spices using ionizing radiation up to 30 kGy is allowed in the USA. The FDA requires that an irradiated spice must be labeled with the irradiation logo and the statement 'treated with/by irradiation.' However, if the irradiated spice is used in a food as an ingredient, the finished product does not have to be labeled as being irradiated. Irradiation of spices is very effective (killing 95–100% of microorganisms); however, many consumer groups are opposed to this procedure, owing to concerns about radiation, nuclear wastes, and unknown byproducts in the food. After the sterilization procedures (if required), the spices can be cleaned to remove foreign material. Magnets are used to remove ferrous metal during the cleaning and grinding operations. Nonmetallic foreign material can be removed from spices using a variety of methods, depending upon the foreign material present and the type of spice. Three basic types of cleaning techniques are typically used, alone or in combination with each other: air, gravity, and centrifugal separators. Each of these methods uses the difference in weight or specific gravity of the spice to separate it from the lighter or heavier foreign material. Gravity separators or air tables are

the most commonly used pieces of cleaning equipment. This technique uses air forced through a porous moving plate (deck) to suspend the particles into layers of different densities. The lighter material moves downhill, and the heavier material moves uphill. Proper adjustment of this system allows the processor to separate the product into many different density fractions (dust, lights, heavies, stones, etc.). (*See* **Irradiation of Foods**: Basic Principles; **Sterilization of Foods**.)

After cleaning, the spice is checked for cleanliness and other quality attributes. If the spice meets these specifications, it can be packaged and sold as whole spice or ground into smaller particles.

Spice Milling

Since ancient times, milling has been used to release the natural aromatic compounds contained by the plant's protective cell wall. Milling shatters the cellular material, starting the slow release of volatile aromatic compounds. During milling, not all the plant cells are disrupted; consequently, ground spices retain a portion of their original aromatic components during processing and storage.

Using a variety of milling techniques and equipment, millers encounter a wide range of different physiological material. The use of high-speed mills, which generate large quantities of heat with rapid air movement, results in the loss and/or deterioration of volatile components. Therefore, milling is carried out using as little grinding as possible with high-speed disintegrators, various types of hammer mills, and slow-speed vertical and horizontal burr stone mills in a wide range of sizes and capacities. During traditional milling, the frictional heat of grinding can increase to 93 °C, causing the loss of volatile oil and the development of off-aromas and flavors. Volatile oil losses of up to 1.5% during the milling of different spices between 42 and 95 °C are common. (*See* **Milling**: Characteristics of Milled Products.)

Cryogenic milling has been utilized to reduce these problems. In this procedure, spices are ground with liquid nitrogen to reduce the loss of volatile oil. The liquid nitrogen cools both the spice and grinding zone by instantaneous evaporation, absorbing any frictional heat. Grinding zone temperatures well below −73 °C with theoretical grinding zone temperatures approaching −195 °C have been reported.

There are several advantages to the 'Cryomill' process of spice milling.

1. It reduces the oxidation of spice oil, thereby increasing stability and flavor intensity by expelling air from the grinding zone.
2. It permits production of exceedingly fine particle size because the low temperatures solidify spice oil, making the spice very brittle.
3. The fine spice particles disperse uniformly throughout the finished product to give a uniform flavor, eliminate speckling, and reduce settling in liquid products.
4. It reduces the loss of volatile aromatic compounds, increasing flavor intensity.
5. The low-temperature treatment may reduce the microbial load.
6. The milling rate is increased, by reducing spice stickiness.
7. Cryogenically milled spices show a reduced cost when the increased flavor strength is factored into the cost.

Spice Oleoresins

Spices can also be solvent-extracted to produce oleoresins or steam-distilled to produce essential oils. Oleoresins are liquid, semisolid, or a solid residue composed of volatile oils, fixed oils (nonvolatile plant oils), pigments, pungent constituents, and natural antioxidants. Because oleoresins contain all of the volatile and nonvolatile flavor components of the spice, they provide a more rounded, closer duplication of the original spice. For example, the oleoresin of ginger contains pungent (hot sensation on the tip of the tongue or back of the throat) gingerol, shogal, paradol, and zingerone; white and black pepper contain piperine, and hot chillies (capsicum) contain capsaicinoids such as capsaicin, dihydrocapsaicin, and nordihydrocapsaicin. The oleoresins also contain natural antioxidants such as romaridiphenol and romariquinone in rosemary. Mace, sage, thyme, cloves, oregano, allspice, and cinnamon have also been reported to have antioxidant properties.

Both oleoresins and essential oils are very concentrated flavors and can be difficult to use in food processing. Extractives are typically used at levels of less than 0.01% of the finished food product. Standardization of the extractive is necessary, owing to crop year, geographical origin, age and lot-to-lot variation. In order to overcome these difficulties, extractives are usually incorporated into food products by being (1) dispersed on a dry carrier (salt, dextrose, flour), (2) solubilized with Polysorbate 80, (3) encapsulated inside vegetable gums or food starches (spray-drying), and (4) made into a water-dispersible liquid using emulsifiers. The amount of residual solvent in the spice oleoresin is also of concern, and levels are monitored by federal agencies. For example, in the USA, Title 21 of the Code of the Federal Regulations, parts 173 and 182.20, gives essential oils and

oleoresin generally recognized as safe (GRAS) status and defines the maximum solvent residue for hexane, acetone, isopropyl alcohol, and ethylene dichloride (25, 30, 50, 30 p.p.m., respectively) allowed in the spice extract. The label of a food containing oleoresins or essential oils need only state 'natural flavors.'

Fruits and Seeds

G D Bagchi and G N Srivastava, Central Institute of Medicinal and Aromatic Plants, Lucknow, India

Introduction

There are about 30 types of fruits and seeds that are commonly used as spices and for flavoring purposes throughout the world. Their frequency of use varies in different parts of the world. In this article, some of the most commonly used spices and flavoring crops are discussed in detail, and the remaining equally important ones are summarized in **Table 1**: each section deals with an individual spice in terms of its common name, botanical name, family, and parts used, along with diagnostic, morphological and anatomical characters; details of handling, drying, and storage have also been given wherever available.

Allspice or Pimento

Allspice consists of the dried fruits of *Pimenta officinalis* Lindl. (Myrtaceae). Dried berries are globular, 4–7 mm in diameter, hard, and dark reddish brown; the surface of the berry is rough with protuberances, and the apex bears the remains of the calyx and the style; there is a short stalk, or its scar at the base. The berries are bilocular each with hard, dark brown, reniform seeds (**Figure 1a** and **b**).

The epidermis of the exocarp bears stomata and nonglandular hairs up to 150 μm in length. The mesocarp, towards the outside, consists of numerous oval or rounded oil cavities up to 210 μm in diameter; numerous scattered, variable, pitted stone cells occur singly or in groups; beneath, there is a zone of fibrovascular bundles; ground tissue is parenchymatous, and contains 'rosette' calcium oxalate crystals. Group of stone cells, 30–60 μm in diameter, are present towards the inner side. The endocarp consists of a few layers of compressed parenchyma (**Figure 1c**).

Allspice is aromatic and pungent, and possesses the flavor and aroma of clove, nutmeg, cinnamon, and black pepper, hence the name 'allspice.' Mature berries are removed from the twig when still green by hand or flail, sorted, and dried in the sun for 6–8 days; when dull reddish brown, the berries are packed in jute bags. At present, sun drying of berries is done on a concrete barbeque. Because of frequent shifting of the berries in and out of the sheds during rainy days, many berries break. Hence, mechanical drying is preferable, and it is also more economical than

Table 1 Some other commonly used spices from fruits and seeds

Botanical name	*Common name*	*Family*	*Part used*	*Characters*
Aframomum korarima (Pereira) Engler	Korarima cardamom	Zingiberaceae	Fruit and seed	Fruits ovate, about 4 cm by 2 cm pointed seeds reddish brown, striated
Aframomum melequeta (Rosc.) K. Schum.	Grains of paradise	Zingiberaceae	Fruit and seed	Fruits ovoid 10 cm long, pointed. Seeds inverted subpyramidal, somewhat four-sided, 2–3 mm by 2.5 mm, testa rich reddish brown, papillose
Amomum subulatum Roxb.	Greater or Nepal Cardamom	Zingiberaceae	Fruit and seed	Fruit is dark red–brown, globose capsule, 2.5 cm long; several cardamom seeds, similar to true cardamom, embedded in a vicid pulp
Bunium persicum (Boiss.) Fedts	Black caraway	Apiaceae	Fruit	Mericarp oblong (3–4 mm by 0.7–1.0 mm), yellowish dark brown with ridges
Dipteryx odorata Willd.	Tonka beans	Fabaceae	Fruit	Fruit egg-shaped with hard shell and pulpy flesh surrounding a single seed with a black wrinkled surface
Garcinia indica Choisy	Kokam	Clusiaceae	Fruit	Fruit globose or spherical 2.0–3.75 cm in diameter, dark purple when ripe
Juniperus communis L.	Juniper	Pinaceae	Fruit	Fruit subglobose, 5–9 mm in diamter externally smooth, shining, purplish black to dusky red purple internally yellowish brown to dusky yellow flesh, containing many large, schizogenous cavities; ripe fruits are collected, and dried flavor diminishes after storing fruits for more than a year
Mangifera indica L.	Amchoor	Anacardiaceae	Fruit	Fruit a drupe, variable in form and size, leathery, dotted with glands; mesocarp of unripe fruit hard, acidic; ripe fruits juicy; endocarp stony; skin of unripe fruit removed, mesocarp sliced and dried in sun; the dried product is packed in wooden casks and may also be seasoned before drying
Nigella sativa L.	Black cumin	Ranunculaceae	Seed	Seeds trigonous, black, rugulose and tuburculate; seeds are collected mostly from wild plants
Piper cubeba Linn. f.	Cubeb	Piperaceae	Fruit	Fruit globular, 3–6 mm in diameter with a stem-like portion about 7 mm long, apex with four remains of stigma; dusky red, brown or, rarely, grayish; coarsely reticulate; nearly full grown fruits are collected and dried in sun
Piper longum L.	Long pepper	Piperaceae	Fruit	Catkin is subcylindrical, up to 40 mm by 5–7 mm; greyish black and composed of numerous small immature drupes and bracts embedded spirally in the axis; immature catkins are harvested and immediately dried in the sun or oven to prevent formation of mold
Pistacia vera L.	Pistachio	Anacardiaceae	Fruit	Drupe oblong, linear to globose, laterally compressed, 10–20 mm by 6–12 mm; outer husk variously colored, readily separating from the dehiscent or indehiscent grayish white, bony keeled nutshell (endocarp) enclosing yellow to green kernel
Punica granatum L.	Anardana (pomegranate)	Punicaceae	Seed	Seeds hard, angular, covered with a juicy red, pink or yellowish white pulp; seeds of ripe fruits are taken out and sun-dried or dehydrated
Sisymbrium irio L.	London rocket (khub-kalan)	Brassicaceae	Seed	Seeds ovoid (1.3 mm long), reddish or yellowish brown, mucilaginous

Table 1 Continued

Botanical name	*Common name*	*Family*	*Part used*	*Characters*
Trachyspermum ammi (L.) Sprague	Bishops weed (Ajowan)	Apiaceae	Fruit	Cremocarp ovoid (2–3 mm long), muricate, grayish brown; mericarps compressed with distinct ridges and tuberculate surface harvested when fruits turn brown; plants are pulled out and dried completely on threshing floor; fruits are separated by rubbing.
Tamarindus indica L.	Tamarind	Fabaceae	Fruit	Fruits 5–20 cm by 2 cm in size; epicarp surface rough, brownish hard and brittle; mesocarp pulpy light brown changing with age to dark brown or black; containing some branched fibers and numerous seeds
Vanilla pompona Schneider	Pompon or West Indian vanilla	Orchidaceae	Fruit	Pods are 10–17.5 cm long and 2.5–3.3 cm in diameter
Vanilla tahitensis J.W. Moore	Tahitian vanilla	Orchidaceae	Fruit	Pods 12–14 cm long and about 9–10 mm wide with tapering ends; pods are harvested when tips of the pods turn brown
Xylopia aethiopia (Dunal) A. Richard	Xylopia, Netawu	Annonanaceae	Fruit	Mature carpels cylindrical, incurved, about 5 cm long, embedded in the center of the receptacle; seeds glabrous, ellipsoid (about 0.5 mm by 0.25 mm), brown

sun-drying. (*See* **Drying**: Drying Using Natural Radiation; **Sensory Evaluation**: Aroma; Taste.)

Anise

Anise is the dried fruit of *Pimpinella anisum* L. (Apiaceae). The schizocarps are 2–5 mm, ovoid–conical, grayish brown, and pubescent, with a pedicel attached; they are crowned with a short, bifurcate stylopod. The mericarps, attached to the carpophore, are broadly ovoid; they are flat or concave on the commissural side, convex and pubescent on the dorsal side (Figure 1d and e).

The exocarp has an outer striated cuticle with stomata and rectangular epidermal cells bearing surface hairs up to 150 µm in length. The mesocarp consists of five fibrovascular bundles underlying ridges, two to four vittae on the commissural side and 20–40 vittae on the dorsal side. The endosperm of the seed is composed of thick-walled parenchymatous cells containing oil and aleurone grains and one or two small 'rosette' calcium oxalate crystals (Figure 1f and g).

Anise has a characteristic and agreeable aromatic odor and a pleasant taste. Fruits are harvested when their color changes from green to gray; shattering is minimized by avoiding overripening and harvesting during the morning with scythes or reaping machines. The crop is piled into small stacks and allowed to wither for 2–3 days; it is then threshed and dried in partial shade. After winnowing, sieving, and cleaning, the crop is dried naturally to 18% moisture followed by artificial drying at 80–90 °C; it is then packed and stored in a cool, dry room. For keeping spices belonging to family Apiaceae, the maximum tolerance limit of moisture is 10%. Reducing the moisture below 8% can generally have a bad effect on the quality due to loss of volatile oils. Crushed or ground spice is stored in airtight containers. (*See* **Drying**: Theory of Air-drying.)

Black Pepper

Black pepper consists of the dried, unripe fruit of *Piper nigrum* L. (Piperaceae). It is the oldest and most important spice and commonly known as the 'King of spices.' There are about a hundred cultivars of black pepper under cultivation. There is considerable variability among the accessions with regard to various morphological as well as floral characters like leaf shape, size, spike length, density, composition of male, female and bisexual flowers in the spike, fruit set, shape, weight and volume of the fruit, and time taken for maturity. The fruit, though known as a berry, is a sessile globose drupe with a pulpy pericarp. The berry is globular, 6 mm or less in diameter, brownish black, with a coarsely reticulate surface, and single-seeded. The seed is almost white hollow, and adheres to the pericarp (Figure 1h and i).

The exocarp is cutinized and darkly pigmented, with rectangular cells beneath containing calcium oxalate crystals. The hypodermis consists of stone cells interspersed with parenchyma. The mesocarp is comparatively broad: the outer seven to eight layers

Reproduced from Spices and Flavoring (Flavouring) Crops: Fruits and Seeds, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press. Abbreviations: Ad, amylodextrin granules; Ag, aleurone grains; Ar, aril; Bc, beaded cells; Bel, beaker cells; C, cuticle; Cc, compressed cells; Ch, chloroplast, Col, colenchyma; Cot, cotyledon; Cp, carpophore; Cr, crystal; Crc, crystal cells; Cro, cross cells; Dl, dehiscence line; Em, embryo; End, endocarp; Ep, epidermis; Es, endosperm; Exo, exocarp; Fl, fiber layer; Fo, fixed oil; Gc, giant cell; H, hair; Hc, hourglass cells; Hp, horny protein; Hy, hypodermis; Li, light line; Mc, mucilage cells; Mes, mesocarp; Mp, mesophyl; O, oil; Oc, oil cavity; Ocl, oil cells; Or, oleoresin; P, pedicel; Pa, parenchyma; Pal, palisade; Pe, perisperm; Pl, placenta; R, raphe; Rc, reticulated cells; Re, resin; Rub, rudimentary vascular bundle; Sc, seed coat; Scl, sclerenchyma; Sd, seed; Se, secretory cells; St, starch; Stc, stone cells; V, vittae; Vb, vascular bundle.

are parenchymatous with scattered oleoresin cells, and beneath, there is a zone of fibrovascular bundles, a region of compressed cells, a layer of large oil cells, and two layers of small parenchyma cells. The endocarp consists of a layer of 'beaker cells,' the radial and inner walls of which are strongly lignified. The seed coat is differentiated into the distinct layers, and whereas the outer perisperm cells contain aleurone grains, the inner cells contain starch grains (Figure 1k).

The fruits are aromatic and pungent. The quality of black pepper depends upon piperine and essential oil present in the oleoresin. Piperine contributes to the pungency, and essential oil is responsible for the characteristic flavor. The harvested green berried spikes are heaped for a day and spread on a mat or floor. The berries are separated from spikes by rubbing. After separation, the berries are cleaned and put out for drying. The fresh harvested berries will have a moisture content of 80%, and this has to be dried to 8% moisture content for safe storage. A blanching treatment by dipping the berries for 1 min in boiling water gives a glossy appearance to the dried berries and reduces the microbial load on the product. Due to enzymic oxidation of color compounds present in the skin, the colour of pepper turns black during drying, which effectively masks the green color that is left in the berries after drying. The berries are dried under sun for 4–7 days until the outer skin of the berries becomes black in color with a wrinkled appearance. Small and light berries are removed from the dried produce. Berries can be dried in a solar cabinet dryer in 4 days with a spreading density of $18\,kg\,m^{-2}$ and resulting in a black dried produce. By contrast, sun-dried berries take 5 days to dry with a spreading density of $5\,kg\,m^{-2}$ and resulting in a dull black color. Dark black berries obtained from solar cabinet drying are preferred in trade over the dull black berries obtained from open sun drying. Sixty kilograms of fresh pepper can be dried in the indirect heating type of dryers in about 30 h. After drying, the pepper has to be garbled. Ungarbled pepper contains fractions, dust, stalk, pinheads, and immature, overmature, and large berries. The grading is done by a combination of size sieving and weight classification by air blast. The major grade is the average-sized black pepper known as 'Malabar Garbled,' which constitutes 95% of India's export. The recovery of black pepper from fresh berries is 35–36%. For black pepper powdering, a normal pin type of hammer mill is used so that there is no temperature rise during grinding. The ground pepper is only used as a raw material for oleoresin and in the oil industry. White pepper (Figure 1j) is usually prepared from overripe berries. In this state, the skin comes off easily, and the resultant product is dried. White pepper fetches double the price of black pepper. The piperine content also is found to be apparently higher in white pepper due to its concentration in the endosperm of the berries. In India, the berries are dipped in water and the skin removed by rubbing with hand. The skinless berries are dried in open sun for 7 days to obtain white pepper. Skin is also removed in a pulping machine after steam cooking. At the National Research Centre for spices in Calicut, a process of steaming and boiling the despiked pepper for 13 min and rolling it in a container in running water to remove outer skin has been developed.

After sun-drying, the berries are cleaned and polished with a piece of cloth. The recovery of white pepper is about 28% of the fresh ripe berries. In European Countries, the green or fresh flavor of pepper is desired in certain food preparations. Green pepper is made in canned and bottled forms. In the canned form, it is prepared by heat-sterilizing green berries and packing them in 2% brine solution for protection. However, the rupturing of berries and making the covering liquid turbid are problems associated with this method. These problems have been overcome with proper canning methods and the introduction of a trace of pepper oil into the can before sealing. In bottled green pepper, heat processing is avoided, but a higher salt strength of 15–20% of the covering liquid is essential for good preservation. At CFRI, undermature berries are dried by arresting the enzyme action responsible for oxidative blackening and drying by mechanical means at low temperatures. The product has an excellent green flavor.

Capsicum

Capsicum is composed of dried fruits of the genus *Capsicum* L. (Solanaceae). Cayenne pepper and red pepper are two of the various synonyms of *C. frutescens* L., whereas paprika is *C. annuum* L. The fruits of *C. frutescens* are 6–150 mm long, laterally compressed, musky brownish to deep red, smooth or wrinkled, and bi- to tetralocular with central placentae united at the base-apical placentae with longitudinal ridges; the seeds are numerous, discoid, flat, hard, smooth, yellow, and about 2–5 mm long (Figure 1l and m).

The exocarp consists of five to seven rows of subrectangular cells, 25–60 μm by 15–20 μm; the outer epidermis is cuticularized and the mesocarp is parenchymatous, 30–85 μm by 15–20 μm. Many cells contain oil droplets and chromatophores, or sandy crystals. The innermost layer consists of larger cells, 0.8–1.7 mm by 0.2–0.4 mm. The endocarp is single–layered, consisting of parenchymatous and

sclerenchymatous cells, the latter directly beneath a layer of giant cells possessing thick, lignified, porous walls. The dissepiment consists of a zone of tangentially elongated, collapsed cells (some containing microcrystals) and epidermal cells on either side, radially elongated, containing capsaicin (Figure 1n).

The odor of the spice is characteristic, sternutatory but agreeable, mildly to intensely pungent. The stem of the entire plant is cut, hung, and exposed to the sun to remove 80% moisture; it is then dried further in a dryer to a critical moisture level; pricking the skin longitudinally reduces the drying time. Completely dried fruits are removed by a dressing machine and packed in polythene bags.

Caraway

Caraway is the dried fruit of *Carum carvi* L. (Apiaceae). The mericarps are separated, crescent-shaped, 3–7 mm by 1–2.3 mm, and brown, with five lighter-colored, filiform primary ribs, between which, on the dorsal surface, there is a secondary rib (Figure 1o and p).

In transverse section, the epicarp consists of slightly tangentially elongated epidermal cells, and its outer surface is cuticularized; the mesocarp consists of a zone of several rows of collapsed, tangentially elongated parenchymatous cells, with fibrovascular bundles located in the rib portion; large vittae, two and four in number, are present on the commissural and dorsal side, respectively; the endocarp contains inner epidermal 'cross cells' that are closely adherent to the seed coat (Figure 1q and r).

The odor and taste of caraway are characteristically aromatic. The endosperm structure of the seeds, and handling, drying, and storage of the spice are the same as for anise.

Cardamom

Cardamom is the dried fruit of *Elettaria cardamomum* Maton (Zingiberaceae). It is popularly known as the 'Queen of spices.' There are many varieties, which are classified on the basis of their capsule size and color. Some of the important varieties are Alleppy, Mysore, Malabar, and Mangalore cardamoms. The capsules are trilocular, containing seeds on an axile placenta; they are 1–2 cm long, oblong-ovoid, three-sided, greenish to pale buff or yellowish in color; each locule contains five to eight seeds, 3 mm by 2–3 mm, dark reddish brown, adhering together with a membranous aril to form a single mass (Figure 1s and t). The pericarp in transverse section shows an outer exocarp with cells up to 30 μm long. Parenchymatous cells of the mesocarp are up to 180 μm long, containing one or more calcium oxalate crystals. The inner mesocarp contains fibrovascular bundles and resin cells. Endocarp cells are compressed and invaginate into locular partitions (Figure 1u). Seeds, in transverse section, show a three-cell-layered aril containing a pale-colored substance and calcium oxalate crystals. It has an outer epidermis followed by a layer of pigmented, large, clear cells containing volatile oil, a one- to two-layered parenchyma, and a layer of sclerenchymatous, thick-walled, dark brown 'beaker cells,' each with a nodule of silica; the perisperm consists of starch-containing polygonal cells, the endosperm cells containing proteinaceous substance having a waxy or horny nature, and the embryo cells containing aleurone grains and fixed oil (Figure 1u and v).

The seeds are much more aromatic than the pericarp and possess a characteristically warm and slightly pungent taste. Fruits on the same raceme ripen at different times, and ripe fruits are collected before splitting. A green curing method is common in commerce. Fully mature green capsules, not having excessive shrinkage and splitting, which are not fully ripe yet, retain a good color after drying. The temperature and relative humidity of drying air inside the drying chamber are the two important factors to be controlled in the cardamom drying system. The recommended temperature for cardamom is 45–55 °C. Cardamom are dried by different systems by kiln, driers, electric driers, or infrared driers. Cardamom drying has two phases; in the first phase, the surface moisture and moisture in fleshy parts of the mesocarp have to be removed, and in the second phase, the moisture in the seeds inside has to be removed. Controlled temperature, quick removal of the moisture, and quick flushing out of moisture-laden air from inside the drying chamber to prevent condensation are basic criteria in the retention of a green color. The dried cardamom capsules are placed into a wiremesh cylinder. The wiremesh cylinder is swung to separate the flower stalks, and the capsules are cleaned by winnowing. The cleaned capsules are packed in gunny bags lined with black polythene sheet for better retention of green color during storage. Grading of green cardamom is done according to the standard specifications at the exporter level. Extra Bold and Bold are the superior qualities.

Bleached Cardamom or White Cardamom

This processing is resorted to, especially in varieties that do not retain the green color during drying or lose the color during storage. This product fetches lower prices. Freshly harvested ripe capsules are pretreated by soaking in a 1% solution of bleaching powder for 30–60 min followed by dipping the lot

in dilute HCl solution (0.2–0.5%) for 2–3 min. The treated capsules are washed and sun-dried to 8% moisture level. But the sulfur dioxide content was found more in the capsule treated by the above method, a simple treatment with hydrogen peroxide (solution of 0.5% strength) has been standardized to overcome this problem. Complete drying using a solar cabinet dryer is obtained in 3 days in comparision with 5 days under open sun-drying, and the color of the capsules was white, the required bleaching obtained without sulfur bleaching. The volatile oil in cardamom is responsible for cardamom's aroma and therapeutic properties. Green cardamom yields more oil than bleached cardamom.

Celery

Celery is the dried fruit of *Apium graveolens* L. (Apiaceae). The schizocarps are ovoid and laterally compressed and occasionally possess a pedicel. The mericarps, usually separated, are ovoid, slightly curved, 1–2 mm by 0.5–1 mm, and light to olive brown; the commissural surface is flat and the dorsal surface convex and smooth, with five longitudinal ridges (**Figure 1w** and **x**).

In transverse section, the mericarps are equilaterally pentagonal; the exocarp has a striated cuticle, and the epidermis has stomata – some of the cells are papillose; the mericarp is parenchymatous, has four to 15 vittae, of which two are on the commissural side, and fibrovascular bundles occur in each primary rib; the endocarp consists of a layer of tangentially elongated cells with yellowish orange to greenish yellow walls, and the spermoderm consists of collapsed cells. The structure of the endosperm is similar to that of anise (**Figure 1y** and **z**).

The fruit bear a characteristic celery aroma and taste. Celery yields 2–3% of pale yellow volatile oil, which is valued both as a fixative and as an ingredient of perfumes. Handling, drying, and storage of the spice are also similar to those of anise. The quality of celery depends upon its volatile oil content, and hence, the higher the oil content, the better the quality. The seed yield shows a significant and positive correlation with plant height, total umbels per plant, number of umbellets per umbel, weight of the main umbel, and number of seeds per umbel. All these characters have a positive effect on celery seed yield.

Coriander

Coriander spice is derived from the dried, ripe fruits of *Coriandrum sativum* L. (Apiaceae). It was one of the earliest spices used by mankind. The schizocarp is globular, yellowish brown, 2–5 mm in diameter, with five calyx teeth and a short, conical stylopodium at the apex. Each mericarp has five prominent, straight, longitudinal primary ribs and four undulate, secondary ribs, which are easily separated, being deeply concave on the commissural side and convex on the dorsal side (**Figure 2a** and **b**). In transverse section, the exocarp consists of a layer of small, thick-walled epidermal cells, and the mesocarp consists of several rows of thin-walled, somewhat collapsed parenchymatous cells, separated from a broad continuous zone of thick-walled, strongly lignified sclerenchyma fibers. The commissural side has two large elliptical vittae. The endocarp is a layer of tabular cells, and the cells of the seed coat are tangentially elongated and brownish. The structure of the endosperm is similar to that of anise (**Figure 2c** and **d**).

The spice has a characteristically pleasant and fragrant odor and an aromatic taste. Significant variations for oil content in coriander have been observed, ranging from 0.17 to 0.26%. The preferred cultivars of the plant for essential oil production are the small fruit varieties with a variable oil content of 4% or more. For spice use, however, it is the larger fruits from Morocco and India that are more commonly preferred. It has been reported that large thick skinned fruits are less aromatic and have a lower oil content than the smaller thin skinned fruits. There is no correlation between the number of fruits in the main umbel and yield. The flowers on the branches in the middle of the stalk are the most productive. It has been found that the number of umbels per plant is the chief contributing character and that the plant height determines the yield. Handling, drying, and storage are similar to those for anise.

Cumin

Cumin consists of the dried, ripe fruit of *Cuminum cyminum* L. (Apiaceae). The schizocarps are about 6 mm long, attached to short pedicels, and separated into mericarps. The fruit resembles caraway, but can be distinguished by its straighter mericarps and bristly hairs along the ribs (**Figure 2e–h**).

In the transverse section, the exocarp has an outer epidermis bearing stomata, and a thin and striated cuticle; the hairs on the secondary ridges are larger than those on the primary ridges, being up to 2 mm long, and multicellular with broad bases and rounded apices; the mesocarp is parenchymatous, consisting of five fibrovascular bundles beneath the primary ridges, two vittae on the commissural side, and four vittae on the dorsal side. The parenchymatous cells of the endocarp have pale yellowish walls, and the seed coat consists of a layer of epidermal cells, each containing a prismatic crystal of calcium oxalate.

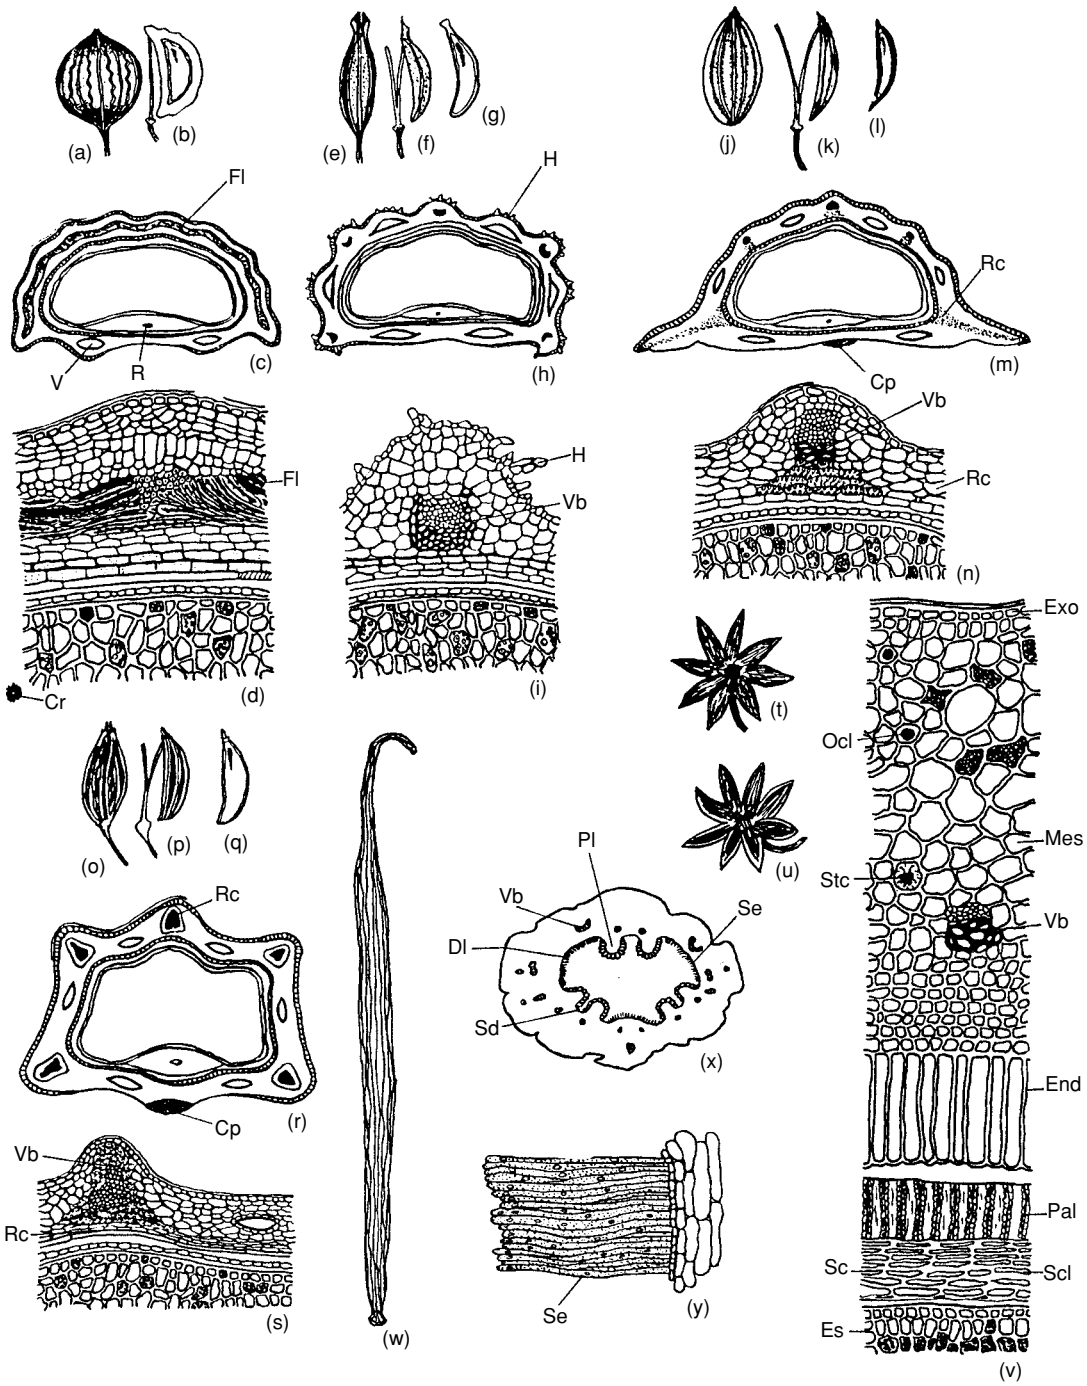

Figure 2 Spices from fruits. **Coriander:** (a) schizocarp; (b) mericarp; (c) cross-section of mericarp; (d) cross-section through primary ridge of pericarp. **Cumin:** (e) schizocarp: (f, g) mericarp; (h) cross-section of mericarp; (i) cross-section through ridge of pericarp. **Dill:** (j) dorsal view of mericarp; (k, l) side views of mericarp; (m) cross-section of mericarp; (n) cross-section through ridge of pericarp. **Fennel:** (o) schizocarp; (p, q) mericarp; (r) cross-section of mericarp; (s) cross-section through ridge of pericarp. **Star anise:** (t, u) fruit; (v) cross-section of fruit and seed. **Vanilla:** (w) fruit; (x) transverse section of fruit; (y) secretory hairs. Reproduced from Spices and Flavoring (Flavouring) Crops: Fruits and Seeds, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press. Abbreviations: Ad, amylodextrin granules; Ag, aleurone grains; Ar, aril; Bc, beaded cells; Bel, beaker cells; C, cuticle; Cc, compressed cells; Ch, chloroplast, Col, colenchyma; Cot, cotyledon; Cp, carpophore; Cr, crystal; Crc, crystal cells; Cro, cross cells; Dl, dehiscence line; Em, embryo; End, endocarp; Ep, epidermis; Es, endosperm; Exo, exocarp; Fl, fiber layer; Fo, fixed oil; Gc, giant cell; H, hair; Hc, hourglass cells; Hp, horny protein; Hy, hypodermis; Li, light line; Mc, mucilage cells; Mes, mesocarp; Mp, mesophyl; O, oil; Oc, oil cavity; Ocl, oil cells; Or, oleoresin; P, pedicel; Pa, parenchyma; Pal, palisade; Pe, perisperm; Pl, placenta; R, raphe; Rc, reticulated cells; Re, resin; Rub, rudimentary vascular bundle; Sc, seed coat; Scl, sclerenchyma; Sd, seed; Se, secretory cells; St, starch; Stc, stone cells; V, vittae; Vb, vascular bundle.

The endosperm is similar to that of anise fruits (Figure 2h and i).

The spice has a peculiar, strong odor, and the flavor is warm and slightly bitter. The volatile oil content varies from 3 to 6%. Handling, drying, and storage of cumin are the same as those for anise.

Dill

Dill consists of the dried and ripe fruits of *Anethum graveolens* L. (Apiaceae), usually composed of separated mericarps, which are brown, glabrous, broadly oval, and compressed (about 4 by 2.5 mm) with five ribs – three short dorsal, and two lateral, yellowish and wing-like (Figure 2j–m).

The exocarp has a striated cuticle and an epidermal layer of rectangular cells bearing stomata. The parenchymatous mesocarp has three fibrovascular bundles below the dorsal ridges and two in lateral ridges. The inner side of the vascular bundles consists of several tangentially elliptical, sclerenchymatous cells having reticulate thickenings. The mesocarp has two vittae on the commissural side and four vittae on the dorsal side. The seed coat consists of a layer of epidermal cells, and the endosperm is similar to that of the anise fruits (Figure 2m and n).

The aromatic odor and taste of dill are similar to those of caraway. Handling, drying, and storage are as described for anise.

Fennel

The spice is the dried fruit of *Foeniculum vulgare* Miller (Apiaceae). The schizocarp is oblong-oval or elliptical, usually with long pedicels (4–5 mm by 1–3.5 mm); at the end is a short, conical stylopodium. The mericarps are attached to a divided carpophore and separate easily. Each is broadly elliptical, more or less curved (dorsal surface is convex), and light brown to light olive in color, with five prominent, longitudinal, primary ribs (Figure 2o–q). Based on the appearance of the plant and seed and the compositional data of the volatiles from the fruit, fennel is classified into two subspecies and further classified into numerous varieties. The important varieties are:

- *F. vulgare* ssp. *piperitm* wild fennel
- *F. vulgare* ssp. *capillaceum* with three varieties
  1. var. *vulgare* – bitter fennel
  2. var *dulce* – sweet fennels
  3. var. *azoricum* – culinary florence fennel.

In transverse section, the epidermis of the exocarp shows polygonal tabular cells, having occasional stomata and a smooth cuticle; the mesocarp is parenchymatous with two to four vittae on the commissural side and four vittae on the dorsal side, whereas the endocarp consists of narrow, elongated cells in a parquetry arrangement in a transverse section as long, narrow, rectangular cells with groups of short cells. The endosperm has a structure similar to that of anise (Figure 2r and s).

Fennel has a pleasant, aromatic odor and a taste resembling that of anise. The volatile oil content in fennel ranges from 0.7 to 6.0%. The main constituent of oil is anethole. Handling, drying, and storage of this spice are also similar to those of anise.

Star Anise

Star anise is the ripe, dried fruit of *Illicium verum* Hook. Filius (Magnoliaceae). The fruit whorl (2.5–4.5 cm in diameter) is formed of six to eight (rarely seven to nine), one-seeded, boat-shaped, woody, wrinkled, ridged, reddish brown follicles that are internally smooth, lustrous, and light brown, about 9–19 mm in length and surmounted on a curved peduncle. The seed is light brown, compressed-ovoid, shiny, and smooth with a conspicuous hilum and raphe (Figure 2t and u).

In transverse section, the exocarp consists of a striated cuticle and epidermal cells bearing stomata. The mesocarp consists of parenchymatous cells with brown contents. The cells towards the central zone are larger (up to 220 μm in length), and the inner mesocarp cells have thicker walls, the thickness increasing towards the dehiscent side of the carpel. Resin and stone cells occur scattered throughout the mesocarp, and vascular bundles occur in between the central and inner regions. The endocarp consists of thin-walled, sclerenchymatous palisade cells up to 440 μm in length. The seed coat consists of an outer, thick-walled epidermis of sclerenchymatous, pitted palisade cells up to 200 μm in length, followed by five layers of sclerenchyma and two or more layers of parenchyma containing numerous calcium oxalate crystals (Figure 2v). The odor and taste of star anise are anise-like. The plant starts fruiting at the age of 6 years and continues until it is over 100 years old. Fruits are collected before full maturity and dried in the sun.

Vanilla

Vanilla is the cured, fully grown, unripe fruit of *Vanilla planifolia* Andr. (Orchidaceae). The fruits are linear and flattened (120–350 mm by 5–9 mm), and both ends taper; the fruit occasionally splits into three parts in the tip; fruits are externally dusky to moderate brown, longitudinally wrinkled and covered

with minute crystals of vanillin; many minute seeds are embedded in a brownish black, balsamic fluid (Figure 2w and x).

In transverse section, the outer epidermis of the epicarp shows red to brown bodies, some with calcium oxalate and vanillin crystals. The hypodermis is composed of collenchymatous cells with dark-colored contents, and the sarcocarp consists of loosely arranged, large deeply undulate parenchyma, becoming smaller on the inner side; most cells contain brownish contents and oily globules, and some have raphides of calcium oxalate up to 400 μm long. There is an interrupted circle of leptocentric fibrovascular bundles surrounded by a few spiral or pitted tracheae. The cells of the inner epidermis of the endocarp are elongated into numerous, thin-walled, nearly straight, glandular hairs containing a gummy, resinous secretion (Figure 2x and y).

At the time of harvest, in the vanilla fruit or pods, the normal aromatic components forming the characteristic vanilla flavor do not exist in their final form, but appear only following a curing (fermentation) process involving enzymatic actions on glucosides, the most important of which is glucovanillin, which produces vanillin (the main aromatic component of vanilla) and sugar as a result of the action of glucosidase. Similarly, aldehydes, protocatechoic acid, benzoic acid, vanillic acids, anisic alcohol, etc. are also formed. These different compounds impart subtlety to the fragrance of natural vanillin.

The different stages of the curing methods are as follows:

1. Cessation of the vegetative life of the bean to allow the onset of enzymatic reactions.
2. Raising of the temperature to promote this action and to stimulate at first rapid drying, thereby preventing the appearance of harmful fermentation.
3. Slower drying followed by the production of different fragrance components.
4. Conditioning of the product, during which the procedures for commercial presentation and to obtain a good preservation are carried out.

The improved method involves sorting or grading, scalding or blanching, autoclaving, loading, and mechanically drying in a tunnel dryer, followed by drying in the shade. After scalding and autoclaving, the vanilla are chopped into 20- or 30-cm pieces. This leads to an acceleration of the oxidative and enzymatic reactions. The cuts are put through the dryer at a temperature of 65 °C each day. As soon as they come out, they are put into an isothermal chest for the next 24 h, with the temperature being maintained at around 50 °C. These operations are repeated for 12 days, after which a product containing 20–25% moisture is obtained, with a yield of about 4.5 to 1.0. The transfer to the isothermal chests after the tunnel drying is vital, in addition to equilibrate their moisture content. The process requires a series of sheds or buildings for 'sunnings' and 'sweatings' and 'mahogany sweating boxes' or 'aging boxes.' The total process takes about 5–6 months, including aging. Finally, the beans are graded, bundled, and packed in special tins lined with waxed paper.

The best-grade beans are very dark, chocolate brown in color, and oily in appearance with a strong vanilla odor. Vanilla should be stored in a cool, dry place in an airtight container to stop the beans becoming brittle.

Fenugreek

Fenugreek is the dried seed of *Trigonella foenum-graecum* L. (Fabaceae). The seeds are yellowish brown, oblong–rhomboidal (2.5–5 mm by 2–3.5 mm) with an oblique furrow on one side, smooth, hard, and mucilaginous. The hilum is in a notch, the raphe short, the endosperm translucent, and the embryo waxy and yellow (Figure 3a–d).

In cross-section, the spermoderm consists of an outer cuticle followed by a layer of palisade cells (measuring 65–70 μm by 8–20 μm) with flat bases and pointed apices, a layer of hourglass cells and four to five layers of parenchyma. The endosperm consists of an outer layer of cells containing aleurone grains, followed by several layers of thin-walled mucilaginous cells; the embryo cells contain aleurone grains and fixed oil (Figure 3d).

Fenugreek possesses a strong, pleasant, sweetish odor and tastes mucilaginous, farinaceous, and slightly bitter. The pods split easily and are threshed on the floor with sticks to free the seeds. The seeds are then winnowed, cleaned, and further dried in the sun. Dried fenugreek seeds can be stored for about 2 years.

Mustard

Mustard is composed of the dried, mature seeds of the following *Brassica* L. species (Brassicaceae): *B. nigra* (L.) Koch (black mustard), *B. alba* Boiss. (white or yellow mustard), and *B. juncea* (L.) Czern & Coss. (Rye or Indian mustard).

Black mustard seeds are globular, 1–1.6 mm in diameter, dark brown to nearly black, minutely reticulate, and mucilaginous. The kernel is greenish yellow and oily (Figure 3e and f). White mustard seeds are spherical, about 2 mm in diameter, minutely

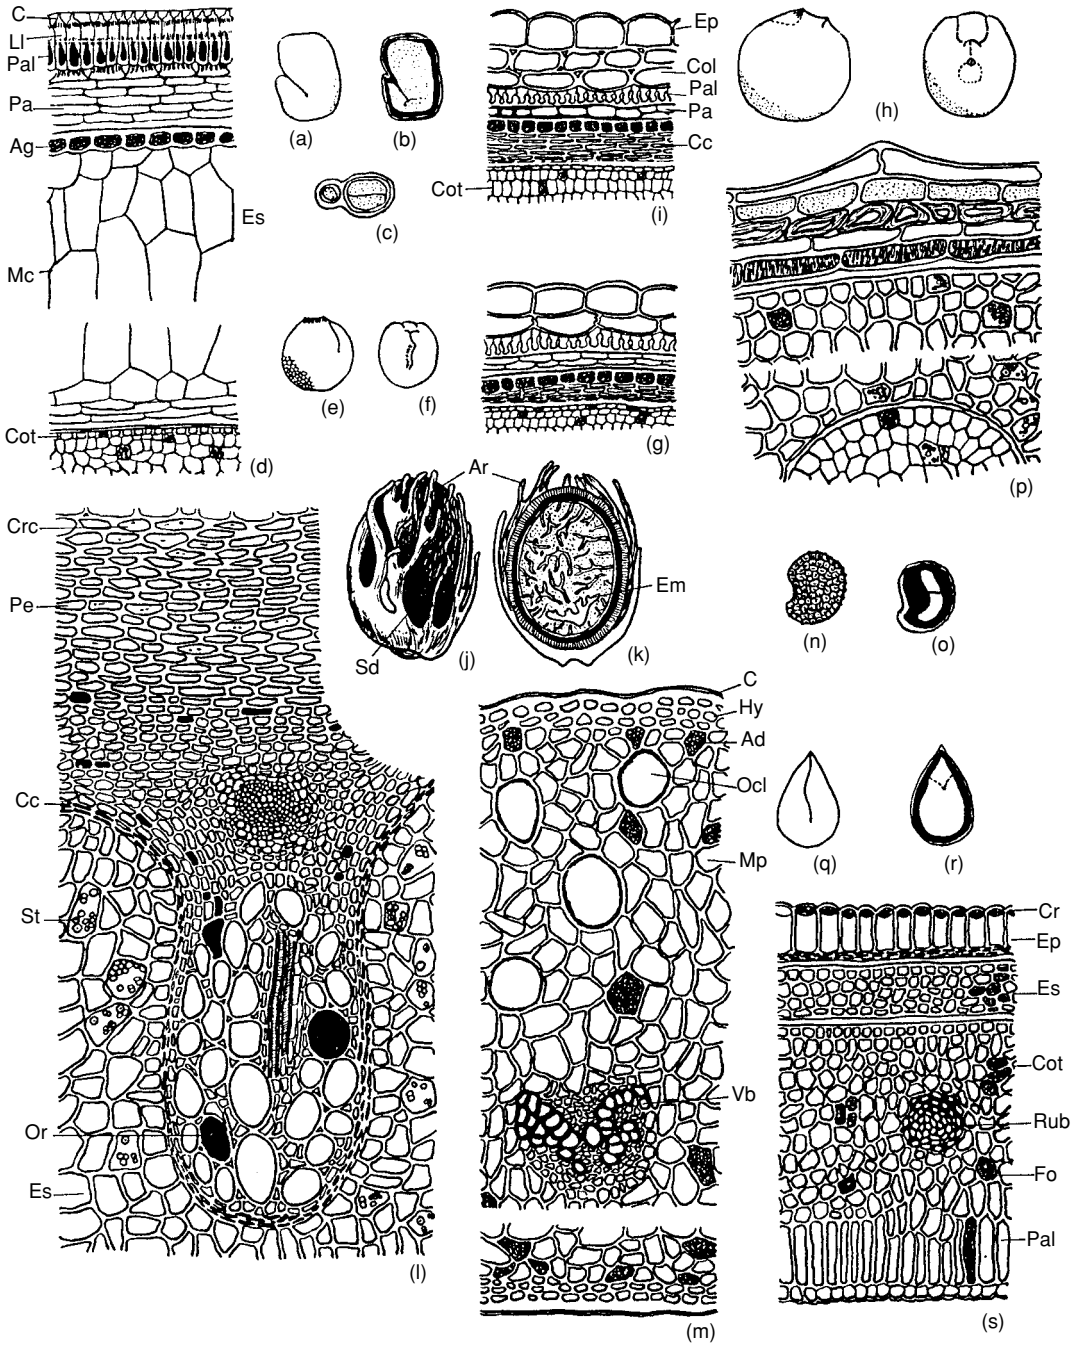

Figure 3 Spices from seeds. **Fenugreek:** (a) seed; (b) longitudinal section of seed; (c) transverse section of seed; (d) cross-section through seed coat, endosperm and part of cotyledon. **Mustard black:** (e, f) seed; (g) cross-section through seed coat, endosperm and part of cotyledon; (h) **Mustard, white or yellow:** (i) cross-section through seed coat, endosperm and part of cotyledon. **Nutmeg and mace:** (j) nutmeg surrounded by mace; (k) same as (j), cut longitudinally; (l) cross-section through perisperm and endosperm of nutmeg; (m) cross-section through mace. **Poppy:** (n, o) seed; (p) cross-section through seed coat, endosperm and part of cotyledon. **Sesame:** (a, r) seed; (s) cross-section of seed. Reproduced from Spices and Flavoring (Flavouring) Crops: Fruits and Seeds, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press. Abbreviations: Ad, amylodextrin granules; Ag, aleurone grains; Ar, aril; Bc, beaded cells; Bel, beaker cells; C, cuticle; Cc, compressed cells; Ch, chloroplast, Col, colenchyma; Cot, cotyledon; Cp, carpophore; Cr, crystal; Crc, crystal cells; Cro, cross cells; Dl, dehiscence line; Em, embryo; End, endocarp; Ep, epidermis; Es, endosperm; Exo, exocarp; Fl, fiber layer; Fo, fixed oil; Gc, giant cell; H, hair; Hc, hourglass cells; Hp, horny protein; Hy, hypodermis; Li, light line; Mc, mucilage cells; Mes, mesocarp; Mp, mesophyl; O, oil; Oc, oil cavity; Ocl, oil cells; Or, oleoresin; P, pedicel; Pa, parenchyma; Pal, palisade; Pe, perisperm; Pl, placenta; R, raphe; Rc, reticulated cells; Re, resin; Rub, rudimentary vascular bundle; Sc, seed coat; Scl, sclerenchyma; Sd, seed; Se, secretory cells; St, starch; Stc, stone cells; V, vittae; Vb, vascular bundle.

pitted, and mucilaginous (Figure 3h). Indian mustard seeds resemble black mustard but are larger and brown in colour.

The testa of black mustard in transverse section consists of an outer epidermis of polygonal tubular cells, 40–50 μm long, containing mucilage; hypodermis consists of empty, polygonal cells, 10–105 μm by 60–90 μm; the inner epidermis of testa consists of slightly lignified, palisade cells (unequal in height) followed by cells of tegmen containing tannin. The endosperm has an outer aleurone layer of thick-walled cells containing fixed oil and aleurone grains and an underlying layer of collapsed cells. Embryo cells are polyhedral and thin-walled, containing fixed oil and aleurone grains (Figure 3g). White mustard in transverse section resembles black mustard but differs in that it has two layers of somewhat collenchymatous cells beneath the epidermis of the testa; the palisade cells have no tannin (Figure 3i).

Black mustard is slightly odorous, and tastes acrid and pungent when crushed and moistened. White mustard seed is not pungent. The fruits are harvested when they begin to turn yellow. Then, they are threshed by beating with wooden mallets. The threshed seeds are separated from the husks by winnowing and then dried in the sun for a couple of days. Seeds are stored in seed bins or gunny bags. Storage of the whole seed for 12 months reduces the volatile oil content by 54%, but for ground seeds, the loss is 84%.

Nutmeg and Mace

Nutmeg is the dried kernel, and mace is the dried aril of the seed of *Myristica fragrans* Hout. (Myristicaceae). The kernel constitutes 16–17% and mace constitutes 2.0–2.5% by weight of the fruit. Nutmegs are ovoid (2–3.5 cm by 1.5–3 cm) and the kernels are grayish brown externally and reticulately marked with small furrows. Numerous minute, dark reddish brown points and lines, constituting a thin layer of perisperm, grow inwards into the endosperm at the furrows; the hilum lies in a small, circular depression at one end (Figure 3j and k). Mace consists of flattened lobed pieces about 25 mm or more in length, somewhat less in breadth, 1 mm thick, buff or light brown, translucent, smooth, horny and brittle (Figure 3j and k).

In longitudinal section, nutmeg has a perisperm about 0.12 mm thick. The cells of the peripheral perisperm are flattened and polyhedral; some contain prisms of an unidentified crystalline substance. The cells of the inner perisperm are parenchymatous, and grow into endosperm, blunt-ended ruminations, each containing a vascular strand and numerous volatile oil-containing cells. The endosperm contains abundant bunches of needle-shaped, fat crystals, small, irregular aleurone grains with large crystalloid and rounded (up to 22 μm in diameter) simple or compound starch grains and scattered tannoid cells (Figure 3l).

In transverse section, mace has the following: anouter epidermis of irregularly shaped, thick-walled cells covered by cuticle; a hypodermis consisting of a layer of thick-walled cells and one or more additional layers of comparatively thin-walled cells; a parenchymatous mesophyl consisting of densely packed amylodextrin granules, numerous large oleoresin cells and vascular tissues (Figure 3m).

Nutmeg and mace have a characteristic nut-like aroma and taste. The volatile oil content of nutmeg and mace is 15 and 20%, respectively. The fruits are harvested when split on the tree or, more usually, gathered after they have fallen to the ground. Mace is separated from the pericarp by hand or between boards, without breakage (which reduces its quality), and dried in the sun or artificially. Drying of mace and its storage is a delicate process. Mace has to be dried to a 5% moisture level, for which it takes about 16 h under open sun, 24–28 h in the shade, and 5–6 h in mechanical drying. A mild blanching followed by sulfiting helps in the retention of color and quality of mace. Nutmegs are dried in their shells on large wooden trays and turned daily for uniform drying and to avoid fermentation. Artificial drying between 35 and 40 °C prevents cracking of the shells and any melting of fat in the kernels. Various traditional methods are practiced to crack the nuts, which are stored and graded according to size and quality. This involves immersing the nutmegs in water and separating unhealthy or floating ones; the sound ones are drained, air-dried, and stored in bins before packing. Introducing a little carbon disulfide prevents insect attack.

Poppy Seeds

Poppy seeds are obtained from *Papaver somniferum* L. (Papaveraceae) capsules. The seeds are white, yellow, brown, bluish or nearly black, and subreniform (1–1.25 mm long), with a reticulate surface; the hilum and micropyle are situated in a depression near one end (Figure 3n and o).

In cross-section, the seed consists of an outer epidermis of tangentially elongated, thin-walled cells, a layer of parenchymatous cells containing numerous very small prismatic crystals of calcium oxalate, a layer of thick walled cells, a layer of parenchymatous cells, and a layer of thick-walled reticulate cells. The cells of the endosperm and embryo are polygonal and

contain aleurone grains and globules of fixed oil (Figure 3p).

The odor and taste of the seeds are pleasant and nut-like. For the collection of the seeds, the capsules are dried on the plant for about 15 days. After plucking by hand, these are threshed, and the seeds are separated and stored.

Sesame

Sesame is the seed of *Sesamum indicum* L. (Pedaliaceae). The seeds are yellowish white, brown, gray to black, flat pyriform (2.5–3.5 mm by 1.2–2 mm by 1 mm), and finely punctate, with four delicate, longitudinal ridges at the edges of the flat faces. The raphe extends from the hilum at the pointed end as a line along the center of one flat face to a broader end, and the scanty endosperm surrounds a large embryo. The hulled seeds are cream or pearly white in color (Figure 3q and r).

In cross-section, the seed coat consists of an epidermis of radially elongated cells (30–60 μm on sides and 45–130 μm at ridges), with thin, cutinized outer walls; each cell contains a 'rosette' calcium oxalate crystal; the rest of the testa consists of collapsed cells containing numerous, prismatic calcium oxalate crystals, and the endosperm and cotyledons consist of polygonal parenchymatous cells containing fixed oil and small aleurone grains measuring 2–10 μm (Figure 3s).

The seeds have a faint nutty odor and taste, and are ripe at the end of about 5 months. The whole plants are then cut down and made into stooks to dry, and the seeds are shaken out from the capsules and stored.

Leaf and Floral Structures

G D Bagchi and G N Srivastava, Central Institute of Medicinal and Aromatic Plants, Lucknow, India

Introduction

The aromatic leaves and floral structures of more than 30 plants are commonly used as spices and for flavoring purposes. Leaves and floral structures have delicate flavors, and these spices require proper care, particularly during the drying process. Leaf spices are also used fresh. The diagnostic morphological and anatomical characters of the most commonly used spices are dealt with in detail, along with their common names, botanical names, family and parts used. Handling, drying, and storage details are given wherever available. Other spices, which have specific, but equally important, uses are summarized in **Table 1**.

Chervil

Chervil consists of the dried leaves of *Anthriscus cerefolium* Hoffm. (Apiaceae). The leaves are decompound and oval, and the leaflets alternate, thin pale green 2–5 × 2–4 cm and pinnate; a few hairs occur on the mid-vein and the margins of leaflets (**Figure 1a**).

In surface view, the lower epidermal cells have more wavy walls than those on the upper epidermis; stomata are numerous on the lower epidermis, but absent on the upper; hairs, usually unicellular and pointed, are on both surfaces of the main vein and the margins, but more arise on the lower surface; the mesophyll consists of a row of palisade cells, 18–75 × 16–35 μm in size, followed by spongy parenchyma containing vascular bundles; an oil duct is found below the mid-vein (**Figure 1b** and **c**).

The odor of chervil somewhat resembles that of caraway and anise. Leaves, after collection, are then dehydrated by circulating hot air (50 °C) and are then fragmented mechanically and packed in plastic–lined bags. (*See* **Drying**: Theory of Air-drying.)

Laurel or Sweet Bay

The leaves are derived from *Laurus nobilis* L. (Lauraceae). They are lanceolate-acuminate, 10 cm or more long, coriaceous, pellucid–punctate, and with revolute, entire margins; the upper surface is glabrous and shiny, olive green to brown; the lower surface is dull olive to brown with a prominent mid-rib and veins (**Figure 1d**).

Table 1 Some other commonly used spices from leaf, flower, and flower parts

Botanical name	*Common name*	*Family*	*Part used*	*Characters*
Allium ascalonicum L.	Shallot	Liliaceae	Bulb	Bulbs about the size of a nut, white, leaves basal; bulbs may be taken up and dried or allowed to remain in the ground and dug up when needed; after lifting, they are skinned, washed and tied in bunches for marketing
Allium cepa L.	Onion	Liliaceae	Bulb	Bulbs are variable in size: small bulbs are silvery, and large bulbs are red or yellow in color; bulbs are harvested when mature, which is indicated by the tops drooping just above the bulb, while the leaves are still green; onions are stored in crates, before storage, they are thoroughly cured
Allium fistulosum L.	Leek	Liliaceae	Leaf	Leaves terete and hollow, usually clustered
Allium sativum L.	Garlic	Liliaceae	Bulb	Compound bulb, subglobose, has eight to 15 bulblets, bulblets ovoid, three- to four-sided, covered with whitish scale leaf which encloses whitish flesh, one or two translucent scales, in the center, two or three yellowish to yellowish green leaves present; harvested when tops turn yellow, exposed to sun for 4–5 days and winnowed; after a fortnight of curing, they are packed in bags and stored
Allium schoenoprasum L.	Chive	Liliaceae	Leaf	Leaves 10–25 cm, terete or grooved above, scape 15–35 cm; the cut leaves are gathered into bunches of about 2.5 cm diameter, secured and packed in layers in trays
Angelica archangelica L.	Angelica	Apiaceae	Leaf and young stem	Leaves ovate, 30–90 cm, two- to three-pinnate, ultimate pinnae toothed; leaves cut for drying and freezing in early summer; the stems should be harvested before the plant flowers
Cinnamomum tamala Nees & Eberm	Tejpat (Indian cassia lignea leaf)	Lauraceae	Leaf	Leaves subcoriaceous, opposite, triple nerved rarely alternate, elliptic oblong, acute base, acuminate, glabrous, shining, leaves are collected and dried in sun for 3–4 days and packed in a cylindrical bamboo nets for marketing
Gaultheria fragrantissima Wall.	Wintergreen	Ericaceae	Leaf	Leaves alternate, oblong-lanceolate to elliptic rhomboid, 7–13 × 2–6 cm, serrate, stiffly coriaceous, glands dotted
Hyosopus officinalis L.	Hyssop	Lamiaceae	Leaf	Leaves sessile, 13 × 2–8 mm, opposite, linear or lanceolate, entire, hairy on both surfaces; harvested just as flowers begin to bloom
Levisticum officinale Koch	Lovage	Apiaceae	Leaf and flowering top	Lower leaves large with long petioles, up to three pinnate, about 70 cm long, uppermost leaves entire and lanceolate; flowers yellow in stiff umbels; fresh leaves are generally used; drying of thick leaves takes 4–5 days
Marrubium vulgare L.	Farasiyum	Lamiaceae	Leaf	Leaves opposite, petiolate, downy, oval, up to 5 cm long, surface wrinkled and has protuberances, margin dentate; harvested before full flowering and dried in the shade below 35 °C
Melissa officinalis L.	Balm	Lamiaceae	Leaf	Leaves opposite, ovate or triangular; up to 3.5 cm long, hairy, margin broadly dentate; usually, fresh leaves are used; for drying, stems are cut and tied in small bunches and hung in airy space.
Mentha pulegium L.	Pennyroyal	Lamiaceae	Leaf	Leaves shortly petioled, up to 1.25 cm long, round to oval, entire or slightly crenate and pubescent; leaves are used fresh or in dried form
Murraya koenigii L. Spreng.	Curry leaf	Rutaceae	Leaf	Leaves imparipinnate, leaflets nine to 25, ovate-lanceolate, dentate, acuminate, base oblique, glabrous above, pubescent beneath, gland dotted; fresh or shade dried leaves are used
Nepeta cataria L.	Catnip	Lamiaceae	Leaf	Leaves ovate, coarsely crenate; harvested when in full bloom

Continued

Table 1 Continued

Botanical name	*Common name*	*Family*	*Part used*	*Characters*
Pimenta racemosa (P. Miller) J. W. Moore	West Indian bay	Myrtaceae	Leaf	Leaves obovate or elliptic, leathery, shining above; during harvesting, either leaves are stripped from the trees or both shoots and leaves are removed and tied in bundles for drying
Ruta graveolens L.	Rue	Rutaceae	Leaf	Leaves alternate, 15 cm long, two to three pinnate, oblong to spathulate, with many small oil glands; leaves are usually used fresh
Salvia sclarea L.	Clary, clary sage	Lamiaceae	Leaf	Leaves petiolate, opposite, ovate, apex obtuse, base cordate, crenate margin, thinly hairy above
Tanacetum vulgare L.	Tansy	Asteraceae	Leaf and flowering top	Leaves downy, one to two pinnate, margin dentate, capitula in flat umbels, golden yellow, about 1 cm in diameter; collected when in flower and dried in the shade at below 35 °C

In cross–section, the leaf has a thick cuticle, and the epidermal cells, in surface view, have sinuous, pitted and thick walls; the lower epidermal walls are more curvilinear and distinctly beaded; the lower epidermis alone bears stomata arranged singly or in pairs; the mesophyll is differentiated into two layers of palisade parenchyma, a region of spongy parenchyma containing scattered spheroidal oil reservoirs, fibrovascular, and collenchyma tissues; the latter occurs above and below the vascular bundle of mid-rib, but not in the veins (Figure 1e–h).

The leaves are characteristically fragrant when crushed but taste bitter and aromatic. (*See* **Sensory Evaluation**: Aroma; Taste.)

Marjoram (Sweet)

Marjoram consists of dried leaves, with or without flowering tops, of *Majorana hortensis* (L.) Moench (Lamiaceae). The pinnate leaves are obovate to broadly elliptical, 21×11 mm in size with entire margins and short petioles; both surfaces are gray–green, glandular punctate, and pubescent. The floral parts are: bract – light grayish yellow, obovate, thin, up to 5.5×3.5 mm; calyx – gamosepalous, about 3 mm long with five prominent teeth; corolla – gamopetalous, white to pink or pale lilac, about 3.5 mm long (Figure 1i).

In a transverse section and/or surface view, it is possible to see an epidermis with a thin cuticle, one to two palisade layers and upper and lower epidermal cells with slightly wavy, knotty, vertical walls. Glandular and nonglandular hairs occur on both surfaces, and the latter are uniseriate, two to five cells in length and more or less bent inwards at apex; some are papillose. Glandular hairs are of two types, one with a one- to two-celled stalk and a one- to two-celled glandular head, the other with no stalk and a large, eight-celled head; the latter is sunk in a depression in the epidermis; stomata occur on the lower epidermis with two 'neighboring' cells (Figure 1j and k).

The odor and taste of sweet marjoram are aromatic, characteristic, and slightly pungent; the plants are harvested as soon as they flower. The plants are cut and tied in bunches and dried in the open air, or spread on wire trays in ventilated rooms and dried by circulating warm air. (*See* **Drying**: Drying Using Natural Radiation.)

Mint

Mint consists of the dried leaves and flowering tops of *Mentha piperita* L. (peppermint) and *M. spicata* L. (spearmint) belonging to the family Lamiaceae. *M. piperita* is a hybrid between *M. spicata* and *M. aquatica* since *M. spicata* itself is a hybrid. Therefore, *M. piperita* is a triple hybrid. It is an allohexaploid, $2n = 6x = 72$. However, this species has a variable chromosome number, which ranges from $2n = 36$ to $2n = 134$ with polyploid and anueploids. *M. spicata* ($2n = 48$) has originated by hybridization between *M. longifolia* and *M. suaveolens* and doubling of chromosomes. The resultant polyploid behaves as allotetraploid. Peppermint leaves are dark green, about 4.5×2.3 cm, petiolate, ovate and with serrate margins. The apex is acute and the midrib prominent, and dot-like oil glands are visible with a hand lens. Nonglandular hairs are present on the lower epidermis over the mid-rib and veins at margins, and a few arise on the mid-rib of the upper epidermis. Verticillaster inflorescences are usually arranged in compact, oblong or oval terminal spikes: calyx – gamosepalous, purplish, about 3 mm long, glandular punctate and five-toothed; corolla – short, tubular, light purple and four-cleft; stamens – four; style with bilobed stigma (Figure 1l). Spearmint differs from peppermint in having a sharply pointed, long, narrow spike, an absence of nonglandular hairs in the upper epidermis, fewer and shorter hairs on the

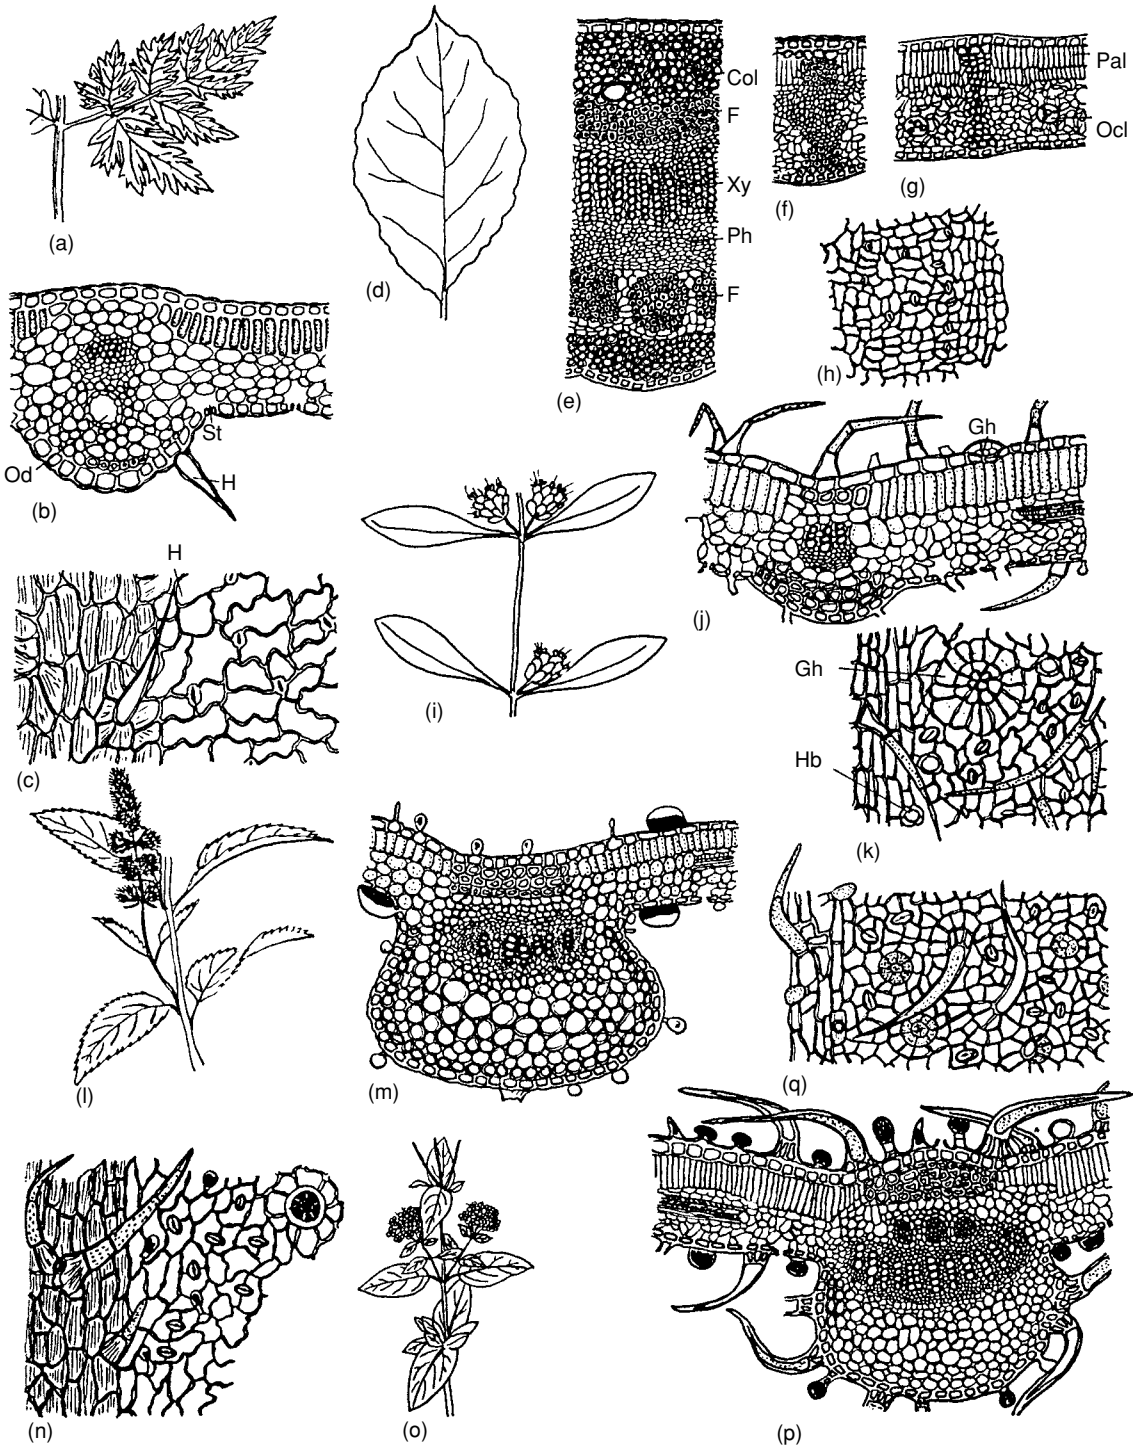

Figure 1 Spices from leaves and flower tops. **Chervil**: (a) leaf; (b) cross-section of leaflet through mid-rib; (c) lower epidermis in surface view. **Laurel**: (d) leaf; (e) cross-section of leaf through mid-rib; (f) vein; (g) leaf blade; (h) lower epidermis in surface view. **Marjoram**: (i) a portion of flowering twig; (j) cross-section of leaf through mid-rib; (k) surface view of lower epidermis; **Peppermint**: (l) a portion of flowering twig: (m) cross-section through mid-rib of leaf; (n) surface view of lower epidermis. **Origanum**: (o) a portion of flowering twig: (p) cross-section through mid-rib of leaf; (q) lower epidermis in surface view. Reproduced from Spices and Flavoring (Flavouring) Crops: Leaf and Floral Structures, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press. Abbreviations: C, calyx; Col, collenchyma; Cor, corolla; Cp, compressed parenchyma; E, endocarp; F, fiber; Gh, glandular hair; H, hair; Hb, hair base; Hy, hypodermis; Mes, mesophyl; O, ovary; Oc, oil cavity; Ocl, oil cell; Od, oil duct; P, pericarp; Pal, palisade; Pap, papilla; Pg, pollen grain; Ph, phloem; Pp, pigmented parenchyma; R, receptacle; Rc, reticulate cells; S, stigma; Sc, stone cells; St, stomata; Sta, stamen; Sty, style; Vb, vascular bundle; Xy, xylem.

lower surface over the mid-rib, with few, if any, over the veins, and the absence of crystals in the glandular hairs.

In cross-section, peppermint leaves show a cuticle covering both the upper and lower epidermis; upper epidermal cells having moderately thicker outer walls than the lower epidermal cells; glandular hairs containing groups of crystals; a mesophyll consisting of a layer of palisade cells and spongy tissue; between the upper epidermis and the vascular tissue of the mid-rib and veins is a conspicuous group of collenchyma cells. In the surface view, the cuticle is striated over the mid-rib, veins and margins, and upper epidermal cells are irregular with wavy walls, except in the latter regions; numerous small crystals are present in the cells of upper and lower epidermis (**Figure 1m** and **n**).

Peppermint has a characteristic aromatic odor and taste, with a cooling sensation on the breath, whereas the odor and taste of spearmint are characteristic and aromatic but not followed by a cooling sensation. Mints are harvested, when in bloom, in bright sunny weather, by cutting with a sickle 2–3 cm above the ground. The harvested herb is allowed to dry partially in the open. Drying is completed by circulating warm air, which avoids overheating and obviates drying for too long. After attaining the desired brittleness, the leaves are stripped from the stem and completely dried. Afterwards, they are fragmented mechanically or through wire sieves.

Origanum or Oregano

This consists of the dried leaves and flowering tops of *Origanum vulgare* L. (Lamiaceae). The leaves are light green to greenish brown, with crenate to crenate–serrate margins and are about 3 cm long and glandular punctate. The flowers are in spike-like clusters: bracts – broadly ovate, 2.5–3 × 2 mm with prominent hairs on the outer surface; calyx – gamosepalous four-toothed and deeply clefted on two sides; corolla – 5 mm long, gamopetalous; stamens – four, epipetalous; style – plumose (**Figure 1o**).

In surface view and/or transverse section, the epidermal cells of both surfaces of the leaf are irregular in shape with uneven and thickened walls; both surfaces have numerous curved, pointed, unicellular, nonglandular hairs up to 900 μm long; the surfaces of some hairs are smooth, whereas many have papillose surfaces. Uni- to multicellular glandular hairs are present on both surfaces (**Figure 1p** and **q**).

Origanum has a strong camphoraceous odor and a warm, pungent, bitter, camphoraceous taste. The plant is collected when in flower and dried in the shade at less than 35 °C.

Parsley

Parsley consists of the dried leaves of *Carum petroselinum* Hoffm. (Apiaceae). The leaves are pinnately compound of three-lobed leaflets; each lobe is divided into smaller, tooth-like segments that are usually curly (**Figure 2a**).

The upper and lower epidermal cell walls are, in surface view, sinuate, and stomata are few in the upper and numerous in the lower epidermis. In cross-section, beneath the upper epidermis, the mesophyll consists of a layer of palisade cells about 40–55 μm long followed by spongy parenchyma; below the vascular bundle of the mid-rib is an oil duct (**Figure 2b** and **c**).

The dried leaves have a characteristic, agreeable, aromatic odor and taste. Fresh leaves are dried rapidly under controlled conditions of heat and air flow to avoid loss of essential oils, and to preserve a good, green color. (*See* **Essential Oils**: Properties and Uses.)

Rosemary

Rosemary consists of the dried leaves of *Romarinus officinalis* L. (Lamiaceae). The leaves are about 3.5 cm long and 2–4 mm wide, numerous, opposite sessile, linear, leathery, entire and slightly glossy with revolute margins. The upper surface is dark green, whilst numerous branched trichomes on the lower surface make it gray and wooly and glandular punctate with a prominent mid-rib (**Figure 2d**).

In surface view, the cells of the upper epidermis are polygonal with unevenly thickened and beaded walls, whilst the lower epidermal cells are larger and thin-walled. In cross-section, the collenchyma tissue present below the upper epidermis forms a thick-walled hypodermal layer; collenchymatous cells also surround the vascular bundle of mid-rib. One to three layers of palisade cells are up to about 80 μm in length and are followed by a zone of spongy parenchyma. A dense, tangled mass of branched, multicellular, smooth hairs covers the lower epidermis, and the tips of the hairs are pointed and curved; glandular hairs are uni- to multicellular. In the mid-rib vascular bundle, the vessels are arranged in radial rows (**Figure 2e** and **f**).

The odor of rosemary is characteristically aromatic, having a slight camphoraceous note; the taste is pungent, aromatic, bitter, and camphoraceous. Rosemary is harvested when flowering has started. At that time, 30–50 cm of the top along with leaves and flowers are harvested with sickle or by forage harvester. Care should be taken not to cut the woody portions of the stem. The first harvest is obtained approximately 6 months after planting, and

Figure 2 Spices from leaves and flower tops. **Parsley**: (a) a portion of flowering twig; (b) cross-section leaflet through main vein; (c) surface view of lower epidermis. **Rosemary**: (d) a portion of flowering twig; (e) cross-section through mid-rib of leaf; (f) lower epidermis in surface view. **Sage**: (g) a portion of flowering twig; (h) cross-section through mid-rib of leaf; (i) cross-section of a portion of leaf blade; (j) lower epidermis in surface view. **Savory**: (k) a portion of flowering twig; (l) cross-section through mid-rib of leaf; (m) cross-section through leaf blade; (n) lower epidermis in surface view. **Sweet basil**: (o) a portion of flowering twig; (p) cross-section of leaf through mid-rib; (q) cross-section through side vein; (r) surface view of upper epidermis. Reproduced from Spices and Flavoring (Flavouring) Crops: Leaf and Floral Structures, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press. Abbreviations: C, calyx; Col, collenchyma; Cor, corolla; Cp, compressed parenchyma; E, endocarp; F, fiber; Gh, glandular hair; H, hair; Hb, hair base; Hy, hypodermis; Mes, mesophyl; O, ovary; Oc, oil cavity; Ocl, oil cell; Od, oil duct; P, pericarp; Pal, palisade; Pap, papilla; Pg, pollen grain; Ph, phloem; Pp, pigmented parenchyma; R, receptacle; Rc, reticulate cells; S, stigma; Sc, stone cells; St, stomata; Sta, stamen; Sty, style; Vb, vascular bundle; Xy, xylem.

subsequent harvests can be obtained every 4 months. Harvested leaves are dried in the shade.

Sage

Sage consists of the dried leaves of *Salvia officinalis* L. (Lamiaceae). The leaves are grayish green, oblong–lanceolate, about 8.5 × 2.5 cm, petiolate, apex acute, margins finely crenate, densely pubescent and glandular punctate with glands obscured by hairs (Figure 2g).

The upper epidermal cells, in surface view, have few stomata and straight, beaded walls, whereas the lower epidermis bears numerous stomata, and the cells have wavy, beaded walls; numerous nonglandular and glandular hairs occur on both the surfaces. The nonglandular hairs are uni- or multicellular, and the multicellular hairs are more numerous, very long, narrow pointed and mostly smooth, but some have a papillose surface; glandular hairs are also uni- or multicellular. The mid-rib vascular bundle is surrounded by parenchymatous and collenchymatous cells, and the mesophyll consists of one to three layers of palisade cells followed by spongy tissues (Figure 2h–j).

Sage is aromatic in odor and somewhat bitter in taste. The leaves are gathered for use while the plants are in flower and are dried in the shade or indoors by circulating warm air.

Savory

Savory consists of dried leaves and flowering tops of *Satureja hortensis* L. (Lamiaceae). The leaves are green to grayish green, nearly sessile, entire, linear oblong to spathulate when unfolded, glandular punctate, acute to rounded at the apex, tapering at the base, 12–35 × 1–2 mm and pubescent. The flowers are tubular–bilabiate, purple and up to 5 mm long in leaf axils; calyx – campanulate, hispid on nerves and with five subulate teeth; corolla – about 4–5 mm long; stamens – four and didynamous; style with bilobed stigma (Figure 2k).

In the surface view, epidermal cell walls of the upper and lower surfaces are sinuate and beaded; the stomata are elliptical. The nonglandular hairs are uniseriate and numerous, with up to six cells and a pointed, distal cell; the glandular hairs are numerous and have an up to 12-celled head and one-celled stalk (Figure 2l–n).

The odor of savory is characteristically aromatic, and the taste is aromatic and warm. The leaves are collected when the plants are in flower and are dried in the shade, or indoors by circulating warm air, before packaging.

Basil (Sweet)

Sweet basil consists of the dried leaves of the *Ocimum basilicum* L. (Lamiaceae). The leaves are ovate, tip acute, petiolate, green, up to 5 cm long and finely serrate. Hairs arise on the veins, especially on the underside of the leaf, which is also glandular punctate (Figure 2o)

In surface view, the upper and lower epidermis have wavy cell walls, and the nonglandular hairs are one- or multicelled, uniseriate, with pointed apices; the surfaces of the hairs are finely warty. Glandular hairs have a two- to four-celled head, and occur on both surfaces but more on the upper surface. In transverse section, a single palisade layer lies beneath the upper epidermis, followed by a zone of spongy parenchyma; the vascular tissue of the mid-rib and large veins is separated from the upper and lower epidermis by parenchymatous and collenchymatous tissues (Figure 2p–r).

The odor of basil is fragrantly aromatic, and the taste is warmly aromatic and pungent. Fresh leaves can be dried in the open air but more efficiently indoors by controlled artificial heat and circulating air. Dried leaves are fragmented by machines and graded fine, medium, or coarse before packaging.

Tarragon

Tarragon consists of the dried leaves of *Artemisia dracunculus* L. (Asteraceae). The leaves are lanceolate, entire, sessile, glabrous, and bright green. The edges of dried leaves curve towards the lower surface, and are finely revolute, 4 × 3.5 mm in size (Figure 3a).

The cuticle on both surfaces is striated over the mid-rib and veins. The epidermal cell walls of both surfaces are undulate; occasionally, small, inconspicuous glandular hairs of 35–40 μm diameter are present on the epidermis. The mesophyll consists of two rows of palisade cells towards the upper surface and a single row towards the lower. Below the mid-rib vascular bundle are a few collenchymatous cells, and on the upper side, two secretory ducts are present (Figure 3b and c).

The odor and taste of tarragon are agreeable, aromatic, and like that of anise. The leaves are dried indoors by artificial heat and circulating air to insure retention of aroma and color. After being crushed by machine into particles of a suitable size, the product is packed in bags and kraft paper.

Thyme

Thyme consists of the dried leaves and flowering tops of *Thymus vulgaris* L. (Lamiaceae). The leaves are linear/linear–lanceolate, ovate or oblong, up to 6 × 0.5–2 mm, apex acute, base obtuse tapering into

Reproduced from Spices and Flavoring (Flavouring) Crops: Leaf and Floral Structures, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press. Abbreviations: C, calyx; Col, collenchyma; Cor, corolla; Cp, compressed parenchyma; E, endocarp; F, fiber; Gh, glandular hair; H, hair; Hb, hair base; Hy, hypodermis; Mes, mesophyl; O, ovary; Oc, oil cavity; Ocl, oil cell; Od, oil duct; P, pericarp; Pal, palisade; Pap, papilla; Pg, pollen grain; Ph, phloem; Pp, pigmented parenchyma; R, receptacle; Rc, reticulate cells; S, stigma; Sc, stone cells; St, stomata; Sta, stamen; Sty, style; Vb, vascular bundle; Xy, xylem.

a petiole and with revolute margins. The upper surface is light gray or light brownish gray to weak olive green with numerous hairs; the lower surface is grayish, pubescent, and glandular punctuate. About 12 flowers arise in axillary whorls: calyx – tubular, bilabiate, about 4 mm in length, pubescent, nine to 12-nerved with the upper lip three-toothed; the lower lip has two hairy, ascending, attenuate divisions, and the throat is hairy; the corolla is about twice as long as the calyx, purplish and bilabiate; the stamens are four and didynamous, style with bi-lobed stigma (Figure 3d).

The epidermis of both leaf surfaces in the surface view shows wavy walls and numerous nonglandular and glandular hairs; the nonglandular hairs are uni- or multicellular with papillose walls, and are stiff and pointed. The glandular hairs are of two types: one with a short stalk and unicellular head, and the other with an eight- to 12-celled head, which measures up to 18 μm in diameter, and no stalk. In cross-section, the mesophyll consists of one or two layers of palisade cells, variable in size, followed by spongy tissues; the vascular bundle of the mid-rib has numerous fibers; the lamina contains two to three small vascular bundles on both sides of the mid-rib (Figure 3e and f).

Thyme has a fragrant and aromatic odor when crushed, and the taste is aromatic, warm, and pungent. About 15 cm from the tops of the plants is harvested, when in bloom, and the clipped stems are dried in the sun or in well-ventilated shed or room.

Cassia Buds

Cassia buds consist of the dried flowers of *Cinnamomum cassia* Blume (Lauraceae) gathered shortly after opening. They are dark brown, club, urn- or top-shaped bodies, enclosed within a grayish brown, cup-shaped calyx with a dome-like visible top of the pericarp. The calyx tube is rough and hard, and frequently has the pedicel attached; the exposed pericarp is smooth and lustrous with the small protuberant base of the style visible (Figure 3g and h).

In longitudinal section, the cortex of the calyx contains parenchyma cells up to 75 μm long, secretion cells up to 66 μm long and stone cells up to 80 μm long. The pericarp consists of a sclerenchymatous epicarp about 45–58 μm in radial thickness; the parenchymatous mesocarp contains prismatic calcium oxalate crystals, stone cells, secretion cells, and vascular tissues. The endocarp sclerenchymatous cells of the ovary canal are thick-walled and without a lumen, whilst the cells of the remaining region are rectangular, moderately thick-walled, and contain large prismatic crystals of calcium oxalate (Figure 3h).

Cassia buds have a cinnamon-like odor and a sweet, warm pungent taste akin to that of cassia bark.

Cloves

Cloves are dried flower buds of *Syzygium aromaticum* (L.) Merril & Perry (Myrtaceae). Cloves are like small, round-headed nails, about 10–17.5 mm long and blackish brown in color. The stalk consists of a cylindrical hypanthium, above which is a bilocular ovary containing numerous ovules on axile placentae; the 'head' consists of four, slightly projecting, calyx teeth, four membranous petals and numerous incurved stamens surrounding a large style (Figure 3i–l).

In transverse section, the hypanthium (receptacle), cut below the ovary, shows an epidermis with a thick cuticle and numerous, scattered, ranunculaceous stomata on the surface. The outer cortex contains two or three rows of large, ovoid to elliptical oil reservoirs (up to 200 μm in length) lined by a secretory epithelium and embedded in parenchyma; beneath is a zone consisting of an interrupted circle of bicollateral, fibrovascular bundles accompanied by a few sclerenchyma fibers and crystal fibers containing rosette calcium oxalate crystals. The bundles are embedded in parenchymatous cells with sinuate walls, and beneath these is a zone of parenchyma, in which some cells possess thickened angles and wavy walls, whereas others form chains around intercellular air spaces. Next is a zone of small-celled parenchyma followed by a second or inner zone of fibrovascular bundles, along with a few thick-walled, pericyclic fibers (Figure 3m).

The sepals have an epidermis similar to the hypanthium, with numerous stomata on the outer surface, a mesophyl with a few slender, vascular strands and numerous, ovoid oil glands and rosette crystals of calcium oxalate. The petals have straight-walled epidermal cells, an undifferentiated mesophyll containing oil glands, rosette calcium oxalate crystals, and small vascular strands. The filament of the stamen bears oil glands beneath the epidermis, and the connectives bear a large oil gland at the apex.

Cloves have a strong, pungent and spicy odor and a pungent, aromatic taste. Cloves are propagated by seeds. Hulled washed seeds produce better seedlings than unhulled fruits. The seeds are planted in shaded nurseries, and seedlings are raised. Shade and wind breaks are necessary in the early stages of growth. Trees begin to flower at about 4–5 years and continue to produce until 70 years of age. The crimson buds are picked before the corolla expands and are evenly spread under the sun on a concrete floor or on mats and gently stirred to bring about uniform drying. In good weather, drying is completed in 4–7 days. Quick drying produces the best-quality spice. Some cloves are dried on zinc sheets or in kilns. Cloves are apt to absorb moisture if, while drying, they are left in the

open overnight. The average annual yield of dried cloves per tree is about 3 kg but yields of 18 kg or more per tree are also not uncommon. Finally, they are packed in sacks known as 'mats' made of coconut leaves and stored in a dry room. Prolonged storage may cause a loss of volatile oils.

Saffron

Saffron is made from the dried stigmas of *Crocus sativus* L. (Iridaceae). The three stigmas are attached to the top of the style, and are 25 mm long, cornucopia-shaped, dark red and with fimbriate margins. The styles are about 10 mm long, cylindrical, solid and yellowish brown to pale yellowish orange (Figure 3n–p).

The stigma consists of thin-walled parenchyma containing coloring matter and covered by a thin-walled epidermis. The distal end of the stigma shows numerous bladder-like, cylindrical papillae up to 150 μm in length, among which occur a few smooth, spherical, pollen grains from 40 to 120 μm in diameter (Figure 3q–r).

The odor of saffron is strong and characteristically aromatic, and the taste is bitter/aromatic. The flowers are collected every morning, as they open, and the stigmas are then collected, either by pulling them out or cutting them off with the fingernails, after which the flowers are discarded. The value of saffron depends heavily on the methods by which the stigmas are processed. The stigmas are placed in sieves in layers 2–3 cm thick. These sieves are placed 15 cm above an almost spent fire for drying. By stacking them and by changing their order or position, the product is carefully dried. Stigmas are protected against dampness as well as light, because light bleaches saffron to a dull yellow color. Saffron should be preserved in amber-colored bottles or tin boxes.

Tubers and Roots

K K Sinha, T. M. Bhagalpur University, Bhagalpur, India

Background

The use and cultivation of spice plants date back to the beginning of our history. Most of the spices that we value today were known to the ancient civilizations of China, Egypt, Greece, Rome, the East Indies, and the rest of the Old World. Spices have also been responsible for the rise and fall of empires and the great sea voyages to explore the distant corners of the globe. The search for spices by early European explorers also led to the discovery of new continents and waterways.

Spices are derived from different plant parts, including roots, stem, leaves, flowers, fruits and seeds. This article, however, deals only with those spices and flavoring crops which are obtained from tubers and roots. These are categorized into two groups, major and minor crops, depending upon their distribution and usage in different parts of the world.

Major Crops

Ginger

Ginger is the most important of all the spices obtained from underground plant parts. It has been in use in India and China since very ancient times. However, it is difficult to trace with certainty the exact place of its origin. Ginger was mentioned by the Chinese philosopher Confucius (551–479 BC) in his *Analects*. Ginger was also one of the first oriental spices to be known to the Europeans. The Greeks and Romans first obtained ginger from the Arab traders. It was known in Germany and France in the ninth century and in England during the tenth century.

Ginger is derived from the rhizomes of *Zingiber officinale* Rosc., a plant belonging to family Zingiberaceae. It is a slender perennial herb, mostly grown as an annual, 30–100 cm tall with a robust rhizome borne horizontally just below the soil surface. The fleshy sympodial rhizome is hard and thick, somewhat laterally compressed, often palmately branched and varying in shape and size in different cultivated types. It is covered with small, distichous scales with an encircling insertion, and with fine fibrous roots in the top layers of the soil. It is pale yellow in color externally and greenish yellow within.

The crop is always propagated vegetatively using small fragments of the rhizome known as 'seeds' or

'setts.' It is also grown both as a pure crop and as an intercrop. It may be grown in rotation with paddy-rice, samai (*Panicum miliare*). If irrigation facilities are available, ginger may be rotated with vegetables, chilli, groundnut, ragi (*Eleucine coracana*) and maize. Ginger is sometimes grown mixed with turmeric, which grows rapidly early on and provides partial shade to the developing ginger. It is harvested at different stages depending upon the requirements of the user. Green ginger is harvested between 5 and 7 months after sowing, and the rhizomes are used for preservation as *preserved ginger*. Final harvesting is carried out after 8–10 months from planting for the production of *dried ginger*. Shriveling, yellowing, and withering of the leaves, accompanied by drying and lodging of the aerial shoots, indicate maturity of the rhizomes.

The maturity of the rhizome has a significant influence on both its quality characteristics and its suitability for processing into preserved or dried ginger. The optimum time for harvesting ginger in India is 245–260 days from planting, after which the rhizomes become more fibrous. Harvesting of the mature ginger is mostly done by hand using a spade, hoe, or digging fork. In advanced countries, the late crop is also harvested by mechanical diggers. Extra care is required for the harvesting of healthy rhizomes. The soil, roots and shoots are subsequently removed, and the rhizomes are carefully washed and dried for storage. *See* Plates 1 and 2.

Several commercial types of ginger are recognized in cultivation, which are generally named after the localities where they are grown. The types with less fiber, which varies from 1.7 to 9.0%, have a higher demand. Some of the prized types of ginger in international trade include Jamaican ginger, Indian ginger, African ginger, and Chinese ginger, and these vary in taste and aroma.

Since the rhizome is perishable, it is susceptible to attack by the soilborne fungi, insects, and white ants. Rhizome rot or soft rot is the most serious disease found all over the ginger-growing areas of the world. Healthy and disease-free rhizomes are thus selected for storage. The use of specific fungicides for the treatment of rhizomes before storage is recommended on a regional basis. The treated rhizomes are air-dried under shade to remove excess moisture. The optimum conditions for the storage of fresh ginger have been investigated in detail in Hawaii. Harvested rhizomes should be washed immediately and then air-dried in the shade for 1–2 days. The rhizomes can be stored safely for up to 6 months by maintaining the temperature at 12 °C and the relative humidity at 65%.

In India, the ginger is loosely stored in pits, which may be up to 1 m deep. These pits are cool and provide protection against sunlight. A layer of sand or sawdust is spread at the bottom of the pit before storing the rhizomes. The pit is left uncovered or covered with a wooden plank, which in turn is plastered with mud, with a hole in the center for aeration.

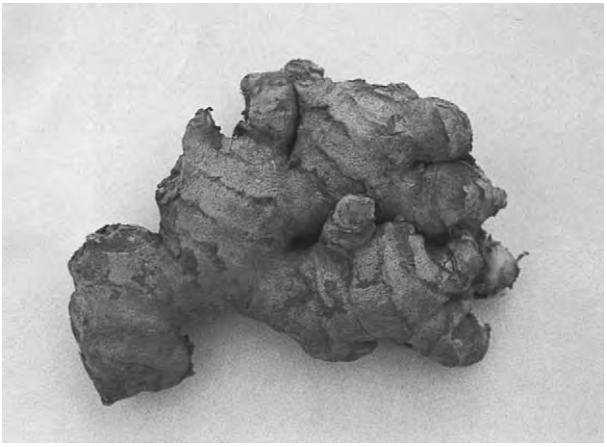

Plate 1 (see color plate 130) Spices and flavouring crops: Rhizome of green ginger (*Zingiber officinale*).

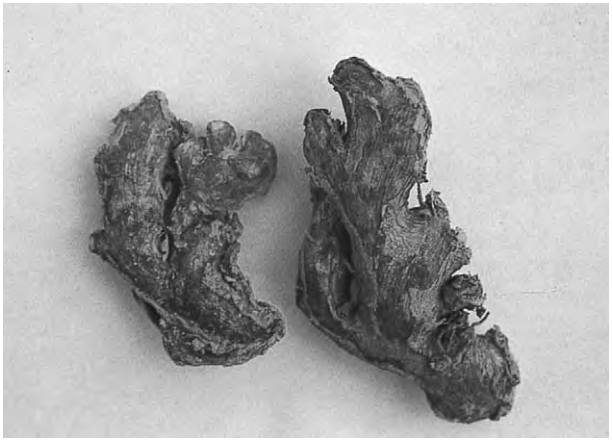

Plate 2 Spices and flavouring crops: Rhizome of dried ginger (*Zingiber officinale*).

As mentioned earlier, there are three primary products of ginger rhizomes: fresh or green ginger, preserved ginger in syrup or brine, and dried ginger. Green ginger is consumed mostly in the areas of production and nearby places. Preserved and dried products are the major forms in which ginger is traded internationally. Dried ginger is used as a spice and also for the preparation of its extracts.

Commercial preparation of preserved ginger is mostly practiced in China, Hong Kong, Australia, and India. Young juicy rhizomes are dried, cleaned, and boiled in water until they become tender. They

are then peeled, scraped, and boiled several times in a sugar solution. Sometimes, preserved ginger is also prepared in the dry state by dusting the drying rhizomes with crystalline sugar.

The preparation of dried ginger involves processing the cleaned rhizomes by peeling, splitting them into pieces, immersing them into boiling water for about 10 min, and, finally, drying. The appearance of processed ginger (black or white), the contents of volatile oil and fiber, the pungency level, and an assessment of the aroma and flavour are important in the quality evaluation of dried ginger.

The characteristic pleasant and aromatic odor of ginger is due to essential oil, which can be separated from the dried rhizome by steam distillation. The essential oil, known in the trade as 'oil of ginger,' is greenish to yellow in color, mobile (viscous on aging), with the characteristic warm and aromatic odor, but not the pungent flavor of the spice. The pungent principles of ginger are nonvolatile oleoresin, commonly known in the trade as 'gingerin.' This can be extracted from dried ginger by percolation with a suitable solvent. It is a viscous and dark brown oil and retains the full pungency of the spice. Besides the pungent principles, the oleoresin also contains gingerol, shogaol, and zingerone.

In medicine, ginger is used as a carminative and digestive stimulant. It also dilates the blood vessels in the skin, causing a feeling of warmth. Its preparations are also useful in the treatment of coughs and colds. Ginger is extensively used in culinary preparations such as soups, puddings, pickles, gingerbread, and cookies, and is an ingredient of all curries, except those used with fish. Ginger is also popular for flavoring beverages such as ginger ale and ginger beer.

Turmeric

Turmeric, another important spice, is also obtained from the underground plant part, i.e., the stem. The plant, a native of south-east Asia, is widely cultivated in India, Sri Lanka, Indonesia, China, Taiwan, Peru, Haiti, and Jamaica, of which India is by far the largest exporter.

Turmeric is obtained from the rhizomes of *Curcuma domestica* Val. (syn. *C. longa* L.), also a member of the family Zingiberaceae. The plant is a robust perennial herb with a short stem and tufted leaves. The rhizomes, brownish yellow in color, consist of a central bulbous portion bearing a number of finger-like lateral offshoots. Although the characteristic yellow matter is distributed throughout the plant, it is highly concentrated in the rhizome. There are several varieties of turmeric distinguished by the names of the localities in which they are grown. Turmeric cultivated in the hills is said to be of a better quality than that raised in the plains. Even the same variety which is grown in plains and on the hills shows distinct differences in quality and yield. *See* Plate 3.

Cultivation of turmeric requires a hot and moist climate, a liberal water supply, and a well drained soil. It can be grown successfully in rice fields on raised beds beyond the reach of stagnant water. It is usually rotated with ragi (a cereal grass cultivated in Africa and Asia), paddy, and sugarcane. It is rarely cultivated as a pure crop and is usually grown mixed with castor bean, maize, ragi, onions, brinjal, and tomato. The plants thrive well in partially shaded areas, but shade adversely affects the yield.

Turmeric is a good host for many pathogenic microorganisms and insectpests. Rhizome rot and leaf spot caused mainly by *Taphrina maculans* Butler are the important diseases of turmeric. The use of Bordeaux mixture or any other nonmetallic fungicide has been suggested as a remedy.

The crop is ready for harvesting in about 9–10 months, when the lower leaves turn yellow. The rhizomes are carefully dug up with hand-picks. The leafy tops are then cut off, and the roots are removed. The adhering soil particles are removed by brisk shaking or by rubbing, and the rhizomes are then thoroughly washed with water, placed in small heaps, covered with turmeric leaves, and left to dehydrate. The fingers and bulbs (or mother rhizomes) are then separated and cured separately.

The curing of turmeric involves boiling or steaming the fresh rhizomes in water, followed by drying and polishing. The rhizomes are boiled for 45–60 min

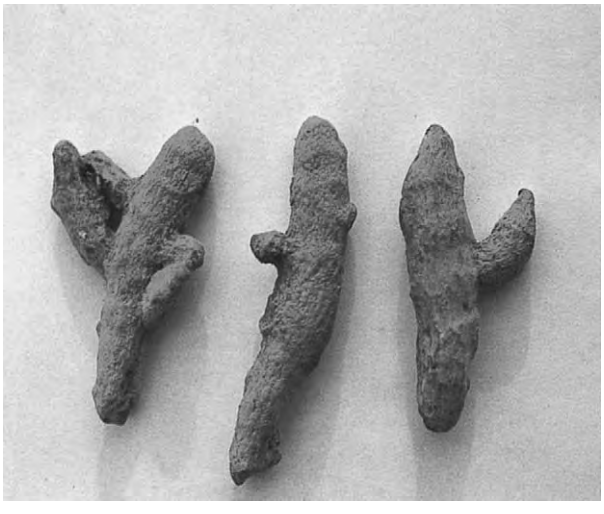

Plate 3 (see color plate 131) Spices and flavouring crops: Rhizome of turmeric (*Curcuma domestica*).

over a slow fire until they become soft. The rhizomes are then cooled and spread out to dry in the sun. Boiling of the rhizomes in very dilute solutions (0.05–0.1%) of mild alkali modifies the color of the core of the rhizome to the desired yellow–orange. The duration of boiling markedly affects the color and aroma of the final product. After boiling, the rhizomes are dried in sunlight for 10–15 days. Sun-drying gives rise to a surface-bleaching effect. After drying, the rhizomes become quite hard and brittle, and break with a metallic sound. Drying is followed by polishing, which includes cleaning off the outer skin, rootlets and adhering particles of soil, and making the rhizomes smooth. Polishing is performed either manually or in power-operated drums. The dried turmeric is coated with a slurry of turmeric powder in the course of polishing to impart a better color to the rhizomes.

The cured rhizomes are stored in pits dug at a raised site. The bottom and sides of these pits are lined with *Saccharum spontaneum* (commonly known as Rellu grass) and palmyrah mats. The pits, after being filled with cured turmeric, are covered with mats and grass and, finally, with earth. The produce may be stored for a year. The turmeric is also stored in 'godowns' or warehouses in gunny bags.

The coloring matter of turmeric is yellowish crystalline curcumin, which can be extracted from the powder either by direct solvent extraction or by extraction with alkali and subsequent precipitation with acid.

Turmeric is mainly used for domestic culinary preparations and is an important constituent of curry powder. Turmeric is also used as coloring agent in the textile, food, and pharmaceutical industries. In the Indian system of medicine, turmeric is used to some extent as a stomachic (i.e., promoting the appetite or assisting digestion), tonic, and blood purifier. The juice of the fresh rhizome is used as an antiparasitic for many skin diseases. Oil of turmeric, distilled from the dried rhizome, shows antiseptic properties.

Minor crops

Spices obtained from Roots

Angelica Angelica has been in use as a spice since AD 1500. It is obtained from the roots of *Angelica archangelica* L., a member of the family Apiceae. It is native to Syria but is known to occur in many parts of Europe and western Asia. In India, it is grown in the Kashmir valley.

The plant is a stout perennial herb with large, pinnately compound leaves and small, greenish white flowers. The dry rootstocks yield 0.35–1% of essential oil, the main constituent of which is β-phellandrene. The roots contain several furocoumarins such as angelicin, bergapten, xanthotoxin, etc. in addition to umbelliprenin and several phenols. The dried roots are frequently used for flavoring cakes, candy, and beverages. Angelica root is the main flavoring ingredient of gin. It is also used in perfumery and medicine. In medicine, the roots have been shown to possess stimulant, expectorant, and diaphorectic (i.e., inducing perspiration) properties.

Horse-radish The horse-radish (*Armoracia lapathifolia* Gilib.) is a member of the family Brassicaceae and has been in use as a condiment since ancient times. The plant is a native of southeastern Europe and is widely grown in Europe, America, and the hilly regions of India.

The plant is a tall, hardy herb with glossy green, toothed leaves. The roots are fleshy, yellowish white, and cylindrical. Initially, the root is about 2.5 cm in diameter, but it may reach a length of 1 m. The English refer to the plant as 'red cole,' perhaps due to the hot sensation experienced when ingesting even small pieces of root. The roots are dug up and are scraped or grated before use. Both fresh and dried roots are used as a condiment, which aids digestion and prevents scurvy. It is similar to mustard in most of its properties. The smell and flavor of horse-radish come from the glycoside sinigrin, which decomposes in the presence of water by enzyme action to form mustard oil.

Asafoetida Asafoetida is the dried latex obtained mainly from living rootstocks or tap roots of several species of *Ferula*, namely *F. foetida* Regel., *F. alliacea* Boiss., *F. rubricaulis* Boiss., *F. asafoetida* Linn., and *F. narthex* Boiss, of the family Apiaceae. The plants are perennial herbs which are mainly distributed from the Mediterranean region to Central Asia. The main regions of asafoetida production are eastern Iran and Western Afghanistan. Some species are also found in the Punjab and Kashmir regions of India.

The plants bear large, carrot-shaped roots, 10–15 cm in diameter at the crown after 4–5 years of growth. At the time of flowering, the upper part of the root is laid bare, and the stem is cut off close to the crown. The exposed surface is covered by a dome-shaped structure made up of twigs and mud. The exudate (milky juice) oozing out from the cut surfaces is scraped off after a few days. The collection of the resin and the slicing of the root are repeated until exudation ceases.

Asafoetida occurs in three forms in commercial trade: tears, mass, and paste. The tears make the

purest form of resin, it is bitter and acrid in taste and emits a strong and peculiar odor.

Asafoetida contains mainly resin (40–64%), gum (25%), and volatile oil (10–17% on a dry-weight basis). The resin portion consists mainly of asaresinotannol, free or combined with ferulic acid. Umbelliferone seems to be present in combined state. Oil of asafoetida is obtained by steam distillation of the gum resin.

Asafoetida is generally used for flavoring curries, sauces, and pickles. Medicinally, it stimulates the intestinal and respiratory tracts and the nervous system. It is useful in asthma, whooping cough, and chronic bronchitis.

Sarsaparilla Sarsaparilla is obtained from the dried roots of several tropical species of *Smilax*, a member of the family Liliaceae. Some of the important spice-yielding species include *S. aristolochiaefolia* Mill. (Mexico), *S. officinalis* H.B. & K. (Honduras), and *S. regelii* Killip & Morton (Jamaica). The plant thrives best in hot and humid climates and on light, well-drained sandy loam rich in humus.

The plants are climbing or trailing vines with prickly stems. The rhizomes are short and thick, with very long, thin roots. The plants are harvested after attaining 2–3 years of age. They are carefully dug up and cut off near the stock, which is then covered up again with surface soil. The harvested roots are then washed well, dried in the sun, and tied up in bundles. The roots contain a bitter principle which is used as a flavoring agent. It is chiefly used as a beverage condiment for the preparation of soft drinks. Sarsaparilla is mostly used in combination with winter green and other aromatic plants.

Medicinally, sarsaparilla has been used to treat syphilis and other skin diseases.

Spices obtained from Rhizomes or Tubers

Zedoary Zedoary (*Curcuma zedoaria* Rosc. syn. *C. zerumbet* Roxb.) closely resembles turmeric (*C. longa*) in appearance. It is a native of northeast India and is widely cultivated in many parts of China, Sri Lanka, and India.

The plant bears green leaves with brownish purple veins and grows up to a height of 50 cm. The rhizomes, which are large and fleshy, are cut into small pieces and dried. Dried slices have a bitter and strong, camphoraceous taste and are used for commercial purposes.

Steam distillation of the rhizome yields a light yellow oil. The odoriferous consitutent is said to be a sesquiterpene alcohol belonging to the tricyclic group.

Zedoary was an important spice in the past, but these days, it is usually used only for flavoring liqueurs and curries. The rhizomes have aromatic, stimulant, and carminative properties. Besides its use as spices, the rhizomes are also used for the preparation of shoti starch (flour), a substitute for arrowroot and barley. It is highly valued as a dietary item, especially for infants and convalescents. A red powder, 'abir,' is also prepared from powdered rhizomes by treatment with a decoction of sappan wood.

Mango ginger Mango ginger (*Curcuma amada* Roxb.) is a member of the family Zingiberaceae. The plant is native to India and occurs in the wild state in parts of Bengal, Konkan, and Madras. *See* **Plate 4**.

The plants are herbaceous, and the rhizomes have the characteristic odor of green mangoes. At the time of harvesting, entire plants are lifted up with a crowbar, and the rhizomes are collected, cleaned, and dried in the shade. On distillation, the rhizome yields essential oil, which consists mainly of pinene, ocimene, and linalool. The rhizome is mostly used in pickles and is considered stomachic and carminative. It is also applied over contusions and sprains.

Galangal Galangal is of three types: lesser galangal, greater galangal, and light galangal. The reddish-brown rhizomes are used as condiment and have an aromatic spicy odor and a pungent taste.

The lesser galangal (*Alpinia officinarum* Hance.), a member of the family Zingiberaceae, is a native of southern China. The plant is a perennial herb with a raceme of showy flowers and attractive foliage. The rhizome is smaller and has a stronger odor and taste. The lesser galangal is used as a spice in cooking, and also in medicine and for flavoring liqueurs. It is also used to impart a pungent flavor to vinegar.

The greater galangal (*Alpinia galanga* (L.) Willd.) is also a perennial herb with showy flowers and

Plate 4 (see color plate 132) Spices and flavouring crops: Rhizome of mango ginger (*Curcuma amada*).

beautiful foliage. It is commonly found in Indonesia and Malaysia, and is also cultivated in Bengal and southern parts of India. The green rhizomes contain essential oil consisting mainly of methyl cinnamate and cineol. It gives a pungent taste like a mixture of pepper and ginger. Medicinally, it is useful in respiratory troubles, especially in children. The rhizomes are also carminative and stomachic.

The light galangal (*Alpinia speciosa* (Wendl.) K. Schum) is a native of the Eastern Archipelago, off the Coromandel Coast of south-east India. Its rhizome is much larger and is generally used as substitute for greater galangal, and even as a substitute for ginger in many preparations.

Properties and Analysis

C Jian Qin, Perfumery Research and Development Center of Yunnan, Kunming, Yunnan, China

Background

In the vegetable kingdom, there are many plants that are odorous. A range of spices used in foods is shown in **Table 1**. This article reviews the properties of these odor-bearing molecules as well as the technology of extraction. In addition to their odorant properties, many herbs and spices have an important effect on taste, as well as heating/cooling in the mouth. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics; **Sensory Evaluation**: Aroma; Taste.)

Range of Compounds Present

The odorants are chemically mainly of three types, and they can be present in any organ of the plant, such as the seed, fruit, flower, leaf, root, rhizome, and/or bark, even in moss. Some of the more important compounds found are shown in **Table 2**, with their structures in **Table 3**. (*See* **Essential Oils**: Properties and Uses.)

Terpenes

Most odorous compounds present in plants are monoterpenes, sesquiterpenes, and their derivatives. This kind of compound is derived from secondary metabolites of biosynthesis via coenzyme A. Their chemical structure is essentially formed by a number of units of 2-methylbutadiene (trivially called isoprene), so that their general formula is $(C_5\ H_8)_n$. If n equals 2, the compound is called monoterpene; if n equals 3, it is called a sesquiterpene, and so on.

Derivatives of Phenylpropane

Although this type of compound is less widely distributed than the terpenes, it is very important from the fragrance point of view, for example, *trans*-anethole in anise and star aniseed oil and cinnamic aldehyde in cinnamon bark oil. These compounds are also products of secondary metabolites; in comparison with terpenes, biosynthesis is via shikimic acid, which is an intermediate in the synthesis of lignin.

Aliphatic, Heterocyclic, and Phenolic Compounds

The third type of flavoring compounds consist of derivatives of aliphatic heterocyclic and phenolic compounds. These compounds can be associated with the two preceding types of odorants as minor compounds in essential oils. However, they are frequently encountered; for example, 6-methyl-5-hepten-2-one is found in most citrus essential oils. Some plants contain only aliphatic and heterocyclic compounds without either terpenes or derivatives of phenylpropane; for example, rose, jasmine, and violet. They are found in the plant in the flowers, leaves, and/or fruits. (*See* **Phenolic Compounds**.)

These compounds can belong to a wide variety of chemical groups:

Table 1 Spices used in food preparation/processing

Type and number	*Common name*	*Latin name*	*Class/order family (bot)*	*Cultivation region*
Fruits				
1	Pepper, black	*Piper nigrum*	Piperaceae	Tropical and subtropical regions
2	Vanilla	*Vanilla planifolia*	Orchidaceae	Madagascar, Comore Island, Mexico, Uganda
3	Allspice	*Pimenta dioica*	Myrtaceae	Caribbean Islands, Central America
4	Paprika (red pepper)	*Capsicum annuum*	Solanaceae	Mediterranean and Balkan region
5	Bay tree[a]	*Laurus nobilis*	Lauraceae	Mediterranean region
6	Juniper berries	*Juniperus communis*	Cupressacceae	Temperate climate region
7	Chilli	*Capsicum frutescens*	Solanaceae	Tropical region
8	Aniseed	*Pimpinella anisum*	Apiaceae	Temperate climate region
9	Caraway	*Carum carvi*	Apiaceae	
10	Coriander	*Coriandrum sativum*	Apiaceae	
11	Dill[a]	*Anethum graveolens*	Apiaceae	
Seeds				
12	Mustard	*Sinapis alba*[b] / *Brassica nigra*[c]	Brassicaceae / Brassicaceae	Temperate climate region
13	Nutmeg	*Myristica fragrans*	Myristicaceae	Indonesia, Sri Lanka, India
14	Cardamom	*Elettaria cardamomum*	Zingiberaceae	India, Sri Lanka
Flowers				
15	Clove	*Syzygium aromaticum*	Myrtaceae	Indonesia, Sri Lanka, Madagascar
Rhizomes				
16	Ginger	*Zingiber officinale*	Zingiberaceae	South China, India, Japan, Caribbean Islands, Africa
17	Turmeric	*Curcuma longa*	Zingiberaceae	India, China, Indonesia
Barks				
18	Cinnamon	*Cinnamomum zeylanicum, C. aromaticum, C. burmanii*	Lauraceae	China, Sri Lanka, Indonesia, Caribbean Islands
Roots				
19	Horse-radish	*Armoracia rusticana*	Brassicaceae	Temperate climate region
Leaves				
20	Parsley	*Carum petroselinum*	Apiaceae	Temperate climate region
21	Marjoram	*Origanum majorana*	Lamiaceae	Temperate climate region
22	Oregano	*Origanum heracleoticum, O. onites*	Lamiaceae	Temperate climate region
23	Rosemary	*Rosmarinus officinalis*	Lamiaceae	Mediterranean region
24	Sage	*Salvia officinalis*	Lamiaceae	Mediterranean region
25	Thyme	*Thymus vulgaris*	Lamiaceae	Temperate climate region

[a]Fruits and leaves.
[b]White mustard.
[c]Black mustard.
From Belitz H-D and Grosch W (1987) *Food Chemistry*. Berlin: Springer.

- Aldehydes, alcohols, esters, ketones, and lactones, which are formed by the metabolism of lipids and glycosides.
- Phenols, which result from the metabolism of proteins and glycosides.
- Sulfides and nitrogenous compounds (mercaptans, thiophenes, thiazoles, pyrazines and pyridines), which arise from the metabolism of proteins.
- Carboxylic acids, which come from the metabolism of sugars and glycerides.

They have a delicate fragrance and are generally responsible for floral notes and fruit flavor; their odor, therefore, is very different from that of terpenes. It must be noted that the heterocyclic compounds can be formed not only by biosynthetic processes but also by fermentation by microorganisms or thermal reactions, including the Maillard reaction. (*See* **Browning**: Nonenzymatic.)

Extraction and Isolation

Process Using Water Vapor

Essential oils can be produced by use of water vapor. The term 'oil' refers to their lipophilic nature, which causes them to separate from aqueous distillate. The adjective 'essential' refers to its origin in a living plant. (*See* **Essential Oils**: Isolation and Production.)

Table 2 Major components of the essential oils of spices

Spice[a]	*Components*[b]
Pepper (1)	22% α-Pinene [**29**], 21% sabinene [**25**], 17% β-caryophyllene [**49**], Δ^3-carene [**32**], limonene [**9**], β-pinene [**30**]
Allspice (3)	70% Eugenol [**50**], β-caryophyllene [**49**], methyleugenol, 1,8-cineole [**23**], α-phellandrene [**11**]
Bay leaf (5)	50–70% 1,8-Cineole [**23**], α-pinene [**29**], β-pinene [**30**], α-phellandrene [**11**], linalool [**4**]
Juniper berries (6)	36% α-Pinene [**29**], 13% myrcene [**1**], β-pinene [**30**], Δ^3-carene [**32**]
Aniseed (8)	80–90% Anethole [**54**]
Caraway (9)	55% Carvone [**21**], 44% limonene [**9**]
Coriander (10)	Linaool [**4**], linalyl acetate, citral[c]
Dill fruit (11)	35% Carvone [**21**], 12% dihydrocarvone, 10% limonene [**9**], carveol [**16**], α-terpinene [**10**]
Nutmeg (13)	27% α-Pinene [**29**], 21% β-pinene [**30**], 15% sabinene [**25**], 9% limonene [**9**], safrole [**55**], myristicin [**56**]
Cardamom (14)	20–40% 1,8-Cineole [**23**], 28–34% α-terpinyl acetate, 2–14% limonene [**9**], 3–5% sabinene [**25**]
Clove (15)	80–90% Eugenol [**50**], 9% caryophyllene, eugenol acetate
Ginger (16)	30% (−)-Zingiberene [**42**], 10–15% β-bisabolene [**41**], 15–20% (−)-sesquiphellandrene [**43**], (+)-arcurcumene [**60**], citronellyl acetate
Turmeric (17)	30% Turmerone [**62**], 25% arturmerone [**63**], 25% zingiberene [**42**]
Cinnamon (18)	50–80% Cinnamaldehyde [**57**], 10% eugenol [**50**], 0–11% safrole [**55**], 10–15% linalool [**4**], camphor [**33**]
Parsley (20)	1,3,8,*p*-Menthatriene [**58**], 1-methyl-4-isopropenylbenzene [**59**], β-phellandrene [**12**], myrcene [**1**]
Marjoram (21)	49–65% 1,8-Cineole [**23**], 25% estragole [**53**], 15% α-terpineol [**17**], 11% eugenol [**50**], linalool [**4**], geranyl acetate, ocimene [**2**]
Oregano (22)	Carvacrol [**51**], thymol [**52**], *p*-cymene [**61**], carvacrol methyl ether
Rosemary (23)	1,8-Cineole [**23**], camphor [**33**], β-pinene [**30**], camphene [**31**]
Sage (24)	1,8-Cineole [**23**], camphor [**33**], thujone [**26**]
Thyme (25)	Thymol [**52**], *p*-cymene [**61**], carvacrol [**51**], linalool [**4**]

From Belitz H-D and Grosch W (1987) *Food Chemistry*. Berlin: Springer.

Steam distillation This process, which is an indirect distillation, involves putting raw materials above the vapour current without previous maceration. The saturated vapors bearing volatile organic compounds are condensed on a cold surface, and the essential oil is recovered by decantation. This process allows treatment of raw materials that are heat-sensitive.

Hydrodistillation In this case, the raw materials are immersed in boiling water. The volatile compounds are carried away with the water vapor and collected after condensation and decantation, as in steam distillation.

Hydrodistillation is generally carried out at atmospheric pressure. Nevertheless, we can improve the relationship between the weight of material carried and that of evaporated water, which represents an improvement in energetic efficiency. Such material as vetiver rhizome can be treated with this technique, because it bears many compounds of high molecular mass, which cannot be evaporated easily at atmospheric pressure.

Microwave hydrodistillation Recently, a microwave technique has been developed for treating aromatic plants. The advantage of this technique is that it allows the recovery of odorant compounds present in smaller quantities in plants. In addition, the time of extraction is very short in comparison with traditional steam distillation. However, it seems as if this method will not be commercially available because of difficulties in the choice of microwave frequency.

Hydrodiffusion In contrast to the usual direct steam distillation, this process allows steam to enter from the top of the vessel. The resulting solution is condensed and separated by decantation, as mentioned above. The main advantages of this technique are in saving energy owing to reduced steam consumption and in the elimination of hydrolysis, because the raw material is never in contact with water, only with steam.

Vacuum distillation In many cases, the essential oils produced either by solvent extraction (see below) or by steam distillation do not exactly fit the perfumers' and the flavorists' needs. It is sometimes necessary to eliminate certain constituents, such as terpenes or heavy colorings, or to increase the percentage of major aroma compounds. Figure 1 shows a distillation column on which different compounds can be separated according to their boiling points. The temperature gradually increases during the distillation, the most volatile compounds being isolated first. The better the vacuum, the lower the distillation temperature, which in turn protects the odorants from degradation.

Extraction Techniques

Extraction with organic solvents This technique is frequently used, like steam distillation. It involves putting aromatic plants in a static extraction vessel and covering them with an organic solvent, such as hexane, benzene, toluene, ethanol, or light petroleum or a binary mixture. Once equilibrium has been reached (or at least nearly so), the solution is separated, and the solvent is evaporated in a vacuum to yield the extract. Two particular methods are extraction with water and extraction with aqueous alcohol.

The choice of the solvent depends on many technical and economic parameters, in particular: selectivity; boiling point; diffusivity; miscibility with water; facility for recycling; safety – in general, the solvent chosen must be of as low a toxicity as possible both for operation of the extraction process and for consumption of the product.

The process of extraction used also depends on the nature of vegetable matter, such as its thermal lability, the operating temperature ranging from ambient to the boiling point.

According to the technique and solvent used, the products are known by one of the following names:

- *Tinctures*: obtained either by treating natural raw materials with ethanol or ethanol–water mixtures or by dissolving an extract in these solvents.
- *Oleoresins*: concentrated extracts with a characteristic odor and/or flavor, obtained from a natural raw material.
- *Resinoids*: concentrated nonaqueous extracts with a characteristic odor obtained from a dried natural raw material.
- *Concretes*: concentrated nonaqueous extracts with a characteristic odor and/or flavor obtained from a fresh natural raw material.

Besides odorant compounds, the organic solvent also extracts such undesirable substances as waxes and lipids, which are responsible for the nature of 'concretes.' In fact, a transformation is needed from concrete to absolute. Because waxes are not soluble in alcohol at low temperatures (about $-10\,^{\circ}C$), the concrete is diluted with alcohol at 30–40 °C and strongly stirred. When this alcohol solution is refrigerated at -5 to $-10\,^{\circ}C$, waxes precipitate and are filtered off. The filtrate is concentrated under vacuum, and after elimination of alcohol, the absolute remains. Generally absolutes are in liquid form, though they may be viscous or 'pasty.'

CO_2 extraction This process (see **Figure 2**) uses high pressure and, depending on the characteristics desired in the product, employs either liquid carbon dioxide (300 bar, 30 °C) or supercritical carbon dioxide (350

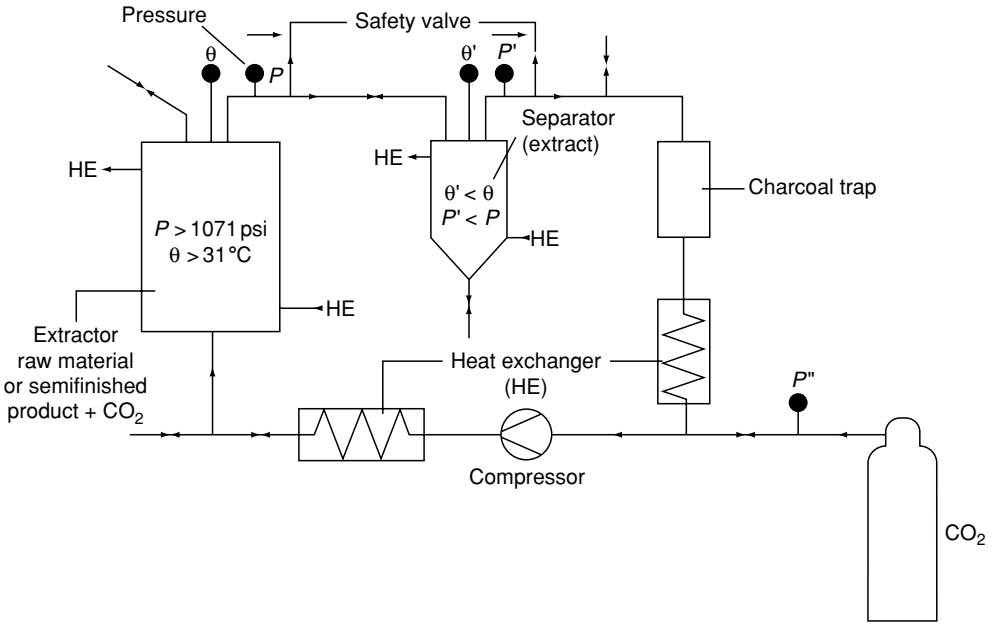

Figure 2 CO_2 extraction system. Reproduced from Spices and Flavouring Crops: Properties and Analysis, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

bar, 50 °C). The separation of extract takes place in the gas phase by a simple separation of gas and liquid.

The principle of the method is based on good solubility in carbon dioxide of most odorants of vegetable matter and semifinished products, such as concrete or even essences. The technique has the following advantages:

- No residual toxic solvent, particularly important for materials used in flavors.
- Low process temperature, important when processing unstable and heat-sensitive products.
- Selectivity (e.g., in caffeine extraction).
- Lack of fire hazards.
- Energy efficiency (no loss of organic solvents such as hexane or benzene, which have to be redistilled for use again).

Carbon dioxide as a solvent is relatively nonpolar, so its solubilizing powers are comparable to, but slightly more polar than, those of hexane. The latter is used frequently in the production of aromatic vegetable matter.

Extraction using ultrasound This process consists of vibrating the material by means of supersonic waves, which, owing to resonance, disintegrates the product matrix. More particularly, when the process is carried out in a liquid medium, the vibrational energy applied produces pressure variations that greatly facilitate the dispersion of the desired products in the solvent after they have been separated from their natural matrices.

Expression

Expression of oil at low temperature is a response to two particular features of the essential oils of citrus plants: (1) these oils contain terpene peroxides and polymerizable terpenes, so that they are heat-sensitive to hydrodistillation temperatures; (2) the oils are located in the porous pericarp, which is easily torn. It is therefore preferable to recover the essential oils by simple mechanical action.

It is the only process for treatment of aromatic plants without using a fluid extraction phase and involves either expressing the pericarp by water pressure or crushing whole fruits in a metallic cylinder. The essences so produced have low densities and can be separated from the aqueous phase by centrifugation. They are also designated 'essential oil.'

Specialized Extraction Techniques

Molecular distillation Molecular or short-path distillation is used to obtain colorless products; more stable products, because of the elimination of constituents with higher molecular weight (acids, pigments); and more delicate notes, because of the increase in the proportion of odorant in the oil.

Because of the high vacuum (0.05–0.0005 torr), the boiling point and extraction time are greatly

reduced, thus preventing the loss of some heat-sensitive notes in the oil. The product to be processed is combined with a heavy, and a light solvent and is then passed through the first short-path evaporator; the most volatile components condense together with the light solvent on a so-called 'finger' in the middle of the evaporator and are recovered as the first distillate (see **Figure 3**). The other components condense on the walls of the evaporator and are pumped into a second short-path evaporator. Here again, the next most volatile components of the oil condense on the inner 'finger' and are recovered as the second distillate. The residues and the heavy solvent condense on the walls and are recovered in the residue tank.

Simultaneous distillation/extraction This original process was designated by Likens and Nickerson. It uses two fluids; the volatile compounds are removed by steam distillation, and a nonpolar solvent continuously extracts them from the aqueous distillate.

The geometry of the apparatus enables the steam carrying the volatiles and the solvent vapor to meet in the condenser. The condensate separates into two phases, which are directed to their respective vapor generators. Eventually, the evaporation of the solvent allows recovery of a concentrated solution of odorant.

The relative position of two vapor generators differs according to the density of the solvent used. The method is particularly applicable in the study of rare vegetable materials.

Capture of headspace Three methods have been used as follows:

- Adsorption in liquid, which allows capture of the volatile components by passing the head space vapors through a solvent, and then concentrating the solution by evaporation.
- The cryogenic method, which condenses the volatile components in a series of refrigerated traps.

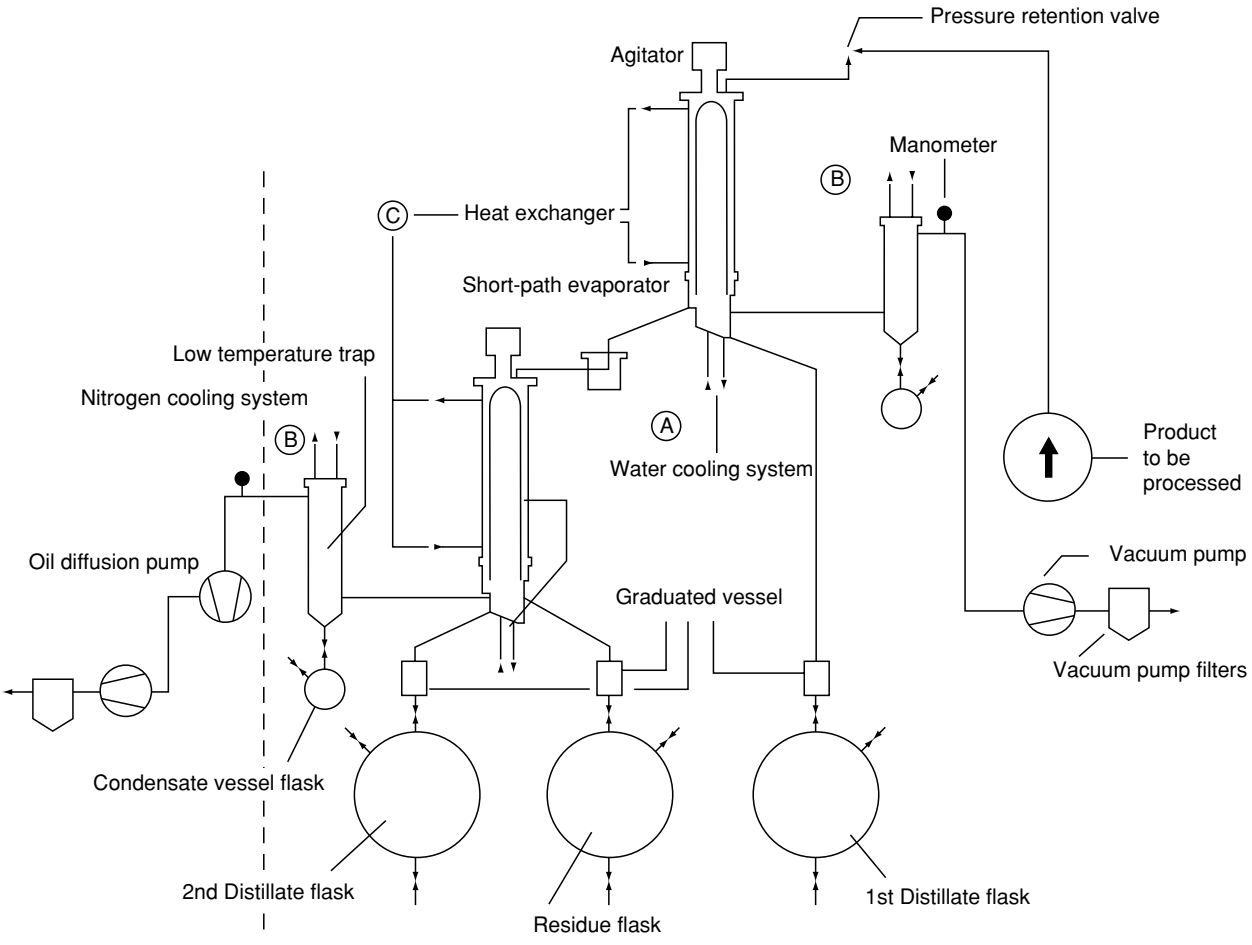

Figure 3 Molecular distillation unit. Reproduced from Spices and Flavouring Crops: Properties and Analysis, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

This method has been used particularly for the capture of the volatile components of fruit.

- Adsorption of solids, which involves passing the headspace over an adsorbent, such as XAD-4 (polystyrene) or TENAX [poly(2,6-diphenyl-*p*-phenylene oxide)]. The volatiles are recovered by thermal desorption or by elution with an organic solvent.

Volatiles

Odorants must be volatile to some extent, and this property is common in those molecules that contain fewer than 10 carbon atoms, for example, monoterpenes and their derivatives. It must be noted that aldehydes, ethers, and esters generally have a stronger odor than their parent hydrocarbons. This is why they are used for head notes in the formation of perfumes, cosmetics, and deodorants.

Volatiles of higher molecular mass evaporate relatively slowly at room temperature; because of this property, such compounds provide the more persistent odors.

Nonvolatiles

Nonvolatiles such as sugar, salt, piperine, and caffeine, may affect taste, although they cannot be detected by smell at room temperature.

Mechanism of Degradation and Staling

During steam distillation of an essential oil, terpenoid compounds are susceptible to degradation. Terpene alcohols and esters, especially, undergo a variety of well-known chemical reactions (hydrolysis, hydration, and cyclization), in particular under acidic conditions. For example, low pH values induce considerable hydrolysis of linalyl acetate and extensive rearrangement reactions. It is well known that tertiary alcohols and their esters are protonated in aqueous media to yield oxonium ions, which split to form a tertiary carbocation; thus, degradation reactions and rearrangements can be observed under the conditions of steam distillation.

In the mechanism of linalyl acetate thermal degradation, the generation of a primary allylic carbocation – the linalyl carbocation, which creates a *p*-menthane skeleton by cyclization – explains the presence of nerol and geraniol among the degradation products.

Some degradation can take place during the storage of essential oils, especially for oxygenated components. For example, citronellal can be resinified in a basic medium or oxidized in contact with air in the presence of light.

Since flavoring compounds are volatile, they can be lost easily by evaporation, thus leading to staling if the conditions of storage are not appropriate.

Microbiological Contamination

A number of essential oils, as well as some spices and aroma extracts, e.g., thyme and cloves, which are rich in phenolic compounds, possess antifungal and antibacterial properties. In general, essential oils have a good bacteriological quality, provided humidity is not too high. In contrast, the chemical stability of some essential oils is limited on account of oxidation, for example, those that are rich in limonene. Such essential oils must be protected against oxidation during storage. (*See* **Spoilage**: Chemical and Enzymatic Spoilage; Bacterial Spoilage.)

Bacteriological contamination is a hazard for spices and aroma extracts, particularly if they are aqueous extracts, for example, alliaceous extracts. It is necessary to ensure their bacteriological quality. The chemical stability for certain extracts, such as pepper and rosemary, is protected by the presence of natural antioxidants. (*See* **Antioxidants**: Natural Antioxidants.)

SPOILAGE

Contents

Chemical and Enzymatic Spoilage

N F Haard, University of California, Davis, CA, USA

Introduction

The storage life of foodstuff is limited by the occurrence of chemical reactions which alter edible quality, including deterioration in optimal color, appearance, texture, aroma, flavor, nutrition, safety, and functional properties. When food undergoes deterioration in quality, it is not always clear whether the reaction causing the problem is of nonenzymatic, enzymatic, or microbial origin. For example, development of bad odor in stored coleslaw prepared with mayonnaise and sour cream was first attributed to microbial spoilage. However, investigation of the problem revealed that endogenous enzymes in the cabbage were activated by the anaerobic conditions in the package and were responsible for the formation of offensive- smelling volatiles. Likewise, enzymatic reactions rather than microbial spoilage was shown to be the primary cause of early spoilage in chilled, properly handled fish, by studying the initial quality loss of the flesh in sterile and nonsterile fish. In most cases, chemical and microbial spoilage acts in concert. For example, in cold-smoked salmon microbial activity causes production of characteristic spoilage off-odors and off-flavors while autolytic enzymes from the fish tissue are responsible for the characteristic texture deterioration. Moreover, there are also many instances where chemical, enzymatic, and microbial spoilage reactions are interactive processes. For example, products of nonenzymatic browning have been shown to inhibit other enzymatic, nonenzymatic, or microbial spoilage reactions.

Chemical Reactions that Contribute to Spoilage

Chemical spoilage includes enzyme-catalyzed reactions as well as nonenzymatic reactions. In general, enzyme-catalyzed reactions are of primary concern in untreated plant and animal tissues and nonenzymatic reactions predominate in properly processed foodstuffs. There are, however, some exceptions to this general rule. In addition, enzymatic and nonenzymatic spoilage reactions may act in concert. For example, discoloration of the surface of red meats is caused by a nonenzymatic reaction, oxidation of myoglobin (Fe^{2+}) to form metmyoglobin (Fe^{3+}). However, enzymatic reactions involved with respiration at the tissue surface can lower oxygen concentration and indirectly promote nonenzymatic oxidation of myoglobin. Some muscle tissues also contain the enzyme metmyoglobin reductase, which catalyzes the reduction of metmyoglobin back to myoglobin. Likewise, the nonenzymatic denaturation and aggregation of myosin primarily cause texture deterioration during frozen storage of certain species of fish. However, these reactions may be accelerated by the action of trimethylamine oxide demethylase, which forms formaldehyde, or by phospholipase, which forms free fatty acids. It is normally possible to distinguish between enzymatic and nonenzymatic catalyzed spoilage reactions by conducting simple experiments (Table 1).

Physiological Processes

Some spoilage reactions are of biological origin, i.e., are 'of or pertaining to living organisms,' and these include sets of enzyme-catalyzed reactions. For example, a set of biological reactions described under the general heading 'postharvest physiology of fruits and vegetables' are important because they may contribute to deteriorative processes such as plant senescence, wound response, chilling injury, and other types of stress response. Physiological processes in fruits and vegetables also lead to desirable changes such as fruit ripening, wound healing after harvest, and the reduction of reducing sugars during the 'conditioning' of potato tubers. Likewise, 'postmortem physiology of food myosystems' describes a set of reactions that normally cause a desired conversion of muscle to meat.

Table 1 Some general characteristics that can distinguish enzymatic and nonenzymatic catalyzed reactions

Treatment	*Characteristics*
Thermal inactivation	As proteins, most enzymes are inactivated by a brief heat treatment, while catalysts of nonenzymatic reactions are normally heat-stable
Dialysis	As macromolecules, enzymes are nondialyzable, while catalysts of nonenzymatic reactions are normally low-molecular-weight and removed by this treatment
Specificity	The number of reactants and products in enzymatic reactions are normally less than in the corresponding nonenzymatic reaction. Enzyme catalysis and inhibition are characterized by stereospecificity
Proteolysis	Enzyme catalysts, as proteins, are often inactivated by treatment with proteolytic enzymes
pH	While nonenzymatic reactions are often acid- or base-catalyzed, enzymatic reactions are characterized by a relatively narrow pH optimum
Temperature coefficient	The Q_{10} of nonenzymatic reactions is normally much lower than that of enzymatic reactions

However, in some cases postmortem reactions may contribute to poor-quality meat, e.g., 'burnt tuna,' 'pale, soft, exudative pork,' 'cold shortening,' and 'thaw rigor.'

Spoilage reactions in the case of harvested and stored plant and animal tissues are, for the most part, catalyzed by enzymes. Myriad enzymes occur naturally in biological tissues used by humans for food. There is remarkable similarity in the basic metabolism of biological cells. However, the amounts and different kinds of specific enzymes present in a given cell may be quite distinctive because of heritable characteristics, intrinsic factors such as age of the source organism, and extrinsic factors such as preharvest stress, growing conditions, and diet. Only a small set of enzyme-catalyzed reactions has thus far been clearly identified with food spoilage. Many important deteriorative processes in food are caused by families of enzymes operating in sequence and catalyzing a net change in the tissue, such as synthesis of lignin in asparagus. Some other examples of multistep reactions, which contribute to losses in food quality, are summarized in Table 2. The detailed mechanisms and biochemical controls for many of these multistep reactions are not completely understood. For example, until the advent of rDNA technology it was generally believed that the increased solubility of pectin and the associated texture softening of fruit are caused by hydrolysis of α-1,4 galacturonate linkages in pectin, a reaction catalyzed by polygalacturonases (EC 3.2.1.15; EC 3.2.1.67). However, blocking the synthesis of polygalacturonases in ripening tomato fruit was not completely effective in preventing the softening of transgenic fruit. Since pectin contains small amounts of other sugar residues in addition to α-1,4 galacturonate linkages, it now appears that other, not yet identified, mechanisms play a role in tomato fruit softening.

Other Endogenous Enzymes

One-step enzyme-catalyzed processes may also contribute to quality deterioration, particularly in processed foods. For example, for orange juice, in which a stable colloidal suspension is desired, the action of endogenous pectin methylesterase (PME; EC 3.1.1.11) is undesirable since demethylation of pectin, catalyzed by this enzyme, leads to separation of serum from particulates in juice. Heat processing of orange juice to inactivate PME is undesirable since a nonenzymatic chemical reaction adversely affects the delicate flavor of the product. Hydrolases, like PME, as well as oxidoreductases are the most studied enzymes in connection with food spoilage. Examples of enzymes and their contribution to quality loss in specific commodities are summarized in Table 3.

Nonenzymatic Reactions

In the case of heat-treated or other processed foodstuffs where enzymes have been destroyed or their activity has otherwise been arrested, nonenzymatic chemical reactions play a more important role in food spoilage than enzyme-catalyzed reactions. As with enzyme-catalyzed reactions some, but not all, nonenzymatic changes that occur during food processing and storage will result in loss of quality. Examples of nonenzymatic reactions that can lead to deterioration in food quality are listed in Table 4. The two nonenzymatic reactions in foods which appear to be of most widespread importance are Maillard browning and lipid oxidation. These reactions are discussed in detail in other sections.

Factors Influencing Chemical Reactions in Food

The rate of chemical reactions in foodstuffs is a function of one or more variables, including pH, temperature, ionic strength, concentration of reactants, presence of catalysts, mobility of reactants, oxidation

Table 2 Some multistep enzyme-catalyzed reactions that contribute to food spoilage

Net reaction	*Contribution to food spoilage*
Glucosestarch	Loss in sweet taste of some vegetables, e.g., sweetcorn
Glucose$CO_2 + H_2O$	Respiration rate is directly related to spoilage rate of fruits, vegetables, and seed crops
Starchglucose + fructose	Cold sweetening of some vegetables leads to excessive Maillard browning, e.g., potato tuber
Glycogenlactic acid + H_2O	Glycogenolysis and glycolysis are of central importance in postmortem myosystems. The rate and extent of associated pH decline directly (e.g., water-holding capacity, protein denaturation) and indirectly (e.g., rate of other enzymatic and nonenzymatic reactions) to influence quality
ATPhypoxanthine	The rate and extent of adenosine triphosphate catabolism in myosystems influences meat quality in several ways, e.g., the acceptability of fish is directly related to the accumulation of hypoxanthine
Methionineethylene	The plant hormone ethylene is synthesized by the 'methionine cycle' during specific developmental change or as a consequence of wound injury. In turn, increased ethylene can initiate biosynthesis of enzyme cascades, e.g., chlorophyll destruction or lignin biosynthesis
Insoluble pectinsoluble pectin	Texture softening and increased vulnerability to saprophytic microorganisms and physical damage in some fruits and vegetables, e.g., ripe tomato
Phospholipidaldehydes, ketones, free radicals	Lipoxygenase cascades can decrease the amounts of essential nutrients, and cause off-flavors
Collagenpeptides, amino acids	Postmortem degradation of collagen is catalyzed by a family of enzymes and can influence physical integrity, appearance, and yield of fish fillets

Table 3 Some endogenous enzyme-catalyzed reactions that contribute to food spoilage

Enzyme	*EC number*	*Food*	*Importance*
Lipoprotein lipase	3.1.1.34	Milk	Releases short-chain fatty acids from milk fat leading to hydrolytic rancidity
Alkaline protease	3.4..24.40	Milk	Since this enzyme is stable to heat it may contribute to gelation in products processed at ultra high temperatures
Thiaminase	2.5.1.2, 3.5.99.2	Shellfish	Loss of thiamin in fermented products
Phospholipase	3.1.1.4, etc.	Fish	Releases fatty acids in frozen product causing denaturation of muscle proteins and texture deterioration
Trimethylamine oxide demethylase	4.1.2.32	Fish	Releases formaldehyde in frozen gadoid fish that contributes to protein aggregation and texture deterioration
Lipoxygenase	1.13.11.12, etc.	Legume seeds	Formation of specific hydroperoxides can lead to bleaching of pigments, offensive flavor formation, as well as texture change and loss of nutrients
Peroxidase	1.11.1.1, etc.	Vegetables	Decomposition of hydroperoxides with generation of free radicals appears to cause bleaching of pigments, off-flavors, etc.
Ascorbic acid oxidase	1.11.1.11	Citrus	Results in loss of vitamin C activity in orange juice
Chlorophyllase	3.1.1.14	Green vegetables	Removal of the phytol side chain from chlorophyll appears to be part of the degreening process during plant senescence
Polyphenol oxidase	1.10.3.1	Fruits, shellfish	Enzymatic browning

reduction potential, competing reactions, decompartmentation of reactants, and the physical state of the reaction milieu. One of the most important variables influencing chemical changes in food is temperature. The Arrhenius relation gives the influence of temperature on reaction rate:

$$k = k_o^{-E_a/RT}$$

where k is the reaction rate constant, k_o is the preexponential constant, E_a is the activation energy in kilojoules per mole, R is the gas constant, and T is the absolute temperature in Kelvin. E_a is normally much lower for enzymatic reactions than for nonenzymatic reactions. Thus, in general, the rate of a nonenzymatic reaction is more sensitive to temperature change than is an enzymatic reaction. Enzymes, like other proteins, are subject to thermal denaturation. Accordingly, the range of temperature in which catalytic rate increases with a rise in temperature is limited by the enzyme's thermal inactivation temperature. Because of these two considerations, the 'master' chemical reaction, i.e., that which limits the storage

Table 4 Some nonenzymatic reactions that can lead to loss in food quality

Reactant(s)	*Product or result*	*Importance*
Chlorophyll, H^+	Pheophytin, Mg^{2+}	Loss of Mg^{2+} from chlorophyll results in olive-brown discoloration of green vegetables. Reaction occurs rapidly at low pH and high temperature
All-*trans* β-carotene	*Trans–cis* rearrangement	Isomerization of carotenoids is promoted by light or heat and results in isomers, which absorb light in shorter wavelength and with lower extinction coefficients, and loss of provitamin A activity
Cysteine	H_2S, NH_3, acetaldehyde	Thermal degradation of sulfur-containing amino acids can directly produce aroma and also lead to other reactions involving the products
RCHO, RNH_2	Maillard browning	The Maillard reaction is one of the most important reactions in foods, affecting color, flavour, nutrition, and possibly safety
Amylose	Crystallization	The alignment of linear starch chains by hydrogen bonding to form insoluble precipitates, a process called retrogradation, is important in processed products containing gelatinized starch, e.g., bread staling
Anthocyanin, SO_2	Decolorization	The addition of SO_2 to the 4-position of anthocyanins to form a bisulfite addition product results in loss of color
Organic acid, Ca^{2+}	Ca-chelate	Organic acids like phytic acid or citric acid can destabilize polygalacturonate in the middle lamella by sequestering Ca^{2+} and thereby influence texture
Ascorbic acid	2-Furaldehyde, CO_2	The nonenzymatic degradation of vitamin C occurs by an acid/metal ion-catalyzed reaction or by an oxidative mechanism. In addition to loss in nutritive value, carbonyl degradation products, such as diketogulonic acid, can contribute to Maillard browning
Fatty acid, O_2	Autooxidation	Autooxidation is a free radical reaction which can be catalyzed by metal ions; the reaction rate increases with degree of unsaturation; a primary effect on quality is formation of off-flavors; however, all quality indices, including nutrition, color, texture and safety may be influenced under appropriate conditions
Protein	Denaturation	Loss of protein native structure can lead to protein aggregation and loss in functional properties with the possibility of influence on all quality indices under appropriate reaction conditions
Myoglobin, thiol compound, TMAO	Green tuna	Precooking tuna containing a high content of trimethylamine oxide (TMAO) can lead to green discoloration of tuna by an oxidation reduction reaction
Aspartame, peptides, nitrite	Mutagenic compounds	Naturally occurring dipeptides and the artificial sweetener aspartame can form mutagenic compounds after nitrosation. Aspartame is also unstable under alkaline conditions and heat
Arginine	1-Methylguanidine	High-temperature (e.g., 150–210 °C) treatment of arginine results in formation of mutagenic compounds, such as those found in cooked grain-based foods
Thiamine, H^+ or OH^-	2-Methyl-4-amino 5-aminethyl pyrimidine, etc.	Vitamin B_1 is destroyed by various reactions, including acid- or base-catalyzed reactions, redox reactions, photolysis, and reaction with bisulfite

life of a given product, normally differs with the temperature at which the product is stored (Figure 1). It is also important to recognize that E_a for a given reaction in a particular temperature range is also a function of other parameters (e.g., pH, glass transition). The extent to which other parameters influence thermal response depends on the particular reaction under consideration.

The extent and direction to which chemical transformations are influenced by parameters other than temperature depend on the reaction under consideration. For example, removal of oxygen from fish tissue decreases the rate of enzymatic or nonenzymatic lipid oxidation and the development of off-flavors, but at the same time it increases the rate of enzymatic trimethylamine oxide (TMAO) demethylation and associated protein aggregation. Likewise, reducing the water concentration of food by dehydration may decrease the mobility of water-soluble reactants, but it does not serve the same function for fat-soluble reactants and may even promote lipid oxidation by exposing lipid substrates to oxygen and increasing the availability of a metal catalyst.

It is also important to consider that, food-processing and storage conditions, designed to minimize one detrimental reaction, may inadvertently alter other

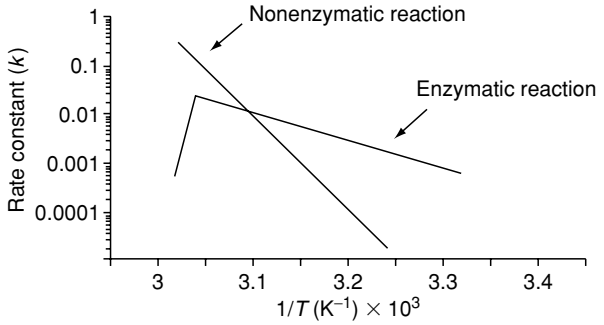

Figure 1 Typical temperature dependence of enzymatic and nonenzymatic reactions. Reproduced from Spoilage: Chemical and Enzymatic Spoilage, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

parameters which, in turn, may function to promote the same detrimental reaction. For example, while freezing of food lowers temperature and water activity, and thus is expected to lower the rate of reaction, it may serve otherwise to accelerate the rate by unexpected changes in pH, ionic strength, or reactant availability.

Moreover, storage or processing strategy designed to minimize a reaction that adversely affects storage life may accelerate other reactions that cause a different, but equally unacceptable, quality. For example, pasteurization of kiwi fruit juice (pH 3.5) inactivates enzymes and spoilage organisms that contribute to spoilage; but at the same time, heat treatment causes rapid pheophytinization of chlorophyll and loss in the characteristic green color of the product. Because of the complexity of food systems it is often difficult to predict the consequences of processing and storage conditions on quality. Accordingly, efforts to minimize the contribution of chemical reactions to food spoilage require an empirical approach, at least in part.

Bacterial Spoilage

E A Zottola, (retired) University of Minnesota, St. Paul, MN, USA

Introduction

Food for humans is obtained from plants and animals. The nutrients in these foods serve not only human needs but are also vital to the growth and survival of bacteria. Thus, if food is not immediately utilized or preserved after harvest, it spoils. Bacterial spoilage is inherent in foods. The spoilage process begins as soon as the food is harvested or slaughtered, and if steps are not immediately taken to prevent spoilage, the food will become unacceptable for human use. Spoilage of food can be caused by many factors: enzyme activity, physical damage, chemicals, rodents, insects, and metabolic activities of microorganisms, bacteria, yeasts, and molds. Foremost among the causes of food spoilage is the growth and utilization of the food by bacteria. Food is spoiled by bacteria when it becomes esthetically unacceptable to the user. What is spoiled to one may be a delicacy to another. It may have a foul odor or off-flavor, or be discolored, slime may be apparent, or there may be visible microbial growth on the food. These obvious

defects are revolting to the consumer and make it unacceptable for consumption. Food is also considered spoiled if the potential for the spread of foodborne disease exists. For example, food contaminated with high numbers of *Staphylococcus aureus* and possibly staphylococcal enterotoxin would not have any obvious defects that would make it apparently unacceptable, but it could make the consumer very ill and from this point of view it is spoiled. Food contaminated with industrial chemicals, pesticides, herbicides, or any material that should not be in the food would be considered spoiled. There are many facets of food spoilage. In this article, food spoilage caused by bacteria is reviewed. Foodborne illness is discussed in other sections of the *Encyclopedia*. (*See* **Wastage of Food**.)

Food as a Habitat for Bacteria

In its natural state, food, whether derived from animals or plants, is very susceptible to the action of bacteria and is easily spoiled by their metabolic activities. The processing of food is designed, among other things, to control the activity of bacteria and other microbes to preserve the food for later use. As food is processed, the type of bacterial spoilage that may occur will change. The major thrust of this article will be to describe how varying process methods affect food spoilage by bacteria. The growth of bacteria in foods is affected by several factors inherent in the food or by conditions external to the food. These include the acidity or pH of the food, the availability of water (water activity, a_w), the oxidation reduction potential (redox or E_h) of the food and the environment, availability of the nutrients in the food, the temperature of the food and the environment, and time available for bacterial growth to occur. (*See* **pH – Principles and Measurement**; **Water Activity**: Effect on Food Stability.)

Processing of Food and Bacterial Spoilage

The extent of processing of foods varies. Some foods are not processed prior to use and are very perishable. Others are lightly processed and are easily spoiled by bacterial action. The use of two or more preservation methods will give a food product additional stability, but does not make it immune to bacterial spoilage. This process of using one or more minimal preservation processes on a food to extend its quality retention time is referred to as the 'hurdles concept.' By adding another process to the food a hurdle is created, that is, one more factor that the bacteria have to overcome before they will grow and spoil the food. Thus the use of several hurdles should have a very positive effect on the quality retention time. There are a significant number of high-quality minimally processed foods that utilize the hurdles concept to control bacterial spoilage and effectively increase quality retention.

Foods given a more severe preservation process, such as drying or canning (high-temperature thermal process), are not as easily spoiled by bacterial action. With these concepts in mind it is possible to classify foods into spoilage potential categories based on the type of preservation process applied to it:

1. Highly perishable, no preservation process (such as fresh poultry) with a quality retention time of 1–3 days
2. Semiperishable, lightly processed (such as pasteurized milk) with a refrigerated quality retention time of 1–3 weeks
3. Semishelf-stable, two or more preservation processes used (the hurdles concept), such as vacuum-packaged cooked meat products, with a quality retention time from 1 to 4 months
4. Shelf-stable, highly processed foods, such as canned vegetables or dried milk products with a quality retention time exceeding 1 year

Thus, the processing or lack of processing that the food receives significantly influences the type of bacterial spoilage that occurs in foods. By developing and understanding the factors affecting the growth of bacteria, such as the chemical, physical, and compositional properties of food and the processing applied to the food, it is possible to predict with some reliability the type of bacterial spoilage that may occur in food. (*See* **Canning**: Principles; **Drying**: Theory of Air-drying.)

The Spoilage of Food by Bacteria

Bacterial spoilage of food occurs when a number of factors are in place:

1. The food must be contaminated with spoilage bacteria
2. The food must be suitable for growth of the contaminating bacteria
3. The environment associated with the food must support microbial growth
4. The bacteria must grow and produce metabolites which 'spoil' the food
5. There must be sufficient time for the bacteria to grow

Control of these five factors will markedly influence the growth of bacteria in food and the resultant spoilage.

Source of Bacteria in Food

Bacteria come into contact with or contaminate food from several sources. Food obtained from plants that is consumed by humans is in direct contact with soil. Fertile soil will contain up to 10^9 microbes per gram of soil. Consequently, foods that grow in or on the soil will be contaminated with significant numbers of bacteria. Animals used as food for humans are contaminated on the outside by soil and manure bacteria and internally by bacteria associated with the digestive system of the animal. When slaughtered, the flesh becomes contaminated with the internal bacteria as well as the external ones. Foods obtained from marine sources are contaminated by bacteria from the water in which they live and by bacteria in their digestive system.

Animal, plant and marine foods have native or indigenous microflora associated with them. In general, bacteria on the exterior of these foods are usually aerobic and frequently psychrotrophic, whereas, bacteria in the interior of the animal, plant, or marine food will be obligate or facultative anaerobes. The interior of these food sources will have reduced E_h values or a negative oxidation reduction potential, creating anaerobic conditions, which encourages the development of these organisms. Regardless of the source of the organisms, under the right conditions all are capable of causing food spoilage.

Food is also contaminated with bacteria from people who handle the food. These bacteria are usually mesophilic and may occasionally be pathogenic. A primary source of contamination of food with spoilage bacteria is the equipment used to handle and process the food. If the equipment is not clean, microcolonies, called biofilms, composed of surface dirt and bacteria will develop and consequently millions of bacteria will be present on the surface: when the food comes in contact with the biofilms on the surface they can be transferred to the food. This concept of bacteria transfer to foods from biofilms is referred to as the biotransfer potential. Control of direct human contact with the food and proper cleaning and sanitizing of food contact surfaces and nonfood contact surfaces are critical in preventing bacterial contamination of foods. (*See* **Cleaning Procedures in the Factory**: Overall Approach.)

Bacterial Food Spoilage Based on Preservation Processes

Highly Perishable Foods

Highly perishable foods are those that have been harvested or slaughtered and are utilized with little or no further processing to prevent bacterial spoilage. This category includes, but is not limited to, the following fresh foods: raw vegetables, raw fruits, raw milk, fish, poultry, and red meats. Of these food groups, fresh raw fruits are the least susceptible to bacterial spoilage since the pH of the fruits retards bacterial growth. The environment in which the food is maintained affects bacterial spoilage of these foods. Under low-temperature storage, between 0 °C and 7 °C, the primary bacterial spoilage is caused by psychrotrophic bacteria. These organisms are able to grow slowly at low temperatures; they have optimum growth temperatures in the mesophilic range and could also cause spoilage of these foods at higher temperatures. The majority of these bacteria are in the family Pseudomonaceae and are species in the genera *Pseudomonas, Xanthomonas, Gluconobacteria, Achromobacter, Flavorbacterium*, and *Alcaligenes*. Growth of these bacteria in highly perishable foods results in a variety of sensory defects (off-flavors – putrid, rancid, bitter, etc. – formation of slime, color changes, or strong odors).

The temperature of raw unprocessed foods, in essence, selects the type of bacteria that will grow and spoil the food. If these foods are stored at ambient temperatures of 18–43 °C, mesophilic bacteria of many types will grow and spoil the food. Species in the genera *Clostridium, Bacillus, Erwina, Streptococcus, Lactobacillus, Escherichia, Proteus, Enterobacter*, and many others, will grow and cause spoilage of the food.

It should be clear from the discussion up to this point that many different types of bacteria are able to grow on raw, unprocessed foods. Even refrigeration will not stop bacterial spoilage of these foods. The identification of genus and species of the bacteria causing food spoilage is not critical to preventing food spoilage; however, it may be useful to identify the bacteria if the source of the spoilage organisms is important. What is critical is that bacterial spoilage of food is recognized and that appropriate steps are taken to control or prevent the spoilage. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs; **Fish**: Spoilage of Seafood; **Meat**: Preservation.)

Food is processed to prevent spoilage. As the intensity of the preservation process increases, the types of bacterial spoilage are changed or eliminated. Spoilage of the other three categories of processed foods reflects these changes.

Semiperishable or Lightly Processed Foods

Semiperishable or lightly processed foods are subject to much the same type of spoilage as the unprocessed or perishable food described above. The preservation

processes used with this type of food are usually a mild heat treatment coupled with refrigerated storage, below 7 °C. Pasteurized refrigerated dairy products or pasteurized refrigerated egg products are good examples of lightly processed foods. The heat treatment used with these foods will usually destroy psychrotrophic bacteria and nonspore-forming mesophilic bacteria, but the handling of the foods after heat processing usually results in contamination of these products with spoilage-type bacteria. Such spoilage bacteria have been found in unclean equipment, moisture droplets on the equipment, and in liquid drain traps. During subsequent refrigerated storage, the psychrotrophic bacteria will grow and, if storage time is long enough, spoilage will result. The same genera given above for the raw or unprocessed foods can be involved in the spoilage of the lightly processed foods. Foods that have received this type of processing will usually maintain desired quality attributes for 1–3 weeks. (*See* **Heat Treatment**: Chemical and Microbiological Changes; **Pasteurization**: Principles.)

Semishelf-stable Foods

Semishelf-stable foods are preserved utilizing more than one preservation process. This process has been referred to as the hurdles concept. The hypothesis of the hurdles concept is that each less than lethal preservation process becomes one more hurdle for the bacteria to overcome before they can initiate growth in the food. These types of foods are becoming popular as they best reflect the quality attributes of fresh foods. They are often referred to as 'fresh-like' or 'chef-like,' implying a freshly prepared product, which they are not. Foods that have been processed using the hurdles concept will usually maintain desired quality attributes for anywhere from 1 to 6 months.

This concept might best be explained by following a product through such a series of processes or hurdles. For example, in the processing of cooked beef products, such as roast beef, several steps are involved. Usually the processor will receive 'box beef' which would be containers of the particular cut of meat to be used. These cuts were initially processed in another facility and shipped by refrigerated transport. The first step in the processing of the beef roasts involves trimming and shaping the meat piece. This removes some surface contamination but does little to extend the shelf-life. The second step might involve massaging the meat and adding salt and other seasonings. The salt and seasoning will have minimal effect on extension of shelf-life, unless the salt concentration is above 4 or 5%. If sodium nitrite is used in the seasonings, some inhibition of spore germination may result. This would be the first hurdle.

The seasoned, massaged meat is next put into heavy polyethylene cook bags and slowly cooked in water to the desired internal temperature. This process usually takes several hours and should result in the destruction of psychrotrophic and mesophilic spoilage bacteria, the most common types of bacteria that might spoil this product. The cooking process is a major hurdle as it effectively destroys most spoilage organisms.

The cooked meat is cooled to less than 7 °C and the cook bag removed. It is at this point in the process that recontamination with psychrotrophic and mesophilic spoilage bacteria can occur. The meat is cut into pieces of a size suitable for resale, rebagged in oxygen impermeable polyethylene bags and vacuum-sealed. The vacuum package changes the oxidation reduction potential in the package and prevents the growth of aerobic psychrotrophic bacteria. The finished package should be maintained at low temperature – less than 2 °C – until utilized.

A cooked beef product, processed as described, should have a shelf-life of at least 60 days, if not 120 days. It is not shelf-stable, as spoilage will occur – usually, thermoduric, psychrotrophic, facultative; heterofermentative lactobacilli will cause spoilage which becomes apparent by the swelling of the bag caused by the gas produced and acid flavor of the product.

A further look at each step will help to form an understanding of how the hurdle process achieves better maintenance of quality attributes in the food. (*See* **Preservation of Food; Chilled Storage**: Packaging Under Vacuum.)

The cooking step will kill the potential psychrotrophic spoilage bacteria, but others, such as thermoduric bacteria and spore-forming bacteria, will survive the heat process. The addition of salt and nitrite to the meat will deter the growth of spore-forming bacteria, but will have little effect on nonspore-forming bacteria. Vacuum packaging changes the E_h from positive to negative, which inhibits the outgrowth of psychrotrophic aerobic spoilers but allows the growth of anaerobic and facultative anaerobic bacteria. The endresult is that the meat will eventually spoil. In other words, it becomes esthetically unacceptable as a result of the growth of thermoduric, psychrotrophic, facultative anaerobic bacteria that grow slowly at refrigeration temperatures.

Shelf-stable Foods

Shelf-stable foods have undergone preservation processes that have produced foods that are considered

to be 'commercially sterile,' i.e., will not spoil or cause disease under normal conditions of handling and distribution. These foods are not completely sterile and are subject to some type of bacterial spoilage. For example, aciduric and thermoduric bacteria may spoil foods rendered shelf-stable by reduction of the pH to less than 4.6 and application of a pasteurization heat treatment. Certain species of *Lactobacillus*, *Clostridium*, and *Bacillus* are capable of surviving a pasteurization heat process and, under the right conditions, will grow in high-acid foods. It is generally recognized that high-acid foods are more susceptible to spoilage by yeasts and molds but, as indicated above, some bacteria will grow and spoil even heat-processed acid foods.

Canned foods are given a severe heat process, which is primarily designed to destroy spores of *Clostridium botulinum*. Other spore-forming bacteria such as *C. sporogenes* PA 3679 and *Bacillus stearothermophilus* will not be destroyed by a thermal process designed to control *C. botulinum* and subsequently may grow in canned foods. Canned food spoilage, referred to as 'flat-sour' spoilage, is caused by the outgrowth of *B. stearothermophilus*, which produces acid but no gas in the canned food. Other *Bacillus* may also survive minimal heat process and cause spoilage of canned foods.

The outgrowth of spores of *C. sporogenes* in canned foods produces considerable amounts of noxious gas and may lead to rupture of the cans. Canned food spoilage will also occur if the food has been underprocessed, i.e., not given sufficient heat treatment to produce a commercially sterile product. Spore-forming bacteria which have survived the process usually cause canned food spoilage of this type. This type of spoilage is apparent from the sour or putrid odor and frothy or viscous appearance of the spoiled canned food. (*See* **Canning**: Quality Changes During Canning.)

Failure of the double seam in canned foods results in what is termed 'leaker spoilage.' This type of spoilage is characterized by the presence of several different types of bacteria in the food. These bacteria may cross the defective double seam from the cooling water, dirty conveyor system, can unscramblers, or other can-handling equipment. Foods thermally processed in glass containers will spoil in much the same manner if the closure mechanism used on the glass jar is defective or does not seal properly.

Dried foods are also considered to be shelf-stable or 'commercially sterile.' The available water in dry food systems is less than 0.80 and, as a result, they are not subject to spoilage by bacteria as long as the available water remains low. Yeasts and molds are more tolerant to low available water and may spoil these type of foods if the a_w is more than 0.60 but less than 0.80. Foods preserved by controlling water activity are more frequently 'spoiled' by the action of enzymes than by direct bacterial growth in the foods. (*See* **Drying**: Theory of Air-drying.)

The spoilage of food by bacteria is preventable if the food is processed and handled properly. The preservation processes used affect the probability and type of spoilage that will occur. The greater the number of hurdles that the bacteria have to overcome to grow, the longer the time for spoilage to occur. Contamination with spoilage bacteria can occur at any point in the system that transfers food from the point of initial production to final consumption. Constant attention to the prevention of bacterial contamination of food at each of these process steps will insure a continued safe and wholesome food supply.

Fungi in Food – An Overview

L B Bullerman, University of Nebraska-Lincoln, Lincoln, NE, USA

Introduction

The kingdom Fungi includes eukaryotic organisms which range from microscopic, unicellular yeasts, to multicellular molds, to the macroscopic mushrooms. Fungi are heterotrophic organisms which obtain food by absorption and require organic compounds for energy and carbon. In terms of food safety and food spoilage by fungi, we are concerned primarily with molds (microfungi) and yeasts. (*See* **Mushrooms and Truffles:** Classification and Morphology.)

Molds

Molds are eukaryotic, multicellular, multinucleate, filamentous organisms that grow as compact masses of intertwining, branching, hairlike filaments. The total mold organism can frequently grow to macroscopic size and be visible to the unaided eye. Thus, the molds are not true microorganisms, but parts of mold structures are microscopic in size. Molds are sometimes referred to as microfungi because they are much smaller than the so-called macrofungi, such as mushrooms. The individual mold filaments are called hyphae (singular: hypha) and a mass of these branching filaments, forming a mold colony or portion of mold growth, is referred to as a mycelium or (plural) mycelia. The hyphae may be submerged, or growing in a food substrate. The submerged hyphae, also called vegetative hyphae, serve to anchor the mold to the substrate and take up nutrients and water by absorption. In this respect they are not unlike plant roots. Hyphae that grow above the substrate, the visible part of the mold, are called aerial or fertile hyphae. They are called fertile because they give rise to reproductive structures known as conidiophores or sporangiophores which produce millions of spores – conidiospores, or conidia, and sporangiospores, or sporangia.

Conidiospores are produced free by special cells on the ends of conidiophores and are not enclosed in any type of structure. Conidia are microscopic in size, very light-weight, and very dry. The conidia are not easily wetted and are hydrostatic, tending to associate with and behave like dust particles. Thus, these spores are readily spread through the air and are disseminated on air currents to new surfaces and habitats. If the spores settle where conditions are favorable for growth, they rapidly germinate and begin to form a new mold colony. Sporangiospores are spores that are produced in an enclosed, sac-like structure, called a sporangium, at the end of the sporangiophores. These spores are released into the air when the sporangium ruptures. Conidia and sporangiospores are common in the molds found in foods. In addition, individual molds may form other types of spores, such as arthrospores, resulting from fragmentation of septate mycelia, and chlamydospores which result from a thick wall that develops around individual mycelial cells. These spores are all referred to as asexual spores, i.e., they are formed by nonsexual means and without exchange of any genetic material by two different molds. Many of the molds that are important in foods reproduce in this way, without sexual stages in their life cycles, and are known as anamorphs. In older literature these are placed in a group known as the Fungi Imperfecti. These are molds for which the sexual cycles are unknown.

Some of the molds that are important in foods also reproduce by sexual means in addition to asexual means. They form, by sexual processes, other types of spores, including ascospores and zygospores. These are referred to as teleomorphs (perfect molds, or the perfect state in older literature), or the teleomorphic state. Ascospores are usually formed in some type of enclosed, sac-like structure located down in the mycelial mass. These structures are known as asci (singular: ascus). The asci are enclosed in a fruiting body called an ascocarp. An ascocarp that is spherical or flask-shaped and with no opening is known as a cleistothecium. A spherical or flask-shaped ascocarp with an opening (ostiole) is called a perithecium. A saucer or cup-shaped ascocarp that is open is known as an apothecium. A zygospore is formed when the tips of two hyphae come together and their contents fuse. The zygospore develops as a thick-walled structure between the two hyphal tips. All sexual spores result from the fusion of two haploid nuclei.

Occurrence

Molds are ubiquitous organisms, which literally means they are found everywhere. The natural habitat of most molds is the soil, where they grow on and break down decaying vegetable matter. Molds rot wood, leaves, and other organic debris to form humus in the soil. During growth on organic debris, molds form their spores which are readily picked up by air currents and widely disseminated. When there is decaying organic matter in an area, there are often high numbers of mold spores in the atmosphere of the area. Thus most plant materials, including grains and seeds, will have a microflora that includes mold spores. In addition, some grains and seeds

will be colonized by mold while yet in the field, and these too will become a part of the microflora of these products. Many of these molds are capable of growth within the seed under proper conditions. Molds are therefore common contaminants of food and animal feed materials, and occur throughout the environment.

Growth Requirements

Molds can tolerate relatively harsh environments and adapt to more severe stresses than most microorganisms. Molds require less available moisture for growth than bacteria or yeasts and can grow on substrates containing concentrations of sugar or salt that bacteria cannot tolerate. Molds can also grow on drier substrates than bacteria and can survive in dehydrated environments. Molds can tolerate and grow in high concentrations of acid and over a wide pH range (2.0–9.0). Since molds are slower-growing than bacteria and yeasts, the dry or acidic conditions that inhibit the growth of these organisms, especially bacteria, flavor the growth of molds. If competitive growth of bacteria is eliminated by either lower moisture or low pH, mold growth will be enhanced. Thus mold growth in grains and animal feeds with lowered moisture content may sometimes occur if the moisture content is not too low. Some molds can obtain moisture from the atmosphere, as well as the respiration of other organisms, such as insects, and begin to grow at even low moisture levels. Once mold growth begins it will probably continue, being fed by moisture released through its own respiration.

Most molds are highly aerobic, i.e., they require oxygen for growth, and an abundant supply of oxygen enhances growth. Carbon dioxide, on the other hand, inhibits mold growth, and if the carbon dioxide concentration becomes high enough it can totally prevent mold growth. Some molds are better adapted than others to growth in elevated concentrations of carbon dioxide. Molds also grow over a wide temperature range, but most have their optimum growth temperatures between 25 °C and 35 °C. Mold growth is especially rapid under conditions of high temperatures and high humidity. Some molds can grow at temperatures as low as 0–5 °C and a few species can even carry on growth processes just below freezing. A few molds can grow at extremely high temperatures, even above 60 °C.

Molds have simple nutritional requirements. They can utilize a range of organic substrates, from simple to complex, requiring primarily a source of carbon and simple inorganic nitrogen. Molds are capable of synthesizing their own vitamins and growth factors. Molds can readily utilize simple carbon sources such as glucose and other sugars, as well as complex carbohydrates such as starch and cellulose. Molds can also utilize inorganic nitrogen in the form of nitrate and ammonium salts, and organic nitrogen such as that found in proteins, amino acids, and nucleic acids. Because molds possess a vast array of hydrolytic enzymes, they are capable of dissimilating and utilizing a very wide array of substrates. Thus most organic materials are subject to deterioration by molds if the conditions of moisture and temperature are not limiting.

Molds and Food Spoilage

Molds are very efficient in converting nutrients into cell material and mycelial biomass. If a substrate is composed of nutrients in moderate amounts, most of the substrate will be converted to cell biomass and products of primary metabolism for essential life processes. If nutrients are available in large or excessive amounts, a variety of breakdown products may be excreted into the medium, and storage reserves of carbohydrates and lipids may accumulate in the mycelia. At some point in the life cycle of the mold, when growth slows and conditions are appropriate, the mold may convert these carbohydrates and lipids to alcohols, organic acids, and complex heterocyclic biochemical compounds. This process is known as secondary metabolism since the metabolites or compounds produced have no apparent purpose in essential life processes. These 'secondary metabolites' may thus accumulate in the substrate, causing off-flavors and other problems, including toxicity. The filamentous hyphae of the molds are well adapted to growth over surfaces and through or into porous and solid substrates. The hyphae provide a large surface area relative to the mold biomass to excrete enzymes that break the substrate down into available nutrients, which in turn are absorbed back into the hyphae. The nutrients may be transported to the actively growing hyphal tips, where they are utilized for energy and to produce primary metabolites and form new active cytoplasm. The nutrients may also be used for maintenance of cellular activities, or be converted to cellular storage reserves and secondary metabolites.

As a result of the metabolic activity of molds in a substrate, a number of consequences – desirable or undesirable – can occur. If the substrate is a food or an animal feed, the biochemical activities of the mold may result in deterioration and spoilage as the substrate is broken down, and undesirable byproducts accumulate, causing off-flavors, loss of dry matter and nutrients, as well as toxicity and other problems. Particularly in drier substrates, such as grains and

animal feeds, such deterioration will result in spoilage. Some of the secondary metabolites of certain molds are compounds that are toxic to humans and animals. These toxic substances are collectively known as 'mycotoxins.' (*See* **Mycotoxins**: Occurrence and Determination.)

Control of Mold Through Processing and Storage

Mold growth is affected by a number of factors, including atmosphere, moisture content, relative humidity, temperature, microbial competition, and chemicals in the substrate. Since molds are very tolerant of acidic conditions, and have few nutritional requirements, the pH and nutrient content of a substrate cannot be used to affect to any significant extent the ability of molds to grow.

Moisture and temperature, however, are probably the two most critical factors affecting mold growth that can be used as control factors, and it is difficult to discuss one without the other. The moisture content of a substrate is less meaningful, in terms of understanding the effect of water on mold growth, than water activity (a_w). Water activity has taken the place of moisture as the most useful expression of the availability of water for microbial growth. The a_w of a substrate is defined as the ratio of the vapor pressure of the substrate to that of pure water. (*See* **Water Activity**: Effect on Food Stability.)

The a_w of pure water is 1.0; therefore the a_w of any substrate will be less than 1.0. The a_w is a measure of the amount of water not bound by the substrate, and which is available to microorganisms for their growth. The lower the a_w, the less water is available to molds for growth. Moreover, the a_w of the substrate is affected by the relative humidity (RH) of the environment in which the substrate is found. RH refers to the moisture in the atmosphere surrounding the substrate, and a_w is a property of the substrate and its moisture content. In a closed system, the a_w of a substrate and the RH of the atmosphere surrounding it will be in equilibrium. Under equilibrium conditions, the a_w of a substrate will be equal to the RH of the atmosphere surrounding it divided by 100. Thus the final moisture content of a substrate, i.e., food or feed, will depend upon the substrate reaching equilibrium with the atmospheric RH to which it is exposed.

The concept of a_w is important in understanding how molds may grow in a seemingly dry substrate. Conditions such as high humidity or a microenvironment affected by insect respiration can cause the a_w of a small portion of a substrate to rise to a level that may permit mold growth. Once growth has been initiated, respiration of the mold will also contribute to increasing a_w of the surrounding substrate. In this way the mold growth may become a spreading, self-perpetuating process, with the pocket of growth becoming ever larger. This is what causes 'hot spots' in a mass of stored grain or animal feed.

The minimum a_w at which microorganisms associated with foods and feeds will grow have been studied extensively. The minimum a_w for the general groups of microorganisms are given in Table 1. Halophilic bacteria, xerophilic molds, and osmophilic yeasts are adapted to growth at very low a_w. Most spoilage and toxigenic molds grow over the a_w range 0.72–0.94. Mold growth is completely inhibited at a_w values below 0.65. This would be equivalent to moisture contents well below 20%.

Temperature and a_w interact to affect microbial growth. If temperature is near the optimum growth temperature of a mold, the range of a_w over which the mold can grow will be greatest, and at any temperature the ability of a mold to grow will be reduced as the a_w is reduced. Conversely, if the a_w of a substrate is high, molds will be able to grow over a wider range of temperatures and will be able to grow at lower temperatures.

Atmospheric gases, other than moisture, also affect mold growth. Molds require oxygen to grow, and are inhibited by increasing concentrations of carbon dioxide or decreasing concentrations of oxygen from those found in air. A concentration of 40% carbon dioxide in air depresses fungal growth, but the carbon dioxide level must be increased to more than 90% to inhibit growth completely. Likewise, reducing the oxygen content of air to less than 2.0% depresses mold growth, but to prevent growth the oxygen level must be reduced to 0.2%. Complete replacement of air with a nitrogen atmosphere will also inhibit mold growth. Controlled-atmosphere (CA) storage of commodities has been studied as a measure of preventing mold deterioration. Both the carbon dioxide and oxygen concentrations are usually controlled. Controlled atmosphere with 10% carbon dioxide and 2.0% oxygen greatly increases the time

Table 1 Minimum water activity (a_w) requirements of microorganisms

Microorganism	*Minimum* a_w
Most spoilage bacteria	0.90
Most spoilage yeasts	0.88
Most spoilage molds	0.80
Halophilic bacteria	0.75
Xerophilic molds	0.65
Osmophilic yeasts	0.60

for mold growth to begin and reduces the amount of growth. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

The presence of other microorganisms tends to restrict fungal growth if conditions are favorable for the growth of the other microorganisms. Bacteria and yeasts are capable of more rapid growth than molds and tend to overgrow molds. The rapid growth of bacteria on fresh meat, for example, is the probable reason for the fact that molds are rarely seen growing on these substrates. Lactic acid bacteria have been shown to be competitive with molds, and to suppress mycotoxin production. Molds are also competitive with each other, and under certain conditions one mold may prevent the growth of another mold or may alter its growth patterns and metabolism. Competition by bacteria and yeasts and between mold species is affected by the microenvironment of the substrate. The a_w, RH, and temperature all have an impact on competition and growth and will determine which organism or group of organisms will predominate. (*See* **Lactic Acid Bacteria**.)

Mold growth is also affected by chemicals in the substrate which have antimicrobial or antifungal properties. These chemicals may be naturally occurring compounds in the substrate, or they may be added for the purpose of preservation. Naturally occurring substrates, such as benzoic acid in cranberries, and components of essential oils in herbs and spices, may restrict or prevent fungal growth. Mold growth may also be prevented in foods and feeds by the addition of antifungal or antimycotic chemicals. These substances may be organic acids such as sorbic, propionic, and benzoic acids, among others, or salts of these acids, antibiotics such as natamycin, chemical dyes such as gentian violet in the case of poultry feeds, antioxidants, or combinations of these and various other chemicals. In most cases the levels of the chemicals used are such that they are fungistatic, i.e., they prevent or delay mold growth, but do not kill or completely inhibit growth for an indefinite period of time. Molds are not very heat-resistant and are readily killed by most thermal processes, such as cooking, baking, etc. (*See* **Essential Oils**: Properties and Uses; **Fungicides** ; **Preservation of Food**.)

Classification and Specific Genera of Molds

There are about 100 000 different species of fungi, although relatively few of these are directly involved in the deterioration of food and agricultural products, and/or mycotoxin production in these products. Genera that are of particular interest because of their involvement in deterioration of foods and agricultural commodities, and potential mycotoxin production are as follows: *Aspergillus, Penicillium, Fusarium, Alternaria, Trichothecium* and *Trichoderma*. Other genera, important primarily as spoilage organisms, include *Rhizopus, Mucor*, and *Cladosporium*. The most significant mycotoxin-producing molds are considered to be numerous species in the genera *Aspergillus, Penicillium*, and *Fusarium. Alternaria, Trichothecium*, and *Trichoderma* contain a few individually toxic species that are important. Descriptions of nine of the most common genera of molds found in foods are given below. The first eight are septate molds, i.e., the hyphae have cross-walls, while the last one is representative of nonseptate molds, in which the hyphae do not have cross-walls.

Aspergillus

Aspergillus is a very important genus of molds, very widespread, with species involved in food spoilage, mycotoxin production, and fermentations. The *A. flavus–oryzae* group contains the species *A. flavus* and *A. parasiticus*, which can produce aflatoxins. This group also contains *A. oryzae*, which is nontoxic and is used in oriental food fermentations to produce items such as soya sauce and miso. The *A. ochraceus* group includes *A. ochraceus* and other species that are capable of producing ochratoxins and penicillic acid. The *A. niger* group is widespread, and often involved in food spoilage. *A. niger* is now known also to be a producer of ochratoxin. What used to be called the *A. glaucus* group is now known as the anamorph of the genus *Eurotium*, which includes *E. glaucus* and *E. repens*. These are xerotolerant molds that can grow on foods that are very dry or contain high concentrations of sugar or salt. The aspergilli reproduce by producing conidia, which are produced on a conidiophore that arises from a special cell in the mycelium called a foot cell (**Figure 1**). The entire conidiophore appears to be a single cell that grows upright and terminates in a globose, elliptical, or clavate swelling known as a vesicle. Arising from the vesicle are bottle-shaped structures called sterigma (phialides) in which the conidia are produced. The conidia are pushed out of the end of the sterigma and remain loosely attached to one another, forming chains. The colors of the conidia of the aspergilli are characteristic for different groups and species, and this is helpful in recognizing the different groups. Spores of the *A. flavus–oryzae* group are different shades of olive-green to yellow-green; spores of the *A. niger* group are jet-black to brownish-black to purple-brown; spores of the *A. ochraceus* group range from buff-tan to yellow in color. *E. glaucus* and *E. repens* possess conidia that are some shade of

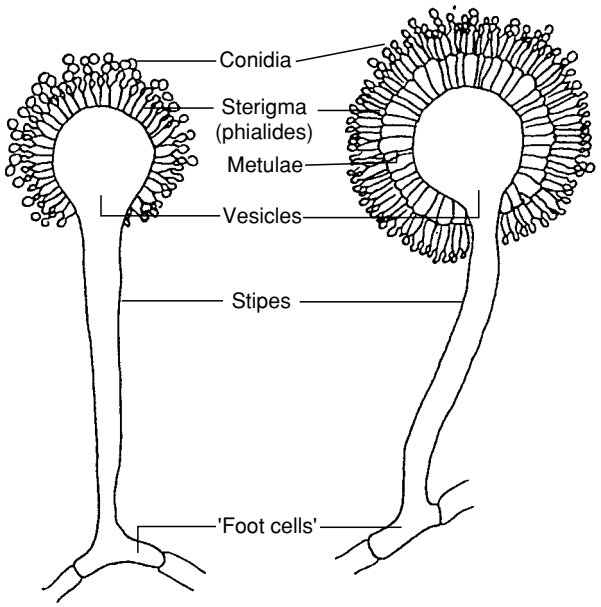

Figure 1 Conidiophores characteristic of *Aspergillus* species, showing a single layer of phialides or sterigma (uniseriate) and double layer of cells, phialides and metulae (biseriate). green, but also produce brightly colored yellow to reddish cleistothecia. Many *Aspergillus* species also produce sclerotia, which are macroscopic, hard, dense masses of hyphae that appear as small, dark-colored masses in the mycelia. *Aspergillus* species often occur in grains, nuts, oil seeds, and on certain types of dry cured meat.

Penicillium

Penicillium is also a widespread genus that is important in foods. *Penicillium* species contaminate a wide variety of foods and are capable of growing at refrigeration temperatures. Thus they often spoil refrigerated foods, especially cheese. They are also common on grains, breads, cakes, fruits, preserves, cured and aged hams and sausages, and in the spoilage of certain fruits. The penicillia produce conidia from conidiophores that branch near the apex, forming a brush-like structure or penicillus (Figure 2). At the apex of the conidiophore are somewhat enlarged cells known as metulae. From the metulae arise the sterigma or phialides. It is in these structures that the conidia are produced and pushed out in chains. The conidia of the penicillia are colored, but mostly in shades of gray to blue to blue-green. The colors are not as distinctive for the various species as for the aspergilli, and are therefore not as helpful in the identification of species. Some species form ascospores in cleistothecia and are also placed in the teleomorphic genera of *Talaromyces* or *Eupenicillium*. There are a number of important *Penicillium* species. *P. verrucosum*, *P. viridicatum*, and *P. aurantiogriseum* are common in grains and some can also occur on cheese. They can produce a number of mycotoxins, including ochratoxin, penicillic acid, and others. *P. martensii*, a synonym for *P. aurantiogriseum*, has been found growing in high-moisture corn and can produce penicillic acid. *P. expansum* causes rots of fruits, especially apples, and produces patulin. *P. digitatum*, with green-colored conidia, causes soft rot of citrus fruit, usually at ambient temperatures, whereas *P. italicum*, which has blue spores, causes soft rot of citrus at refrigerated temperatures. *P. roqueforti* has blueish-colored conidia and is used in the ripening of blue-veined cheeses. However, wild types of *P. roqueforti* often occur in dairy environments and also contaminate other types of cheeses, such as Cheddar and Swiss, and grow and cause spoilage under refrigerated storage. *P. camemberti* produces grayish spores, and is used for surface ripening of Camembert and Brie cheeses. Many other *Penicillium* species are known to produce various toxic substances, many of which also have antibiotic properties, but appear to be too toxic for therapeutic use. The most famous antibiotic, penicillin, which has been used to cure countless bacterial infections, is produced by *P. notatum*. (*See* **Cheeses: Chemistry and Microbiology of Maturation.**)

Fusarium

Fusarium species are capable of growing on stored foods, but more commonly occur in the field, where they infect grain plants and may also invade the grain itself. *Fusarium* colonies on agar appear to be cottony owing to dense growth of white hyphae. They produce various pigments, with colors ranging from white, through pink, salmon-pink and carmine red, to purple. Some species also produce yellow and brown pigments. *Fusarium* species produce septate, curved to crescent or sickle-shaped conidia, called macroconidia which are, to some extent, characteristic of species (Figure 3). The macroconidia are slightly curved and tapered towards each end (fusiform) and are sometimes also referred to as boat-shaped. In some species the apical cell of the macroconidium is elongated and the basal cell, where the conidium was attached, is shaped like a foot cell. In addition, some species also produce smaller, one- or two-celled conidia known as microconidia. The microconidia may be pear-shaped (pyriform), fusiform or ovoid, and straight or curved.

Fusarium species are widely distributed throughout the world, in both temperate and tropical regions. They are found in the soil, especially cultivated soils, and actively degrade organic matter in the soil. Many species are also considered to be plant pathogens, capable of causing a range of plant diseases such as root and stem rots, blights, and wilts. Two plant diseases that occur in the field, but which affect grain quality and safety, are wheat scab, also called *Fusarium* head blight, and ear rot in corn (maize). One of the species involved in both of these conditions is *F. graminearum*, which invades the grain (wheat or corn) in the field and produces deoxynivalenol (DON), also called vomitoxin. *F. graminearum* is most common in North America, whereas a closely related species, *F. culmorum*, is more common in Europe. *F. graminearum* and *F. culmorum* also produce zearalenone. *F. verticillioides (moniliforme)* produces fumonisins and other metabolites in corn, as does *F. proliferatum*. *F. proliferatum* and *F. subglutinans* also produce moniliformin and other compounds. Other species can also invade grains and produce other toxins. *Fusarium* species can also invade fresh fruits and vegetables during storage, causing various rots and spoilage.

Some of the *Fusarium* species have a sexual stage and are placed in the teleomorphic genera of *Gibberella, Nectria, Calonectria*, and *Plectoshaerella*. For example, the telemorph of *F. graminearum* is *Gibberella zeae*. *Fusarium* species are very important as plant pathogens and as potential mycotoxin-producing organisms. They can therefore cause both spoilage and safety problems in foods, especially cereal grains and foods containing cereal products. (*See* **Cereals:** Dietary Importance.)

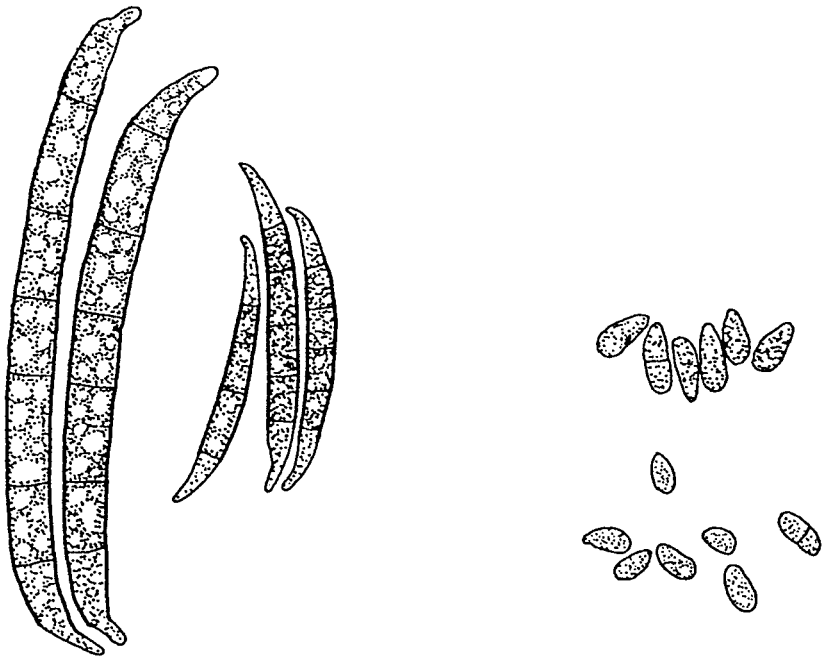

Figure 3 Macro- and microconidia typical of the genus *Fusarium*. Reproduced from Spoilage: Fungi in Food – An Overview. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Alternaria

Species of *Alternaria* occur worldwide on many foods and plant materials. They have septate hyphae and appear to be dark, gray-green in color, and almost black on the reverse side of colonies growing on agar. They produce septate conidia which are also dark-colored (Figure 4). The septa are both transverse and longitudinal, and spores are oblong in shape, sometimes with an elongated apical cell. The spores are produced in chains. *Alternaria* can cause spoilage of a variety of foods, including tomatoes and fresh vegetables, such as bell peppers. *Alternaria* species have been found in the core area of apples, in nuts, including peanuts, hazelnuts, and pecans, in grains such as wheat and sorghum, and in cold-stored meat and spices. *Alternaria* are capable of growing at low temperatures on refrigerated foods. Common species include *A. alternata*, which is considered synonymous with *A. tenuis*, and *A. tenuissima*. *Alternaria* species are capable of producing several mycotoxins and thus present both food spoilage and potential safety hazards.

Trichothecium

Trichothecium is a common genus of mold which occurs throughout the world. A common species is *T. roseum*, which is pink in color, and has been found growing on various fruits and vegetables, as well as cereal grains, such as barley, wheat, and corn, and cereal products such as flour. It has also been found on beans, pecans, filberts, and meat. *Trichothecium* species produce clusters of two-celled or single-septate conidia that are elliptical to pear-shaped. Some strains of *Trichothecium* have been shown to produce trichothecenes.

Trichoderma

Two of the most common species of *Trichoderma* are *T. viride* and *T. harzianum*. *Trichoderma* colonies are bright green. *Trichoderma* contaminate many food products, including stored grains such as barley, wheat, and oats, nuts such as peanuts and pecans, and various fruits and vegetables, such as tomatoes, sweet potatoes, and citrus fruit.

Cladosporium

Cladosporium has dark mycelia which may be brown to blackish-brown or gray-green in color. The reverse side of a colony of *Cladosporium* on agar is very dark greenish-black or blue-black. *Cladosporium* species produce many one-celled conidia, but two- and three-celled forms are also common. Two common species are *C. cladosporioides* and *C. herbarum*. *Cladosporium* species, which can grow at low temperatures, tend to be slow-growing and form black spots on foods. *Cladosporium* species have been isolated from cereal grains, peanuts, fruits, and refrigerated meat, particularly beef. *Cladosporium* is very common and can grow under refrigerated storage conditions. The main consequence of *Cladosporium* species in foods is spoilage and discoloration.

Geotrichum

Geotrichum has septate mycelia which readily fragment into arthrospores (Figure 5), which are the organism's primary means of reproduction. The only species that is significant in foods is *G. candidum*; other names for this organism are *Oidium lactis* and *Oospora lactis*; it produces ascospores, and the

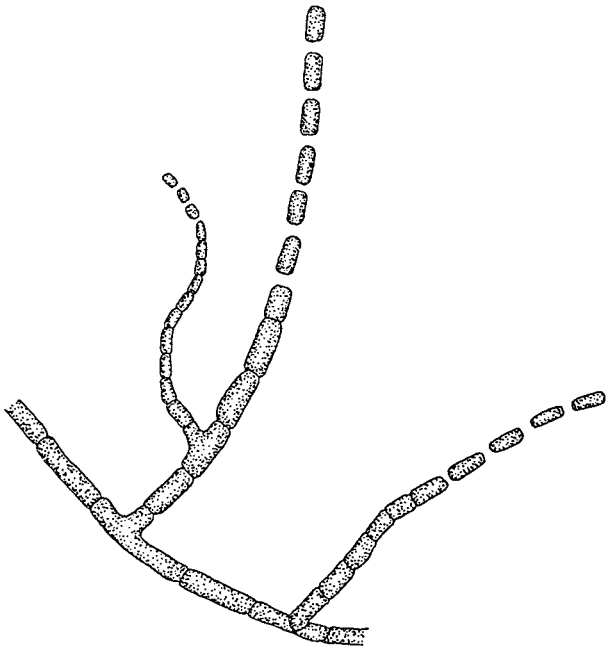

Figure 5 Arthrospores typical of *Geotrichum*. Reproduced from Spoilage: Fungi in Food – An Overview. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

telemorphic state is known as *Endomyces geotrichum*. *G. candidum* is referred to as a yeast-like fungus because it exhibits a dimorphic form and readily fragments into arthrospores, which appear to be single-celled. In addition, colonies of this organism can be white, soft, creamy, and yeast-like in appearance. *G. candidum* is a problem on food-processing equipment, particularly in vegetable-processing plants, and is referred to as 'machinery mold.' Unclean equipment provides a favorable environment for rapid growth of this organism. It attacks citrus fruits, as well as other fruits. It is able to infect fruits mainly through injuries to the skin, as well as growing on overripe fruit. *G. candidum* has also been obtained from cheese, meats, and frozen foods, particularly vegetables.

Rhizopus

Rhizopus differs from the molds previously described, because it is nonseptate and produces sporangiospores rather than conidia. It is a very-fast-growing, spreading type of mold which has white mycelia and black sporangia. *Rhizopus* species form rhizoids at the base of the sporangiophores, and columella in the sporangium (Figure 6). Young sporangia are white before turning black with age. Probably the most common of the *Rhizopus* species is *R. stolonifer*, the so-called bread mold. Besides bread, *Rhizopus* causes spoilage of strawberries, other berries, fruits, and vegetables. *Rhizopus* species have also been isolated from cereal grains, nuts, and meat. *R. oligosporus* is used in making tempeh and certain other mold-fermented foods. *Rhizopus* is placed in the taxonomic order Mucorales and is somewhat typical, and probably the most common genus of that order to contaminate foods. Other genera in the order Mucorales which are nonseptate and produce sporangiospores are *Absidia*, *Mucor*, *Rhizomucor*, *Syncephalastrum*, and *Thamnidium*. All of the Mucorales genera that contaminate food are found in the family Mucoraceae. These genera are sometimes referred to as mucoraceous fungi. They are a part of the

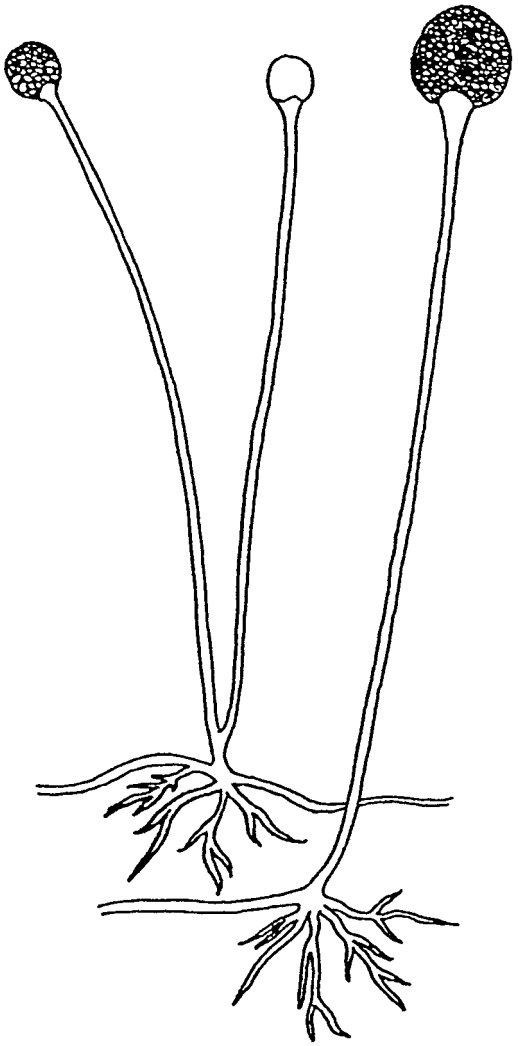

Figure 6 Sporangiospore typical of *Rhizopus* and other mucoraceous fungi. Reproduced from Spoilage: Fungi in Food – An Overview. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

class Zygomycetes and form zygospores by sexual processes and chlamydospores (Figure 7). They require high-moisture conditions for growth.

For more detailed descriptions of these and other genera of molds, refer to the references given in the Further Reading Section at the end of this article.

Recognizing Molds

Molds are recognized primarily as visible fuzzy, cottony, or colored growth on the surfaces of substrates such as foods or other organic materials. In grains, seeds, and animal feeds, however, such growth may not always be visible in this manner. Internal mold contamination and growth in nuts, seeds, and grains may not always be visible as filamentous growth. However, mold growth in nuts, whole grains or seeds often results in discoloration and altered appearance. In corn (including popcorn), for example, invasion and growth of mold in the germ area may produce darkened, greenish- or blueish-colored germ areas in affected kernels. When this growth is attributable to certain blue-colored *Aspergillus* or *Penicillium* species, and a blueish line appears in the germ area, the condition is known as 'blue eye.' In other grains, such as wheat, white to pinkish discolored and shrivelled kernels may indicate mold invasion. Likewise, with nuts, shrivelled or misshapen kernels may be caused by mold, although that is not the only cause of such problems.

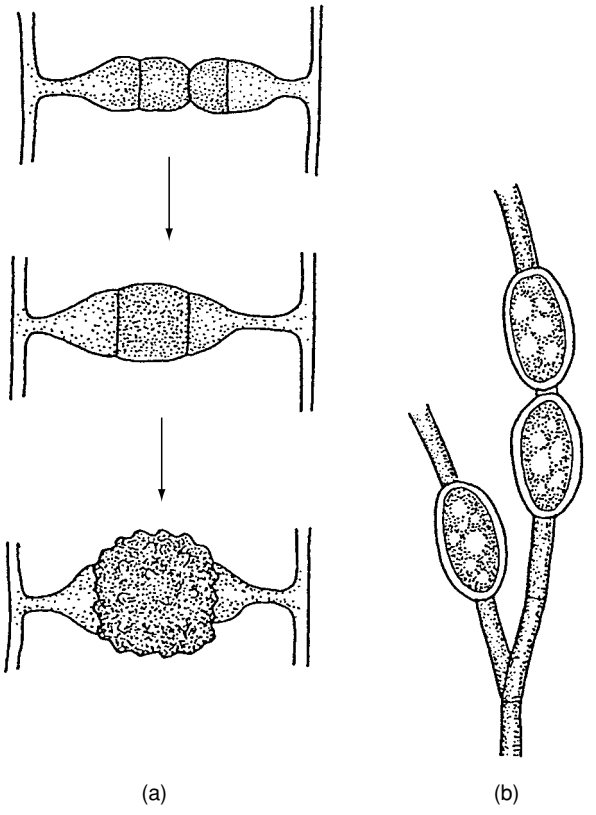

Figure 7 (*a*) Zygospore and (*b*) chlamydospores. Reproduced from Spoilage: Fungi in Food – An Overview. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Health Implications

Mold deterioration of foods and agricultural commodities is a serious problem worldwide. Besides deterioration of food and feed products by causing damage that reduces quality, grades, and prices, resulting in economic loss, the presence of molds in foods and commodities poses hazards to human and animal health. A serious hazard associated with mold growth in foods and feeds is the possible production of mycotoxins – substances which are toxic and some of which are carcinogenic. (*See* **Aflatoxins**; **Mycotoxins**: Classifications.) Additional hazards arise from the presence of the molds themselves. A wide spectrum of human and animal diseases are attributable to molds, ranging from mycotic abortion to aflatoxin poisoning in animals, and from allergic reactions to life-threatening systemic infections in humans. In recent years, invasive mycoses have become a more frequent and important cause of morbidity and mortality in humans, particularly in individuals who are immunosuppressed as a result of organ transplantation, underlying disease (acquired immune deficiency syndrome or AIDS), chemotherapy, radiation therapy, or age. The environment, including foods, is the source of these molds. Certain occupational niches, such as grain handling and storage, pose additional hazards to agricultural workers through exposure to high levels of mold spores and endotoxins in grain dusts. These dusts may also be a significant source of exposure to mycotoxins. Various lung diseases in grain handlers, farmers, and food-producing animals are associated with molds and grain dust.

Yeasts

Yeasts are single-celled microscopic organisms that are larger than bacteria, and are oval, elliptical, spherical, or elongated into rod shapes. Most yeasts reproduce by a process called budding (Figure 8). Budding is an asexual process in which a bulge (bud) develops on the cell wall, and protoplasm, including replicated nuclear material, fills the bulge. The bulge grows in size and eventually a wall forms between the bulge and the parent cell, forming a new cell. The new cell then separates from the parent cell. Buds may form in

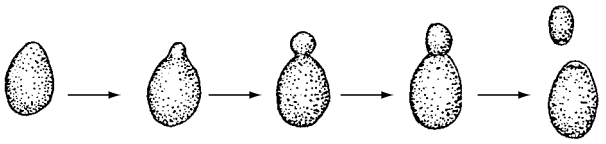

Figure 8 Diagrammatic representation of budding in a typical yeast cell. Reproduced from Spoilage: Fungi in Food – An Overview. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

a polar position or multilaterally. Some yeasts reproduce by binary fission, similar to fission in bacteria, but these are few in number. One yeast reproduces by both fission and budding. So-called true yeasts also reproduce by a sexual process involving conjugation of two cells and the resultant formation of ascospores within the cells. The cell containing ascospores is then known as an ascus. A few yeasts produce ascospores without conjugation, but the resulting ascospores then undergo conjugation. True yeasts are referred to as ascosporogenous yeasts and are classified in the subdivision Ascomycotina, which used to be called Ascomycetes. Asporogenous yeasts, also called false yeasts, do not produce ascospores or other sexual spores, and are placed in the subdivision Deuteromycotina, also called Fungi Imperfecti.

Another type of spore formed by some yeasts is called a chlamydospore. A chlamydospore forms when a thick wall surrounds the yeast cell, and is similar to chlamydospores formed by molds. These appear to be resting or survival structures, and are asexual. Yeasts that form pseudomycelia can also produce by fragmentation spores known as arthrospores and blastospores.

Growth Requirements

Individual yeasts vary in their growth requirements, but some generalizations can be made. Yeasts are aerobic and facultatively anaerobic. Some yeasts are extremely aerobic and oxidative in their metabolism. These oxidative yeasts grow on the surface of liquids and are known as film yeasts. Yeasts that are aerobic and facultatively anaerobic can grow both ways. When growing aerobically, yeasts produce mainly biomass, i.e., more yeast cells. When growing anaerobically, yeasts have a fermentative metabolism and produce carbon dioxide and ethanol. For the most part, sugars are the best source of energy for yeasts, but the film yeasts can oxidize organic acids and alcohol for energy. Yeasts can utilize simple nitrogen compounds, such as ammonia, urea, and amino acids. Some yeasts can also hydrolyze proteins and polypeptides.

Yeasts require somewhat less available moisture than bacteria, but more than molds. In terms of a_w, the lower limits for most yeasts are 0.88–0.94. Some yeasts, known as osmophilic yeasts, can grow in the presence of high concentrations of sugars or salt at a_w as low as 0.62–0.65. Each yeast will have its own characteristic optimal a_w and a range of a_w over which it can grow. The minimum and optimum a_w for a given yeast may change depending on outside factors, such as nutrition, pH, temperature, oxygen, and presence of inhibitors.

The optimum temperature for growth of yeasts is in the mesophilic range of 25–30 °C. Yeasts in general can grow over a range of temperatures from 0 °C to 47 °C. Yeasts grow well under acid conditions, at pH 4.0–4.5. They can grow at lower pH than most bacteria, but do not grow well under alkaline conditions. Yeasts are widely distributed in nature and commonly occur on grapes and other fruits. They are also found in dust and water, and may be found on the skin and in the intestinal tract of humans and animals.

Food Spoilage and Effects of Processing on Yeasts

Some yeasts, mostly in the genus *Saccharomyces*, are very important industrially for leavening of bread and production of wine, beer, alcohol, glycerol, and invertase. Other yeasts, referred to as wild yeasts, can cause spoilage problems in foods. Film yeasts can oxidize enough lactic acid to allow spoilage in sauerkraut and pickle fermentations by nonacid-tolerant organisms. Yeasts can grow in vacuum-packaged wieners and other cured meats, forming visible colonies or slime. Other salt-tolerant yeasts can grow in curing brines, salted meats and fish, soya sauce, tamari sauce, and miso. Osmophilic yeasts can grow well in foods with high concentration of solutes, especially sugars and salts, and cause spoilage of salad dressings, honey, syrups, concentrated fruit juices, and even dried fruits. Certain other yeasts, known as apiculate or lemon-shaped yeasts, can contaminate wine fermentations, causing off-flavors, low yields of alcohol, and production of volatile acids. Yeasts can also reach high numbers in frozen vegetables prior to freezing or after thawing, especially if the vegetables are mishandled.
