The commercial production of lowbush blueberries is largely confined to approximately 50 000 ha in Maine (USA) and Quebec and the Maritime Provinces of Canada. Maine has only 43% of the hectarage, but generates over half of the production. Annual production now exceeds 55 000 t. Cranberry production is over 200 000 t annually from over 15 000 ha, primarily in Wisconsin, Massachusetts, New Jersey, Washington, Oregon, and Nova Scotia. A major planting of cranberries was also recently made in Chile, along with modest plantings in Ireland, the UK, and northern Europe. Lingonberries are commonly harvested in Scandinavia, the former USSR, Poland and several other European countries, and in eastern Canada, whereas bilberries are gathered and consumed primarily throughout northern Europe, Siberia, and northeastern China.

Varieties

Highbush blueberry breeding was begun by Dr. Fredrick Coville of the US Department of Agriculture in 1908. Over 70 cultivars are now available, although only two, Bluecrop and Jersey, constitute more than half the hectarage. Bluecrop is the most dominant cultivar, owing to its high yields and long storage life, and now encompasses about a third of the total hectareage. It is the leading cultivar in nearly all production regions, and its acreage is still increasing. Most of the Jersey acreage is located in Michigan, and it is no longer being actively planted. Among the newer releases, Elliott and Duke are the most popular. Other important cultivars include Croatan, Blueray, Bluetta, Weymouth, Berkeley, Patriot, Bluejay, and Rubel.

Beginning in the 1970s, the introduction of highbush cultivars with a low chilling requirement for budbreak (so called 'low-chill' or 'southern' highbush) heralded the extension of 'highbush type' blueberry culture into more southern latitudes in the USA and Australia. Sharpblue is now the most widely

planted southern highbush blueberry. Other important low-chill cultivars are Reveille, O'Neal, Star, Misty, Gulfcoast, and Floridablue. Of the half-high types released for northern cold regions, Northblue and Northland are the most popular.

Over 25 cultivars of rabbiteye blueberries have been released since their breeding began in the 1930s. Tifblue and Climax form the foundation for the present industry, and Brightwell Premier and Powderblue are also being actively planted. In addition, the very-low-chilling cultivars Beckyblue and Bonita are gaining in importance in Florida.

Although lowbush breeding programs existed in Maine, Michigan, West Virginia, Wisconsin, Minnesota, and Nova Scotia at various times, the industry is still based on native selections. Only seven cranberry cultivars account for about 90% of the crop, and all these varieties were selected from the wild in the nineteenth century. Early Black, Stevens, and Searles represent at least half of the area, with most of the remainder being Ben Lear, Pilgrim, Howes, and McFarlin. Most of the new hectareage is Stevens, Ben Lear, and Pilgrim because of their high color.

Selection and breeding of lingonberries was initiated in the late 1960s in Sweden, and the crop is now being domesticated at several locations across Europe, Scandinavia, and, most recently, the USA. At least 12 cultivars have been released: Sussi and Sanna in Sweden, Koralle, Ammerland, and Red Pearl in The Netherlands, Erntekrone, Erntedank, and Erntesegen in Germany, Masovia in Poland, and Splendor and Regal in the USA.

Morphology and Anatomy of the Fruits

The fruits of all flesh-fruited ericaceous species are berries containing many seeds. A waxy cuticle covers the epidermis of the fruit. In blueberries, the fruit are held on corymbs or racemes. Pure inflorescence buds are formed in the late summer and autumn on shoots of the current season. In cranberries, the fruits are borne singly at nodes 3 to 5 on upright shoots that develop from mixed buds on the trailing vines. Fruit of lingonberries are held in drooping racemes on terminal inflorescences. Bilberries are borne singly in the axils of the lowermost leaves of the vegetative shoot.

The *Vaccinium* berry contains one to 50 seeds surrounded by a fleshy and, usually, colorless mesocarp. In most genotypes, seeds are necessary for normal fruit development, although varying levels of parthenocarpy exist. The ultimate size of fruits is strongly correlated with the number of seeds per fruit.

Blueberry fruit enlarge following pollination, according to a double sigmoidal growth curve, and they go through several phases of color development: (1) immature green, (2) translucent greenish white, (3) greenish pink, (4) blue–red, and (5) completely blue. Up to 50% of the increase in berry volume occurs during the shift from greenish pink to blue. Flowering occurs in early spring, and the fruits are ripe in 40–60 days, depending on the variety and environmental conditions. (*See* **Ripening of Fruit**.)

Cranberries also go through several stages of color development, including green, white, and red. However, the size development of the fruit is more linear than blueberry. Once berry growth begins, it continues at a relatively constant rate for 4–6 weeks. Cranberry fruit matures between 60 and 120 days after blossom.

The anthocyanin pigments that give the fruits their characteristic colors are in the cells of a surrounding endocarp layer. A layer of wax often covers the surface of the berry. The light blue color of many blueberry cultivars results from the combination of dark blue pigments overlaid by the translucent wax. Temperature plays an important role in the development of color, as picked fruit will develop a normal color at 16–27 °C whether they are shaded or not, whereas lower temperatures stop normal development. The blueberry and cranberry are mildly climacteric, with only modest elevations in respiration and ethylene production associated with fruit ripening. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Chemical and Nutritional Composition

An average blueberry fruit is composed of approximately 83% water, 0.7% protein, 0.5% fat, 1.5% fiber, and 15.3% carbohydrate (Table 2). Cranberries contain 88% moisture, 0.2% protein, 0.4% fat, 1.6% fiber, and 7.8% carbohydrate. Blueberries are 3.5% cellulose and 0.7% soluble pectin, and cranberries contain 1.2% pectin. The total sugars of blueberries amount to more than 10% of the fresh weight, bilberries average 14%, and cranberries contain 4%. The predominant reducing sugars in blueberries are glucose and fructose, which represent 2.4%. The edible portion of the cranberry is composed of 2.66% glucose, 0.74% fructose, and 0.14% sucrose. Its pulp contains measurable amounts of lignin, glucose, arabinose and xylose. Refer to individual nutrients.

The overall acid content of *Vaccinium* fruit is relatively high. Ripe cranberries range from 2 to 3%, whereas blueberries fall in the range of 1–2%. The primary organic acid in blueberries is citric acid

(1.2%). They also contain significant amounts of ellagic acid, a compound thought to reduce the risk of cancer. The cranberry contains high levels of several organic acids, including quinic (1.3%), citric (1.1%), malic (0.9%), and benzoic (0.6%); lingonberries also have very high levels of benzoic acid. Ingestion of cranberries or lingonberries leads to increased acidity of the urine through conversion of its high quinic and benzoic acid contents to hippuric acid by the body. The high acidity and possible antibacterial effects of hippuric acid may relieve urinary tract infections and reduce some types of kidney stones. (*See* **Acids:** Natural Acids and Acidulants.)

Compared with other fruits and vegetables, blueberries and cranberries have intermediate to low levels of vitamins, amino acids and minerals (Table 2). Blueberries contain 22.1 mg of vitamin C per 100 g of fresh weight, and cranberries contain 7.5–10.5 mg. Bilberries contain 5 mg of N per 100 g of alcohol-soluble nitrogen, whereas blueberries contain 15–60 mg of N per 100 g. Blueberries are unusual in that arginine is their most prominent amino acid. Glutamic acid and valine predominate in bilberries, and lingonberries contain high levels of serine and aminobutyric acid. Lingonberries also possess appreciable levels of the unusual amino acids 1-aminocyclopane-1-carboxylic acid and 5-hydroxypipecolic acid.

In general, blueberries and bilberries are two of the richest sources of antioxidant phytonutrients among the fresh fruits, with total antioxidant capacity ranging from 13.9 to 45.9 μmol of Trolox equivalents per gram of fresh berry. Berries from the various *Vaccinium* species contain relatively high levels of polyphenolic compounds, with chlorogenic acid predominating. Total anthocyanins in blueberry fruit range from 85 to 270 mg per 100 g, and species in the subgenus *Cyanococcus* carry the same predominant anthocyanins, aglycones and aglycone sugars, although the relative proportions vary. The predominant anthocyanins are delphinidin monogalactoside, cyanidin monogalactoside, petunidin monogalactoside, malvidin monogalactoside, and malvidin monoarabinoside.

Among the other *Vaccinium* spp., cranberries have total anthocyanins varying from 25 to 100 mg per 100 g fruit, with the most important anthocyanins being cyanidin-3-monogalactoside, peonidin-3-monogalactoside, cyanidin-3-monoarabinoxide, and peonidin-3-monoarabinoside. Cowberries contain high quantities of cyanidin-3-galactosides. Bilberries contain high quantities of hydroxycinnamic acid and possess very high levels of quercitin-3-glucoside, rhamnoside, and arabinoside. The various Ericaceae species also contain appreciable amounts of several carotenoids.

The major volatiles contributing to the characteristic aroma of blueberry fruit are *trans*-2-hexanol, *trans*-2-hexanal, and linalool. The predominant volatiles in the bilberry are *trans*-2-hexanal, ethyl-3-methyl butyrate, and ethyl-2-methyl butyrate. In the cranberry, 2-methyl butyrate is rare, but α-terpineol predominates. Benzaldehyde also contributes to the aroma of the cranberry. (*See* **Sensory Evaluation:** Aroma.)

Handling and Storage

Most fresh-marketed fruits of *Vaccinium* are harvested by hand, although lowbush blueberries are commonly removed from the bush with hand-held rakes. Highbush and rabbiteye berries are mechanically harvested for the processed market with over-the-row machines that shake or beat the fruit on to catching pans or conveyors. Fruits are mechanically harvested as a clean-up operation after several hand-pickings, or when 60–70% of the fruit on a bush are

blue. A limited amount of fruit is mechanically harvested for the fresh market, but only with careful sorting to remove defective fruit.

Cranberries are mechanically harvested either dry or wet. Dry harvested fruit are generally stripped from the vines with a picking machine that combs or scoops fruit off the plant. To wet harvest fruit, the bogs are flooded to lift the vines, and the floating fruit are raked or beaten off the surface of the water. Wet harvesting recovers a higher percentage of the fruit, but water-raked berries deteriorate more rapidly.

A typical grading line for fresh-marketed blueberries consists of a 'blower' to remove leaf material and small green berries, a 'tilt belt' to separate soft from firm fruit, and a sorting line, where four to eight people visually scan the fruit for defects. Grading lines for processing berries are usually composed, in order, of a blower, tilt belt, a water tank, where ripe berries sink, a fruit destemmer, and a sorting line. Processed berries are generally frozen either in bulk or individually quick-frozen. The color of blueberries is well preserved by freezing, although they form exudates and redden upon thawing.

Dry-harvested cranberry fruit are generally sorted by bouncing them over a barrier board. Sound berries bounce and travel forward on a conveyor belt, and soft berries are collected below. Small and large berries are then separated over a wire screen and carried along moving belts for further sorting. Water-harvested berries are first dumped on a long, inclined mesh belt that passes through a dryer to prepare them for sorting. Flotation tanks are also used in some instances to sort both wet- and dry-harvested fruit.

Suggested quality standards for sorted blueberry fruit are as follows: (1) pH at 2.25–4.25; (2) citric acid at 0.3–1.3%; (3) soluble solids, greater than 10%; (4) ratio of soluble solids to acid, 10–33%; (5) firmness, greater than 7 g of force for 0.01 cm of deformation on the Instron testing machine; (6) diameter, greater than 10 mm; (7) color, blue with less than 0.5% of the surface having a pink coloration. Cranberry quality is largely determined by its color, particularly in juice products. Other important quality traits are sweeter, darker, uniform-colored fruit for fresh marketing, increased aromas, firmness, uniform size and shape, organic acids, and glossiness. Methods have been devised for sorting *Vaccinium* fruit by firmness and optical density, and these are growing in popularity.

Cranberry fruit can be successfully stored for several months without any significant losses in quality. Fruit were once stored for the fresh market in large ventilated rooms at ambient temperatures, but now refrigerated storage is recommended at 2–4 °C. Processed berries are generally frozen. Most cranberries are stored in bulk, but some berries are prepackaged in perforated 0.45-kg cellophane bags or unsealed cardboard boxes. Storage life can be extended up to 12 weeks if berries are kept cool in bulk and packaged just before harvest. Controlled-atmosphere storage does not appear to have significant benefits, except that treatment with ethylene gas after harvest may increase the anthocyanin content of the fruit. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs; **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability.)

Blueberry fruit are generally packaged in plastic pint or quart 'clam shell' containers, or open containers that are covered loosely with cellophane or shrink-wrapped. Shelf-life can be greatly extended by lowering fruit temperatures to 0 °C (**Figure 1**). Decreasing the storage temperature slows respiration and other metabolic processes, but even more importantly, it greatly reduces the activity of decay organisms (**Figure 2**). In addition, spore germination of *Alternaria* and *Botrytis* occurs only very slowly at 0 °C, whereas germination of *Glomerella* spores is stopped altogether. During long-term storage (3 weeks or more) at 0 °C, senescent breakdown can occur in the berry flesh, leading to the formation of watersoaked areas and the bleeding of blue skin pigments into the normally colorless mesocarp. However, few precautions other than modest chilling

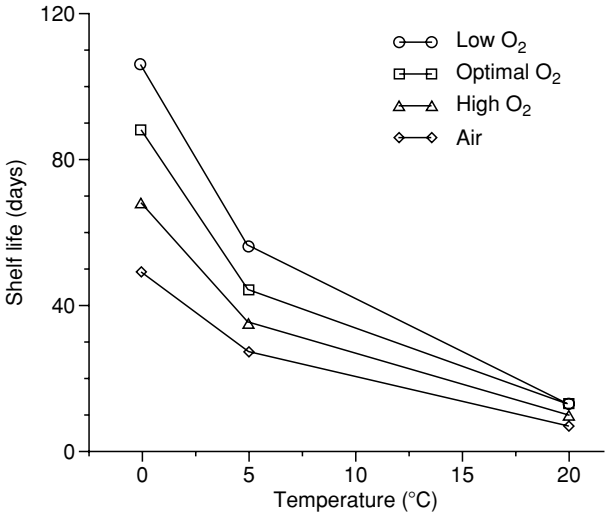

Figure 1 Effect of storage temperature and atmosphere composition on the visual shelf-life (days in marketable condition) of Bluecrop blueberry fruit sealed in low-density polyethylene packages. For the various oxygen (O_2) treatments, the approximate O_2 and carbon dioxide (CO_2) concentrations were, respectively, as follows: low O_2, 0.8% and 12%; optimal O_2, 2% and 7%; high O_2, 7% and 3%; air, 21% and 0%.

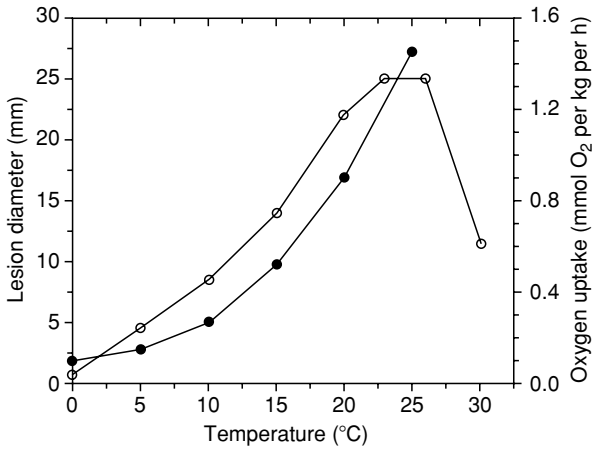

Figure 2 Effect of temperature on (○——○) the development of decay lesions (generalized curve redrawn from Kader AA, Kasmire RF, Mitchell FG, *et al*. (1985) *Postharvest Technology of Horticultural Crops. Extension Bulletin 311*. University of California at Davis.) and (●——●) respiratory metabolism of Bluecrop fruit at ambient oxygen levels. Adapted from Beaudry RM, Cameron AC, Shirazi A and Dostal DL (1992) Modified atmosphere packaging of blueberry fruit: effect of temperature on package oxygen and carbon dioxide. *Journal of the American Society of Horticultural Science* 117: 436–441, with permission.

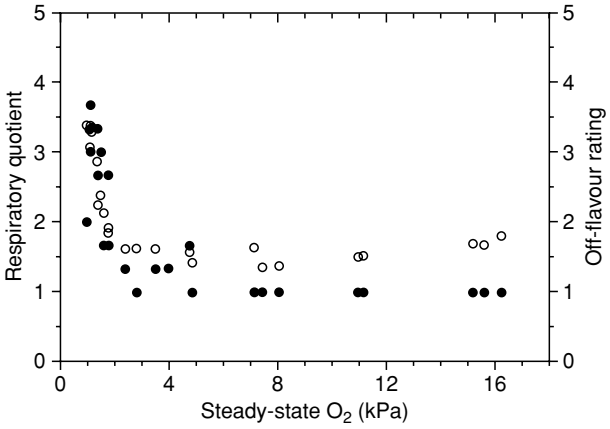

Figure 3 Effect of oxygen (O_2) concentration on (○) the respiratory quotient (RQ) and (●) off-flavor development of Bluecrop blueberry fruit at 20 °C. The increase in the RQ as O_2 levels decline below 2 kPa is indicative of fermentation.

are generally taken to attain a storage life of 7–10 days. Once the fruit have been cooled below approximately 10 °C, they must be kept chilled to avoid condensation ('sweat') upon returning the fruit to warm conditions.

Modified atmospheres (elevated CO_2 and low O_2 conditions) can enhance the visual shelf life of blueberry fruit (Figure 1), although temperature management plays the most important role in maintaining fruit quality. Lowering O_2 to 2% does not have a significant benefit by itself, but combinations of low O_2 and high CO_2 can improve storability. CO_2 levels of 8–10% or greater can significantly reduce decay development of blueberry fruit, but may not slow the decline in internal condition that normally occurs during storage. Packaging systems presently under development rely on the fruit, the packaging film, and temperature control to generate and maintain optimal O_2 and CO_2 levels. Packages must be designed to avoid excessively low O_2 levels, or fermentation and off-flavors will result (Figure 3; note that O_2 partial pressures are in kPa, which can be read as %). Packaging systems that boost package CO_2 levels and/or provide some level of humidity control have been developed for other products and may have considerable potential for packaged blueberry fruit. Chlorine and fungicide dips can also reduce postharvest decay. (*See* **Chilled Storage: Use of Modified-atmosphere Packaging**; **Chill Foods: Effect of Modified-atmosphere Packaging on Food Quality**; **Fungicides.**)

Industrial Uses

Blueberries and bilberries are eaten both as dessert fruits and in processed forms. About 46% of the rabbiteye crop and 50% of the highbush crop are marketed fresh, and the remainder are processed. Nearly all commercially harvested lowbush blueberries, cranberries, and lingonberries are processed.

The first widespread use of cranberries was to make sauce as a speciality item served at Christmas and the American holiday, Thanksgiving. During the 1960s, juice products made their appearance in the USA and now dominate the market. Cranberry 'cocktail' is drunk alone or mixed with other juice products. Cranberries are also made into a syrup, a dried raisin-like product, and a natural red food coloring, which has been used successfully to enhance the color of cherry pie filling.

Blueberries are used primarily in pie fillings, yogurts, icecream, and prepared muffin and pancake mixes. Blueberries are sometimes added to dried products after dehydration using an explosion-puffing process. Syrups, jams, and preserves are also produced, but in limited quantities. The juice of blueberries is rarely consumed directly as it has a very strong flavor and dark color.

Lingonberries are quite tart, but quite edible when cooked and are commonly used for juice, pie fillings, and jam. Bilberries are used fresh or in juice, preserves, or wine. Fruit extracts are also used in pharmaceutical preparations for the treatment of microcirculatory diseases.

Factors Affecting Quality

W S Conway and M Faust, Beltsville Agricultural Research Center, Beltsville, USA
C E Sams, University of Tennessee, Knoxville, USA

Introduction

The primary goal of the fruit grower is to produce a product of such quality that it is attractive to the potential consumer in both appearance and taste. In order for quality fruit to reach the consumer, it must be properly grown in the orchard, harvested at the time of proper maturity, and stored in such a manner that the quality is maintained. Economic losses occurring in postharvest channels are greater than often realized, and the avoidable loss of quality 'between the farm gate and the consumer' is the cause for real concern. Fresh fruit increases several-fold in unit value while moving from the field to the consumer, because of the added cost of careful harvesting and handling. Factors that affect fruit quality can be classified into three groups: (1) nutritional factors during growth; (2) factors associated with the time of harvest; and (3) factors associated with storage. These factors, as they relate to the quality of the major temperate fruits, including apples, apricots, cherries, peaches, pears, and plums, will be discussed.

Tree Nutrition

In order for the fruit tree to produce quality fruit, it must be supplied with the proper mineral nutrients and photosynthates. Orchard trees grow and produce fruit in the same place for 15–50 years. By the time these trees are mature enough to produce a crop, they have developed extensive root and branch systems and are able to acquire nutrients from the soil, intercept light, and produce photosynthates. The perennial nature of the tree and the necessity of producing large crops of fruit regularly imposes demands for nutrition not found in herbaceous plants or forest trees. The tree has changing nutrient needs during the year, particularly when it sets and raises its fruit. These occasional high mineral nutrient needs may not be met by uptake through the roots and must be supplied by foliar application. Fruit nutrition must often be concerned with the nutrition of not only the whole tree but also individual organs. For example, fruit should have a certain nutrient content for maximum storability. This requires techniques other than nutrition for maintaining the tree. First, nutrients must be applied and the translocation and

Table 1 The importance of nutrient effects on fruit quality

[a]Important during postbloom.

accumulation of these nutrients into the fruit must be understood and horticultural techniques applied to direct such nutrients into the fruit in quantities to attain the goal. Mineral nutrients that affect fruit quality include boron, calcium, magnesium, phosphorus, and potassium. A summary of known effects of nutrients on fruit quality is given in Table 1.

During the development of the tree, branches grow, and leaves intercept more and more light and produce more carbohydrates. At the same time, if the tree is not pruned properly and the inside is shaded, these shaded leaves are unproductive photosynthetically. In apples, one fruit must be supported by 25–30 leaves which are exposed to the sun to produce sufficient carbohydrates to result in sweet, red fruit. Shade-grown fruit are low in sugars and remain green. Small fruit, such as cherries, require less support by the leaves (1.5 leaves per fruit) than larger fruit. To some extent, carbohydrates should be considered as organic nutrients. If less than 75% of the light which is measured above the canopy reaches the leaves, red color will not develop. If the light is less than 50%, sugar accumulation in the fruit is decreased and fruit size will remain small. Similar to changing mineral nutrient demands, the need for photosynthates also changes. Photosynthates are especially needed soon after bloom and again when fruit accumulates sugars close to harvest. (*See* **Carbohydrates**: Classification and Properties.)

Calcium

Calcium is probably the most important mineral element determining fruit quality. It is especially important in apples and pears where it can prevent a number of metabolic disorders. The effect of calcium cannot be substituted by other factors. Calcium is also important in other fruits because it has the general effect of delaying ripening. Fruits high in calcium can be transported better and maintain their quality longer. The tissue calcium concentration at which desirable effects are achieved is usually higher than concentrations that the fruit normally accumulates. Therefore, calcium accumulation into the fruit must be forced by proper horticultural techniques. Calcium nutrition is complicated by the fact that calcium is needed most in the fruit. Consequently, calcium not only needs to be taken up by the tree but also needs to be directed to the fruit. (*See* **Calcium**: Properties and Determination; Physiology.)

Increasing the calcium content of fruit is difficult to achieve through normal fertilization. One method of increasing calcium in the growing fruit is to apply it to fruit trees as a spray. This spray must be applied to the fruit itself because calcium applied to the leaves will not translocate to the fruit or any other part of the tree. Because of dilution during growth, calcium concentration decreases depending upon the growth rate of the fruit. This is an important factor in determining storage quality. Large fruits usually have very poor storage quality. Small fruits, however, possess high calcium concentrations and store well.

The direct application of calcium to the storage organ would appear to be the most effective method for increasing its calcium content. The calcium content of apples has been increased by foliar sprays and postharvest dipping in calcium chloride solutions. Postharvest dipping with additives such as food thickeners in the dip solutions further increases calcium levels in apple fruit. Utilizing temperature differentials, especially dipping warm apples into a cold solution of calcium chloride, also results in additional uptake of the solution. Even more successful was vacuum or pressure infiltration of calcium chloride solutions into the fruit. In studies comparing treatment of Delicious and Golden Delicious apples with solutions of calcium chloride, the calcium concentration of fruit flesh was increased the most using pressure infiltration, followed by vacuum infiltration, with dipping being a distant third. In another study comparing treatment of peaches with calcium chloride solutions, preharvest spray applications were less successful than postharvest pressure infiltration.

Increasing the calcium content of fruit tissue makes the fruit more resistant to postharvest decay caused by soft-rotting fungi. This may be attributable to the fact that calcium ions bound to the pectins present in the cell wall increase the number of cation cross-bridges between pectic acids or between pectic acids and other polysaccharides with acid groups, and may make the cell wall less accessible to enzymes produced by fungal pathogens that cause decay. Fruit with sufficient or high calcium content maintain quality in storage better than fruit which are low in calcium. Calcium content of fruit flesh may be a factor when considering whether to store fruit from a particular orchard following harvest or sell it immediately. Calcium analysis at harvest is often used for making such decisions.

Potassium

Potassium is needed in relatively large quantities. When potassium levels are low, the fruit does not color normally. It is likely that insufficient potassium concentration decreases the photosynthesis of leaves, which in turn lowers sugar concentrations, and this affects the color. It is well established that cell extension is the consequence of the accumulation of potassium in the cells. Maintenance of high turgor pressure associated with potassium is needed for the enlargement of the fruit. This is especially important in peaches and nectarines which need an extra water supply during the last phase of fruit growth. Small peaches are relatively poor in quality. (*See* **Potassium**: Physiology.)

The accumulation of organic acids is often the consequence of unbalanced potassium transport. When protein synthesis is impaired, potassium is in excess, and acids are synthesized for charge balance. Organic acids and potassium also accumulate in the affected spots of the apple disorder Jonathan spot.

Phosphorus

Phosphorus is involved in the energy transfer mechanism, including the generation of adenosine triphosphate (ATP) and the formation of sugar and alcohol esters. In addition to these roles, phosphorus also has a regulatory function in many enzymatic processes where inorganic phosphorus controls the rate of reaction. (*See* **Phosphorus**: Properties and Determination.)

The uptake of phosphorus in fruit of the apple tree closely follows the weight increase of the fruit, and uptake continues until harvest. Phosphorus levels in apples have been positively correlated with fruit firmness and negatively with low-temperature breakdown; it is therefore important to insure high enough levels of phosphorus in the tree to avoid these disorders.

Magnesium

The fruit requires considerable amounts of magnesium. In the leaves of the apple tree the calcium concentration on a dry-weight basis is about five times that of magnesium, whereas in the fruit the magnesium concentration is twice as high as that of calcium. Starch usually accumulates in magnesium-deficient tissues (starch decomposition, sucrose formation, and phloem loading require energy and ATPase activity, which all depend on magnesium), and thus photosynthates are not partitioned into the fruit. Magnesium-deficient trees also usually produce small fruits. The overall photosynthesis of the tree is also severely affected by defoliation. Thus the small fruit size of magnesium-deficient trees may be attributable to more than one factor affecting photosynthesis. (*See* **Magnesium**.)

Some disorders of fruit may be accentuated or their development may be triggered by a high concentration of magnesium. All of these effects are known to be caused by either lower calcium concentration in the fruit or factors which counteract the beneficial effect of calcium. Bitter pit, the collapse of cell clusters usually after storage of the fruit, is generally prevented by sufficient calcium and accentuated by high magnesium.

Boron

Boron-deficiency symptoms are often noticed in the fruit before symptoms appear in the shoot. In apple, the mildest effect of boron deficiency is a flattening of the fruit. If the deficiency is slightly more severe, internal cork, i.e., round or irregular brown regions within the core area, is clearly visible upon cutting the fruit. The dead cell masses become dry, hard, and corky. In pears, similar brown areas are closer to the surface and, if they develop early, the surface above the spots is depressed. Plums show only malformed fruits without browning. If boron deficiency develops early, external cork develops on apple before the fruit is half-grown. In the early stages the areas appear water-soaked, after which they harden and crack. The fruit appears dwarfed and misshapen. (*See* **Boron**.)

There is very little margin between sufficiency and toxicity where boron is concerned. Boron toxicity manifests itself in early maturation of fruit, premature fruit drop, shortened storage life, and senescence breakdown in storage. Boron toxicity is often caused by boron in the irrigation water. Irrigation water should be free of boron.

Fruit Maturity

Fruits developing during the growing season usually reach a point when they are mature. If they are

Table 2 Relative effect of maturity at the time of harvest on fruit quality

Fruit	*Immature*	*Overmature*
Apple	---Poor flavor, metabolic diseases	---Storage breakdown
Apricot	–Poor flavor, low sugars	–Softening
Cherry	---Low sugars	–Softening
Peach	---Poor quality	–Softening
Pear	–Poor flavor	---Storage breakdown
Plum	--Poor flavor, high acids	–Softening

–Relative importance of maturity on fruit quality.

harvested at this time, they can maintain high quality in storage. If they are picked in an immature state, and only a few days separates immature from mature in the case of peaches or apricots, the quality of the fruit remains low. If they are harvested when they are overly mature, the storage quality is poor and breakdown may occur during storage. The transition from the mature to the ripe state is accompanied by a number of enzymatic processes. The fruit softens, the green color (chlorophyl) is destroyed, yellow under-color develops, acids are depleted to a large extent, and starch is converted to sugars. The rates of these processes depend upon the species, and the determination of harvest maturity is more or less critical in influencing the quality of the fruit. The relative importance of maturity on fruit quality is given in Table 2. (*See* **Ripening of Fruit**.)

The time at which fruit mature is generally determined by genetics. In most cases it is well known that fruit matures in a certain number of days after bloom depending upon the variety (e.g., apples mature 80–200 days after bloom; for McIntosh it is 123 days, Delicious 150 days, and Fuji 200 days). Other species follow similar patterns. The temperature during the first 3 weeks after bloom influences the time of maturity. If the temperature after bloom is warm, maturation time is shorter; if the temperature is cool, the time of maturation is longer.

Storage Conditions

Once fruit has been harvested at the right stage of maturity, it is important to maintain the quality of the fruit during storage. Postharvest losses are economically greater than equivalent losses in the field prior to harvest. Fruit with bruises, skin breaks, and other external distortions should not be placed in storage. Not only are these blemishes unsightly, but they also provide avenues of entry for postharvest decay-causing pathogens which will reduce fruit quality. Mechanical damage can also increase the amount of moisture loss during storage, again reducing the quality of fruit. Optimum maturity is a very important factor to consider when deciding which fruit to put in storage. Storage life of fruits can be reduced if they are harvested in an overmature or undermature state. (*See* **Storage Stability**: Mechanisms of Degradation; Parameters Affecting Storage Stability.)

Refrigerated storage retards senescence caused by ripening, softening, and textural and color changes. Refrigeration reduces unwanted metabolic changes, heat produced through respiration, moisture loss and resultant shriveling, and slows decay caused by postharvest pathogens.

Controlled atmosphere (CA) is a process or system which is used to supplement refrigeration in maintaining fruit quality in storage. It involves a change in storage atmosphere that replaces air with an atmosphere containing 1–2% oxygen, 1–5% carbon dioxide, and 93–98% nitrogen. In conjunction with refrigeration, CA can extend the storage life of apples and pears and result in quality of fruit beyond that of refrigeration alone. Controlled-atmosphere storage (CAS) cannot be applied to cherries, peaches, plums, or apricots. (*See* **Controlled-atmosphere Storage**: Effects on Fruit and Vegetables.)

Effect of Refrigeration and Controlled Atmosphere

In order to obtain maximum results from cold storage, it is necessary for the temperature in storage rooms to be held fairly constant. The best temperature at which to store most apple cultivars is between $-1\,^{\circ}C$ and $0\,^{\circ}C$. If the temperature rises 1 or $2\,^{\circ}C$ above the upper limit of $0\,^{\circ}C$, or if apples are not promptly cooled to the desired temperature, there is a real danger of increased decay and ripening. This danger increases as the period during which the temperature is above the optimum is extended. At 1.5–$2\,^{\circ}C$, 3 or 4 days would have little effect since the temperature of the fruit will not rise as quickly as that of the air, but 10 days at this temperature would reduce the storage life of the fruit by about a week and could result in greater losses owing to decay. Conversely, if the temperature falls several degrees below $-1\,^{\circ}C$ for apples, there is a chance that the fruit will freeze.

Table 3 Storage requirements and storage periods for fruits grown in temperate climates

Fruit	*Cold storage*		*Controlled atmosphere*	
	Temperature[a] *(°C)*	*Duration*[a]	*Temperature*[a] *(°C)*	*Duration*[a] *(months)*
Apple	−1 to 4	3–6 months	−0.5 to 4.4	7–9
Apricot	−0.5 to 0	1–3 weeks		
Cherry	−1 to 0	2–3 weeks		
Peach	−0.5 to 0	2–4 weeks		
Pear	−1.5 to 0	2–7 months	−1.5 to 0	7–9

[a]Depends on cultivar; range is given.

It is important to maintain a uniform temperature throughout the storage room. Temperature variation within the room could result in a mixture of overripe and prime fruit being removed from storage, as well as increased losses owing to decay in some areas of the room. A summary of storage requirements and average storage durations for various temperate climate fruits is given in Table 3.

Apples

Apple cultivars such as Delicious and Golden Delicious can be stored under proper cold-storage conditions for 5–6 months. Early or summer-maturing apples are more perishable then the later-maturing cultivars, and go directly to market rather than being stored for long periods. (*See* **Apples**.)

Refrigeration, however, is desirable for storing apples even for a short period. At 4 °C, apples respire and soften twice as fast as at 0 °C, and three times as fast at 15 °C as at 4 °C.

For the majority of apple cultivars, the optimum storage temperature is between − 1 °C and 0 °C in combination with 90–95% relative humidity (RH). Since the highest freezing point for apples is approximately − 1.5 °C, most apples can be stored at − 1 °C or above. However, a − 1 °C storage temperature requires well-controlled storage temperatures to avoid freezing.

As an example of the importance of proper storage temperatures, for Delicious apples, the cultivar grown in the greatest abundance in the USA, storage at − 1 °C will extend storage life approximately 25% over fruit stored at 0 °C.

While the more popular cultivars such as Delicious and Golden Delicious apples can be stored at − 1 °C to 0 °C, some other cultivars, owing to a greater susceptibility to low-temperature disorders, should be stored at somewhat higher temperatures. Cultivars such as Jonathan and McIntosh should be stored at 2 °C.

CAS, as previously stated, uses refrigeration in a gas-tight room, where the atmosphere within is controlled so that this atmosphere is higher in carbon dioxide and lower in oxygen than normal. Apples stored in CA respire, ripen, and soften more slowly and have fewer disorders than those in air storage. This results in a longer storage life and longer shelf-life after removal than fruit stored in air. These fruit, however, must be harvested at the proper maturity and be of the highest quality to realize the benefits resulting from CAS. CA rooms in which apples are to be stored usually contain an atmosphere of 1.5–3% oxygen, 1–8% carbon dioxide, the remainder being nitrogen. The exact combination of gases is cultivar-dependent. The storage life in CA for McIntosh, for example, may be nearly double that in regular cold storage. The use of CA also allows the fruit to be stored at slightly higher temperatures with good results. Cultivars such as Jonathan and Yellow Newton, which may develop low-temperature disorders at 0 °C in regular cold storage, may be stored at 2 °C and still retain excellent quality. In addition, large quantities of Delicious and Golden Delicious, the most popular apple cultivars, are stored in CA, at − 0.5 °C to 0 °C.

More recently, even better quality retention has been realized with a lower oxygen level of 1% rather than the 2–3% used for McIntosh, Delicious, and Golden Delicious apples. Oxygen at this level, however, must be maintained very precisely at 1%, because when oxygen drops below 1%, injury to the fruit may occur.

Apricots

Although apricots are seldom stored commercially for long periods of time, they may keep well up to 3 weeks at −0.5 °C to 0 °C, with a RH of 90–95% being desirable. Unfortunately, fruit picked when they are mature enough to ship or store are at the same maturity as those used for canning and lack the taste of tree-ripened fruit. The biggest hazard of shipping and handling apricots is decay, and since mature fruit is more susceptible to decay than immature fruit, it is not possible to allow the fruit to reach the stage of maturity for fresh-market use. (*See* **Apricots**.)

Cooling apricots quickly to 4 °C immediately after harvest and then holding them at 0 °C will retard decay and ripening. If the storage temperature is

kept at 4–7 °C, the fruit will have a more 'mealy' texture after ripening then fruit kept at 0 °C.

Cherries

Fresh sweet cherries have a handling limit from harvest to arrival at the market of about 2 weeks if temperatures do not exceed 2 °C. If sealed polythene liners are used in containers, the cold-storage period can be extended by about a week. Sweet cherries covered with polythene and stored at −1 °C to 0 °C for 2 weeks after harvest (90–95% RH is also desirable) will then have a week remaining for distribution in marketing channels. If sweet cherries are held longer than the 2–3 weeks indicated, there is a loss of flavor and brightness. Moisture loss is a critical factor detracting from the fresh appearance of both the fruit and the stems. Cherries harvested in the field should be covered with a moisture barrier at harvest until packaged for shipment. Sweet cherries are extremely perishable and rapid deterioration occurs if the fruit are not refrigerated. Sour cherries are usually unsuitable for storage. They are harvested directly into ice water for immediate cooling and may be held at 0 °C for several days to lengthen the processing period. (*See* **Cherries**.)

Peaches

Peaches are usually stored for only a short period and usually only to escape an overabundance on the market at a given period, or to extend their processing life. Peaches harvested at the proper maturity can usually be stored at −0.5 °C to 0 °C for 2–4 weeks. Early-maturing cultivars have a shorter storage life, while the later-maturing cultivars may be successfully stored for 3–4 weeks. If peaches are stored for longer than 3–4 weeks in cold storage, they often fail to ripen when moved to higher temperatures. The flesh of these fruit may become dry and mealy, or wet and mushy, and may brown internally around the stone. There is a deterioration of flavor, and a dull appearance results. This malady is called internal breakdown. Storage of peaches at 2–5 °C for 7–14 days results in internal breakdown. (*See* **Peaches and Nectarines**.)

Rapid cooling of peaches to 4 °C at harvest is necessary to retard ripening and decay. Brown rot, a fungal disease of peaches, can cause large losses in storage, and refrigeration is an effective method of retarding the development of this disease.

Pears

Pears are very sensitive to the temperature at which they are stored. Most pears in the USA are grown in the Pacific North-west, and are stored at − 1 °C with a RH of 90–95%. The recommended storage temperature for pears is − 1.5 °C to 0.5 °C with a RH of 90–95%. As an example of the sensitivity of pears to storage temperature, Anjou and Bartlett (Williams) pears have approximately a 40% longer storage life at − 1 °C than at 0 °C. It is necessary to maintain precise temperature control at these low temperatures to prevent freezing. It is also necessary to cool the fruit rapidly (remove field heat) to store these fruit successfully for long periods. When pears are being cooled, temperatures as low as − 3.5 °C to − 2 °C can be used, but should then be raised to − 1 °C as the fruit temperatures approach − 1 °C. Since pears also lose moisture rapidly, an RH of about 90% is desirable. (*See* **Pears**.)

Proper maturity at harvest is also conducive to long storage life. If pears are harvested at full maturity, they are less likely to be susceptible to physiological disorders and will ripen properly after storage. However, pear fruit gain much of their weight close to harvest. If growers delay harvest by a week, they may gain 1–2 (US) tons of fruit per acre (2268–4535 kg ha^{-1}), but storage quality will be poor.

The length of time for which pears can be safely stored at − 1 °C varies with cultivar. Holding pears beyond their normal storage period may result in fruit which will not ripen properly. Anjou pears can usually be safely stored for 6–7 months, while pears of the Bartlett (Williams) or Bosc cultivars can only be stored for 3–4 months.

CA, as with apples but to a lesser extent with pears, has been used successfully to extend the storage life of pears and to maintain a greater capacity for ripening. It is generally considered that 2–2.5% oxygen and 0.8–1.0% carbon dioxide is the optimum atmosphere in which to store pears safely.

Plums

In general, plums, including fresh prunes, are not well adapted to long cold-storage periods. Storage period, however, differs according to cultivar. The damson-type cultivars store better than the softer, oriental cultivar fruit. Well-matured fruit of the firmer varieties can be safely stored for 4–5 weeks at − 0.5 °C to 0 °C. Although ripening proceeds very slowly at these temperatures, there is some loss in flavor. If stored beyond 5 weeks, flesh browning and abnormal flavors often result.

Improvement and Maintenance of Fruit Germplasm

R M Brennan and S Millam, Scottish Crop Research Institute, Invergowrie, Dundee, UK

Background

Fruit crops have been cultivated for centuries, both commercially and in amateur gardens, and many species covering a wide range of trees, shrubs, and nonwoody perennials have been the long-term subjects of germplasm improvement programs. For example, different varieties of apples (*Malus* spp.) were recorded by the ancient Greeks, and selection and breeding of apple have continued since then. In contrast, the cultivated strawberry *Fragaria* × *ananassa*, an octoploid interspecific hybrid, was developed in the eighteenth century, and the highbush blueberry *Vaccinium corymbosum* was only domesticated in the twentieth century.

Fruit crop species have certain common characteristics: they are long-lived, usually highly heterozygous, and clonally propagated from an elite mother plant. They are also invariably economically minor crops compared with large-scale arable species such as cereals or potatoes, as reflected in the relative research and development resources available. However, fruit is increasingly recognized as an important component of a healthy diet, and consumption of temperate fruit and fruit products, especially juices and dairy derivatives, has risen sharply over the past decade.

Fruit Germplasm Improvement

Breeding Objectives

Breeding objectives in fruit have traditionally concentrated on improving yield or reducing the influence of abiotic factors such as low temperatures on yield. However, resistance to pests and diseases is increasingly important, particularly as chemical controls are reduced on environmental and toxicological grounds. There is also a rising demand for fruit of a defined quality in terms of biochemical characters (content of flavonoids, vitamins, soluble solids, etc.) as well as physical characters (fruit size and shape, skin strength, juice yield). The move towards healthier diets worldwide, but especially in western Europe and the USA, has impacted strongly on breeding and selection priorities, and screening of germplasm, including potential donor species, for nutritional attributes such as antioxidant activity has been reported in several fruit crop species.

Other breeding objectives such as machine harvestability, storage potential, environmental adaptability, and precocity of cropping remain important for most breeding programs.

Financial support for the great majority of fruit breeding programs in western Europe has in the last 15 years moved from the public to the private and commercial sectors. The products from these programmes are more exactly aligned with the sponsors' specific requirements, especially regarding fruit quality, although much of the underpinning genetics research remains in the public domain.

Breeding Methodology

The breeding of new fruit cultivars, as with most clonally propagated crops, begins with the selection of parental genotypes with complementary characteristics suitable for the achievement of the breeding objectives. After hybridization between the parental types, promising phenotypes are selected from the segregating F_1 population, multiplied vegetatively through further screening cycles and eventually released as cultivars. The timescale over which this process operates is substantial: in small fruits, the time from initial hybridization to commercial release is in the order of 15–20 years, and this may be even longer for top fruit. It is therefore vital that (1) the most appropriate hybridizations are made in the first instance, (2) the progenies produced are sufficiently large to allow enough variation for selection of the desired phenotypes, and (3) the most efficient and timely selection criteria are used to select out appropriate phenotypes. The latter process can be

significantly assisted by the use of molecular-marker technologies (see below).

The majority of fruit crop species, particularly tree fruit, produce little or no fruit during the first 2–5 years at least, and these early crops cannot in any case be used as an accurate guide to future cropping worth. It is usual to use this juvenile period for the assessment of vegetative characters such as plant habit and pest/disease resistance. It is clearly important that desirable genotypes be selected as early as possible to maximize the efficiency of the breeding program. The increased emphasis on development of molecular markers will potentially give major advances in terms of early selection of desired segregants from a seedling population. Also, there are sometimes morphological markers that can be used, for example, in *Rubus* where progenies can be screened out at the cotyledon stage for the presence of glandular hairs linked to the later development of undesirable spiny plants.

Once the plants are producing flowers, the evaluation of fruit quality and cropping potential can begin. Promotion of earlier flowering by training to a single stem, glasshouse culture, and high-density planting has been achieved in apple, while grafting of seedling scions on to mature trees has been used extensively to hasten fruiting in both apple and grape.

Interspecific Hybridization

For many fruit crop species, the use of interspecific hybridization is increasing, in order to utilize naturally occurring sources of pest and disease resistance, fruit-quality components, etc. within the available germ plasm (Figure 1 shows a typical hybrid) Some examples are:

- blackcurrant (*Ribes nigrum*): *Ce* gene for resistance to *Cecidophyopsis ribis* introgressed from gooseberry *R. grossularia*;
- highbush blueberry (*Vaccinium corymbosum*): reduced chilling and greater soil pH adaptability from *V. darrowi*, dwarfing habit from *V. angustifolium*;
- apple (*Malus* × *domestica*) – improved winter hardiness from *M.* × *asiatica* and *M. pumifolia*.

The ease with which hybrids can be made across species barriers varies considerably, and the range of techniques for achieving this is described below. Many of the domesticated fruits that are presently in existence are originally hybrids between species, e.g., apple (*Malus* × *domestica*), where several species have contributed to present-day cultivars, strawberry (*Fragaria* × *ananassa*), which is a hybrid between the North American species *F. chiloensis* and *F. virginiana*, and highbush blueberry (*Vaccinium corymbosum*), which is a tetraploid hybrid formed from several diploid races of *Vaccinium* from the southern USA. In many genera, notably *Fragaria* and *Vaccinium*, there are ploidy barriers to interspecific hybridization, but nevertheless there is considerable interest in breeders for overcoming these problems, for example, in the creation of synthetic octoploids in *Fragaria*.

For top fruit species (*Malus* spp., *Pyrus* spp., *Prunus* spp.), there is also considerable effort devoted to rootstock breeding. The earliest progenies of these fruits were grown from seed, and the best selections were then propagated on seedling rootstocks of

Figure 1 (see color plate 67) Interspecific hybridization in *Rubus* breeding (*R. phoenicolasius* is used as the donor of resistance to raspberry beetle (*Butyrus tomentosus*)), showing the wild accession (left), a commercial red raspberry (right), and the resultant F_1 hybrid.

the same or closely related species. Now, the variable seedling rootstocks have been supplanted by the selection and breeding of uniform, often dwarf, rootstocks, and this type of program is of key importance to the future development of these fruits.

Genetic Resources and Genebanks

The elimination in the wild of potentially valuable species material will inevitably have serious repercussions for fruit breeders unless there is adequate conservation of representative genotypes. Most temperate fruits have centers of origin in the northern hemisphere, and it was suggested by Vavilov in the 1930s that wild species show the most genetic variation around or near their center of origin. These centers of diversity, both primary and secondary, are crucially important in the conservation of genetic resources, and the collection of relevant germplasm is seen as a priority by many breeders and researchers. In fruit germplasm collecting expeditions, it is now recognized as important for the wild populations to be both sampled for specific characters relevant to existing needs within the breeding program but also randomly sampled, for less predictable needs in the future.

In addition, there are several more recently domesticated fruits where accessions from the wild have formed the basis of commercial production; for example, some of the first blackcurrant (*Ribes nigrum* L.) cultivars released in Scandinavia were superior selections from the wild, and present day cranberry (*Vaccinium macrocarpon*) production in the USA relies heavily on cultivars selected from the wild – a total of 132 wild selections compared to only seven from controlled hybridization.

Germplasm collections must contain adequate representation of all important taxa and, where appropriate, specific ecotypes and accessions that may possess unique and important characteristics that can be utilized in long-term plant improvement programs. The ability to access new sources of important characters, and to generate sufficient variation in progenies to select out improved seedlings of commercial value, is key to the future of fruit breeding.

Plant genetic resources can be maintained *in situ*, whereby whole environments are conserved and the plants therein preserved through the protection of their habitat. For the maintenance of entire populations, this method of conservation may be appropriate. However, for accessibility, it is invariably preferable to have the germplasm maintained in an *ex situ* form.

Ex situ genebanks, where diverse genotypes are collected and maintained, usually at research centers, in field or laboratory conditions, can provide both a core collection of representative accessions and an active collection that can be easily utilized by the breeder. To be of significant value, material within the collection must be fully phenotyped and characterized, and increasingly, molecular data on each accession are collated.

For clonally propagated material like fruit germplasm, it is best to keep the material as an active field-based collection, or clonal repository, although this has associated problems in terms of cost (land use, culture, labor), pests, and pathogens (causing damage and potential loss of accessions and hence erosion of diversity) and manageability (only relatively low numbers of accessions, particularly of large plants such as fruit trees, can be maintained compared to seed banks).

The use of seed banks is of limited use in clonally propagated crops such as fruits, but it can be important for the storage of wild populations, since often the preferred method of collection in the wild is to obtain fruits of the desired accessions to avoid removing the entire plant. Also, many breeding programs maintain seed of controlled hybridizations, in most cases to allow further populations from interesting crosses to be planted out.

In vitro collections are predominantly used for the long-term storage of base collections of representative genotypes. The plant material can be cryopreserved in liquid nitrogen at $-196\,^{\circ}C$, by which all the normal plant processes are suspended. Systems for successfully cryopreserving a range of plant parts (apical meristems, cell cultures, shoot sections) of several fruit crop species have been developed, but cryopreservation is best considered as a complementary method for situations where other conservation strategies are not appropriate.

The use of *in vitro* storage of plant accessions over short- to medium terms in conditions where growth is reduced, usually at *c*. $4\,^{\circ}C$, is another potentially important method for the maintenance of valuable germplasm. By reducing the temperature at which *in vitro* cultures are grown, often with the presence of osmotic or growth regulatory inhibitors in the culture medium, subculturing intervals can be extended from a few weeks to periods of a year or more. However, the effects on stability have not been quantified for many species.

Overall, *in vitro* techniques are potentially useful for the maintenance of fruit germplasm, but considerably more research is required on long-term stability and the risks of mutations before they can be routinely used. The latter is now fairly easily monitored using molecular techniques, although the risk of mutations varies with species also. The use of

in vitro genebanking has similar requirements in terms of replication and plant health as conventional genebanks maintained in the field or as seed.

Future Breeding Requirements and Prospects

Fruit production in some parts of the world, notably Asia, is presently in a period of significant increases, particularly for apples, pears, and strawberries. However, fruit breeding is not showing a similar increase, either in number of breeding programs or available resources, and in general, there is a trend towards fewer major cultivars worldwide. A highly restricted range of cultivars are grown in a range of locations; for example, cv. Cox apples can be obtained from the UK, continental Europe, and New Zealand, and Elsanta strawberry accounts for the majority of production throughout Europe. This leads inevitably to a loss of local cultivars and a contraction of the genetic base for the crop in general. The breeders' ability to produce new and improved cultivars, responding to developing market requirements, is thus impaired.

The increasing interest worldwide in reduced input production systems, often incorporating aspects of integrated pest management, together with a need to drive down production costs, has led to an increasing emphasis on the development of pest- and disease-resistant cultivars of fruit. Also, processors and marketing groups are demanding specific fruit-quality traits in the available fruit, and the achievement of these objectives through plant breeding represents a major challenge to breeders into the future.

Biotechnological Approaches to Fruit Crop Improvement

Conventional crop-breeding techniques have enabled major advances to be made in the yield and quality of temperature fruit crops this century. However, in recent years, the impact of a range of techniques based on plant tissue culture, recombinant DNA technology, or a combination of both has become realized. This has facilitated the more precise and targeted genetic enhancement of a number of temperate fruit crop species to date and offers the potential for future wider application.

Plant Tissue Culture

The concept of totipotency (first postulated by Schwann and Schleiden in 1838) is unique to plant cells. The capacity for individual cells to regenerate into intact plants underpins all plant tissue culture manipulations. Fruit crops, historically, were among the first species to be investigated in cell culture, with the culture of grapevines *in vitro* (albeit in a relatively unsophisticated form) reported as early as 1944. Most temperate fruit species have now been established in tissue culture, and these systems are of significant economic and scientific importance. Problems associated with the establishment of, particularly woody, fruit germplasm *in vitro* include the long reproductive cycle of the plants, which restricts the availability of the juvenile tissue necessary for the establishment of a tissue culture system to a short time period. However, the advent of increased knowledge in this area in recent years has resulted in the range of species amenable for such technology being widened.

Micropropagation Propagation of plants under sterile conditions, in optimized environmental conditions, at a high density is known as micropropagation. The principal advantage is the provision of clean, clonal material in high volumes at greatly accelerated rates of proliferation compared to conventional propagation. Simple and cost-effective methods for the micropropagation of such species as strawberry, grape, kiwifruit, apple, raspberry, and blackcurrant are in widespread use for the routine commercial production of plants, regardless of climatic or seasonal constraints.

Associated advantages of the use of sterile micropropagation techniques include the potential for cleaning up and rejuvenating diseased or damaged plant material. This has increasing importance, for the provision of clean starting material for application in breeding programs or as high-quality stock for initiating conventional propagation. Meristem culture, in which the apical 12–20 cells are cultured *in vitro*, sometimes with associated heat treatment, is a valuable method for the elimination of viruses from fruit germplasm and has been widely used in the production of virus-free lines of apple, strawberry, and other fruits. A range of other applications can be facilitated by the use of micropropagation. These include the conservation of unique or valuable material *in vitro*, the relatively easy storage of material for programmed cropping systems, and enabling the transport of material in a cost-effective form.

Regeneration from tissue explants Micropropagation is based on the use of preexisting buds, e.g., shoot tips or axillaries. However, methods exist for the *de novo* initiation of shoots from explants such as leaf discs of apples and strawberries, stem sections of *Ribes*, nonclonal material such as immature embryos and cotyledons of *Prunus* spp. (peach, cherry, and apricot), and immature achenes of *Fragaria*. Often, a callus phase involving de-differentiated cells is involved prior to the regeneration of shoots, generally mediated by the application of exogenous growth

regulators. The callus phase provides a possible source of induced variation and novel genetic recombinations in the form of somaclonal variation. This can occur spontaneously or can be induced by the application of mutagens such as γ-irradiation to the initial material. While, in the context of maintenance of a germplasm collection, this type of variation is highly undesirable, in a germplasm enhancement context, there are precedents for its use. These include inducing variation and screening regenerant material of peach germplasm for bacterial resistance, and the production of dwarf cherry rootstocks by applying either γ-irradiation or the chemical mutagenizing agent, colchicine, to *in vitro* cultures to generate novel variants.

Other techniques Several other plant tissue culture-based methodologies are available for the improvement and maintenance of fruit germplasm. These include:

1. Somatic embryogenesis, i.e., the initiation and development of embryos from vegetative cells. This approach has been demonstrated in both grape and apple.
2. Gametic embryogenesis, i.e., the regeneration of plants from cells derived from the gametophytic cycle of the plant, usually pollen or microspores. This technique is a potentially powerful breeding tool, as plants derived from this system would be haploid (or half the native chromosome number), and subsequent chromosome doubling would produce homozygous lines. This represents a considerable time-saving from the many generations of inbreeding required to achieve this by conventional crossing and selection methodology. The method has been demonstrated in *Vitis*, *Prunus*, and *Pyrus* species, and very recent work has successfully applied both anther culture and microspore systems to apple.
3. Cell-suspension cultures can be established from calluses of plants maintained in liquid medium in various forms of rotating vessel. These systems offer great potential for the production of specific compounds such as specific flavorings and colorings for use in the food-processing industry. Of even higher value is the use of such cell-culture systems for the production of secondary metabolites and pharmaceuticals derived from selected plant cells.

Protoplasts Protoplasts (individual plant cells that have been isolated and had their cell wall removed enzymatically) offer an alternative method for genetic manipulation. Earlier work in fruit crops was limited to *Vitis*, *Prunus*, *Pyrus*, and *Malus*, but recent work has been described in a wide range of soft fruit species such as *Ribes* and *Rubus*. Possibly the most significant application of protoplast technology in plant germplasm improvement is in the area of protoplast fusion (somatic hybridization) where hybrid constructions can be made between taxonomically distant species beyond the normal limits of sexual compatibility, and cells with novel nuclear and cytoplasmic construction created. During the last 15 years, numerous reports of successful somatic hybridization at the intraspecific, interspecific, and even intergeneric levels have been published. Although the applications of the techniques in fruit breeding to date have been more limited than in other species, reports of fusions between *Rubus* species and between *Pyrus* and *Prunus* (cherry) protoplasts have been made. The potential for generating novel genetic combinations remains high, however, with useful targets including the introgression of disease resistance from incompatible wild species into cultivated lines. The use of protoplast fusion in creating interspecific *Malus* hybrids is considered by some apple breeders as an important prospect for future development of apple cultivars.

Gene Transfer

Although protoplast fusion enables the potential for whole or partial genome transfer between plants, a more targeted approach for the introduction of known genes or nucleotide sequences into plants is mediated by the application of a range of methods, generically described as transformation technologies.

Agrobacterium-mediated transformation The most widely used method for the transformation of higher plants is by utilization of the natural gene transfer characteristics of *Agrobacterium*. *Agrobacterium tumefaciens* is a naturally occurring soil bacterium that readily infects a large number of dicotyledonous plants. It is unique in that the bacterium integrates its own DNA into the plant genome. Since the first report of the successful transformation of a plant in 1983, over 120 plant species have since been transformed, including a significant number of fruit species. These include *Malus*, *Fragaria*, and *Vitis* species. Transgenic plants of *Malus* have been shown to display stable patterns of expression and Mendelian segregation of transgenes. Modern vectors for transformation have been refined to minimize the amount of foreign DNA incorporated into the recipient plant. Many of the most desirable traits for improvement in fruit crops such as increased yield, better growth habit, and low-temperature hardiness are polygenic (i.e., controlled by more than one gene) and as such, owing to the limitations in gene transfer,

may not be readily improved by transformation technologies. However, single gene traits can be readily introduced into fruit plant species. Examples include:

1. Insect resistance: gene transfer programs have been reported for the insertion of the gene sequence coding for the expression of *Bacillus thuringiensis* (Bt) toxin into *Malus* species. Improved levels of pest resistance have been reported in several studies using this strategy. In addition, the cowpea protease trypsin inhibitor (*CpTi*) gene, encoding for an antimetabolite to a wide range of lepidopteran and coleopteran pests, has been inserted into several fruit species, and the results of field trials of such material have been promising.
2. Virus resistance: the introduction into the plant of part of the nucleotide sequence of the viral genome, e.g., coat-protein sequence has been demonstrated to confer resistance to viral infection. The mechanism is thought to be in much the same way as field-grown plants may be protected against a second viral infection through the cross-protection response afforded by an earlier viral attack, as demonstrated for tobacco mosaic virus. The expression of coat protein genes integrated into the plant via transformation has been shown to result in an elevated degree of protection against viral infection in tomato and other species. The introduction of an *Arabis* mosaic virus coat-protein gene into certain soft fruit species is currently being undertaken, and reports of the implementation of pathogen-derived resistance to plum-pox virus have also been made.
3. Fruit quality: a range of the component factors associated with fruit quality, such as sugar content and various ripening processes have been the subject of a number of recent gene-transfer research programs.

In recent years, not only has the host range of species amenable to *Agrobacterium*-mediated transformation been widened, but also alternative systems for gene delivery and transfer have been developed. These include the use of a helium-powered biolistic gun to propel plasmid DNA on gold bullets into plant cells. This technique is widely used for recalcitrant plant species and assists in overcoming problems both with *Agrobacterium* infectivity and in the necessity of efficient tissue regeneration systems. The main problems precluding the uptake on a wide scale of transgenic crops are probably not technology-based but related to the issues of public acceptance of transgenic products. The scope and potential of transgenic crop technologies are extremely wide, but each case must be considered on its merits.

Molecular Markers

Methods for the identification, characterization, and quantification of genetic variability have enormous potential application in germplasm enhancement programs and can, if applied successfully, offer great timesaving benefits. Previously, the use of isozyme analysis in fruit for genotype identification has proved successful in species such as apple, pear, and cherry, but less successful in species where polymorphism is lower. Isozymes tend to have relatively low genomic coverage and do not always provide sufficient polymorphism to prove useful in genetic analysis. However, the last few years have witnessed a dramatic rise in the sophistication and applicability of a range of DNA-based molecular markers.

The rapid development of genomics technologies, particularly those based on the polymerase chain reaction, has enabled significant progress to be made recently in both genetic mapping and the identification of diagnostic molecular markers that can facilitate breeding and selection of specific characters. The marker systems of choice are now amplified fragment length polymorphisms (AFLPs), simple sequence repeats (SSRs) and single nucleotide polymorphisms (SNPs). Major advances have been made in the mapping of specific fruit genomes, notably apple but also *Rubus*, *Ribes* and *Vaccinium*, and in the development of markers linked to both single gene traits, such as some pest resistances, and more complex quantitative traits, particularly those relating to fruit quality. The use of these markers in fruit breeding programmes will increase in future and should greatly assist the speed, focus and productivity of fruit germplasm improvement.

FRUITS OF TROPICAL CLIMATES

Contents

Commercial and Dietary Importance

S J R Underhill, Horticulture Postharvest Group, Hamilton, Queensland, Australia

Background

Tropical fruit are a botanically diverse group of fruit indigenous to tropical regions. Their representatives come from numerous families, including Anacardiaceae (mango, hog plum, imbu), Sapindaceae (rambutan, taun, lychee, longan), Passifloraceae (passion fruit), Bromeliaceae (pineapple) and Annonaceae (custard apple, soursop, sugar apple). Traditionally, tropical fruit were consumed locally, either grown in a subsistence-style agricultural structure or gathered from the wild. (*See* **Mangoes; Pineapples.**)

Increasing production, a more efficient transportation system, and refrigerated storage have led to increased global consumption in recent years. Considerable quantities of tropical fruit are now exported each year to European, Japanese, and American markets. The vast majority of this production is consumed fresh, although processing industries have also been established. In an increasingly health-conscious population, tropical fruit are seen as an appropriate source of nutrition, added variety and exotic appeal.

Production

Tropical fruit production is a large, rapidly expanding industry (**Table 1**). Bananas and pineapples, particularly from the Philippines, China, Mexico, and Brazil, represent the majority of world trade in tropical fruit. Collectively, these countries produced over 12×10^6 t of bananas and 3×10^6 t of pineapples in 1988. Although world production figures continue to rise, other fruit, such as mango, papaya, and lychee, are becoming increasingly popular. The subtropical regions of the world, particularly Colombia, Florida,

South Africa, Vietnam, Panama, and Mexico, have rapidly expanded their tropical fruit production over the last 20 years. In many of these countries, tropical fruit have become an important source of export revenue. (*See* **Bananas and Plantains**.)

Historically, fruit production was highly regionalized within the tropics. However, much of the current horticultural production is now removed from the place of origin of the particular species. For example, 91 860 t of lychee were produced by India in 1987, substantially more than the fruit's native China production of 61 820 t. Granadilla (*Passiflora quadrangularis*), native to the Americas, is now widely grown throughout the world.

History

The increasing horticultural status of tropical fruit comes from their progressive importation into the more temperate regions of the world. This 'Westernization' of tropical fruit has become prominent over the last 100 years. Its origins extend back to the early 1550s with the transportation of pineapples from South America, and the shipment of bananas across the Caribbean in the 1770s. Many of these journeys have been immortalized in the history books: the expedition sponsored by King George III and Sir Joseph Banks to transport breadfruit (*Artocarpus altilis*) to the West Indies, and the ensuing 'mutiny on the *Bounty*,' is a good example. Although this early distribution was fundamental to the subsequent development of tropical horticultural production, most of these fruit were already widely used by the local population. With transportation by air, it is now possible to move large quantities of tropical fruit anywhere in the world in a matter of days. Increased production and better cultivars will further aid the development of the fresh fruit industries in the future.

Economic Status

To assess their commercial importance, tropical fruits need to be divided into three arbitrary groups. Thus, familiar, well-established fruit, such as banana (*Musa* spp.) and pineapple, represent the majority of current tropical fruit production (Tables 1 and 2). In 1987, the European Community (EC) imported 238 936 t of pineapples, with France (66 304 t), Italy (43 644 t), and Germany (38 877 t) the main markets. Recent importation figures for the USA (1988) are around 100 000 t of pineapples, 2 873 000 t of banana, and 108 000 t of plantains.

Mango and papaya dominate the second group and are characterized by rapid industry growth. In the 5 years from 1983 to 1987, imports of papaya into the EEC rose from 1358 to 5074 t. The UK imported 1556 t of papaya in 1989 alone. These fruit are becoming more widely grown in subtropical regions, such as Jamaica, India, Mexico, Puerto Rico, Israel, the USA and Brazil. (*See* **Papayas**.)

Table 2 Tropical fruit imported by Japan in 1988

Fruit	*Quantity (t)*	*Exporter*
Banana	760 409	Philippines 79%, Taiwan 11%, Ecuador 9%, Colombia 1% (China and Malaysia <1%)
Pineapple	138 156	Philippines 94%, Taiwan 5% (Thailand, Indonesia, Hawaii, China, Malaysia and Australia <1%)
Papaya	5 240	Hawaii 100% (Fiji <1%)
Mango	5 291	Philippines 79%, Mexico 18%, Thailand 1%, Taiwan 1% (Colombia, Fiji, Venezuela and USA <1%)
Lychee	1 149	Taiwan 100%
Durian	104	Thailand 95%, Indonesia 3%, Philippines 2% (Singapore and Sri Lanka <1%)
Passion fruit	15	New Zealand 79%, USA 19%, Colombia 2% (Fiji <1%)
Pitaya (*Hylocereus undatus* B.)	22	Colombia 100% (Mexico <1%)

From Kitagawa H, Matsui T, Kawada K and Agravante JU (1990) Japan as a market of tropical fruit. *Acta Horticultural* 269: 41–45.

The final group is made up of the lesser-known exotic fruits, such as lychee, durian (*Durio zibethinus*), rambutan (*Nephelium lappaceum*), pulasan (*N. mutabile*), mangosteen (*Garcinia mangostana* L.), black sapote (*Diospyros digyna*), jackfruit (*Artocarpus heterophyllus* Lam.), carambola (*Averrhoa carambola*), and abiu (*Pouteria caimito*). These fruit are still relatively unknown in the northern hemisphere, with total imports into the EC around 9000 t in 1988.

Tropical fruit not only represent an important source of income for many countries but also have a valuable social and cultural significance. It is from their diversity of uses that the true socioeconomic value of these fruits becomes evident.

Fresh Consumption

The consumption of tropical fruit is greatest in their place of origin. The average Western European and Northern American consumes about 10 kg of citrus and banana per year. In parts of Africa, plantains may be consumed at the rate of 400 kg per person per year. Similar consumption rates exist for breadfruit in the West Indies. In their place of origin, these fruit represent a cheap and relatively plentiful food source. Historically, much of this production was easily

obtained with relatively little horticultural input. Owing to this large local consumption, it is difficult to assess accurately the true economic value for many tropical fruit, particularly the more exotic types. Production is never fully documented in official records, and in many cases, import–export quantities of tropical fruit are unknown. In Java, for example, 90% of fruit consumed is grown in the home garden. The heavy reliance on subsistence farming makes assessment even more difficult. (*See* **Citrus Fruits**: Types on the Market.)

The processing of tropical fruit has also developed into large industries (Table 3). Fruit have been canned, dried, frozen, or juiced, and marketed either as an individual product or in combination with other fruit types. Canned pineapple is probably the most obvious example. In 1990, over 920 000 t of canned pineapple were produced worldwide. Many of the South-east Asian countries, particularly Thailand, have already developed significant processing industries specializing in the exotic tropicals such as canned lychee and longan, dried mango, and frozen durian. Japan, the USA, and Europe are showing increasing interest in the processing of these more exotic fruit types, particularly mango, passion fruit, and soursop. Although quality is currently highly variable, it is through these products that many people first experience tropical fruit.

Other Uses

The commercial value of tropical fruit is generally equated to their consumption as either a fresh or cooked product. There is, however, a strong dependence on products derived from these fruits. In Africa, large quantities of a weak beer are brewed from banana, representing an important nutritional source. Cashew apple (*Anacardium occidentale*), soursop (*Annona muricata*), and tamarind (*Tamarindus indica*) are all important sources of alcoholic and nonalcoholic beverages in many countries.

Tropical fruits have been extensively adopted in local medicine and religious practices. Bananas are widely favored as a treatment for stomach complaints, particularly ulcers. Tamarind extract is used as the basis of laxatives for bile disorders and in the treatment of fevers. For the more indulgent, carambola has been suggested in the treatment of hangovers.

Much of the medicinal use of tropical fruits is restricted to folk medicine. There are, however, reports in Western medicine of tropical fruit being successfully administered. In 1977, a London hospital reported the control of a postoperative infection in a kidney transplant patient using strips of papaya flesh, where conventional techniques were ineffective. The strong anti-Gram-negative bacterial response of papaya has now been widely documented. Much can be learnt from local folk medicine, and it is likely that with more research, other beneficial chemical compounds will be isolated.

Tropical fruit also have a strong cultural significance. In the Hindu religion, the banana plant is considered a symbol of fertility, and fruit are placed at the doorstep of the dwelling of newly married couples. In South China, bananas are also sometimes planted in the corner of rice fields as a symbol of prosperity for the coming harvest.

Toxicity

Many tropical fruit contain potentially toxic components. In most cases, these are restricted to the nonedible portions – mainly the seed, peel, and latex – and do not pose any real health risk. Many of these products have been widely utilized by the native population in local medicine. Durian seeds are known to induce breathing problems, and an extract made from langsat (*Lansium domesticum*) skin has been used as a hunting poison. The real danger occurs when these so-called nonedible components are inadvertently consumed along with the pulp. For example, jaboticaba (*Myrciaria cauliflora*) skin, which has carcinogenic properties when ingested over a long period, may be accidentally consumed in the same manner as one would eat grape skins. (*See* **Carcinogens**: Carcinogenic Substances in Food: Mechanisms.)

Where ingestion of the pulp itself causes problems, it is usually attributed to the consumption of large quantities. A mild degree of toxicity in mamey fruit (*Mammea americana*) has been known to occur. It has been reported to cause digestive problems in the Caribbean Islands, and extracts fed to dogs have proven fatal. The akee (*Blighia sapida*) and sunsapote (*Licania platypus*) are other such fruit with known toxic properties.

Limitations to Economic Development

Cultivar Selection

The commercialization of tropical fruit has been limited in the past by little plant breeding and the existence of a wide range of cultivar types. Mango, for example, is one of 14 species of the genus *Mangifera*, all of which produce edible fruit. Within the species *M. indica*, there are numerous distinct cultivars. In India alone, there are over 500 named cultivars. Each cultivar may differ in fruit quality, storage life, environmental growth requirements, and disease and insect susceptibility.

Cultivar selection and breeding are essential if the full potential of tropical fruit is to be achieved. Tropical tree fruit breeding is presently both labor-intensive and time-consuming. These limitations may be reduced with the recent advancements in plant biotechnology.

Storage

As more tropical fruit are transported around the world, there is an increasing reliance on storage. Unlike temperate fruit, most tropical fruits are difficult to store. They deteriorate rapidly after harvest and are highly susceptible to pathogen attack. If fruit are stored under ambient conditions, they become inedible within days. Even under optimal conditions, storage life is rarely longer than a few weeks. In the past, this has tended to limit the commercial success of many tropical fruit. In the production areas, rapid local consumption tends to reduce losses, but significant postharvest spoilage still occurs. The development of adequate storage and handling technology is necessary if the tropical fruit industries are to continue to expand. Although considerable postharvest research is under way worldwide, great reliance is still placed on expensive air transport to reduce transportation time. (*See* **Spoilage**: Bacterial Spoilage; **Storage Stability**: Mechanisms of Degradation.)

The accessibility of fruit is also an important criterion in economic success. Many tropical fruits fail to establish a market niche because of irregular, highly seasonal supply, compounded by a short shelf-life. These problems will become less significant as more countries produce tropical fruit and our postharvest technology develops.

Nutritional Value

The consumption of tropical fruit, like temperate fruit, acts to supplement the diet (Table 4). Although tropical fruit are generally a poor source of proteins and lipids, they provide notable amounts of amino acids (tryptophan, methionine, lysine), ascorbic acid (and other organic acids such as malic and tartaric acid), carotenes, vitamin E, carbohydrates, and fiber (hemicelluloses, cellulose and pectic substances, as well as more complex polymers such as lignin). Low concentrations (per 100 g) of various mineral elements, such as calcium (8–125 mg), iron (0.4–1.6 mg), potassium (84–170 mg), sodium (3–28 mg), and phosphorus (24–64 mg), have been reported. (Refer to individual nutrients.)

Tropical fruit with a high starch content, such as plantains and breadfruit, comprise an entirely different dietary niche. These fruit contribute a significant portion of the daily carbohydrate intake. They are widely consumed and have a similar nutrient composition to potato. Compared to the European potato, they actually have a higher carbohydrate content.

Nutritionally, tropical fruit consumption is of greatest importance to populations of the tropical regions. Not only is daily intake of these fruit and their products relatively high, but general dietary habits and total food consumption may be quite poor. This is particularly relevant in the less affluent societies. In Uganda, for example, the laborers' basic rations are based on bananas. In the subtropical and temperate regions, consumption is generally limited to particular social groups. An interesting study of local fruit consumption in Beijing identified the infant component of the population as a significant consumer group (based on daily intake).

Factors Affecting Nutritional Value

The nutritional value of tropical fruit is highly variable. During fruit ripening, storage and subsequent preparation, the nutritional characteristics of the product may be dramatically altered. Other factors, such as the cultivar type, growing region and maturity at harvest, will have a further impact.

Fruit Maturity and Ripeness

The nutritional characteristics of tropical fruit depend on their physiological maturity. During maturation and ripening, fruit undergo numerous biochemical changes, which may affect nutritional status (Table 5). Starch is hydrolyzed into sugars, organic acids are produced, and ash, minerals, and water content are all increased. Fruit maturity becomes an important consideration as many tropical fruit are traditionally consumed at an immature state. Even when fruit are consumed ripe, considerable variability may still exist. The sugar content of pineapples, for instance, increases from 4 to 15% during the last 2 weeks of the ripening process. (*See* **Ripening of Fruit**.)

Preparation

Although the majority of tropical fruit are consumed fresh, there are many cases where consumption is only after some form of preparation. Cooking of the whole fruit, or a paste, is very common for many tropical fruit. This process may be necessary, as some fruit are purgative if eaten raw. The nutritional status of the fruit is dramatically affected as a result. Fresh green plantains, for example, have an energy count of 378–613 J (90–146 cal) per 100 g of edible portion, compared to 1508 J (359 cal) as a dried product and 323 J (77 cal) after cooking.

Cultivar Type and Growing Region

Many cultivar types have distinct nutritional characteristics. Although commonly equated to flavor, color, and taste, differences in ascorbic acid, protein, amino acid, and carotene levels are regularly reported. The growing region is also known to have an effect. Cherimoyas produced in Ecuador have 17 mg of ascorbic acid (per 100 g), whereas a similar cultivar grown in nearby Colombia has just 5 mg of ascorbic acid.

Fruits of the Sapindaceae

C M Menzel, Maroochy Research Station, Nambour, Queensland, Australia

Introduction

The Sapindaceae (or soapberry) family contains more than 1000 species from 125 genera, mostly trees and shrubs, but rarely herbs, and with a wide distribution in the tropics and warm subtropics. The majority of species are native to Asia, although there are a few in South America, Africa and Australia.

Many species are important timber trees or are used as soap substitutes, sources of drugs, beverages, or nuts. However, it is the attractive, eye-catching fruit of the subfamily Nepheleae that are of greater economic interest, especially those that are popular throughout the Orient: lychee or litchi (*Litchi chinensis*), longan (*Dinnocarpus longan*), rambutan (*Nephelium lappaceum*) and pulasan (*Nephelium mutabile*). Lychee is more widely grown than the other species, and is the most important member of the Nepheleae. The four species are similar in growth and fruiting habit, but differ in fruit morphology and climatic adaptation. Lychee is regarded as one of the kings of fruits and has a very long history in China. The fruit are very attractive with a bright red skin covered by angular or conical protuberances. Longan fruit resemble lychee fruit but are smaller, smoother and yellow–tan to brown in color. The fruit are also milder in flavor and less acidic. About a third of people in China and Thailand rate the taste of longan equal to that of lychee or better. Canned longans are also more acceptable than canned lychee. Rambutan and pulasan fruit are similar to lychee, usually with red skin. However, long hairs or spinterns replace the protuberances. Rambutan and pulasan are strictly tropical, cropping only in warm, wet lowland tropical areas. In contrast, lychee and longan bear well in the warm subtropics or at elevation in the tropics.

Origin, Distribution and Commercial Importance

The lychee originated in southern China and possibly in northern Vietnam and the Malay Peninsula, and wild lychee trees can still be found growing in several rainforest areas in these locations. The wild lychee is similar morphologically to cultivated lychee in China, in particular the Jin Feng types. The fruit are edible, but the aril or flesh is relatively thin and sour.

The *Litchi* genus contains two other subspecies that have not been commercialized, *L. chinensis* ssp. *philippinensis* (kumingi), which developed in the Philippines and Papua New Guinea at high elevation (Luzon, Sibuyan, Samar, and Mindanao), and *L. chinensis* ssp. *javensis*, which has been recorded in the Malay Peninsula and Indonesia. Philippines lychee has long oval-shaped fruit with long thorn-like protuberances. Fruit split in the middle when ripe, and the aril only partly covers the seed and is not edible. *L. chinensis* ssp. *javensis* is a rare specimen in Chinese gardens in West Java and Indo-China, and has fruit similar to the cultivated lychee, but the aril is thinner. It is reported to flower and fruit well under wet tropical conditions. Many of the Malayan specimens of *Litchi* belong to ssp. *chinensis* not ssp. *javensis*.

The longan (*D. longana* ssp. *longan* var. *langon*) originated either in subtropical China and Vietnam or in the area between Myanmar and India, and wild trees have been found growing amongst the rainforests on Hainan Island, near northern Vietnam. There are six species in the genus *Dianocarpus*, all from tropical and subtropical Asia, and Australia but longan is the only one grown for its edible fruit. *D. longan* spp. *malesianus* (mata kuching) produces fruit of a similar size to longan. Fruit have a tough skin that is pale dull yellow with dark raised specks. The aril, which envelops a big seed, is whitish, translucent and sweet and in good forms nearly 0.5 cm thick, although it is usually much thinner. Trees grow wild in Malaysia, Borneo, Sumatra, and the Celebes.

Rambutan and pulasan are thought to be native to west Malaysia and Sumatra, although trees that have escaped from cultivation blur the original distribution. They are close relatives of the lychee, and are equally desirable fruit, but are not as well known. The fruit are very similar to each other and may sometimes be confused. Trees are smaller in pulasan, leaflets narrower, and branches more open, and there are fewer fruit in a cluster. The fruit skin is thicker, and the spinterns or tubercles very much shorter. Trees are also reported to be less productive. Other species of *Nephelium* with edible arils that are occasionally consumed include *N. eriopetalum* (lotong), *N. glabrum* (redan), *N. philippense* (bulala), and *N. excrospermoides* (aluao).

The lychee was introduced in the tropical and subtropical world from China from the end of the seventeenth century and is now grown within 15–35° latitude in most countries. The distribution of lychee to the rest of the world has been slow, possibly because of the need for propagation by air-layering and the narrow ecological range of most cultivars. The most important production areas today are China

(1 300 000 t), Vietnam (50 000 t), India (430 000 t), Pakistan, Thailand (80 000 t), Indonesia, Madagascar (35 000 t), South Africa (9500 t), Mexico, and Australia (5000 t). In China, lychee is mainly grown in three southern provinces: Guangdong, Guangxi, and Fujian.

The longan reached Thailand in the late nineteenth century and Hong Kong, Hawaii, Florida, and Australia by the early to mid-twentieth century. However, despite its wide environmental adaptation, longan is commercialized only in China (500 000), Thailand (240 000 t), and Vietnam (365 000 t). Longans are rated 12th in order of total production for tropical fruits in Thailand, with an average of 4–6 times more longans produced than lychees.

Rambutan and pulasan are widely distributed in the humid tropics of South-east Asia. The largest commercial plantings of rambutan occur in Malaysia (80 000 t), Indonesia (148 000 t), Thailand (430 000 t), and the Philippines (20 000 t). In Malaysia, rambutan is the most important fruit crop, whereas in Thailand and Java, rambutan ranks third after mango and tangerine. In the Philippines, rambutan was introduced from Indonesia only in this century and is not listed in the 20 main tree fruits. The pulasan is widely grown in the western part of Java, with smaller plantings in other parts of Indonesia, Malaysia, and Thailand.

Lychees and longans are well known and popular fruit in most Asian countries, and significant quantities are traded each season. The Hong Kong and Singapore markets are well serviced and highly competitive, and have very high standards for imported produce. Consumers know and prefer large highly colored sweet fruit with small seeds and firm flesh.

Hong Kong and Singapore are the main markets for lychees in South-east Asia, with the fruit coming from China, Taiwan, Vietnam, and Thailand. Most of the fruit enter between June and July. The total market is about 20 000 t. Prices range from A$1 to A$11 per kilogram, depending on the fruit quality and supply. In 1994, Thailand exported 6828 t, but mostly as canned fruit (5834 t).

Thailand exports up to 50% of its longan crop in some seasons, and longans are the most important export fruit crop. In 1994, for instance, it exported 46 123 t to Hong Kong, China, Singapore, Malaysia, Indonesia, and the USA, mostly as fresh fruit (32 628 t), but also dried (3335 t), frozen (140 t), and canned (10 020 t). Prices for fresh fruit in Asian markets fluctuate considerably during the season. Early fruit may fetch A$3–5 per kilogram, but as supplies increase, the price drops to A$0.40–1.00 per kilogram. Average prices during the season are about A$1.50 per kilogram. Singapore consumers pay more for Thai fruit because they are normally larger and sweeter than those from China and Taiwan. Retail prices for longan are about half those for lychees.

Lychees share in the growth of exotics in western Europe. Exotics are seen as a bright spot in fruit wholesaling, with increased turnover and higher prices compared with temperate fruits. The UK, France, and Germany import about 15–20 000 t of lychee, mainly from Madagascar and South Africa, with smaller quantities from Reunion, Mauritius, and Israel. Fruit are normally available from November to early March, with peak supplies during mid-December to late January. Prices range from A$4 to A$10 per kilogram.

Exports of rambutan are considerably reduced compared with lychee and longan. Most of the production is sold in the domestic markets. Thailand and Malaysia export about 5000 t, mainly to Singapore and Hong Kong. The export of rambutans does not play a major role in terms of foreign exchange earnings.

Description of Fruit

Lychee fruit are small (3.0–5.0 cm diameter) and variable in shape from round to egg- or heart-shaped. The skin color is bright red, dull red, purple–red or pinkish red, depending on cultivar. Some cultivars also have distinctive yellow blotches on the skin. The skin has protuberances on each segment that can be smooth, sharp-pointed, or hair-like and sharp.

The fleshy edible portion of the fruit is called an aril and is an outgrowth of the seed stalk. It grows as the fruit develops until it completely covers the seed, although in a few cultivars, the aril may not completely envelope the seed, especially during periods of drought. Such cultivars have a low flesh recovery and are poor marketing types, especially in Asian markets. The aril is white and translucent and has the consistency and flavor of a prime muscat grape. Cultivars vary greatly with respect to texture, aroma, and flavor of the aril.

Each fruit normally contains one chestnut brown to dark brown, ovoid to oblong seed about 1.0–3.3 cm long and 0.6–1.2 cm wide. In some cultivars, a high proportion of seeds may be abortive. The abortive seeds are small and shrivelled and are known as ‘chicken tongue’ seeds. Fruit with abortive seeds are preferred, and often attract a higher price, for although they are somewhat smaller than fruit with normal seeds, they usually contain a higher proportion of flesh. The proportion of small or shrivelled seeds is an important characteristic of a cultivar, and varies from season to season and orchard to orchard. Fruit with chicken tongue seed are more susceptible

to environmental stresses and are usually shed before fruit containing normal seeds. The average weight is 16–35 g and flesh recovery 50–70%.

Longan fruit are small (about 1.5–3.0 cm in diameter), globose to round, sometimes with distinctive shoulders. The fruit skin is thin and leathery, and changes from green–yellow to yellow–brown with advancing maturity. The tubercles are typically flattened or indistinct. The aril (flesh) is translucent white to off-white in color, sometimes with a pinkish tinge (after processing), and ranges in texture from juicy to very crisp and in flavor from bland to sweet and aromatic, but seldom acidic.

Seeds are glossy red brown, dark brown to black, small, round to ovoid, and easily separated from the flesh. Most fruit are full-seeded, although some cultivars have up to 20–30% small seeded fruit. Average weight is 12 to 22 g and flesh recovery 60–75%. Fruit size and flesh recovery are related, small fruit normally having a lower flesh recovery.

Rambutan fruit are ovoid or ellipsoid, 3.0–8.0 cm long and 2.5–5.0 cm wide. The fruit has a very attractive appearance with the skin changing from green to various shades of pink, red or yellow during ripening. The skin has hair-like growths or protuberances (spinterns) up to 2 cm in length, densely clustered over the surface. The spinterns vary in color, but are usually red with green tips and are responsible for the common name of the fruit, which is based on the Malay word 'rambut,' meaning hair. The flesh or aril is white or rose-tinted, translucent and juicy, and acid, subacid, or sweet, depending on the cultivar.

The seeds are 2.5–3.5 cm long and 1.0–1.5 cm wide and somewhat flattened. The aril may or may not peel cleanly from the seed. In 'clingstone' cultivars, the aril usually detaches together with somewhat objectionable seed testa. The fruit weight is 20–60 g, and flesh recovery is 30–68%.

Fruit of pulasan are ovoid in shape and 5.0–7.5 cm long and resemble those of rambutan in general appearance. However, the pericarp is thicker, usually dull red, with shorter spines. The aril normally clings to the testa. The flavor and quality of the aril are invariably good, and often sweeter and preferred to that of rambutan.

Chemical Composition and Uses of Fruit

The composition of lychee, longan, and rambutan is shown in Table 1.

Lychees can be eaten directly off the tree or cool-stored, dried, or quick-frozen. Thawed fruit can be used in the same way as freshly picked fruit with only a slight loss of color and flavor. The fruit can be peeled, pitted, and canned in sugar syrup. Fresh or processed fruit can be used alone or with other fruits in tropical fruit salads.

There are substantial canning industries in China, Hong Kong, Taiwan, Vietnam, and Thailand. Canned lychees are not as acceptable as canned longans. This is possibly because the major cultivar that is canned in South-east Asia, Haak Yip, develops an off-flavor with heat sterilization. Fruit of other cultivars are usually acceptable, although the full flavor is lost.

A large proportion of the crop was traditionally dried in China and Vietnam, and often given as presents. Dried lychees are known as 'lychee nuts,' and during drying, the pericarp or outer skin becomes brown and brittle, but retains its shape. The aril or flesh that shrivels around the seed is very pleasant, similar in flavor and texture to a dried date.

Lychees are sometimes fermented for Chinese medicine or used to make wine, jelly, sherbet, yogurt, icecream, and sweets.

Longans can be eaten fresh, dried, or quick frozen. Thawed fruit are quite satisfactory. The fruit can be peeled, pitted, and canned. The juice of most cultivars is sufficiently sweet for processing without adding sugar. Canned fruit are very acceptable and taste much better than canned lychees. Taiwan and Thailand have substantial canning industries. Different cultivars are preferred for canning or drying; others are eaten fresh. Sweet fruit are best used for drying, but those lower in sugar are preferred for canning. Flavor and sweetness are normally related.

Rambutans and pulasans are normally grown for fresh fruit, although a canning industry for rambutans exists in Thailand and Malaysia. Asians generally prefer rambutan cultivars with crisp, nonjuicy fruit, and the testa clinging to the aril is not generally

Table 1 Composition of lychee, longan, and rambutan fruit (data expressed on a fresh-weight basis[a])

regarded as objectionable. Europeans prefer sweet stringless fruit without objectionable testa.

Harvesting and Storage

Immature lychees may sweeten a little once harvested, but do not develop a full flavor. Maturity is judged by a particular shape, skin color, skin texture, and flavor of each cultivar. A maturity index based on a brix/acid ratio of 35 has been developed in Australia. Most fruit can be picked from a tree within 1 week and from a single cultivar in an orchard within 3 weeks. Fruit in local Asian markets are normally sold in clusters within 1–3 days after harvest in baskets weighing about 20–25 kg without any postharvest treatment.

In Australia and South Africa, lychees are detached prior to sale, and a machine for destalking lychees has been developed in Australia. Fruit lose their bright red skin color and turn brown unless moisture loss is controlled within a few days after harvest. Browning is faster under low-humidity conditions. Efforts to maintain humidity tend to cause postharvest rots to develop. Fruit in Australia are generally packed in 2.5-kg plastic bags, with small holes to reduce condensation. Fruit may be air-cooled or hydrocooled to 5–10 °C. Fruit dry out once the bags are opened in the retail outlets. Punnet packs with plastic PVC overwraps allow lychees to be displayed without excess browning and are preferred by many retailers. The film retains sufficient humidity to inhibit browning without condensation clouding the pack. However, fruit are susceptible to rots, especially at higher temperatures. Research is currently investigating the application of pre- and postharvest chemicals, along with packaging and cooling to reduce the rots.

Lychees shipped to Europe from South Africa and Madagascar and, more recently, Israel are normally treated with sulfur to prevent browning. The fruit are placed in a closed container, and 50–150 g of sulfur per cubic meter of air are burnt in the enclosed space for 20–30 min. Alternatively, SO_2 gas can be pumped into the container. The sulfur dioxide bleaches the fruit to a pinkish cream color. Immediately after SO_2, fruit are bright yellow and progressively recover color. Fruit are then often dipped in acid. These treatments have been shown to extend storage life dramatically, inhibit browning and limit the need for specialized packaging and handling. However, there is evidence of sulfur residues and pulp tainting. Treated fruit also never match the bright red appearance at harvest. Recent research in Israel has looked at replacing the sulfur treatment with a cooling/heating cycle, followed by an acid dip. This treatment retains the red skin color. However, eating quality is related to water loss and disease development. Waxes have also been developed in the USA to reduce water loss and fix the red skin pigments. Further research is required in this area.

Longans do not ripen off the tree. They may sweeten a little, but do not develop a full flavor. Maturity is judged by the particular shape, skin color, and flavor of each cultivar. Sending immature fruit to market to gain high early prices damages the reputation of the grower and the longan in the market place.

Most fruit can be picked from a tree in one harvest and from a single cultivar in an orchard within 2 weeks. Consequently, to spread the picking workload, it is essential to plant a range of cultivars in any one orchard. Fruit are harvested by removing the whole cluster plus one or two leaves. Fruit are clipped from the panicles, sorted for size, insect damage, and skin blemishes, and placed in bulk trays.

Disease appears to be the main factor limiting longan storage. With adequate disease control, fruit maintain an acceptable eating quality for 5 weeks at 10 °C and 90% relative humidity, although significant browning of the skin occurs. In the absence of good disease control, storage at 7.5 °C is recommended, but for periods not exceeding about 3 weeks. At lower temperatures, there is a rapid loss of eating quality, principally associated with the presence of off-flavors, whereas above 10 °C, fruit succumb to postharvest diseases.

Unlike lychees, longan fruit do not separate from the fruit stalk easily without the loss of some skin. This could hasten breakdown of the fruit after harvest. Longan fruit, consequently, do not look as attractive as lychees in punnets. Longans marketed attached to the fruit stalk in bunches of about 15–20 fruit have attracted superior prices compared with loose fruit in Australia. A machine for destalking fruit is available in Australia and has a possible use for longan.

In China and Thailand, most fruit are marketed in branches on the fruit stalks in 22–25 kg bamboo baskets and consumed within 3 days without any postharvest treatment. A proportion of the crop is sometimes stored on ice to give a few extra days of shelf-life, but there is generally no precooling or refrigeration. Fruit for sale in Malaysia and Singapore from Thailand are precooled with cold water (hydrocooling) to remove field heat. The fruit usually requires additional top icing to provide further cooling during transportation. This precooling substantially reduces losses due to rots. Fruit exported to Hong Kong are packed with the fruit stalk intact. However, the larger growers consider that average quality is unimpaired when all the raceme stalks are removed.

The Thai industry fumigates longans going to Singapore in SO_2 to control browning and disease.

Sulfur removes blemishes and turns the fruit bright yellow. There is some concern by consumers in Singapore and Hong Kong on SO_2 residues. The optimum SO_2 concentration is a compromise between the rate which is effective in maintaining fruit appearance and the rate which causes tainting of the pulp. The long-term use of sulfur in these crops is under a cloud. Research is continuing in Thailand.

The price of fruit in Thailand depends on the season, cultivar, and fruit quality. Average prices are about A$1.00–1.50 per kilogram, with a range of A$0.50–3.00 per kilogram. The greatest demand is for fruit with a weight of more than 18 g.

As for lychee and longan, fruit maturity in rambutan and pulasan is determined by the color of the skin and aril taste, which vary with cultivar. The whole panicle is normally harvested. In order to harvest all the fruit at correct maturity, it may be necessary to pick trees at 3- to 4-day intervals over a period of 2–6 weeks. The fruit are reasonably hardy, but should be handled carefully to avoid bruising and crushing. In Malaysia and Indonesia, fruit are presented for sale in bunches on panicles, whereas in the Philippines, Indonesia, and Australia, fruit are detached prior to sale. Care should be taken not to rupture the skin when destalking fruit.

Fresh fruit are very attractive and eye-catching. However, ordinarily, the fruit must be consigned to local markets within 3–4 days before browning and decay set in. Removal of the panicle stems hastens deterioration. Moisture loss and browning of the spinterns can be reduced by storage at low temperatures and high relative humidities (95%). Red cultivars can be successfully stored for 14 days at 7.5 °C, and yellow cultivars for 11 days at 12.5 °C. Damage in yellow fruit is much more obvious than in red fruit. Sealed bags are more effective than perforated bags in reducing water loss, but rots and off-flavors may develop. In Australia, fruit are packed in 2.5-kg boxes lined with polyethylene cling wrap or perforated plastic film. Combined with cool storage, fruit may store for a week or more. As with the other members of the Sapindaceae, postharvest handling and storage currently limit domestic and export marketing.

Fruits of the Sapotaceae

S N Vaghani, Gujarat Agricultural University, Navsari, India

Background

Sapotaceae is one of the latex-yielding families, known for the production of Gutta percha, chicle (chewing) gum, timber, edible flowers, fruits, and oil seeds. Some species of *Achras*, *Chrysophyllum*, and *Mimusops* are also cultivated for their edible fruits. The family is included in the order Ebenales, series Heteromerae, subclass Gamopetalae, class Dicotyledon, of division Angiospermae. It is composed of about 50 genera and 1100 species, distributed in the tropical world by habitat. The plants are trees or sometimes shrubs, and the fruit is an indehiscent, one- to eight-seeded berry (sometimes a drupe). The seeds possess crustaceous, shining testas, and are oily and exalbuminous with large, fleshy cotyledons, or

albuminous with flat cotyledons. The family contains very few species that are grown for their edible fruits. However, among these species sapota (*Manilkara zapota* L. van Royen) is the most outstanding edible fruit, and is mainly used for table purposes. The physiology of this fruit is complicated, and very little research work has been performed on its handling, storage, nutrition, and processing.

Manilkara zapota L. van Royen (*Achras zapota* L.)

Vernacular names are sapota, sapota plum, sapodilla, zapotle, chico zapote, chiku, dilly, naseberry, nispero, and chicle tree. Sapota is an evergreen tree, native to tropical America, especially southern Mexico and Central America. In the moist tropics of the world, the trees are often cultivated for their edible fruits. Sapodillas are a favorite desert fruit of tropical America and other warm areas. They are full of translucent yellowish pulp and are delicious. The latex is also tapped from the bark for chicle gum, the base for chewing gum.

Type and Commercial Importance

The fruit of sapota is a fleshy berry. The fully ripe fruit is delicious and sweet, and is chiefly used fresh. In ripe fruit, the skin can also be eaten with the flesh. A small proportion of produce is utilized in various preparations. The fruit imparts a characteristic, pleasant flavor to milk, and is therefore freely utilized in many milk-based products, such as icecream or milkshakes. Chiku halwa, a famous milk-based Indian sweet, is prepared by concentrating sweetened milk to a paste-like consistency, and then adding shreds of sapota fruit previously simmered in ghee. After thorough mixing, the mass is cooked to a thick consistency so as to retain its form. Shrikhand, another milk-based Indian sweet made from curd after draining, is also dressed with cubes of ripe sapota fruit. In coastal areas of India, the fruit slices are soaked in butter for a night and eaten in the morning. It is said to be an excellent prophylactic against biliousness and febrile attacks. In the West Indies, the seeds are known to be aperient and diuretic. The coagulated resinous latex derived from the bark known as chicle is used to make chewing gum. Great forests are cultivated in South America, and tapping the sap of wild trees is quite a cottage industry.

Morphology and Anatomy of the Fruits

The fruit is a fleshy berry, that looks like and is the size of a brown tennis ball, varying in shape from globose to conical to oval, and in size from 5 to 8 cm in length, 3.5 to 7.0 cm in diameter and 75 to 150 g in weight. The skin (rind) is thin, rusty brown, and somewhat 'scurfy,' giving the fruit a striking resemblance to an Irish potato. The flesh is yellowish-brown or red, translucent and soft; it crumbles with a sandy or granular texture. The seeds are endospermic, and vary in number from zero to 12 (or many) depending on the season. Each seed weighs 0.6–1.0 g, and is hard, black and shining, obovate or flattened, about 1.5–2.0 cm long and embedded in pulp around the central axis; the seeds separate easily from the pulp.

Chemical and Nutritional Composition

The principal chemical constituents of the sapota fruit are carbohydrates and tannins. The proximate composition of nutrients in a ripe fruit is presented in Table 1. The major constituent of the fruit is carbohydrate (21%), of which free sugars take a major share: glucose (41%), fructose (38%), galactose (5.4%), maltose (0.5%), lactose (0.1%), and oligosaccharides – as glucose – (6.4%). Galactose, maltose, and lactose are present only in the ripe fruit, but glucose and fructose are present at all stages of fruit development. At the overripe stage, the sucrose content decreases owing to inversion to glucose and fructose. In general, lactose does not occur in fruits; it is mainly of animal origin. However, it occurs in ripe sapota in very small quantities, and differs from that in the mammary gland of animals. The total sugars not only impart sweetness to the fruit, but also mask the astringency caused by the tannins. (Refer to individual nutrients.)

The mature sapota contains polyphenol-like tannins (1.01 g), phenols (4.82 g), flavans (3.11 g), and leucoanthocyanidins (4.81 g per fruit). The fruit is highly astringent when unripe, and this astringency is predominantly caused by the flavans. The polyphenol-like leucodelphinidin and leucocyanidin are the major components, and leucopelargonidin is a minor component. The great resistance of sapota to fungal diseases may be attributed to the presence of large quantities of polyphenols in the ripe fruits. (*See* **Phenolic Compounds**; **Tannins and Polyphenols**.)

Sapota fruits are very low in vitamins (0.1–12 mg%) – as compared to guava (300 mg%) and aonla (700 mg%) – and in minerals. The fruits also contain negligible amounts of fat and protein. Starch is either absent or found in small quantities in the ripe fruit. The seed kernels (50% of the total seed weight) contain liquid fat (20%), saponin (1%), and sapotin (bitter principle; 0.08%). Fruit quality is adversely affected by latex, tannin, aldehyde, and sapotin content, which are present at higher levels in immature and unripe fruits.

Handling and Storage

Sapota fruits are climacteric in nature, and can be ripened artificially after harvest. The mature fruit, after proper ripening, acquires eating and processing qualities, whereas immature fruits develop poorly and are astringent in taste and very sticky in texture. The fruit should therefore be harvested at full maturity for proper ripening. (*See* **Ripening of Fruit**.)

In general, fruits take 8 months to reach harvest maturity from fruit set, and there are two principal seasons of production: February to April and October to December. However, because of the continuous flowering habit, the fruits do not come to maturity at the same time in a season. Fruits at different stages of development are therefore present on the tree all year round. Maturity can be judged by the appearance of a yellowish streak when the fruit is scratched with the fingernails, or by the oozing of watery latex on slight injury. However, indices of this type are destructive and can only be used for crops for which the total harvest time is of short duration. In the sapota crop, the fruiting is continuous and harvesting is carried out almost throughout the year or for a long duration, and hence such destructive indices are not useful. However, they can help the farmer to acquire expertise in making judgments about physical parameters. Shininess of the fruit surface, development of the fruit, and the extent of 'scruffiness' are good indicators of maturity. A fruit with a smooth surface, shining potato color, and rounded stylar end can be considered mature. The fruit contains latex, which decreases towards maturity (1.80–1.05%), and remains constant during the final stages of fruit growth. Latex almost stops oozing out when fruits are mature, and this change is also used as an indicator of maturity. On maturation, the mellowing in astringency is caused by polymeric changes in the polyphenols, and masking by the sugar. The fruits are harvested with their stalks intact; they are collected in gunny bags to avoid bruising and lowered down to the ground carefully. The fruits are cleaned by rubbing with the hand, vigorous rolling in gunny bags made into a 'cradle,' or washing in a water tub; they are shade-dried. The fruits are then graded on the basis of size (big, medium, and small) manually or with a sapota grader. They are packed in corrugated cardboard, wooden or plastic boxes, or in bamboo baskets, for marketing. Fruits are packed by number, e.g., dozens, or weight, having a final weight of nearly 16 kg per container, and priced accordingly.

Sapota fruits attain eating quality only after proper ripening. The ripe fruit has a pleasant, mellow aroma, and is sweet without any astringency and stickiness. During ripening, starch is hydrolyzed with a concurrent increase in sugar, and there are reductions in levels of starch, tannin, latex, sapotin, aldehydes, and acidity during ripening. The major changes in chemical composition of sapota fruit are presented in Table 2. Carbohydrate metabolism during the various stages of ripening produces oligosaccharides (three types), which finally yield glucose, fructose,

Table 2 Chemical composition of mature and ripe fruits (and latex) of two sapota cultivars: Cricket Ball (A) and Oblong (B)

Composition	*Mature (at harvest)*		*Ripe (eating ripe)*

Reproduced from Selvaraj Y and Pal DK (1984) Changes in the chemical composition and enzyme activity of two sapadilla (*Malinkara zapota*) cultivars during development and ripening. *Journal of Horticultural Science* 59(2): 275–281, with permission.

lactose, and galactose on hydrolysis. The hemicellulose content decreases as the fruit matures, and is further depleted during chemical ripening. Part of the hemicellulose is converted to oligosaccharides during ripening, with a simultaneous increase in sucrose content, followed by an increase in glucose and fructose. However, at the overripe stage, the sucrose content decreases by inversion to glucose and fructose.

In general, the fruits are spread on mats or on the floor in a single layer, or sandwiched in paddy straw, or packed in baskets or plastic crates, or kept in gunny bags for ripening. It takes 5–7 days for ripening, but some varieties, such as the Calcutta Round cultivar, require 9–13 days at room temperature. Fruits can be ripened more uniformly and faster with various ripening media, chemicals, and growth hormones. Amongst the various simple ripening media are sawdust and paddy straw; the latter is better, as it accelerates ripening with maximum organoleptic scores. Ethrel at 1000–2500 p.p.m. concentration is most commonly used as a ripening agent for early and uniform ripening. However, at higher concentrations the organoleptic rating for taste declines.

Since fully ripe fruits become soft and have a very short shelf-life (3–4 days), they need quick disposal. Such fruits are very difficult to handle and transport to distant markets. At the peak of the season, or when the market demand is less, the fruits need an extension of storage life. This can be achieved by retarding the ripening process through the use of various chemicals, growth regulators, wax coatings, irradiation, or low temperature in a modified-atmosphere store. Growth regulators, such as 2,4-dichlorophenoxyacetic acid at 3 p.p.m., prolong storage for 8 days. However, at higher concentrations the organoleptic rating for taste is very poor. Gibberellic acid (300 p.p.m.), kinetin (100 p.p.m.), and silver nitrate ($AgNO_3$; 40 p.p.m.) extend shelf-life by 8, 7, and 6 days respectively. Food-grade wax-waxol (3–6%) increases the shelf-life for 16 days, reduces weight loss, maintains freshness, and improves the appearance of the fruit. A fungicide dip like thiobendazole (1%) or Benomyl (0.2%) prevents storage decay. The fungicide and wax emulsion could be used either in mixed form or separately. Exposure of fruit to irradiation at 10 K rad extends the storage life by 3–5 days at 26.7 °C and by 15 days at 10 °C without any decline in ascorbic acid. Low temperature can extend the shelf-life by reducing the oxidative metabolism and release of ethylene. However, the sapota fruit is highly susceptible to chilling injury. Refrigerated storage at less than 1.6 °C causes irreversible chilling injury to the ripening mechanism of the fruit; it is also adversely affected at 6–10 °C. Even ripe fruits lose their taste and flavor when stored at refrigerated temperatures. (*See* **Irradiation of Foods: Applications.**)

Short-term holding of the fruit at 4 °C, before storage at 20 °C, extends its storage life, yet normal ripening only occurs if the duration of exposure to 4 °C is less than 10 days. This combination can extend shelf-life for up to 24 days, and with satisfactory quality. However, exposure to 4 °C for too long (28 days) results in chilling injuries, and the fruits fail to ripen normally even upon transfer to 20 °C. Sapota fruit stored at 20 °C and 25 °C attain the eating-ripe stage after 10 and 9 days, respectively, and, if retained, total shelf-lives of 15 and 13 days, respectively, have been recorded. At 15 °C, fruit can be stored for 22 days, but normal ripening fails and the taste is not good; hence the recommended optimum for storage and ripening is 20 °C. When an extended storage life is desired, fruit can be stored at 20 °C in an atmosphere containing 5–10% (v/v) carbon dioxide (CO_2) – with exclusion of ethylene (C_2H_4) – and a relative humidity (RH) of 85–90%. Levels of 5% and 10% (v/v) CO_2 in the storage atmosphere extend shelf-life by 18 and 21 days, respectively, and the taste is satisfactory, whereas 20% (v/v) CO_2 adversely affects the taste, and the fruits fail to ripen normally. Ripening is delayed when oxygen is removed from the storage atmosphere, but levels of oxygen higher than those in air have no apparent effect. Removal of C_2H_4 produced by the fruit delays the ripening by 23 days, and RH of 85–90% is optimal for sapota storage.

Fruits are packed in corrugated fiber board (CFB) boxes with honeycomb partitions or in telescopic moisture-proof CFB cartons. Unripe sapota fruits are packed in polyethylene bags (500 gage); placing therein a perforated plastic vial containing calcium chloride (10 g per kg of fruits) has increased the storage life for more than 12 days. When kept in a polyethylene bag with permanganate silica gel at 10–12 °C, the fruit keeps well for 18 days rather than 12 days at room temperature. The storage life of ripe fruit could be extended by 6 weeks at 2–3 °C and 85–90% RH. Fruits ripened under RH that is too high or too low are of poor quality. However, a standard method has been developed for better storage and transportation for the distance and export market. The fruits are harvested (6–9 a.m.) with 80% maturity, weighing 65–70 g (nos 145–150) and with a round to oval shape. Fruits are washed and precooled (hydrocooled) in chilled water (12 °C) containing Benomyl (500 p.p.m.) for 20 min and then dried under a fan. Healthy and firm fruits are packed in CFB boxes ($20.5 \times 20.5 \times 5.5$ cm for 16 fruits and $20.5 \times 30.0 \times 5.5$ cm for 24 fruits) containing honeycomb partitions and air holes. Boxes are closed and

fixed with sellotape. They are stored and transported at 13–14 °C and 90% RH. Generally, the shelf-life of fruit is about 25 days with acceptable quality. Fruit can be ripened at 25 °C to a desired eating quality. (*See* **Controlled-atmosphere Storage**: Applications for Bulk Storage of Foodstuffs.)

Industrial Uses

Studies conducted in India and elsewhere do not promise a bright future for the industrial processing of sapota fruit. The principal products tested were poor in characteristic flavor and storage stability. However, drying seems to give some promise. Among various drying techniques, sun-drying is the cheapest and easiest. In this method, slices are prepared by steeping in a sugar solution (40%) containing potassium metabisulfite (KMS) (1%) for 20 min (or dipping in 2% KMS for 2 min), and then sun-dried at a maximum tray temperature of 50 °C for 33 h. The dried (16% moisture) slices, packed in 300-gage polyethylene bags, maintain an acceptable organoleptic quality for 9–11 months at ambient temperature (20–35 °C). An analysis of the sun-dried product is given in Table 3. Sun-dried sapota (9.82% moisture) contained carbohydrate (73.83%), protein (2.61%), crude fat (2.30%), crude fiber (9.70%), minerals (1.74%), calcium (94.55 mg%), phosphorus (36.00 mg%), iron (2.16 mg%), vitamin C (3.50 mg%), and vitamin A (466 in per 100 g). The studies conducted to standardize the technique of sun-drying of sapota fruit slices of cv. Kalipatti demonstrated that the prepared ripe sapota fruit slices seeped in sugar syrup (70%) containing KMS (1%) for 3 h and then dried in the sun for 37 h at a maximum temperature range of 45–53 °C gave a superior dry product. The product had 1.5% moisture and better recovery: drying ratio. These dried sapota slices maintained high organoleptic quality in terms of taste, texture, color, appearance, and physicochemical quality. The product retained its acceptability –throughout the period of storage – 11 months. Therefore, this drying technique is promising for commercialization (Table 4).

Dehydrated sapota can also be prepared by drying the fruit halves, initially at 70 °C and finally at 55 °C for 4 days (8 h operation each day); the yield is approximately 30% dried product on the basis of fresh slices. The dried product, cut and packed in 400-gage polyethylene bags, can remain in good condition for 1 year at 5 °C, or for 6 months under ambient conditions (25–35 °C). Dried sapota slices prepared by predrying of sapota slices through osmotic process by steeping the fresh sapota slices in an osmotic medium containing 80% sugar syrup (70 °Brix), 20% glycerol, 0.5% KMS for 6 h, followed by draining and further drying in an electric tray drier

at 60 °C for 8 h, are better in eating quality and have longer keeping quality. The recovery of the product by this drying process is 360 g kg^{-1} fresh sapota slices (Table 5). However, the technique of drying is in need of standardization; investment in the costly machinery for dehydration could prove risky and development could result in failure. Therefore, practically no such sapota dehydration units exist on a commercial scale. However, home-scale and cottage-scale sun-drying can be attempted, as it involves no risky investment. In steeping preservation, the product prepared by steeping the ripe sapota fruit slices in a sugar syrup (50 °Brix) containing sodium benzoate or potassium sorbate at 1 g kg^{-1}, KMS (0.5 g kg^{-1}), ascorbic acid (1 g kg^{-1}) and citric acid (1.5 g kg^{-1}), are most stable and organoleptically acceptable with an increased level of drained weight, which kept well for more then 1 year. The quality of product under controlled temperature (4–5 °C) was superior compared to ambient conditions (22–35 °C). This technology can be exploited with advantage both at cottage as well as industrial scale (Table 6).

Freeze-drying has shown commercial promise; one such unit has been installed and is running on a commercial scale in Gujarat State, India. Freeze-drying at 20 °C and 0.30–0.05 mmHg pressure gives a stable and good-quality product. The product retains its natural size and shape, but is lighter in weight owing to its low moisture status (< 2%). Studies have shown that the acceptable quality of wine can be prepared from clarified sapota juice. The juice is extracted from pulp using pectinase enzyme (pectolytic enzyme – Trizyme – 0.3%), incubating for 4 h and cold pressing. The total suspended solid (TSS) of juice is adjusted to 25% and pasteurized. The must is inoculated with old culture of wine yeast (*Saccharomyces cerevisiae* var. *ellipsoideus*) at 2% for 24 h and siphoned, then incubated at room temperature for 10 days. The fermented juice is siphoned out and further kept for stabilization for 10 days using potassium tartrate and again siphoned out. Finally, clarified wine is preserved and bottled using a suitable method. Ripe fruits, especially overripe or 'reject' fruit, can be used in liqueur production, or as raw material for the manufacture of industrial glucose and pectin. Other sapota products are canned pulp or slices, jam, jelly, fruit bars, or ready-to-serve beverages. However, these products are often very poor in terms of characteristic flavors, taste, color, and storage stability. The potential of milk-blended products needs to be examined. Sapota fruits, being rich in sugar, are also suitable for making fermented products. Its sap, known as chicle, after much refining and flavoring, becomes chewing gum. A single tree can yield up to 70 l of chicle in just a few hours. The tree is tapped for this, once in 3 years. The bark of the sapota tree also contains about 12% of tannin, which has excellent industrial value. (*See* **Drying**: Drying Using Natural Radiation; **Freeze-drying**: Structural and Flavor (Flavour) Changes; **Preservation of Food**.)

Chrysophyllum cainito L.

Vernacular names are West Indian star apple, cainito, and tulsiphal. It is a native of the West Indies and Central America and is cultivated in warmer parts of India for its delicious edible fruit. The fruits are shining apple-sized berries. The immature fruits are

Reproduced from Vaghani SN and Chundawat BS (1999) Standardization of steeping preservation technology of sapota fruit slives of cv Kalipatti. A PG thesis. India: Gujarat Agricultural University.

astringent and contain a sticky white latex. The fruit is bright green and greenish-yellow to red violet when ripe, and should be eaten when fully ripe. They are quite delectable, full of cool, refreshing snow-white pulp with a puzzling flavor. When allowed to ripen on the tree, the fruits develop a sweet, delicious flesh with a sapotaceous flavor and can be eaten fresh or in preserves.

The fruits are hard, smooth, purple or light green, and globular (5–10 cm in diameter), with five or six distinct ribs. The seeds (4–10) are embedded in white, translucent, edible pulp (star-shaped in transverse section) and arranged stellately inside the flesh. An analysis of fruits (flesh) from Hawaii gave the following data: dry matter, 11.47%; protein, 2.34%; fat, 1.39%; acids as malic, 0.17%; total sugars, 4.40%; fiber, 0.86%; ash, 0.39%. The seeds also contain a bitter substance, lucumin (1.2%), as well as oil (6.6%), saponin (0.19%), dextrose (2.4%), and ash (3.75%).

Madhuca indica Hamilton ex. J.F. Gmel. (Syn. *M. latifolia* Macbr; *Bassia latifolia* Roxb; *M. longifolia* L., *B. longifolia* Koenig.)

Vernacular names are illippe, buttertree, mahuva, and mowra.

Type and Commercial Importance

The fruit is a berry. The outer part is eaten raw or cooked and the inner part is made into a flour for cakes. It is valued for its seeds, which yield an oil (vegetable butter) known in commerce as illeppe butter, bassia fat, mahua butter, or mowra fat. The oil is used direct or for cooking purposes in some rural areas, and it is sometimes used as an adulterant for ghee; for this purpose, it is clarified with buttermilk to mask the odor. It is also used in the production of margarine. Madhuca oil has emollient properties and is used to treat skin diseases, rheumatism, and headaches. It also has laxative properties and is considered useful for the treatment of habitual constipation and hemorrhoids (piles); it can be used as an emetic. The seeds are employed as a galactagogue. The oil cake is used as a cheap substitute for shikakai for washing hair. The succulent carolla are a rich source of sugar and also contain appreciable quantities of vitamins, calcium, and essential oils. These are eaten raw or cooked. The flowers are largely used in the preparation of country-made distilled liqueurs. The flowers are also used in the preparation of vinegar and essential oil (0.05%).

Morphology and Anatomy of the Fruits

The berries are ovoid (up to 5 cm long), fleshy and greenish in color, turning reddish-yellow or orange when ripe. The seeds (usually one or two but up to four in var. *latifolia*) are ovoid, pale brown or yellow, compressed and shiny.

Chemical and Nutritional Composition

The fruit contains the following: moisture, 73.64%; carbohydrates, 22.69; protein, 1.73%; fat, 1.61%; mineral matter, 0.69%; calcium, 45 mg per 100 g; phosphorus, 22 mg per 100 g; iron, 1.1 mg per 100 g; ascorbic acid, 40.5 mg per 100 g; carotene (as vitamin A) 512 IU per 100 g; tannins are also present. Seeds available in the trade contain 5–12% moisture and the seed kernel contains the following: oil, 51.1%; protein, 8.0%; N-free extract, 27.9%; fiber, 10.3%; ash, 2.7%. The seed oil has a specific gravity of 0.856–0.870, an acid value of 5–50, a saponification value of 188–200, an iodine value of 53–70; unsaponifiable matter accounts for 1–3%.

Handling and Industrial Uses

In general, the fresh berries are not stored, but the seeds, having a moisture content of less than 7–8%, can be. Traditionally, the madhuca tree was raised, maintained, and saved for its fleshy, sugary flowers which, as they contain 73% sugar and possess a strong flavor, were used to produce liqueur. In India, this tree is saved and maintained by tribal communities only for this purpose (country liqueur). Traditionally, the fresh berries do not have any importance for table use but the seeds are valued for their oil. The fruit ripens in May–June. The seeds are separated from the fruit wall by pressing, and then dried and shelled to obtain the kernel (70% of the weight of the seed). The kernel constitutes the seeds of commerce. The seed kernel yields 20–30% oil when crushed in a primitive crusher, 34–37% in an expeller, and 40–43% when extracted with solvents. Fresh madhuca oil from properly stored seeds is yellow in color without any unpleasant taste. Commercial oils are generally greenish-yellow in color with an offensive odor and disagreeable taste. The oil is fluid, often throwing out a deposit of stearine in cold weather when the oil solidifies to a buttery consistency. The crude oil has a deep color with a high acidity and an unpleasant odor. Refining and hydrogenation yield a product similar to mutton tallow or cacao butter. Oils having an acid value below 13 may be refined by treating with caustic soda; those with higher acid values are extracted with alcohol and further treated with alkali.

The whole berries can be used in the production of absolute alcohol. The fruits, collected near the ripening stage, are rich in starch, which is hydrolyzed into sugars in 2–3 days. The fruit pulp is used as a source of sugar for alcoholic fermentation and 1 t of dry fruits (freed from seeds) yields 130 l of absolute alcohol. Steam distillation of the fruit yields a bright-yellow, volatile oil with a spicy odor.

Mimusops elengi L.

Vernacular names are Spanish cherry, medlar, maulasri, bakul, and borsali. The ripe fruits are edible, and the berry is yellow, pointed, smooth, fleshy, ovoid (2.5–3.8 cm × 1.3–1.7 cm); young fruits are hairy. Seeds are solitary, rarely two, ovoid (1.5–2.3 cm × 1.0–1.3 cm), blackish or grayish-brown, compressed, shining, smooth, with a hard testa and soft, whitish albumen. Ripe fruits are sometimes used to make preserves and pickles. The seed kernel contains a fatty oil (16–25%). The flowers are also used in distilling otto used in perfumes and stimulants. The tree also yields gum and bark tannin (3–7%).

Manilkara hexandra (Roxb) Dubard (Syn. *Mimusops hexandra* (Roxb))

Vernacular names are bulletwood, Ceylon iron wood, Ceylon wood, khirni, raini, and pal. Ripe fruits, which are sweet but astringent, are eaten fresh or dried. The seed oil is useful for cooking, and are sometimes also used for adulterating ghee. The seeds are useful as a tonic, and are prescribed for leprosy and delirium.

Morphology and Anatomy of the Fruits

The fruit is a fleshy berry, 1.5–2.5 cm long, ovoid or ellipsoid. On ripening, the green berry changes to reddish-yellow. The seeds (one or, rarely, two) weigh 13.2 g per 100 seeds, and are 1.0–1.5 cm long, ovoid, smooth, shining, and reddish-brown.

Chemical and Nutritional Composition

The composition of the ripe fruit is as follows: moisture, 68.61%; carbohydrates, 27.74%; fat, 2.42%; protein, 0.48%; mineral matter, 0.75%; calcium, 83 mg per 100 g; phosphorus, 17 mg per 100 g; iron, 0.92 mg per 100 g; nicotinic acid, 0.66 mg per 100 g; ascorbic acid, 15.67 mg per 100 g; carotene (as vitamin A), 675 IU per 100 g; thiamin, 70.33 μg per 100 g; riboflavin, 77.41 μg per 100 g. The seed contains 24.6% edible oil, having a specific gravity of 0.9150, an acid value of 1.34, a saponification value of 191.1, and an iodine value of 65.1; unsaponifiable matter (probably containing ergosterol) accounts for 1.02%. The oil has medicinal value. The plant also yields tannin (from bark) and gum.

Handling and Storage

As the fresh fruit has little commercial value, no special care is required for handling and storage. However, to minimize losses, it is harvested as per market demand. The remaining berries are left on the tree for drying. Thus, as far as possible, the storage of fresh fruit is avoided. However, the dried fruits, which are packed in gunny bags and stored at ambient temperature, remain in good condition for 1 year.

Industrial Uses

The surplus fruits are used for drying. The ripe berries are shaken from the branches of the tree, or fall naturally and are then collected and spread on mats in a thin layer for sun-drying. After proper drying, they are packed in gunny bags and stored. The seeds are used for the extraction of oil by pressing in a primitive crusher. The oil is pale yellow in color with an odor reminiscent of olive oil.

Pouteria campechiana (Kunth) Baechni. (syn. *Lucuma nervosa* A.DC., L. *Salicifolia* (Kunth))

Vernacular names are eggfruit, canistel, sapote borracho, sapote amarillo, and ti-es. The fruit is edible, subglobose or pear-shaped (10 cm long), and orange or yellow; the sweet pulp has a musky flavor.

Pouteria sapota (Jacq.) H.E. Moore & Stearn. (syn. *Calocarpum Mammosum* (L.) Pierre; *C. sapota* (Jacq.) Merrill, *Lucuma mammosa* (L.) C.F. Gaertner)

Vernacular names are sapote, mammees, maneys sapota, maney colorado, marmalade plum, and marmalade fruit. The fruit is very sweet and edible. An important fruit in lowland, Caribbean areas, it is eaten fresh or made into thick preserves, often in combination with guava fruit.

Pouteria gardneriana (A.DC.) Radlk. (syn. *Pouteria suavis* W.D. Hemsley)

The fruits are highly scented and possess a thin, edible pericarp; they have an agreeable taste and are easily digestible. The fruit is about the size of an apricot and the shape of an apple, and is yellow and scarlet when mature. The seed is semiovoid, rather like a large hazel nut.

Synsepalum dulcificum (Schumach. & Thonn.) Daniell

In West Africa, acid citrus fruits are said to taste sweet after chewing the fruits of this plant; whenee is the common name. The fruit is red, oblong to ovoid (2 cm long, 1 cm in diameter).

Xantolis tomentosa (Roxb.) Rafrain (Syn. *Sideroxylon tomontosum*; Roxb; *Panteria tomentosa* (Roxb) Baehni)

Vernacular names are kanta, kumbul, and kumla. Fruit is a berry (2.0–2.5 cm × 1.3–1.7 cm), pubescent when young, afterward glabrous, yellowish-green, ovoid, and smooth. Seeds are usually solitary (sometimes there are up to five), 1.3 cm long, deep brown, smooth, polished and shining, and compressed. The fruit is eaten in curries and made into pickles. The seeds are also reported to yield a fatty oil (41%). It yields a saponin (2%) and fruit extract is credited with anticholeric principles. The black seeds are rubbed in lemon juice and given as an astringent. The plant also yields gutta percha.

Lesser-known Fruits of Africa

R J du Preez, ARC-Institute for Tropical and Subtropical Crops, Nelspruit, South Africa

Background

In Africa, there are numerous fruit species that are well known and highly prized by local people who often depend on these trees for food security. Africa has a wide diversity of fruits that provide a source of vitamins, minerals, amino acids, and trace elements to rural populations. These wild resources play an important role in the diet of rural people, especially in times of food scarcity. Although there are numerous different fruits, little is known of them except by the local people. Very few fruits from Africa have been developed commercially.

Some of the trees outlined in this paper have the potential to be developed on a small scale and others on a larger scale, if correct market development is undertaken. The development of value adding products will result in a larger market, job creation, and improved quality of life in rural areas. Conservation of the natural biodiversity will also be achieved.

Some of the most common fruits found in Africa are listed in **Table 1**. This is not a comprehensive list, but includes some of the most common fruits. A more detailed outline is given on 12 of the fruits listed in **Table 1**.

Adansonia digitata (Baobab)

Adansonia digitata (baobab) is a spreading tree, about 10–15 m in height. The trees reach a great age and girth. The leaves are alternate, compound usually three- to nine-foliate. Flowers are waxy white and up to 20 cm in diameter, solitary, and pendulous. The fruit is ovoid, 120 mm or longer in length with a hard woody shell, covered with yellowish gray, velvety hairs (see **Figure 1**).

Table 1 Some of the lesser-known fruits of Africa and their uses

Species	*Common name*	*Family*	*Use*
Adansonia digitata L.	Baobab	Bombacaceae	Edible fruit, seeds used in making a refreshing drink, subsistence from wild
Annona senegalensis Pers.	Wild custard apple	Annonaceae	Edible fruit, subsistence from wild
Annona stenophylla Engl. & Diels		Annonaceae	Edible fruit, staple part of diet in certain areas
Antidesma venosum E. Meyer ex Tul.	Tassel berry	Euphorbiaceae	Edible fruit, jelly, subsistence from wild
Artabotrys brachypetalus Benth.	Purple hook-berry	Annonaceae	Edible fruit, alcoholic beverage, subsistence from wild
Azanza garckeana (F. Hoffm.) Exell & Hillc.	Snot apple/Azanza/ Murojwa	Malvaceae	Edible fruit, jelly, subsistence from wild
Berchemia discolor (Klotzsch) Hemsley	Bird plum	Rhamnaceae	Edible fruit, sold in local markets
Borassus aethiopum Mart.	Borassus palm	Arecaceae	Fruit edible, plant sap used to make wine, subsistence from wild
Bridelia carthatica Bertol. F.	Knobbly bridelia	Euphorbiaceae	Edible fruit, jelly, subsistence from wild
Carissa bispinosa (L) Desf. ex Brenan	Num-num	Apocynaceae	Edible fruit, subsistence from wild
Carissa edulis Vahl	Simple spined num-num/carissa	Apocynaceae	Edible fruit, subsistence from wild
Carissa haematocarpa (Ecklon) A. DC.	Karoo num-num	Apocynaceae	Edible fruit, subsistence from wild
Carissa macrocarpa (Ecklon) A. DC	Large num-num	Apocynaceae	Edible fruit, subsistence from wild, confined to South Africa
Carpobrotus edulis	Sour fig	Mesembryanthemaceae	Edible fruit, subsistence from wild
Cordyla africana Lour.	Wild mango	Fabaceae	Edible fruit, contains ascorbic acid, subsistence from wild
Dialium schlechteri Harms	Zulu podberry	Fabaceae	Fruit made into refreshing drink, subsistence from wild
Diospyros kirkii Hiern.	Pink diospyros	Ebenaceae	Edible fruit, jelly, subsistence from wild
Diospyros mespiliformis Hochst. ex A. DC.	Jackal berry/Ebony diospyros	Ebenaceae	Edible fruit, fruit preserve, beer, subsistence from wild
Dovyalis abyssinica (A. Rich) Warb.	Abyssinica gooseberry	Flacourtiaceae	Edible fruit, jelly, subsistence from wild
Dovyalis caffra Hook & Harvey	Kei apple	Flacourtiaceae	Edible fruit, jelly, jam, cultivated as protective hedge
Dovyalis hebecarpa Gard	Ketembilla/ceylon gooseberry	Flacourtiaceae	Edible fruit, jelly
Dovyalis zeyheri (Sonder) Warb.	Oval kei apple/Wild apricot	Flacourtiaceae	Edible fruit, jelly, subsistence from wild
Ekebergia benguellensis Welw. ex C.DC.	Woodland dog plum	Meliaceae	Edible fruit, subsistence from wild
Englerophytum magalismontanum	Stem fruit	Sapotaceae	Edible fruit with ascorbic acid, wine, 'brandy', syrup, subsistence from wild
Ficus capreifolia Delile	Sandpaper fig/riverine sandpaper fig	Moraceae	Edible fruit, subsistence from wild
Ficus ingens Miq.	Red-leaved rock fig	Moraceae	Edible fruit, subsistence from wild
Ficus kirkii Hutch.	Crown-fruited fig	Moraceae	Edible fruit, subsistence from wild
Ficus natalensis Hochst.	Wild fig	Moraceae	Edible fruit, subsistence from wild
Ficus sycomorus L.	Sycamore fig	Moraceae	Edible fruit, subsistence from wild
Flacourtia indica Merrill	Flacourtia	Flacourtiaceae	Edible fruit, subsistence from wild
Friesodielsia obovata (Benth.) Verdc.	Bastard dwaba-berry/ monkey fingers	Annonaceae	Edible fruit, subsistence from wild
Garcinia huillensis Welw. ex Oliv.	Granite garcinia	Clusiaceae	Edible fruit, contains ascorbic acid, subsistence from wild
Garcinia livingstonei T. Anders.	African mangosteen	Clusiaceae	Fruit eaten raw, jelly, subsistence from wild
Grewia bicolor Juss.	Bastard brandybush	Tiliaceae	Edible fruit, subsistence from wild
Grewia flava DC	Velvet raisin bush/ Brandybush	Tiliaceae	Edible fruit, subsistence from wild

Continued

Table 1 Continued

Species	*Common name*	*Family*	*Use*
Harpephyllum caffrum Bernh. ex Krauss	Wild plum	Anacardiaceae	Fruits eaten raw, jelly, wine, subsistence from wild
Hexalobus monopetalus (A. Rich.) Engl. & Di*els*	Shakama plum/ Baboon's breakfast	Annonaceae	Edible fruit, subsistence from wild
Hyphaene petersiana		Arecaceae	Edible fruit, palm wine from juice of young plants, crafts, subsistence from wild
Hyphaene ventricosa		Arecaceae	Edible fruit, subsistence from wild
Lannea discolor (Sond.) Engl.	Live-long	Anacardiaceae	Edible fruit, subsistence from wild
Lannea edulis (Sond.) Engl.	Wild grape	Anacardiaceae	Edible fruit, subsistence from wild
Manilkara mochisia (Baker) Dubard	Lowveld milkberry	Sapotaceae	Edible fruit, subsistence from wild
Mimusops caffra E. Meyer ex A.DC	Coast red milkwood	Sapotaceae	Edible fruit, subsistence from wild
Mimusops obovata Sonder	Red milkwood	Sapotaceae	Edible fruit, subsistence from wild
Mimusops zeyheri Sonder	Moepel/Common red milkwood Dwaba berry	Sapotaceae	Edible fruit, subsistence from wild
Monanthotaxis caffra (Sonder) Verdc.		Annonaceae	Edible fruit, subsistence from wild
Nylandtia spinosa	Skilpadbessie	Polygalaceae	Edible fruit, thirst quenching drink, subsistence from wild
Olea africana Miller	Wild olive	Oleaceae	Edible fruit, subsistence from wild
Pappea capensis Ecklon & Zeyher	Jacket plum	Sapindaceae	Fruits eaten raw, made into jelly, alcoholic beverage, vinegar, seed produces oil, subsistence from wild
Parinari curatellifolia Planch. ex Benth.	Mobola plum	Chrysobalanaceae	Edible fruit, subsistence from wild
Phoenix reclinata Jacq.	Wild date palm	Arecaceae	Edible dates, subsistence from wild
Rhus lancea L. f.	Karee	Anacardiaceae	Edible fruit, fruit used to make beer, subsistence from wild
Salacia kraussii	Salacia	Celastraceae	Edible fruit, subsistence from wild
Schinziophyton rautanenii	Manketti tree/ Mangongo Marula	Euphorbiaceae	Large, edible oily nut, subsistence from wild
Sclerocarya birrea Sonder		Anacardiaceae	Eaten raw, juice, alcoholic beverage, jelly
Securinega virosa (Roxb. ex Willd) Baillon	White berry bush/ Snowberry tree	Euphorbiaceae	Edible fruit, fruit has medicinal uses, subsistence from wild
Strychnos cocculoides Baker	Corky bark monkey orange	Loganiaceae	Large edible fruits, harvested from wild and sold locally
Strychnos innocua Delile	Dull leaved mukwakwa	Loganiaceae	Edible fruit, subsistence from wild
Strychnos madagascariensis Poir.	Black monkey orange/ shiny leaved mukwakwa	Loganiaceae	Edible fruit, fruit dried and stored, subsistence from wild
Strychnos pungens Solereder	Spiny leaved monkey orange	Loganiaceae	Fruit edible when ripe, subsistence from wild
Strychnos spinosa Lam.	Green monkey apple/ spiny monkey apple Morutla	Loganiaceae	Edible fruit, green fruit used medicinally, subsistence from wild
Syzygium cordatum Hochst.	Waterberry	Myrtaceae	Edible fruit, alcoholic drink, subsistence from wild
Syzygium guineense (Willd.) DC.	Woodland waterberry	Myrtaceae	Edible fruit, subsistence from wild
Tabernaemontana elegans Hochst. ex A. DC.	Small fruited toad tree	Apocynaceae	Edible fruit, subsistence from wild
Tamarindus indica L.	Tamarind	Fabaceae	Fruit used commercially
Terminalia sericea Burch.	Silver terminalia/ Mangwe	Combretaceae	Edible fruit, subsistence from wild

Uapaca nitida Muell. Arg	Narrow leaved mahobohobo	Euphorbiaceae	Edible fruit, wood makes a good charcoal, subsistence from wild
Uapaca sansibarica Pax	Lesser mahobohobo	Euphorbiaceae	Edible fruit, subsistence from wild
Vangueria infausta Burch.	Wild medlar	Rubiaceae	Edible fruit, subsistence from wild
Vangueriopsis lanciflora (Hiern) Robyns	False wild medlar	Rubiaceae	Edible fruit, subsistence from wild
Vitex doniana Sweet	Black plum	Verbenaceae	Edible fruit, subsistence from wild
Vitex mombassae Vatke	Smelly berry vitex	Verbenaceae	Edible fruit, source of ascorbic acid, subsistence from wild
Vitex payos (Lour.) Merr.	Chocolate berry	Verbenaceae	Edible popular fruit with coffee-like flavor, subsistence from wild
Ximenia americana L.	Small sour plum	Olacaceae	Edible fruit, oil from seed, subsistence from wild
Ximenia caffra Sond.	Large sour plum	Olacaceae	Edible fruit, oil obtained from seeds, subsistence from wild
Ziziphus mucronata Willd.	Buffalo thorn	Rhamnaceae	Edible fruit, subsistence from wild
Zizyphus mauritiana Lamt.	Jujube	Rhamnaceae	Edible fruit, subsistence from wild

Figure 1 Fruit of *Adansonia digitata* (baobab).

The baobab plays an important role in the economy of the local inhabitants, throughout its distribution. Practically all parts of the tree are utilized. In West Africa, the roots are reputed to be cooked and eaten mainly in times of famine. The trunks are often hollowed out and used for a variety of purposes, the most important being the storage of water. A medium-sized tree can hold 1600 l, while a large tree can contain as much as 8000 l.

Bark fibers are commonly stripped from the lower trunk. The tree, however, survives and generates new bark. The fiber from the inner bark is tough and durable and is widely used for rope, harness straps, strings for musical instruments, baskets, nets, fishing lines, and snares. Leaves, especially the young leaves, are popular as a spinach-type vegetable or are dried and powdered and made into soups and sauces. Fresh leaves are rich in ascorbic acid (vitamin C) and contain uronic acids, rhamnose and other sugars, tannin, and potassium tartrate. Leaves of the baobab are also used medicinally – as an expectorant, against fever, as an astringent and to treat kidney and bladder diseases, asthma, diarrhea, inflammations, insect bites, and general fatigue.

The husks of the fruits may be used as dishes or fashioned into vessels. They can also be used as fuel and provide a potash-rich ash suitable for soap-making. Husks, ground into a powder, are also used as a substitute for tobacco. The acid pith, which is rich in ascorbic acid, is used as a substitute for cream of tartar for baking. It is also ground and made into a refreshing drink. The pulp is also used to curdle milk. In East Africa, an extract from the pulp is used as a hair wash.

Seeds are embedded in a powdery white pulp, which contains tartaric acid and potassium bitartrate. The seeds may be eaten fresh or dried, either sucked or ground, and used to flavor foods. They are refreshing to suck and, when soaked in water, make a palatable drink. They are also used as a substitute for coffee. Crushed and roasted seeds can be applied as a paste to diseased teeth and gums.

Carissa bispinosa (Num-num)

The num-num belongs to the Apocynaceae family. *Carissa bispinosa* is the most common species, but

Figure 2 *Carissa macrocarpa* tree (num-num).

Figure 3 (see color plate 68) Flowers and fruit of *Carissa macrocarpa* (num-num).

other *Carissa* species occur and are utilized by local communities. The other species include *Carissa macrocarpa*, the large num-num, which is confined to South African coastal regions, *Carissa edulis*, the simple spined num-num, and *Carissa haematocarpa*, the karoo num-num.

The num-num is indigenous to Southern Africa and is found growing along the coast of KwaZulu-Natal, the Eastern and Western Cape, and also further inland in the Northern Province, Mpumalanga, and Guateng. In Southern Africa, the num-num is pollinated by small beetles, hawk-moths and other night flying insects. Various degrees of unfruitfulness in the USA have been attributed to inadequate pollination. Some seedlings are light croppers, and others never bear at all. It has been found that unproductive plants, apparently self-infertile, will bear fruits after cross-pollination by hand (see Figure 2).

The growth habit of the num-num is usually a somewhat scrambling shrub, or a small tree up to 5 m in height. The tree usually occurs at medium to low altitudes in dry woodland and coastal scrub. The spines are either once- or twice-forked, very occasionally simple and up to 45 mm long. The leaves are broad to narrowly ovate, leathery with a dark glossy green on the upper surface, and paler green below. The flowers are white to pinkish with a slender corolla tube. The flowers are sweetly scented and borne in terminal clusters or singly. Some plants bear flowers that are functionally male. These flowers are larger than normal with larger anthers and stamens that are much longer than the style. Functionally, female flowers have stamens the same length as the style and small anthers without pollen (see Figure 3).

The fruit is ovoid and fleshy, about 15 mm long and red when mature. The skin is thin, enclosing a firm reddish pulp in which numerous small seeds are embedded. When bruised or cut, the flesh exudes white droplets of a gummy juice. The fruit is edible when ripe.

The num-num is subtropical but survives temperatures of $-3\,^{\circ}C$ when well established. Young plants need protection if the temperature drops below zero. The best growth is obtained in full sun. The plant has moderate drought tolerance and a high resistance to soil salinity and salt spray.

The fruit, when fully ripe, is dark red and slightly soft. It can be eaten fresh and can also be used in fruit salads, icecreams, puddings, or for decoration purposes. Fruit can also be cooked to a sauce, used in pies and tarts or preserved whole by pricking, cooking briefly in a sugar syrup, and then bottling. They can also be made into jams or jellies.

Trees are often planted as a protective hedge, as they form an impenetrable barrier, and fruit is then regarded as a by-product. They are, however, slow growing, and a long time is needed before they form an effective barrier. Efforts have also been directed to the development of dwarf, compact, less spiny types for landscape use. Ornamental cultivars such as Bonsai, Dainty Princess, Low Boy, Nana, Nana Compacta, and Prostrata have been developed mainly as garden species. These dwarf cultivars must, however, be kept under control; otherwise, they are apt to revert to the original type, as vigorous shoots may develop and outgrow the compact form.

Dovyalis caffra (Kei-apple)

Dovyalis caffra is subtropical but can survive brief drops of temperatures to as low as $-6\,^{\circ}C$. It does well in almost any type of soil that does not have a high water table. It is drought-resistant and tolerates saline soil.

It grows as a shrub or small tree, usually 3–5 m in height but sometimes reaching 8 m. It is vigorous growing and rather dense and thorny. The spines are

usually 20–70 mm long, although some trees are spineless. It usually occurs in open bush and wooded grassland. Leaves are often clustered on short spurs and are oblong-obovate 20–50 mm long, glossy, and short-petioled. The flowers are small without petals and clustered in the leaf axils. Female and male flowers are usually borne on separate trees. Fruits are almost spherical, 25–40 mm long, and fleshy, with a bright yellow, smooth but tough skin. The pulp is juicy, highly acid, and apricot-textured (see Figure 4).

Figure 4 *Dovyalis caffra* tree (kei-apple).

Figure 5 (see color plate 69) Fruit of *Dovyalis caffra* (kei-apple).

Most people consider the fruit too acidic for eating out of hand, even when fully ripe. It is best cut in half, peeled, seeded, sprinkled with sugar, and allowed to stand for a few hours before serving as a dessert or in fruit salads. The fruits are pleasantly flavored and make excellent jelly and jam when ripe and underripe as pickles. They are widely cultivated both for their fruits and as a hedge. Fresh ripe fruit contains 80 mg of ascorbic acid (vitamin C) per 100 g of fruit. Fifteen amino acids have been identified in the fruit. Investigators in Egypt have demonstrated that the roots, stem, and fruit, but not the leaves and branches, possess antibiotic properties (see Figure 5).

Englerophytum magalismontanum (syn. *Bequaetiodendron magalismontanum*) (Stem Fruit)

Englerophytum magalismontanum, known locally as the stem fruit, is widely distributed from tropical Africa to KwaZulu-Natal in South Africa. It is very common in the Northern Province, Gauteng, Northwest, and Mpumalanga provinces of South Africa and occurs on rocky hills and mountain slopes in close association with granite or quartzite rocks.

It is a small to medium-sized tree 3–10 m in height with a dense bushy habit, with branches often touching the ground. The bark is brown, flaky, or scaly. The stem is straight with horizontal branches. The young twigs, leaf petioles, and floral parts are densely covered with dark brown hairs. The leaves are alternate, oblanceolate to obovate-elliptic, usually 70–140 mm long with a width of 20–30 mm, glossy dark green above with silvery to golden-brown silky appressed hairs below that may wear away on old leaves. The midrib is prominent on the abaxial leaf surface with the lateral veins prominent, immersed, but clearly visible. The leaf apex is broadly tapering, sometimes attenuate; the base is tapering and the margin entire, slightly rolled under and undulated. The petiole is brown to blackish, rough, and up to 14 mm long.

The flowers are inconspicuous, brownish pink in color and about 10 mm long. They are strongly scented and are borne in few to many flowered clusters on the leafless stems and branches. The fruits are ovoid and fleshy, 15–25 mm long, and 10–18 mm in diameter. They have a definite ridge and a small point at the top, and are densely crowded along the old wood. The fruits change from yellow to orange and finally to a dark, glossy red when fully ripe. Some trees, however, bear fruits that are white to light pink. The skin is quite thick and encloses a purplish fruit pulp that contains a sticky, milky juice, and usually one, but sometimes two, flattened seeds.

Figure 6 Fruit of *Englerophytum magalismontanum* (stem fruit).

The fruits, which ripen during the summer, are edible and have a high ascorbic acid (vitamin C) content. They have a sweet, but somewhat astringent, flavor. They may be used to make jelly, jam, or syrup. Local inhabitants eat the fruit raw but also brew a potent alcoholic drink (see Figure 6).

Traditional medicine uses an infusion of the finely stamped fruit, and the roots are regarded as a treatment for epilepsy. The pulverized bark is used as a cure for rheumatism, while powdered roots are also used to relieve headaches. As the wood is tough and durable, it is suitable for fencing poles, implement handles, and hut building, and the Zulu tribe in South Africa uses the wood to make milking buckets.

In gardens, its evergreen foliage and brightly colored fruits are decorative. The seed germinates easily when fresh, and trees may also be propagated from cuttings. The tree is relatively fast-growing and hardy. The fruit is very susceptible to fruit fly, and a spray control program should be followed.

Mimusops zeyheri (Moepel)

The fairly common moepel *Mimusops zeyheri* is also known as the Transvaal Red-milkwood. In South Africa, it is confined to the northern provinces and occurs northwards into Zimbabwe, as well as Botswana and Mozambique. It usually grows at low altitudes in hot areas. It is frequently found on well-wooded rocky hillsides, in riverine fringes, at the margins of evergreen forests, and in dry open woodlands.

It is occasionally a large shrub, but usually a small to medium-sized tree up to 15 m in height. The bark is gray to dark brown, rather smooth in young trees, later becoming rough (see Figure 7).

The leaves are scattered, ovate, lanceolate to oblong, about 110 mm in diameter, thick and leathery, shiny dark green above, and a paler green abaxially. The young leaves and twigs are covered with dense

Figure 7 *Mimusops zeyheri* tree (moepel).

hairs that are lost by maturity, and the leaf apex is broadly tapering to tapering and is often notched. The leaf base is tapering, and margins are entire and slightly thickened. The petiole is up to 30 mm long.

The normal flowering season is during November and December, when fragrant flowers appear among the leaves. The flowers are creamy white and star-shaped, about 10 mm in diameter, and clustered into axillary groups of three or more flowers, often in profusion. They give rise to green fruit, which ripen in the spring. Fruits are ovoid, fleshy, 20–30 mm in length and 10–25 mm in diameter. They are bright yellow when mature. Beneath the rather brittle skin is a yellowish flesh and several shiny brown seeds. Although the edible flesh is rather dry and floury, it contains about 65% water, 28% carbohydrates, and 90 mg of ascorbic acid per 100 g (see Figure 8).

Fruits of the common moepel are an important item in the diets of rural inhabitants, as well as many wild animals. They are usually eaten fresh but often crushed to extract the juice, which is fermented. Fruit can also be used to make delicious jams and jellies. In some instances, the fruits are dried in the sun and then stored. The tree could be an attractive garden subject if situated in a well-drained area, which has a summer rainfall and a mild winter climate. The moepel can be easily propagated from

Figure 8 (see color plate 70) Fruit of *Mimusops zeyheri* (moepel).

seed and, although it is considered to be rather slow-growing, will flourish if well cared for.

Freshly cut wood is pink, hence the name Red-milkwood, but turns pale brown when dry. The wood is moderately hard with a short, wavy grain and is useful as a general purpose timber. It is also suitable for woodwork, since it gives a smooth finish. It is, however, not very strong or durable. Care should be taken when working with green wood, as it contains an irritant, which causes sneezing.

Sclerocarya birrea (Marula)

Sclerocarya birrea (marula) is a large, dioecious, deciduous tree that grows wild in northern and north-eastern South Africa and parts of eastern Botswana. The marula is an erect tree that reaches heights of 15 m. Male and female flowers occur separately, and although they are usually on separate trees, this is not always so. The fruit form varies from almost spherical to oval with a tough, strong skin, which is light yellow when ripe. The fruit flesh is soft, whitish, and contains fibers. The flesh of its fruit is very juicy and aromatic, and is eaten fresh or processed, yielding quality jams, juices, and alcoholic beverages. The nut, which can be eaten fresh or roasted, has a high protein content and contains a nondrying oil that can be used for soap production as well as in food preparations. The fruit usually ripens from January and falls from the tree

Figure 9 *Sclerocarya birrea* tree (marula).

before it is ripe. The fruit is climacteric and will therefore only ripen after harvesting. There are numerous other uses for the marula tree, all of which present opportunities to rural communities (see Figure 9).

The fruit serves as an important source of ascorbic acid (vitamin C) for the rural people. The marula has a high ascorbic acid content of between 54 and 190 mg per 100 g, depending on the selection. This is much higher than the average amount of ascorbic acid found in the orange. In an area that suffers from problems of malnutrition and mineral deficiencies, demand for the fruit will always be high (see Figure 10).

When mature in February/March, the green fruit abscise, followed by a skin color change to yellow, flesh softening, and aroma development. The most popular product obtained through fermentation of the fruit is an alcoholic beer made by rural communities. Rural communities have a high regard for the marula tree, and so it is not used for firewood and other purposes. The marula has become commercialized over the past few years, although it has not yet been planted in orchards. The fruit has been used to make a creamy liqueur, which is now sold internationally. The fruit pulp is used to make jellies and jams as well as locally sold fruit juice and beers. The biggest potential for marula probably lies in the oil derived from the kernel of the nut because of its unique qualities.

Tamarindus indica (Tamarind)

The tamarind is native to tropical Africa and grows wild throughout the Sudan. It was introduced so long ago into India and other parts of southern Asia that it is often reported as being indigenous there. It has now reached the southern limit of its range in Mozambique and has also become naturalized round Durban

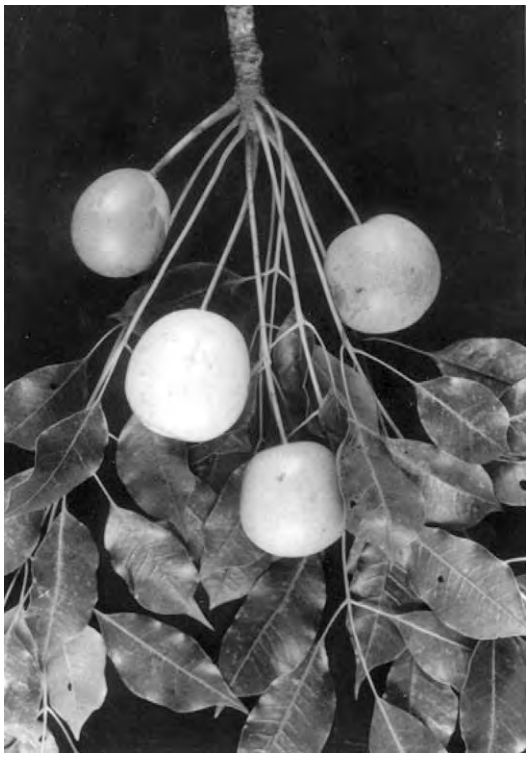

Figure 10 Fruit of *Sclerocarya birrea* (marula).

in KwaZulu-Natal (South Africa). In addition to the usefulness of its fruit, the tamarind has the advantage of being one of the best ornamental trees of the tropics.

The tree is slow-growing and, under favorable conditions, can reach a height of 24–30 m. It is highly wind-resistant with strong supple branches. The mass of bright green, fine, feathery foliage is composed of pinnate leaves, each having 10–20 pairs of oblong leaflets 12.5–25 mm long and 5–6 mm wide, which fold at night. The flowers are inconspicuous and borne in small racemes. They have five petals, of which two are reduced to bristles and are yellow with orange or red streaks. The flower buds are distinctly pink due to the outer color of the four sepals, which are shed when the flower opens.

The fruits are flattish, bean-like, irregularly curved pods, borne in abundance along the new branches, and vary from 50 to 150 mm in length and 20 to 30 mm in diameter. The pods are cinnamon brown or grayish brown externally and initially tender-skinned with green, highly acid flesh and soft whitish underdeveloped seeds. As they mature, the pods fill out, and the juicy pulp turns brown to reddish brown. The skin becomes brittle and is easily cracked, and the pulp dehydrates to a sticky paste enclosed by a few coarse strands of fiber extending lengthwise from the stalk. The seeds are glossy brown and squarish in form.

There are many food uses of the tamarind, ranging from vegetable preparations to flavoring in many types of cuisine and dishes. The most outstanding characteristic of the tamarind is, however, its astringency and its prime use as a souring agent. It is also rich in B complex vitamins. When fully ripe, fruit are also eaten fresh. The pulp is made into a variety of products and is included as an ingredient in many well-known brands of chutneys, curries, and sauces. It also serves as a flavoring in certain fish dishes. Sugared tamarind pulp is often prepared as a confection.

Over-ripe fruits also have their uses; for example, they can be used to clean and brighten silver, copper, and brass. The tamarind also has numerous medicinal uses. The pulp is officially listed in the British, American, and other pharmacopeias, and some 90 000 kg of the shelled fruits are annually imported into the USA for the drug trade. Tamarind preparations are universally recognized as refrigerants in fevers, as laxatives, and as carminatives.

Garcinia livingstonei (African Mangosteen)

Garcinia livingstonei is known as the mangostan or African mangosteen and originates in Southern Africa. It is found growing in the northern coastal region of KwaZulu-Natal, Mpumalanga and Northern Province of South Africa, Mozambique, and Swaziland. It grows northwards as far as Somalia. The mangostan is also found in the northern parts of Botswana and Zimbabwe. It occurs most commonly at low altitudes, in riverine fringes, and in open woodland.

The tree is small to medium with a height of 2–10 m. It has a very distinctive habit, being stiff with rigid branches arising at an acute angle. The tree is evergreen. The leaves are simple and usually in whorls of three, elliptic, oblong to ovate, leathery, glossy dark green above, and paler green below. The young leaves are bright red. The sweetly scented flowers are small, cream to greenish yellow and are borne on slender stalks in groups on short knobbly side spurs clustered along the older stems. The almost spherical fruit are up to 25 mm in diameter and are yellow to orange when mature. Mangostans are usually harvested from November to January (see Figure 11).

The fruit is usually eaten fresh and has a delicious acid-sweet flavor. Fruits are also used to prepare an alcoholic beverage. Potential exists for processing of this fruit into numerous products including beverages, jams, and jellies. Extracts of the leaves and flowers have been tested and show antibiotic properties.

Figure 11 (see color plate 71) Fruit of *Garcinia livingstonei* (African mangosteen).

Cordyla africana (Wild Mango)

Cordyla africana, also known as wild mango, is a large, spreading, deciduous tree up to 25 m in height. It usually occurs at low altitudes in hot areas. The leaves are alternate, compound, imparipinnate with 11–28 leaflets plus a terminal leaflet. Flowers are produced in short, dense axillary sprays, or clustered in the leaf axils. Petals are absent, and the yellow–orange stamens form a spherical head, with the flowers somewhat resembling the characteristic 'powder-puff', but the stamens are stouter and more robust. The fruits usually resemble a semifleshy drupe that is almost spherical and yellow when ripe, with the seeds embedded in the edible fleshy pulp. The fruits vary in size and are usually 40–80 mm in length and 30–60 mm in diameter. They contain ascorbic acid (vitamin C) and are much sought after by the local people, being eaten either fresh or cooked. The wood is brown and hard, and is traditionally used for building purposes or for making African drums. The tree exudes a gum resin.

Harpephyllum caffrum (Wild Plum)

Harpephyllum caffrum is a small to medium-sized evergreen tree, 6–10 m in height. The compound leaves are alternate, crowded at the end of the branches. The leaf consists of four to eight pairs of opposite leaflets plus a terminal leaflet. The leaflets are lanceolate, occasionally ovate, without hairs and dark shiny green. The flowers are small, whitish to yellowish green in small, branched sprays near the end of the branches. Male and female flowers are on separate trees. The fruit is oblong, thinly fleshy, up to 25 mm long, and red when mature.

The fruits are rather sour and relished by children. Good wines and jellies can be made from the fruit. The tree is decorative and is frequently planted as an ornamental.

Parinari curatellifolia (Mobola Plum)

Parinari curatellifolia is an indigenous fruit much sought after by local people. The mobola plum is a large evergreen tree with a spreading habit and can reach heights of 12 m. The leaves are alternate, oblong, and usually about 75 mm in length. The flowers are small and borne in compact heads. The fruits are oval to round approximately 50 mm long and 35 mm in diameter. The skin of the mobola plum is russet to grayish in color and pitted. Its pleasant-tasting yellow flesh has a variety of uses (see Figure 12).

It is eaten fresh and made into a porridge, and a syrup is made from the fruit, providing the basis for a refreshing nonalcoholic drink and also an intoxicating beverage. In traditional medicine, an extract from the bark is used for the treatment of pneumonia, abdominal complaints, and toothache. The root is used for ear and eye complaints. A bark extract is also used in tanning by local peoples. The wood of the tree is hard and resistant to borers and has been used fairly extensively for roof construction, poles, and benches in rural areas.

Vangueria infausta (Wild Medlar)

Vangueria infausta has many common names locally, including wild medlar, mmilo and mispel. It is a small, deciduous tree found in the Eastern and Northern regions of South Africa. It grows well in dry areas and fruits between January and April (see Figure 13).

The fruits are greenish, becoming light brown when ripe. They are almost spherical with a diameter of 25–35 mm (see Figure 14).

Figure 12 (see color plate 72) Leaves and mature fruit of *Parinari curatellifolia* (mobola plum).

Figure 13 Ripe fruit of *Parinari curatellifolia* (mobola plum).

Figure 14 (see color plate 73) Fruit of *Vangueria infausta* (wild maedlar).

The fruits are used by local people, especially during food scarcity, and are relatively high in ascorbic acid (vitamin C). The seed kernels are eaten as a nut and are rich in protein. The potential of the fruit would appear to be in processing, since a number of products can be made from the fruit.

Often, small gall-like growths are noticed on the leaves; these are caused by a fungus, which attacks the leaves.

Fruits of Central and South America

G T Prance, University of Reading, Reading, UK

Background

Tropical America is the source of many familiar fruits, especially avocado, cacao, guava, papaya, passion fruit, and pineapple. However, the region is also the source of a cornucopia of lesser-known fruits of great importance to local peoples. A visit to any market in Central or South America is well worthwhile to see many less familiar fruits that are traded daily. Many of the fruits grown and marketed in the region are from elsewhere in the tropics and are treated in other entries (*See* **Fruits of Tropical Climates**: Commercial and Dietary Importance; Fruits of the Sapindaceae; Fruits of the Sapotaceae; Lesser-known Fruits of Africa; Lesser-known Fruits of Asia), for example, oranges, bananas, jack fruit, carambolas and mangoes. The fruits are arranged here in alphabetical order of the botanical family to which they belong because this brings related fruits together. Some of the lesser known fruits are also described here.

Anacardiaceae (Cashew or Sumac Family)

Cashew Apple (*Anacardium occidentale*)

Cashew is more familiar for the nut, but is also the source of a pseudofruit. The nut is borne on the end of a swollen, pear-shaped, fleshy stalk known as the cashew apple or pear. This technically is not a fruit, since the nut is the actual fruit. The red- or yellow-colored pear is used as a fruit to make a provitamin A and C-rich juice, cashew wine, syrup, preserves, pickles, etc., or is eaten raw. Cashew is widely cultivated throughout Central and Southern America and elsewhere in the tropics, but is a native of the arid lands of northeastern and central Brazil.

Hogplum (*Spondias mombin*)

This is a plum-like yellow fruit of Amazonian origin that is widely cultivated throughout Central and South America, Florida, and elsewhere. It is one of the most

popular fruits in Amazonia as an icecream flavor or for its juice. The ripe fruits rot quickly, and so it is not easy to ship and is used locally where it is grown. A related species is *Spondias dulcis* or the golden-apple from the Pacific is also widely cultivated in tropical America.

Annonaceae (Soursop Family)

This plant family is the source of a wide range of large fleshy fruits, the best-known of which are the cherimoya, the soursop, and the custard apple.

Soursop (*Annona muricata*)

A large compound fruit 15–30 × 10–20 cm in size and weighing up to 3 kg. The fleshy pulp contains many seeds. The fruits are eaten raw or used for juice, icecream or desserts. Soursop originated in northern South America or the Caribbean and is now widely cultivated around the tropics and in Florida. A closely related fruit is the custard apple (*Annona reticulata*).

Sugar Apple or Sweetsop (*Annona squamosa*)

This smaller fruited Annona is also of Caribbean origin, it is cultivated around the tropics and is generally eaten raw rather than processed.

Several other species of *Annona* are used locally, for example, the wild soursop or araticum (*Annona montana*).

Cherimoya (*Annona cherimolia*)

A native of Andean valleys of Ecuador and Peru. The roundish, heart-shaped, green fruits are most popular in Peru and are said to be the tastiest of all the Annonas. The fruit thrives only at higher altitudes.

Biribá (*Rollinia mucosa*)

Although this bright yellow fruit belongs to a different genus, its fruit is similar to the Annonas and can be up to 14 × 16 cm weighing 1.3 kg, although 5-kg fruits have been reported. This species possibly originated in the upper Amazon in the region of the Peru–Brazil border and is widely cultivated in gardens throughout central America, the Caribbean, and Amazonia for its delicious pulp, which is eaten raw.

Apocynaceae (Dogbane Family)

This family contains two little-known but locally important fruits sorva (*Couma utilis*) and mangaba (*Hancornia speciosa*). Sorva is a small round berry with a delicious sweet pulp and many seeds. It is eaten raw. This and other species of *Couma* are an important source of latex used for chewing gum. Mangaba also produces a berry that is usually used in icecream and desserts, and the tree is also a source of latex. Sorva is a native of Central America and mangaba of northeastern Brazil, but both species are cultivated throughout Brazil.

Arecaceae (Palm Family)

Many of the Central and South American palms have edible fruits of considerable local importance as fruit and sources of various types of oils. Six of the most commonly used species are mentioned below.

Assai or Açai (*Euterpe oleracea*)

This multi-stemmed palm is much cultivated in eastern Amazonia for its fruit and as a source of heart-of-palm. The trees produce three to eight branches of fruit a year. The outer pulp of the small round fruits is used to make a drink or icecream flavor. It is colored dark purple and is an important supplement to the nutrition of local people. It has a wide range from Colombia and Ecuador to eastern Amazonian Brazil. Several other species of *Euterpe* are used locally, especially *E. edulis* in the upper Amazon in Peru.

Bacaba (*Oenocarpus bacaba*)

The small round fruits of this Amazonian palm are used in a similar way to assai to make a purple juice that is usually mixed with cassava (*Manihot*) flour.

Buritî (*Mauritia flexuosa*)

This large fan-leafed palm of swampy places in Amazonia is called aguaje in Peru and moriche in Venezuela. The edible fruit is used in all Amazon countries. It is ovoid and covered with small, dark-red, rhomboid scales. Under the scaly exterior is a thin yellow pulp that is often used in icecreams and desserts and is rich in provitamin A.

Patauá (*Jessenia batua*)

The pulp of the fruit of this palm of the upper Amazon in Peru and Colombia is also used to make a beverage similar to that of assai and bacaba. The kernel contains an excellent highly unsaturated oil similar to that of the olive.

Peach Palm (*Bactris gasipaes*)

This is probably the most important of all edible species of American palms. A native of the Andean foothills of Bolivia and Peru, it was spread as far as Central America and the Guianas in pre-Colombian times. The yellow- to red- or orange-colored fruits are much used by indigenous and local peoples. The fruits are boiled and the thick, starchy pulp eaten with salt or honey, and it is often compared with the chestnut

in consistency and flavor. Many other local food preparations and recipes use the peach palm. It is most nutritious, containing both proteins and carbohydrates as well as provitamin A and minerals. Other names for this palm are peijibaye (Central America), pupunha (Brazil), chontaduro (Colombia), pijuayo (Peru), and pijiguao (Venezuela).

Tucumã (*Astrocaryum aculeatum* and *A. vulgare*)

The spiny trunked tucumãs have an ellipsoid fruit with an orangish pulp that is rich in provitamin A. The fruits are usually eaten raw. Both species are native to the Amazon region where they are widely used and often found in markets.

Bombaccaceae (Kapok-tree Family)

Sapote (*Quararibea cordata*)

This is a little-known, but tasty fruit of the upper Amazon around the border of Peru and Brazil. This region is the origin of several Amazonian fruit. The local name sapote or sapota is confusing, because fruits of the Sapotaceae family have the same name. The large irregular-shaped fruit 7–15 × 5–15 cm has a persistent ring around its base formed from the sepals. The thick orange-colored pulp is eaten raw or in drinks. The bitter outer rind must be removed before eating. The sapote trees can reach heights of 45 m.

Bromeliaceae (Pineapple Family)

Pineapple (*Ananas comosus*)

The pineapple is probably the best-known and most widely cultivated fruit of South American origin. Unlike most fruit described here, it is a short herbaceous plant. The fruit is produced at the center of the circle of long, narrow, spiny leaves. The pineapple originated in southwestern Brazil and possibly eastern Paraguay, but was carried from there all over the American tropics before Columbus. Many varieties have been bred from the original wild species and spread around the world. The fruit is formed by the fusion of ovaries and bracts to the axis of the inflorescence, and is technically termed a syncarp. Pineapples are an important source of provitamin A and vitamins B, B_2, and C as well as the minerals iron, potassium, and calcium. The largest producer of this fruit is now Hawaii.

Caricaceae (Papaya Family)

Papaya (*Carica papaya*)

Another popular and well-known fruit of South American origin is the papaya. It probably originated in Central America and was spread southwards into the Andes and entered Amazonia in preColombian times. The fruit is a large berry, filled with black seeds at the center. Papaya trees are usually either male or female, and only the female trees bear fruit (hermaphrodite varieties do occur but are rare). The early travelers to South America soon distributed this delicious and nutritious fruit around the world. The trees are fast-growing and short-lived and produce fruit continuously within a year of sowing the seed. The fruit is a source of provitamin A and vitamins B, B_2, and C, and contains the enzyme papain, which helps the digestion of foods and is used as a meat tenderizer. The papaya is grown commercially around the tropics.

Caryocaraceae (Souari Family)

Piqui (*Caryocar brasiliense*)

The fruit of this low tree of the savanna (cerrado) of Central Brazil is very popular locally and is still mostly harvested from wild trees. The unusual tasting pulp of the fruit is cooked with rice or beans. It is also used to prepare a sweet liqueur. The kernel contains an oil used in cooking and for skin care. The Amazonian species (*C. villosum*) is a much larger tree, the fruit of which is used in the same way.

Chrysobalanaceae (Cocoa Plum Family)

Cocoa Plum (*Chrysobalanus icaco*)

This is a shrub or small tree of coastal sand dunes around the coasts of central and South America and the Caribbean and in similar habitats in Africa. The small plum-like fruit is either eaten raw or, in Venezuela and Colombia, bottled in syrup and is called icacos.

Several other species of this family are used locally and planted in house gardens, especially pajura (*Couepia bracteosa*), a native of the Guianas and Amazonia, marirana (*Couepia subcordata*), a native of Peruvian Amazonia, and oiti-coro (*Couepia rufa*), a native of the Atlantic coastal forests of eastern Brazil. These species of *Couepia* have a large fruit with an oily pulp with an agreeable odor.

Clusiaceae (Mangosteen Family)

Mamey Apple (*Mamea americana*)

A fruit of Central American or Caribbean origin that has now been distributed around the tropics. The large brown fruit can be up to 18 cm in diameter in some varieties. The orange-colored pulp is usually used in compotes and other desserts as well as in a

wide range of liqueurs. This fruit is grown for local use in gardens and small orchards.

Bacuri (*Platonia insignis*)

This most delicious of Amazonian fruits originated in eastern Amazonia. The attractive flowers are about 7 cm long with rose-colored petals and produce a large ovoid berry up to 15 cm in diameter. The pulp is eaten raw or used in icecreams, desserts, and fruit drinks. Some varieties are sweet and preferred for eating, and others quite acid and generally processed.

Another genus of Clusiaceae, *Rheedia*, has several species (e.g., *R. macrophylla*) that produce similar but smaller fruits than bacuri and are generally known as bacupari in Brazilian Amazonia.

Humiriaceae (Humiria Family)

Uchi (*Endlopleura uchi*)

The uchi is a large tree of eastern and central Amazonia. Fruits are generally collected from wild trees after they have fallen from the tree, and are very popular with local people, especially in Pará State, Brazil. The ellipsoid fruit has an unusual but agreeable taste and is eaten raw, or mixed with cassava flour and also used for icecreams, liqueurs, and sweet pastes. The kernel contains an oil similar in composition to olive oil that is used in cooking.

Icacinaceae (Icacina Family)

Umari (*Poraqueiba sericea*)

This low tree is a native of Central and Western Amazonia. The pulp of the plum-like fruit is highly desired by local peoples, and it is always in the markets of Iquitos, Peru and Manaus, Brazil. The pulp has a peculiar smell and flavor that some people find delicious and others repugnant, and is definitely an acquired taste.

Lauraceae (Laurel Family)

Avocado (*Persea americana*)

The avocado is of Mexican and Central American origin, but is now planted around the tropics. This well-known fruit is used as a savory in most places, but is used in sweet drinks and desserts in Brazil. The pulp of the fruit is oily and nutritious and rich in minerals and vitamins. There are three races of avocado recognized: Mexican, Guatemalan, and West Indian. There are also a wide range of cultivars of this important fruit. The name avocado is derived from its Aztec name: ahuacatl. California, Florida, Israel, and South Africa are now important commercial producers of avocados.

Leguminosae (Bean Family)

Inga (*Inga edulis* and Other Species)

Inga is a large South and Central American genus with over 300 species. Several species produce pods with seeds surrounded by a woolly, slightly juicy edible pulp. The most widespread and most cultivated species is *Inga edulis*, which is now so dispersed that its exact area of origin is uncertain. *Inga capitata* has a much thicker and woody pod and is a native of the Guianas and Eastern Amazonia. The fruits of many other species of *Inga* are used locally throughout tropical America. The pulp is eaten raw, and the seeds are spat out.

Malpighiaceae (Barbados Cherry Family)

Acerola or Barbados Cherry (*Malpighia punicifolia*)

This small shrub or tree originated in northern South America or Central America and is widely distributed throughout the Caribbean. The cherry-sized fruits are colored orangish red to scarlet, are slightly three-lobed, and have three stones inside the fleshy pulp. The fruits are one of the richest known sources of vitamin C. They are eaten raw or used in juices, icecreams, jams, and desserts. The acerola is now widely cultivated around the tropics as a source of vitamin C and in recent years has been grown commercially. It is rivaled only by camu-camu (see below) for its content of vitamin C. Consumption of only four fruits meets the daily requirement of vitamin C.

Ciruela or False-coffee (*Bunchosia glandulosa*)

This is a small shrub or tree that produces asymmetric ellipsoid, orange- to scarlet-colored fruits. It is widely cultivated in Central America, the Caribbean, and western South America but is little known elsewhere. The fruits are sometimes eaten raw but more generally made into a sweet paste similar to that of the guava.

Moraceae (Fig Family)

Uvilla (*Pourouma cecropiifolia*)

This fast-growing, short-lived tree is a native of Amazonian Peru, where the grape-like fruit is much used by indigenous peoples. More recently, it has been introduced to Brazil and throughout the Amazon region.

The small, round fruits are borne in clusters and have a tasty sweet pulp. In Brazil, this fruit is called mapati.

Myrtaceae (Myrtle Family)

Perhaps the greatest variety of delicious fruits of tropical America come from the myrtle or guava family.

Guava (*Psidium guajava*)

The guava is a small tree with tortuous branches and a smooth trunk. The fruit is a berry with a fleshy yellow or pink pulp and many seeds near the center. Many different varieties have been developed that vary in color, size and in shape from round to ovoid to pear-shaped. The fruit is often used to make guava paste, but is frequently eaten raw or used for juice or fruit salads. It is rich in provitamin A and vitamins B and C. The guava has been introduced for commercial use to many places in the world, such as Hawaii, where it has become naturalized and an invasive weed.

Several other species of *Psidium* are cultivated for the edible aromatic fruits especially the araçá (*Psidium guineensis*) and the araça-pera (*Psidium acutangulum*). The latter species has unusual quadrangular branches. Both are natives of South America and are widely cultivated.

Feijoa (*Feijoa sellowana*)

The fruits of this small tree are similar in taste to the guava but usually larger and colored green. Feijoa is planted both for its fruit and for its attractive flowers with white petals and a mass of purple stamens. This species is native in the savannas of Paraguay and southern Brazil. It is often grown in subtropical regions such as California and is being strongly marketed by New Zealand.

Araça-boi (*Eugenia stipitata*)

This little-known fruit is a native of the upper Amazon and is probably the most aromatic of all fruits in the myrtle family. The round, yellow fruits can be as large as 12 cm in diameter and weigh 750 g. This very acidic fruit is generally used for its juice mixed with sugar, rather than eaten raw.

Jabuticaba (*Myrciaria cauliflora*)

One of the most popular of all fruits in southern Brazil, the jabuticaba is a native of the Atlantic coastal rainforests. The perfumed flowers followed by the fruits are borne in huge quantities all along the trunk and branches of these low trees. The fruits are round and colored dark purple when mature. Many different varieties with fruits of different sizes have been developed. The fruit is delicious raw and is also used in jams and desserts. Local people make a tasty liqueur from the jabuticaba. Most gardens in southeastern Brazil have a tree where there is always great competition between the owners and birds to pick the fruits.

Camu-camu (*Myrciaria dubia*)

This has only recently been brought to the market and is a native of periodically flooded river banks of the northwestern Amazon. The cherry-sized fruits are borne in great quantities and are reddish when young, maturing dark purple. The fleshy pulp is extremely rich in vitamin C having about 30 times more per gram than citrus. This fruit is used principally for its juice, in icecreams and other desserts. It is very popular in Peru and is still harvested largely from wild trees along the banks of rivers and lakes.

Cayenne Cherry or Pitanga (*Eugenia uniflora*)

This shrub or small tree bears berries of 2–3 cm in diameter that are deeply divided into seven to 10 longitudinal segments. The scarlet fruits are rich in vitamin C and are eaten raw or in juices, jams, and icecreams. The pitanga is native to South America and is widely cultivated in Florida, Hawaii, Central America, and the Caribbean and in many other places around the tropics, especially in the Philippines. It is now grown commercially in a few places.

Passifloraceae (Passion Flower Family)

Passion Fruit (*Passiflora edulis*)

Passion fruits are borne on vines and are one of the best known and most commonly used fruits of tropical American origin. Since they have been widely cultivated throughout the region and elsewhere, many varieties exist. The name passion flower is derived from the cross-like structure of the stigmas emerging from the center of the flowers, and the ring of appendages of the corona that have been likened to the crown of thorns of Christ.

The round to ovoid fruits are usually yellow or purple and contain many seeds surrounded by a gelatinous and tasty pulp. This highly aromatic pulp is extremely popular for juices, icecreams, desserts, and drinks and in numerous other recipes. Passion fruits are a good source of provitamin A. They are often used medicinally as a calmant or sedative.

Several of the other over 400 species of *Passiflora* have edible fruits and are widely cultivated for example *P. nitida*. Passion fruits are cultivated commercially around the tropical and subtropical world.

Granadilla (*Passiflora quandrangularis*)

This is a more robust vine than the true passion fruit and has quandrangular stems that are winged. The

fruits are ovoid and larger, up to 30 × 15 cm in size, and can weigh 2–3 kg. This fruit is cultivated on a large scale in Colombia and the northwest of Amazonia, and is not known from the wild, so its exact place of origin is uncertain. Unlike the passion fruit, it is the pulpy mesocarp rather than the mass around the seeds that is eaten. It is often served as a savory rather than a sweet, but it is also used for juices, icecreams, and other desserts.

Rubiaceae (Coffee Family)

Genipap (*Genipa americana*)

The genipap is a tree up to 15 m tall and is now widely distributed throughout Central and South America and the Caribbean. It probably originated in northern South America but was widely distributed by native peoples in preColombian times. The berry is ovoid, 8–12 × 7–9 cm in size, and weighs 200–400 g. The many seeds are surrounded by a fleshy pulp. The unusual smell and taste make it an acquired taste, but it is nevertheless a very popular fruit with local peoples for drinks and sweets. The fruits must be ripe and soft before eating. The green fruits are the principal source of a black dye used for cloth, fibers, and body paint, and this accounts for the movement of this species over such a wide range by indigenous peoples.

Sapindaceae (Soapberry Family)

Mamoncillo or Limoncillo (*Melicoccus bijugatus*)

This 12–14-cm-high tree produces clusters of small round to ellipsoid fruits with a hard shell. The seeds are surrounded by a juicy and gelatinous pulp, which is eaten and the seeds spat out. This is a native of northern South America and widely cultivated in Florida the Caribbean and Central America. It is often used as a shade tree in cities. In Brazil, much more commonly cultivated is the pitomba (*Talisia esculenta*), which has a similar and equally delicious fruit and is a native of western Amazonia.

Sapotaceae (Sapodilla Family)

This is another plant family that has produced a large number of different edible fruits such as the caimito and the sapota.

Caimito or Abiu (*Pouteria caimito*)

This small tree produces yellow round to elongate-ellipsoid fruit up to 10 cm long. It is native to Amazonia and is cultivated and wild throughout the region. The one to four black seeds are surrounded by a delicious edible pulp. The rind contains a white sticky latex that can adhere unpleasantly to the lips when this fruit is eaten. Many varieties have been developed. Many other species of *Pouteria* are harvested from wild trees throughout Amazonia and are known as *abiurana* in Brazil. The ucuqui (*Pouteria ucuqui*) is a large tree, the fruits of which are very popular in northwestern Amazonian Brazil. The pulp is often mixed with cassava flour to make a porridge-like food.

Sapota or Sapodilla (*Manilkara sapota*)

This is the best-known and most widely cultivated fruit from the Sapotaceae. The trees reach 15–20 m in height and bear round brownish and scaly berries. The one to four flattened seeds are surrounded by a sweet soft pulp that is eaten raw. This species originated in Mexico or Central America and is now cultivated around the tropics. The trunk of this tree is also tapped for its chicle-type latex that is used in chewing gum.

Star Apple (*Chrysophyllum cainito*)

A tree up to 15 m in height with a round fruit 7–10 cm in diameter. When cut in half, the three to 10 seeds appear in a star-like formation, hence the name. These fruits have a bitter white latex in the skin and a pleasant, sweet tasting pulp. The star-apple is a native of the Greater Antilles but is widely cultivated in Central America and elsewhere.

Solanaceae (Nightshade Family)

The Solanaceae of South America have given rise to many plants of extreme economic importance such as potatoes, tomatoes, and bell and capsicum peppers. The latter three are technically fruit, but are used as vegetables and are not discussed further. Several species of *Solanum* are gradually being domesticated for their edible fruit.

Naranjilla (*Solanum quitoense*)

This fast-growing, short-lived subshrub is native to the Andes and grows at 700–2000 m altitude. The orange, round fruits have a greenish pulp around the numerous seeds. The pulp is used mainly as a vitamin-rich drink. It is most popular in Colombia and Ecuador, where it is a native but has also been introduced to Central America. Closely related to this species is the lowland cocona, known in Brazil as cubiu (*Solanum sessiliflorum*), which is a much more widely distributed domesticate than the naranjilla. The cocona berries are larger than those of the naranjilla and are used for juice, as a vegetable, and in salads.

Sterculiaceae (Cacau Family)

Cacau (*Theobroma cacao*)

This species is well known, as the seeds are the source of chocolate. The sweet, aromatic pulp around the seeds is eaten by local peoples. The exact origin of the cacau is uncertain, since it was so widespread in pre-Colombian times, but it possibly came from north-western Amazonia. The large fruits are borne on the trunk and branches of the trees. They are either ellipsoid or round. The rounder fruits are termed the criolo variety. The thick hard outer shell is yellow or red. The edible pulp surrounds 20–40 round seeds arranged in five rows.

Cupuaçú (*Theobroma grandiflorum*)

This species of the cacau genus is cultivated for the aromatic pulp of its most delicious fruits. The small trees produce large ellipsoid football-like fruit 12–25 $\times$ 10–12 cm that can weigh up to 1.5 kg. The exterior has a rust colored scaly covering. Inside, the 20–50 seeds are in five rows and adhere strongly to the thick pulp. The pulp is very popular in Brazil as an ice-cream flavor and for other sweets. The seeds have recently started being used to make cupulate, which tastes much like chocolate but has a different fatty acid profile. The tree is a native of eastern Amazonia, where the fruits are also harvested from wild trees.

The fruits of several other species of *Theobroma* are used locally for the pulp, especially the cacau sacha (*T. speciosum*) in Peru. *Theobroma bicolor* or macambo is commonly cultivated by indigenous peoples of the upper Amazon in Peru for the flat, disc-like seeds, which are roasted and eaten like nuts. This species is widely cultivated from Mexico to Brazil.

Lesser-known Fruits of Asia

M N Normah, Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia

Introduction

Tropical rain forests of South-east Asia in general, and that of the Indo-Malayan region in particular, are known to endow a tremendous variety of plant genetic resources. These include species of valuable and marketable timber species, medicinal plants, and fruit tree species. Many fruits originated from the Malaysian forest. However, out of this wide range of fruits, many are considered rare or lesser-known. They are generally neglected because they have not been exploited commercially and there is a lack of improved varieties. They occur in the wild or grown in scattered home gardens. These rare fruit species are also a source of useful genes for related crop species and promise to add to both nutrition and economic development.

Tropical fruits have been recognized as a rich and natural source of vitamin A and vitamin C, potassium and high dietary fiber. Fruits such as guava (*Psidium guajava*) contain 150 mg 100 g^{-1} vitamin C. Jackfruit (*Artocarpus heterophyllus*) and cempedak (*Artocarpus integer*) are highly nutritious and they are a very valuable carbohydrate source. The seed also has plenty of carbohydrates, as well as a fairly high protein content. The nutritional value of many more tropical fruits is not well documented.

Table 1 shows some examples of the lesser-known species. A more detailed outline is given below on 12 of the fruits listed in **Table 1**.

Artocarpus odoratissimus (Terap, Tarap, Marang)

The terap fruit is a syncarpium, a multiple fruit with numerous carpels fused with the fleshy receptacle. The rind is a mass of closely packed soft spines about 2 cm long with a small nob. It is green when immature and becomes fig-brown and soft when ready to eat. The numerous seeds are embedded in a firm white flesh closely packed together and lightly attached to the central core (receptacle).

Terap is unique to Brunei Darussalam and parts of Sabah and Sarawak in Borneo. Although the fruit was described from and better known in the Philippines, its distribution there is limited and it was probably introduced from Borneo. In the Philippines, the species occurs only cultivated, but in Borneo it is common in the wild state. The large fruit is esteemed

Table 1 Some of the lesser-known fruits of Asia and their uses

Species	*Common name*	*Family*	*Use*
Annona muricata L.	Soursop, durian belanda	Annonaceae	Fresh fruit, juice
Annona reticulata L.	Nona kapri, custard apple	Annonaceae	Fresh fruit
Annona squamosa L.	Nona sri kaya	Annonaceae	Fresh fruit
Artocarpus communis Forst	Sukun	Moraceae	Cooking
Artocarpus odoratissimus Blanco	Marang, terap, tarap	Moraceae	Fresh, ingredient in cakes, seeds roasted or boiled
Averrhoa bilimbi L.	Cucumber tree, belimbing	Ceraniaceae	Pickle, juice
Baccaurea griffithii Hook f.	Larah	Euphorbiaceae	Fresh fruit
Baccaurea motleyana Muell. Arg.	Rambai	Euphorbiaceae	Fresh fruits, juice, jam, organic vinegar, cooking
Baccaurea polyneura Hook f.	Jentik-jentik	Euphorbiaceae	Fresh fruit, novelty
Bouea macrophylla Griff.	Gandaria, kundang	Anacardiaceae	Fresh fruit, juice
Bouea microphylla Griff.	Remia	Anacardiaceae	Fresh fruit, pickle, cooking
Canarium odontophyllum Miq.	Dabai, kembayau	Burseraceae	Fresh fruit (softened in hot water)
Chrysophyllum cainito L.	Kameto, sauh durian	Sapotaceae	Fresh fruit
Citrus aurantifolia Swingle	Limau nipis, sour lime	Rutaceae	Juice, cooking
Citrus microcarpa Bunge	Limau kasturi	Rutaceae	Juice, cooking
Cynometra cauliflora L.	Nam-nam	Leguminosae	Fresh fruit
Dialium indum L.	Tamarind plum, keranji	Leguminosae	Fresh, sugar-coated snacks/titbits
Dimocarpus longan ssp. *malesianus* Leenh. var. *malesianus*	Isau, mata kucing	Sapindaceae	Fresh fruit, canned
Diospyros discolor Wild.	Mentega	Ebenaceae	Fresh fruit
Ficus carica L.	Ara	Moraceae	Cooking
Flacourtia rukam Zoll. and Moritzi	Indian prune, rukam	Flacourtiaceae	Fresh fruit, jam, pickle
Garcinia hombroniana Pierre	Beruas	Guttiferae	Fresh fruit
Garcinia atroviridis Griff.	Asam gelugur	Guttiferae	Cooking
Garcinia cowa Roxb.	Kandis	Guttiferae	Fresh fruit
Garcinia dulcis Kurz	Mundu	Guttiferae	Fresh fruit
Garcinia prainiana King	Cerapu	Guttiferae	Fresh fruit
Gnetum gnemon L. Bulso	Melinjau	Gnetaceae	Chips, curry
Leppisanthes rubiginosa (Roxb.) Leenh.	Kelat layu, mertajam	Sapindaceae	Fresh fruit
Mangifera caesia Jack	Binjai, kemang	Anacardiaceae	Fresh fruit, pickle, culinary
Mangifera cytherea Sonn	Kedondong	Anacardiaceae	Fresh fruit, pickle, cooking
Mangifera foetida Lour.	Bacang	Anacardiaceae	Fresh fruit, jam, pickle, cooking
Mangifera odorata Griff.	Kuini	Anacardiaceae	Fresh fruit, juice
Mangifera quadrifida Jack	Asam kumbang	Anacardiaceae	Fresh fruit
Nephelium rambutan-ake (Labill.) Leenh	Pulasan	Sapindaceae	Fresh fruit
Phyllanthus acidus L. Skeels	Star gooseberry, cermai	Euphorbiaceae	Fresh fruit, pickle
Phyllantus emblica L.	Melaka	Euphorbiaceae	Pickle
Salacca conferta Griff.	Kelubi, asam paya	Palmae	Pickle
Salacca edulis Reinw.	Salak	Palmae	Fresh fruit, pickle
Spondias pinnata Kurz	Amra	Anacardiaceae	Fresh fruit, pickle
Syzygium aqueum (Burm. F.) Alston	Jambu air	Myrtaceae	Fresh fruit
Syzygium malaccense (L.) Merr. and Perry	Malay apple, jambu bol	Myrtaceae	Fresh fruit, juice
Syzygium samarangense (Blume) Merr. and Perry	Jambu semarang	Myrtaceae	Fresh fruit
Tamarindus indica L.	Asam jawa	Leguminosae	Fresh fruit, cooking
Ziziphus mauritiana Lamk.	Bidara	Rhamnaceae	Fresh fruit

for the sweet, juicy, aromatic flesh/pulp surrounding the seeds which can be eaten fresh or used as an ingredient in cakes. The fruit is said to have a finer and more delicate flavor than that of the jackfruit. The seeds are eaten roasted or boiled; boiled seeds have good texture and a delicious nutty flavor. Young fruits are also cooked in coconut milk and eaten as a curried vegetable.

A terap may weigh 1–3 kg and be 13–16 cm long and 10–13 cm wide. The edible portion is the pulp that surrounds the small seed. The rind serves as nutritive roughage for livestock. The terap tree is massive and can attain a height of 30 m or more. Terap trees can thrive on most soils and can serve as useful plants on marginal land to prevent degradation of these areas.

Baccaurea motleyana (Rambai)

Rambai is native to Malaysia and is commonly cultivated in the lowlands. It is also native to Indonesia, for example, Borneo, Sumatra, and Java, where

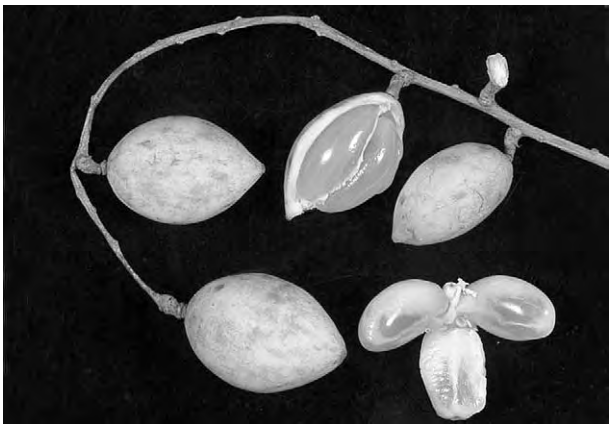

Figure 1 (see color plate 74) Fruits of *Baccaurea motleyana*.

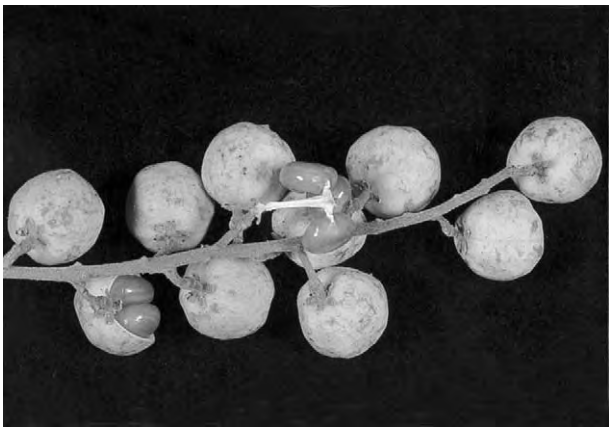

Figure 2 (see color plate 75) Fruits of *Baccaurea polyneura*.

cultivated trees are common. The trees are also found in the wild. The fruits are most pleasant and refreshing; they are eaten fresh and can be processed into juice, jams, and organic vinegar. The fruit is well suited for cooking. The fruits are borne on long stalks hanging down from branches and trunks. The edible portion of the fruits is the segmented juicy translucent pulp. Most rambai is sour but there are trees purportedly producing fruits that are less acid. The fruits are seen in the markets during the season (June to August).

There are usually two compartments in a fruit, with two segments. In a ripe fruit, the segments are enclosed in thin membrane. The juicy pulp adheres firmly to the small flat seed.

The rambai tree grows to a medium size (8–10 m) however, some can reach up to 20 m height, spreading with large green leaves 15–30 cm in length and 7.5–15 cm wide. The thin papery leaves are smooth on the upper surface and darker green than the undersurface. Flowering spikes arise from the trunk and branches but rarely on smaller branchlets. The short spikes grow as the flower buds mature and when the light yellow flowers open, the spikes have already extended and hang down. The strong sweet fragrance of the flowers attracts tiny insects for pollination. Young fruits are green and roundish with straight tapering at the apex. Mature/ripe fruits have a mauve color with less latex present (Figure 1). The rambai tree is hardy and can tolerate a wide range of environments. Fruits are produced in abundance. It would be useful to explore and look into greater use for the fruits, particularly in downstream processing.

Baccaurea polyneura (Jentik-jentik)

Baccaurea polyneura is found only in peninsular Malaysia and Sumatra. The trees are quite rarely cultivated and the fruits are sometimes seen in the market in the northern states of Peninsular Malaysia when in season (July to September). The fruit is an ovoid capsule, 2.0–2.5 cm long, and orange to slightly brown in color (Figure 2). They are juicy and have a sweet-sour taste and are eaten fresh. An interesting characteristic of the fruit is that it can be made to split by flicking and appropriately is called jentik-jentik, i.e., flick-flick.

Canarium odontophyllum (Dabai, Kembayau)

Dabai is a fruit that would seem to have potential as a widespread food source in the tropics. The trees are very heavy-bearing. The fruit is often white when immature, turning black when it is ripe. The oblong fruit, 35–50 × 25–30 mm, is ready for harvest when fruits lose the white sheen covering the fruits. A good-quality fruit has an oily yellow appearance when the black outer skin is removed. The edible portion is the mesocarp which is 2–3 mm thick and surrounds the hard triangular seed. It is a good source of protein and is usually softened in hot water before being eaten with sugar or soy sauce. The sugar or soy sauce enhances the richness of the fruit. By itself, the fruit does not have much flavor but it is popular throughout Sarawak during the season (around October to January). Dabai is also common in Brunei Darussalam, and is found in most parts of the country except in the swamps and coastal sand.

Dimorcarpus longan ssp. *malesianus* var. *malesianus*

Dimorcarpus longan ssp. *malesianus* var. *malesianus* (mata kucing, isau, sau, kakus) trees are found all over Indo-China and Malesia; the greatest variation is found in Borneo. The fruits are globular to slightly

oblong and smooth to warty. The fruit is drupaceous, and is about 2 cm in diameter. Seeds are globular with shining blackish-brown testa enveloped by a thin translucent flesh. In Peninsular Malaysia, the most common form of this taxon is the one with globose smooth fruits which turn brown when ripe. It has a very thin arilloid (flesh) and is hardly worth eating. Superior forms are found in Sarawak, all with densely thick warty fruits and thicker arilloids. The composition of the fruit is not very different from longan, but carbohydrates and energy values are much lower, whereas much higher figures are given for mineral content.

Flacourtia rukam (Rukam, Indian Prune)

Flacourtia rukam is a small tree which is widely distributed but scattered, both cultivated and wild, all over Malesia. The fruit is a round berry, 2–2.5 cm in diameter, light green to pink or purplish-green to dark red with whitish, juicy, acid pulp. There are four to seven flat irregular-shaped seeds. The ripe fruit (Figure 3) can be eaten raw; it is rubbed between the palms of the hand because bruising the flesh eliminates astringency. It is also served in fruit salad (rojak) with a spicy sauce, pickled, or sweetened with sugar to make jam or confectioneries. The young leaves are eaten raw in side dishes. Immature fruit is used to prepare traditional medicine against diarrhea and dysentery. The wood is hard and used to make household utensils such as pestles and furniture.

Garcinia atroviridis

Garcinia atroviridis (asam gelugor, som-maw won) is native to Peninsular Malaysia and Myanmar. It is a distinctive narrow tree growing to about 8–25 m in height with drooping branches, twigs, and leaves.

Figure 3 (see color plate 76) Fruits of *Flacourtia rukam*.

Figure 4 (see color plate 77) Fruits of *Garcinia atroviridis*.

Leaves are commonly about 14–26 cm long and narrow with a pointed tip and upturned edges. They are dark green and glossy, and new leaves are bright pink; all of them droop in a limp way. The female flowers have four cherry-red, slightly convex petals surrounding a thick green ovary which is capped by a dull red stigma. Fruits are solitary on the twig ends and hang down with their weight. They are about 7–10 cm in diameter and fluted from top to bottom with 12–16 deep grooves (Figure 4). The skin between the flutings is smooth and thin. The fruit is green at first, ripening to a bright orange-yellow.

Ripe fruits are acid and astringent in taste. They are sliced and sun-dried, and used in cooking. The young leaves can be eaten fresh or also used in cooking. Although the fruit is not eaten fresh, the narrow tree with drooping branches is conspicuous and would make a beautiful ornamental tree if planted along roadsides.

Garcinia hombroniana

Garcinia hombroniana (manggis hutan, beruas) resembles mangosteen. The tree forms a crown of dark green foliage, some extending 10 m, with tiers of extended branches. The fruit is round, about 5 cm in diameter, like a small mangosteen, and pinkish orange in color when ripe. Fruits are borne at the terminal axil. Between the red fruit rind and the seeds is a sour edible pulp.

The tree thrives on sandy and rocky soil. The hardiness of the tree offers the opportunity for this species to be used as rootstock for the more valuable mangosteen. The tree can also be planted as a shade tree and looks attractive as a roadside tree when planted in a row. Perhaps in the near future, when more information becomes available, the fruits, seeds, and rind may yield exciting products.

Garcinia prainiana

Garcinia prainiana (cerapu, mencupu, cerpu) is another species that is closely related to mangosteen and not less attractive compared to other known species. It is a rather small tree found over a small area of the Peninsular Malay, chiefly about the south end of the main range and also in the state of Perak, often in village orchards. The fruit is round with the top and bottom a bit flattened, and is about 3 cm in diameter. The rind is green, smooth, and shiny when immature and turns into a very attractive color of shiny orange when ripe.

Mangifera caesia syn. Mangifera kemanga

Mangifera caesia (binjai, belunu, kemang) has natural distribution in Sumatra, Borneo, and Peninsular Malaysia. They are rather rare in forests and found more frequently in periodically inundated areas and marshes. In cultivation, binjai has spread to Bali, Peninsular Thailand and, rarely, to western Java. Binjai grows into a huge tree exceeding 30 m with the crown held high above the ground. Branches that hold up the crown are dense. Leaves are 10–30 cm long and 4–11 cm wide, green, and with prominent mid-ribs and veins. At flowering, the crown is covered in a mass of tiny purple, magenta, or pink flowers held together in erect inflorescences.

Mature fruits are 10–15 cm long and 6–8 cm wide, oblong, brownish or yellow in color. The juicy, sweetish-sour binjai fruit can be eaten fresh when ripe. Mature fruits weigh 0.5–1 kg. The flesh is white, juicy, smooth and almost devoid of fiber. The wani form, which is mainly found in Bali but also in East Kalimantan, is much liked this way and fetches a high price in local markets, as the fruit is palatable, juicy, and sweet, almost fiberless, and the strong smell is completely absent. It is excellent for making creamy juices. Binjai is often used to prepare a spice based on chillies (sambal). In some areas, the flesh of ripe fruit is pickled and preserved with salt in jars, to make sambal when there is no fresh fruit. Binjai contains 74.1 mg vitamin C per 100 g edible part.

Binjai has potential as an export fruit, however, there is a need for greater research on the fruit.

Nephelium rambutan-ake syn. *Nephelium mutabile*

The *Nephelium rambutan-ake* (pulasan, kapulasan, bulala, ngoh-khonsan) tree is similar to rambutan, if a little smaller, and the leaves are narrower. Leaves have two to five pairs of leaflets which are about 8–14 cm long and 3–4 cm wide. Fruits are oblong, about 5–7 cm by 4–6 cm. The skin is very dark red when ripe and is covered with short, rather pointed knobs which are thick and fleshy but not elongated, as in the rambutan fruit. The flesh is transparent, whitish or rather yellow and the flavor is very sweet. Pulasan is native to the Malesian region and can be found in Malaysia, Thailand, Indonesia, and the Philippines. There are several different races grown, which produce varying qualities of fruit.

Syzygium malaccense

Syzygium malaccense (Malay apple, jambu bol, jambu merah) originated in South-east Asia but is more restricted to Java, Sumatra, and Peninsular Malaysia. Current distribution ranges from India through South-east Asia to the Pacific Islands. The trees are cultivated in home gardens and along driveways and paths. The tree is about 5–20 m high; the bark is gray and almost corky, and leaves are large, 15–35 cm long, and 7–17 cm wide and are bunched at the twig ends. The base is widened abruptly from leaf stalks which are short and very thick. Flowers, 5 cm across, are very striking, for they are deep pink or cerise, and are in almost stalkless bunches on the upper part of the trunk and on bare mature wood behind the leaves (not at the twig ends).

The fruit is a berry, ellipsoid, 5–8 cm in diameter, usually red with pink or white streaks, or dark red or purplish-yellow or yellow-white. There is one seed in the fruit; this is 2.5–3.5 cm in diameter and brown. There is a central hollow; the flesh is thick, rather dry and scented, and quite pleasant to eat. Eighty percent or more of the fruit is edible. It contains more than 90% water.

Background

In the approach to this discussion of fumigants, an attempt is made to define a fumigant and its uses in the preservation and protection of food, feed, seed, and fiber. This is followed by a listing of common chemicals used as fumigants and their formulations and major characteristics. Finally, there is a discussion of common applications in use today with a listing of suggested readings and resource industries to supplement the presentation.

Most importantly, it must be stressed that anyone planning to use a fumigant should secure the manufacturer's label, application manual, and a Material Safety Data Sheet (MSDS). These documents can usually be secured from the distributor. After reading these completely, all directions should be followed carefully. Local and national government entities may have additional requirements such as training and licensing.

A fumigant can be defined as a chemical that will exist as a lethal gas at ambient temperatures and pressures. As a gas, it will diffuse through air and permeate soil and most products of the farm and forest. This includes food and nonfoods (raw and processed), as well as most packaging materials, with the exception of metals. This permeation interferes with the biological processes of organisms, producing a lethal effect on most living organisms, both pest and nonpests, including man and his domestic animals. This definition excludes aerosols that are particulate suspensions and are dispersed as smokes, fogs, or mists into the space to be treated. Aerosols being particulate in form lack the ability to penetrate the commodity to be treated. Fumigants are rarely commercially available as gases. Availability is usually as cylinders of pressurized liquids that become gas as they are released in normal atmospheric pressure. Hydrogen phosphide (phosphine) is available in a solid form, a metal phosphide, and requires exposure to atmospheric moisture to activate the gas. When safely and effectively used, fumigants are efficacious and important pesticides for those involved in producing, storing, transporting, and processing many products from farms and forests.

A major reason for the wide acceptance of fumigants in the past has been their ease of application and the availability of different application methodologies. Additional modifications of application methods have usually been available to meet varying climatic conditions and storage characteristics. However, in today's approach to pest control, the use of fumigants has been limited in the numbers of fumigants available and in their widespread use. This limitation is due to the adverse effect on our environment, particularly interaction with our food products, resulting in unacceptable residues and in the use of methyl bromide with its adverse effect on our earth's protective atmospheric ozone layer. An ideal fumigant should: (1) have a low cost per effective fumigation; (2) be highly and acutely toxic to all stages of the target pest, but not unduly hazardous to man and his domestic animals; (3) be highly volatile, with a good ability to penetrate, but not be excessively sorbed on and in the commodity, its container or package; (4) have adequate warning properties for easy detection; (5) be noncorrosive, nonflammable and nonexplosive under practical conditions; (6) be of low molecular weight to aid in diffusion and penetration; (7) possess a good storage life; (8) be readily removed by aeration; (9) be noninjurious to seed germination or field and nursery stocks; (10) produce no quality changes in raw and processed foods; and (11) be easy and safe to apply.

Within this area of pest control, fumigants are used in several important areas: (1) in the treatment of wood and wooden structures for infesting insects, primarily termites and boring beetles; (2) in the preplanting treatment of soil for the control of weed seeds, soil infesting nematodes, and insects attacking tobacco, various vegetables and nursery stock; (3) in the control of rodents in and around structures and in orchards; (4) as a preventive treatment in a nation's quarantine activities; and (5) in the treatment of raw and processed stored commodities. It is the use of fumigants in areas 2 and 5 that we are principally concerned with in this presentation.

Today, with our increased ability in chemical analysis, we can now measure minute quantities of pesticides, including fumigant gases and their residues in the air, and on and in the treated commodity. As most pesticides, including all fumigants, are highly toxic to man and the environment, it is now very important that these highly toxic chemicals be only applied by trained and licensed technicians. Anyone planning to use fumigants as a control should investigate what government regulations are in place and what needs to be observed. In the rare event that there is no regulating authority at the location where the

fumigation is to be carried out, the manufacturer's directions accompanying the fumigant should be carefully followed. In the USA, the certification of pesticide applicators and registering of pesticides is vested in the Environment Protection Agency (EPA) and in individual States' Environment Departments.

Physical, Chemical, and Biological Characteristics

The primary factors that will increase or decrease the activity and distribution of fumigants are temperature, atmospheric moisture, application duration, fumigant formulation, dosage, application procedure, storage structure or other fumigation containments, pressure (vacuum), aeration, pest population characteristics and habitat, commodity, and contamination (e.g. dockage in grain).

The safe and effective use of fumigants depends, in large part, on knowledge of the fumigant's primary chemical and physical properties. Table 1 below lists fumigants that are in common use, in limited use, or, in some instances, banned from use in many countries. In the USA, only methyl bromide, hydrogen phosphide (phosphine), and sulfuryl fluoride, Vikane®, are in common use and are approved by the US Environmental Protection Agency. In this presentation, only methyl bromide and hydrogen phosphide will be discussed. Currently, sulfuryl fluoride has very limited approval for use on foodstuffs.

The temperature and atmospheric moisture of the environment and commodity to be treated are the two most important variables in achieving efficacy in fumigation. It is important in a good fumigation for the fumigant to come into equilibrium with the temperature of the commodity being treated. An increase in temperature increases the molecular activity of the fumigant, which facilitates the diffusion and penetration of the gas with decreasing sorption. The opposite effect occurs as the temperature decreases. The biological activity of the pest organism will increase with temperature changes that are within the temperature range of the life processes of the organism. This increase in activity results in a more rapid respiration rate. The acceleration in respiration increases the intake of the fumigant resulting in a quicker kill. Temperature decreases result in a lower biological activity and will lengthen the time of application. Also, it may result in a fumigation failure if the pest does not receive adequate exposure to the fumigant.

The moisture content of a commodity, such as grain, generally increases the sorptive capacity of the kernels, with a resulting loss of fumigant concentration. In general, an increase in fumigant dose or fumigation duration can compensate for sorption and penetration when grain moisture is high. Atmospheric moisture is essential for the activation of phosphine from magnesium or aluminum phosphide. If the atmospheric moisture is too low, insufficient phosphine may be produced in the prescribed time required for insect kill.

In the release of cylinder gases such as methyl bromide and sulfuryl fluoride, moisture can result in increased residues on the commodities treated. Also, with the release of methyl bromide, it may be necessary to heat the pressurized liquid, so when it expands to a gas, it will not use the air's ambient heat, resulting in freezing the moisture that condenses on the nozzle. If this freezing occurs, it may prevent the release of the fumigant. When releasing sulfuryl fluoride, it is necessary to 'shoot' the gas into a warm air stream created by a fan. If this procedure is not used, the cold gas may cause the condensation of the atmospheric moisture and create a fog that will plate out on the

Table 1 Common fumigants and their essential properties

Chemical name	*Molecular weight*[a]	*Boiling point (°C)*[a]	*Specific gravity as a vapor (air = 1)*[b]	*Flammability*[c]
Acrylonitrile	53.06	77.0	1.83	3–17
Carbon disulfide	76.13	46.3	2.63	1.25–44.0
Carbon tetrachloride	153.84	77.0	5.30	Nonflammable
Chloropicrin	164.39	112.0	5.70	Nonflammable
Ethylene dibromide	187.88	164.4	6.48	Nonflammable
Ethylene dichloride	98.97	83.0	3.35	6–16
Ethylene oxide	44.05	10.7	1.52	3–80
Hydrogen cyanide	27.03	26.0	0.93	6–41
Methyl bromide	94.95	3.6	3.27	Nonflammable
Phosphine	34.04	−87.4	1.20	1.79
Sulfuryl fluoride	102.6	−55.2	2.88[c]	Nonflammable

walls of the enclosure or on the commodity being treated.

Methyl Bromide

Soil Treatments

Methyl bromide has been the fumigant of choice in the preplanting treatment of soils, because of its efficacy for a wide range of plant pests residing in the soil including fungus, nematodes, insects, and weed seeds. Additional advantages include its relatively low cost, ease of application, and short duration needed for effective control and ease of aeration. Preplanting fumigations, for the purpose of discussion, can be divided into two general approaches – area application and raised bed and row applications.

The soil preparation, regardless of the application methods, is similar. The soil must be plowed or otherwise tilled to a depth required for an effective treatment. This depth is usually 15–20 cm. The soil must be worked until it is free of clods or large lumps. Crop residues should be burned or worked into the soil after harvest to allow for decomposition. Soil moisture should be sufficient for seed germination and should be maintained for several days prior to treatment for best results. Soil temperatures should be at 15–27 °C at a depth of 15 cm. Fumigations should not be attempted if air temperatures are below 10 °C.

Area applications Area applications should be accomplished with a chisel-type applicator with a spacing of not more than 30 cm between chisels. The fumigant should be injected to a depth of 15–20 cm. The soil should be covered immediately with polyethylene film by simultaneous film laying equipment. If a soil compactor is used, the soil should be covered with film or other suitable cover within 20 min. Recommended applicator rates vary between 200 and 275 kg Ha^{-1}, depending upon the soil texture. Very heavy soils may require greater dosages; in every instance, the fumigant manufacturer's recommendation must be adhered to. Exposure times are usually 24–48 h with a 72-h aeration; however, this aeration period will vary with the crop to be planted. The aeration period will need to be at least 5–7 days if the treated area is to be used for transplanted seedlings.

Raised bed and row applications These are modifications of the area application treatment. In row applications, the polyethylene film is usually in rolls 90–130 cm wide and 305 m long. Alleyways are left between the beds to allow for working the crop. Application of the fumigant is as described above for the area treatment.

The raised bed applications are used in small fields or in greenhouses where table beds are used. Soil preparation is the same as in the area application. To prepare a raised bed, the area around the bed is trenched with the soil thrown to the outside of the bed so it can be used to bury the edges of the tarpaulin. The tarpaulin or polyethylene film will need to be raised and held off the soil to provide a space for the fumigant to evaporate and distribute. This can be achieved by using burlap bags stuffed with paper or straw, flower pots, landscape timbers, etc. On greenhouse tables, tape or glue can be used to hold and seal the tarpaulin.

The introduction of the fumigant is through polyethylene tubing anchored under the tarpaulin to an evaporation pan. One pan should be of the appropriate size to accept the required amount of fumigant and should be of plastic or metal (*do not use aluminum*). In the absence of oxygen, liquid methyl bromide reacts with aluminum to form methyl aluminum bromide, which ignites spontaneously in the presence of oxygen. The fumigant is introduced through the tubes into the pans. Do not remove the pans or tubes until aeration is complete. The fumigant may be vaporized before introduction by means of a commercial heat exchanger or by using a coil of copper tubing immersed in a vat of hot water.

Other soil fumigants that have been used or are currently available include – chloropicrin, dazomet, dibromochloropropane (DBCP), dichloropropene, and metam-sodium.

Space Treatments

Currently, only two fumigants are approved in the USA and used to treat food, feed, and seed and their processed intermediate and end products. These fumigants are methyl bromide and phosphine (hydrogen phosphide). Sulfuryl fluoride is the only other common fumigant used in the USA where it is the fumigant of choice for the control of termites. Sulfuryl fluoride is a proprietary product of Dow Chemical Company and is registered and sold as Vikane®. It is not very effective for the control of insect eggs and therefore is not believed to have much promise for general use in chambers or other types of structures. Vikane® may have some promise for greater use in insect control. It is an excellent fumigant for the control of the active stages of insects. Termites, when they hatch, need to be fed by the active stages of the species to transfer the digestive fauna to the new generation. If no active stages are available, it results in the death of the colony. Currently, Vikane® is being investigated for possible use in a broader range of pest-control problems.

Methyl bromide has both advantages and disadvantages as a fumigant. Recently, a major disadvantage has come to light. This is that the bromide ion has been determined to be a destroyer of our protective ozone layer. Other disadvantages are that it produces both inorganic and organic residues that often exceed acceptable levels. In its application, its great weight produces pools or puddles in the low parts of chambers and other types of structures. This may create hazardous situations that require special attention during exposure and aeration. When methyl bromide is used, it is essential that the following items are removed before the fumigant is introduced: (1) all exposed food, feed and medicines; (2) seeds, bulbs, and living plants unless being treated; (3) all pets (including fish); (4) furs; (5) horsehair products; (6) natural rubber goods; (7) photographic films and blueprints; (8) automobiles; (9) cinder blocks; and (10) all articles containing sulfur. It is also essential to extinguish all flames such as pilot lights, turn off electric heating elements, open all interior doors and openings to attics and crawl spaces, and open all drawers and cabinet doors when treating structures.

The advantages are numerous but not of sufficient importance to overcome all the disadvantages. Methyl bromide is an excellent fumigant for quarantine purposes. It has a low phytotoxicity and therefore can be used to control pests on live plants. It is a relatively quick fumigant, very quick if used in vacuum chambers, and is effective in the control of most living organisms. It also follows a regime of concentration times time ($C \times T$) for the control of insects under a range of temperatures. This allows the fumigator to vary either the fumigant dose or the application duration to affect the desired control. This fumigant behavior is particularly important in the control of quarantine species. There is also a great volume of $C \times T$ data currently available on a multitude of quarantine organisms.

Chamber (vault) fumigations In these fumigations, the material to be treated is loaded into the vault not exceeding 75% of the available space. All the exhaust ports are closed, circulating fans are turned on, and doors are closed. The fumigant is introduced from outside into the chamber above the material(s) to be treated or into a shallow pan in front of a fan to allow for complete vaporization and distribution.

The exhaust ports should be opened, exhaust fans turned on for aeration at the end of the exposure period, inlet ports opened and/or the door opened slightly to allow for fresh air to wash the fumigant out of the chamber. It may be advisable to close the chamber after a period of aeration and allow the load to further degas. Then, further aeration should be carried out until it is determined to be safe to remove the material(s) and distribute. In the USA, it is safe to enter the chamber and handle the products when the gas level is 19 mg m^{-3} or less.

Vacuum chamber fumigations After the materials to be fumigated have been placed in the steel vacuum chamber, a vacuum is drawn to a level of 100–380 mmHg depending on the product to be treated. The methyl bromide is released into the chamber, usually through a heat exchanger, to insure vaporization. After completion of the required exposure, the vacuum is released and the chamber air exchanged at least twice using 380 mmHg per exchange. Released air should be 19 mg m^{-3} or less to unload the chamber safely.

Railcar, truck, van, and container fumigations In the fumigation of these vehicles, two points must be observed. First, they must not be moved while under fumigation. Movement may reduce air pressure on the outside of the vehicle and suck the fumigant out of the vehicle or break the sealing and reduce the available fumigant for the control of the pests. It may also cause a possible hazardous situation. Second, these vehicles are not manufactured to be used as fumigation chambers. Many are constructed using rivets that cannot be assumed to be airtight, or have wooden floors that have cracks between the boards. Containers (ship-truck type) often have wooden floors and large rear doors. Both are very difficult to seal. These containers are also used for air shipments. This use requires that the containers have pressure vents for the equalization of the atmospheric pressure inside the container as it is moved between different altitudes. If there is any doubt as to whether or not the vehicle is sealable, it should be rejected as not being acceptable for fumigation. Aeration of these vehicle containers should be to 19 mg m^{-3} or less before unloading.

Tarpaulin fumigations The material(s) to be fumigated should be stacked on an airtight surface and covered with a tarpaulin that is of sufficient size to provide a gas distribution dome and also allow for sealing the tarpaulin to the floor. The methyl bromide should be released from outside the stack and into shallow pans in the distribution dome, one pan for each 28 m^3.

Aeration should proceed as follows: if fumigation is being conducted inside a closed structure, all doors and windows should be opened to provide cross-ventilation. The tarpaulin should be opened on one end to allow the stack to aerate for at least 30–60 min before removing the tarpaulin completely. Again, it is

important to monitor the vicinity to insure that the fumigant concentration is 19 mg m^{-3} or less, and the material(s) fumigated is safe to handle and distribute. If the fumigation is conducted outside a structure, the aeration should be conducted in steps as above with monitoring of the immediate surrounding vicinity for safety.

Fumigation of Structures

Outside Release of Fumigant

This type of fumigation is somewhat limited in use. With very large buildings and multistory buildings, this method is not usually practical. When treating the building as well as its contents, exterior sealing of the building is usually required. For treating the contents of the building, interior sealing or tarping the contents will be required. Release of the fumigant should be into shallow evaporating pans (one pan per 35.3 m^3) in front of a fan or through a heat exchanger into the building in front of fans for gas distribution. The building should be locked and guards placed outside if required or needed. Opening the doors and starting the exhaust fans followed by opening all the doors and windows to complete aeration should achieve aeration. Entrance must be prohibited until gas levels are at or below 19 mg m^{-3}.

Inside Release of Fumigant

This is the more commonly used method of fumigating buildings with methyl bromide. In this application, cylinders of gas are placed in the upright position throughout the structure after the building has been sealed. The cylinders are arranged so that, as the cylinders are opened, the fumigators can walk away from the released gas as they leave the building. As methyl bromide is a heavy gas, more gas is usually released on the upper floors of multistoried buildings. It is recommended that fans be placed throughout the building (one fan per 1400 m^3) to assure distribution. The entire operation of releasing the fumigant should be completed in less than 30 min. The fumigators, when releasing the gas, should work from a map and in pairs for safety.

In-transit Shipboard Fumigation

Methyl bromide is rarely, if ever, used for this type of fumigation. The weight of the gas makes it difficult to remove it from a ship's hold, and the duration of the treatment is the duration of the voyage, which can be up to a month or more. During long voyages, the methyl bromide is usually sorbed in the commodity, particularly if it is grain in bulk. This can result in unacceptable residues. The methodology of this fumigation treatment has been largely limited to bulk grain fumigation with hydrogen phosphide (phosphine).

Hydrogen Phosphide (Phosphine)

Phosphine is usually produced from either aluminum phosphide or magnesium phosphide in the presence of atmospheric moisture. This chemical reaction is as follows: metallic phosphide + $3H_2O$ > metallic $(OH)_3$ + phosphine gas. The manufacturer, in order to prevent fire and/or explosion, has appropriately buffered this reaction. After the gas has been evolved, the residue remaining consists of the metallic hydroxide that appears as a gray–white powder. A small amount of undecomposed metallic phosphide may be present in this powder, and the phosphide must be deactivated, as directed by the manufacturer before it can be disposed of. Care needs to be taken that this dust is not inhaled.

Phosphine is available in several formulations that facilitate the ease of using this fumigant. Not all the manufacturers or distributors usually have all the brands or formulations available. The various formulations are as follows:

1. Rounded tablets of 3 g each which produce 1 g of phosphine and usually are available in resealable aluminum flasks of 100 and 500.
2. Pellets of 0.6 g each, which produce 0.2 g of phosphine and are available in resealable aluminum flasks of 1660.
3. Sachets, bags, or blister packs of varying shapes weighting 34 g, which produce 11 g of phosphine. This product comes in steel cans, and the sachets, bags, and blister packs are often in chains or fastened together in some manner for ease of application.
4. Phosphine in a mixture of 2 parts of phosphine in 98 parts of carbon dioxide. This mixture is available by employing a firm that has a phosphine generator or by purchase of the premix in cylinders. The gas is applied through a closed system or released in a sealed structure.

Not all formulations are available or approved for use everywhere

Phosphine is very toxic to all forms of animal life, and even any exposure to man in very small amounts must be avoided. The threshold limit value has been set at 0.42 mg m^{-3} by most countries for the 8-h workday. Phosphine produces a toxic effect on the organism's utilization of oxygen. It is known that in insects, this effect is potentiated by the presence of additional carbon dioxide. In the evolving of the gas from the metallic phosphide, the most important

variables are the ambient temperature and atmospheric moisture. An increase in either or both will increase the rate of gas production. All directions provided by the manufacturer – label, material safety data sheet, and application manual – must be followed carefully.

Phosphine as a fumigant has a number of advantages in addition to its toxicity. The small amount of phosphide necessary to generate the gas required makes the fumigant very portable. Its low molecular weight, which is close to that of air, allows the gas to distribute well and rapidly penetrate packaged commodities such as processed foods and kernels of grain and seeds of legumes. Although very toxic, its mode of action on animal respiration is rather slow and allows for the use of low concentrations, particularly when there is sufficient time for long exposures.

There are also several disadvantages in the use of phosphine. It is corrosive to metals such as copper, copper alloys, and precious metals such as silver and gold. This can result in damage to electronics and electrical office and other equipment. It is important to protect such metals and equipment or remove them from the area being fumigated. Areas with low oxygen levels or where insect respiration is low from low temperatures may result in poor or incomplete control. Phosphine can be spontaneously explosive when it exceeds a concentration of 1.79% of the volume of the atmosphere. This prohibits its use in vacuum chambers or in other situations where the atmosphere may be reduced in volume. Phosphine has not been used successfully in the treatment of soil organisms, as many of them use very little oxygen. It also has been difficult to confine the gas to the soil area long enough to be treated because of the inability to seal the area adequately and because of the great activity of the gas. Although it has been recommended for the fumigation of wood and wood products, it has not been used extensively, because of site safety, difficulty in securing a satisfactory seal, and achieving the required penetration during the exposure duration.

However, the use of phosphine as a fumigant has been used successfully in the control of insects attacking a wide range of dried food commodities both raw and processed. Phosphine has been used very extensively for the treatment of grain and grain products in both static and in-transit conditions. It has also been used successfully for treating many nonfood commodities. With the exceptions noted above, phosphine can be used in most situations where methyl bromide has been used or is currently being used.

In every use of a fumigant, it is incumbent upon the fumigator to read carefully and follow the manufacturer's instructions. In countries with a pesticide regulatory authority, the fumigator should secure all the information made available. In most countries with regulatory authority, their instructions on the use of pesticides have the effect of law.

FUNCTIONAL FOODS

F Rincón-León, University of Córdoba, Córdoba, Spain

Concept and Definition

It has been known for a long time that a clear relationship exists between the food we eat and our health. The current concept of functional foods has resulted from the gradual recognition that healthy diets result from eating nutritious foods and from the identification of the mechanisms by which foods modulate metabolism and health. When we eat food, our first and most basic aim is to obtain nutrients for our body and to satisfy our metabolic needs. However, some groups of foods, in addition to their nutritional properties, present other additional properties for health. These types of foods are called functional foods and may be defined as any food that has a positive impact on an individual's health, physical performance, or state of mind, in addition to its nutritious value. Other additional considerations have been proposed to define a functional food, including three additional conditions in particular:

1. it is a food (not a capsule, tablet, or powder) derived from natural ingredients;
2. it can and should be consumed as part of the daily diet;
3. it has a particular function when eaten, serving to regulate a particular body process, such as:
   - enhancement of biological defense mechanisms
   - prevention of specific diseases
   - recovery from specific diseases
   - control of physical and mental disorders
   - slowing of the aging process.

Research supporting the beneficial properties of functional foods to combat cancers, coronary heart disease (CHD), diabetes, high blood pressure, inflammation, microbial, viral and parasitic infections, psychotic diseases, spasmodic disorders, ulcers, etc. is based on chemical mechanisms using *in vitro* and cell-culture systems, various disease states in animals, and epidemiology of humans.

Also, it is important to bear in mind that since a food can be classified as functional only after its potentially beneficial effect has been proven by well-designed and properly executed intervention studies in humans, continuous research is essential in order to obtain more information about the functional properties of food through its effect on biomarkers. For example, it has been reported that plasma triacylglycerol concentrations represent a functional indicator of *n*-3 polyunsaturated fatty acid (PUFA) because *n*-3 PUFA exerts a consistent hypotriacylglycerolemic effect, which is dose-dependent and persistent, or that oligofructose and inulin alter several biomarkers, including gastrointestinal transit time, experimentally induced neoplasia, and colonic microflora, suggesting that these nondigestible carbohydrates are naturally occurring dietary constituents that may improve the quality of life and increase resistance to disease in both humans and animals.

Classification

Functional foods may be classified according to the potential medical benefits and properties of their ingredients. On this basis, the following groups may be deemed to be health enhancing: (1) dietary fiber; (2) oligosaccharides; (3) sugar alcohols; (4) amino acids, peptides, and proteins; (5) glycosides; (6) vitamins; (7) cholines; (8) lactic acid bacteria; (9) minerals; (10) polyunsatured fatty acids; and (11) others (e.g., phytochemicals and antioxidants).

Dietary Fiber

Dietary fiber is commonly defined as plant polysaccharides and lignin, which are resistant to hydrolysis by digestive enzymes in man. Plant cell-wall materials containing cellulose, hemicellulose, pectic substances, and lignin are the major components of dietary fiber. In addition, gums and mucilages are also classified as dietary fiber. Depending on its solubility in hot water, dietary fiber may be classified as water-soluble fiber and water-insoluble fiber.

WSF has been shown to reduce postprandial glucose excursions and is deemed to have hypoglycemic properties. Research results also indicate that a variety of different soluble fibers, including guar, psyllium, pectin, and oat bran, have hypocholesterolemic properties.

WIF sources, such as wheat bran and cellulose, are generally considered to provide protection against the development of colon cancer.

Oligosaccharides

The concept of a 'prebiotic' as a functional ingredient was recently defined as a nondigestible food ingredient that beneficially affects the host by selectively stimulating the growth or activity of one or a limited number of bacteria in the colon. Work with prebiotics has been limited, and only studies involving inulin-type fructans have generated sufficient data to enable a thorough

evaluation of their possible use as functional food ingredients. In order for a food ingredient of a food substance to be classified as a prebiotic, it must:

1. be neither hydrolyzed nor absorbed in the upper part of the gastrointestinal tract;
2. be a selective substrate for one or a limited number of beneficial bacteria commensal to the colon, which are stimulated to grow and/or are metabolically stimulated;
3. consequently be able to alter colonic microflora in favor of a healthier composition; and
4. induce luminal or systemic effects that are benefical to the health of the host.

Oligosaccharides are generally defined as carbohydrates from two to 20 monomeric units long. Recently, interest in oligosaccharides has increased not only because of properties that include sweetening ability and fat replacement, but also because of resistance to digestion in the upper gastrointestinal tract and fermentation in the large bowel. These oligosaccharides are the nondigestible oligosaccharides (NDOs). As regards NDOs, there is a general consensus that:

1. there is strong evidence to indicate the prebiotic effect of NDOs in humans; a prebiotic effect may be defined as a food-induced increase in numbers and/or activity predominantly of bifidobacteria and lactic acid bacteria in the large intestine of humans;
2. there is strong evidence to indicate the impact of NDOs on bowel habit;
3. there is promising evidence to indicate that consumption of inulin-type fructans may result in increased Ca absorption in man;
4. there are preliminary indications that inulin-type fructans interact with the functioning of lipid metabolism;
5. there is preliminary evidence in experimental animals of their preventive effect against colon cancer.

For instance, fructooligosaccharides (FOSs) are fructose polymers and may be classified into two main groups depending on the linkage type of the fructose units, such as inulin with β (2–1) linkages and levans with β (2–6) linkages. They occur naturally in foods such as onions, bananas, garlic, and tomatoes. FOSs, like other fermentable dietary fibers, serve as a substrate for colonic bacteria to produce short-chain fatty acids (SCFAs). FOSs help to maintain and restore the balance of healthy gut flora by creating an environment that supports beneficial bifidobacteria but does not support the growth of some pathogenic bacteria. An example is inulin, which is a linear polymer of lined fructose molecules with a glucose moiety at the end, and in crop foods consists of a mixture of various oligo- and polyfructosides with different chain lengths; its functional properties depend partly on its length distribution. Inulin is widely distributed among plants such as many grasses, onions, asparagus, artichoke, chicory, dahlia, and Jerusalem artichoke.

Sugar Alcohols and Other Alcohols

Sugar alcohols are 'polyols.' This term refers to chemical compounds containing three or more hydroxyl groups. Polyols can be divided into acyclic polyols (alditols or glycitols, which are true sugar alcohols), and cyclic polyols. An example of the first group is xylitol, and an example of the second is *myo*-inositol. In general, different functional properties have been attributed to these groups of substances, such as low caloric intake by incomplete absorption, sweeteners in diabetic diet and caries-reducing agents.

The most ubiquitous sugar alcohols are sorbitol and D-manitol, and their concentrations in some plants and plant exudates may be very high. Fruits belonging to the family Rosaceae, such as pears, apples, cherries, plums, peaches, apricots, etc., contain appreciable amounts of sorbitol. Xylitol is a naturally occurring five-carbon sugar alcohol that can be found in many fruits and berries, being most abundant in yellow plums and greengages. Some research papers have documented the noncariogenic and anticariogenic effects in addition to sweetener properties, and recent studies have indicated that xylitol may have prebiotic properties and other effects on health.

Amino Acids, Peptides, and Proteins

The bioactivities of peptides encrypted in major milk proteins are latent until released and activated by enzymatic proteolysis, e.g., during gastrointestinal digestion or food processing. The proteolytic system of lactic acid bacteria may contribute to the release of bioactive peptides, and the further degradation of these peptides by endopeptidases and exopeptidases of lactic acid bacteria may induce the release of bioactive peptides in fermented milk products, these activated peptides being potential modulators of various regulatory processes in the body.

Several studies have shown that cows' milk proteins may stimulate the growth of *Bifidobacterium* species. For instance, it has been shown that α-lactalbumin and lactoferrin are potent growth promoters for several *Bifidobacterium* species, or that trypsin-digested κ-casein presents bifidogenic activity.

Glycosides

Broccoli and other cruciferous vegetables are a good source of one type of glycosides: glucosinolates.

These are hydrolyzed by myrosinase, an enzyme found in plant cells, resulting in a variety of hydrolysis products, including isothiocyanates and indoles. Indole-3 carbinol (I3C) is currently being studied for its cancer-chemopreventive properties, particularly of the mammary gland. In addition to the induction of phase I and II detoxification reactions, I3C may reduce the risk of cancer by modulating estrogen metabolism.

Vitamins

Because there is a substantial loss of folic acid during cooking, supplementation with folic acid, especially during pregnancy and in the elderly, helps to prevent anemia. So folic acid has been added to some foods, such as enriched breads, pastas, rice and cereals.

L-Ascorbic acid (vitamin C), which is synthesized by most animals but not by man, is one of the most important water-soluble antioxidants. Several molecular and biochemical mechanisms of ascorbate-mediated immunostimulation have also been proposed.

Supplementation with vitamin E may help to prevent CHD, due to at least two mechanisms: one mechanism is by protecting blood lipoproteins against oxidation; the other is by inhibiting blood clotting, a process that is involved in the initiation of a heart attack. So both vitamin C and vitamin E are used to prevent CHD. It has been suggested that mortality resulting from to CHD is inversely related to a cumulative antioxidant index, defined in terms of concentrations in plasma, as

$$[\text{vitamin E}] \times [\text{vitamin C}] \times [\beta - \text{carotene}] \times [\text{selenium}]/[\text{cholesterol}],$$

because α-tocopherol (vitamin E), L-ascorbic acid (vitamin C), and β-carotene (which have vitamin A activity) are excellent antioxidants.

Vitamin D (1,25-dihydroxyvitamin D_3) has recently been identified as an immunoregulatory hormone, serving as an immunostimulatory agent of nonspecific immunity and exerting both stimulatory and inhibitory effects on specific immune responses.

Cholines

Lecithin (phosphatidylcholine) is a major component of crude soybean oil. However, raw lecithins are complex mixtures of lipids, namely, phosphatidylcholine, phosphatidylethanolamine, and phosphatidylinositol as main components. Lecithin plays an important role in normal metabolism, for example, forming part of membrane phospholipids; some metabolites are messengers in cells; choline derived from lecithin plays a role in brain cells in the resynthesis of new phosphatidylcholine molecules needed for cells that envelop the axons of neurones; and choline apparently has a protective role, allowing cells to die rather than to turn into malignant cells (cancers) when they undergo mutations.

Lactic Acid Bacteria

In contrast to prebiotics, which represent a new concept, probiotic activities have been the object of numerous hypotheses and have been known since the turn of the century, when it was postulated that lactic acid bacteria provided health and longevity benefits. It is estimated that over 400 species of bacteria, classified in two broad categories, inhabit the human gastrointestinal tract. The categories are: those considered to be benefical (e.g., *Bifidobacterium* and *Lactobacillus*) and those considered to be detrimental (e.g., *Enteobacteriaceae* and *Clostridium* spp.). The bacteria in the first category are used traditionally in food fermentation and are often referred to as probiotics. Probiotics are viable microbial dietary supplements that beneficially affect the host through their effects in the intestinal tract. They are widely used to prepare fermented dairy products such as yogurt or freeze-dried cultures, and may help to improve human health.

Beneficial effects on human health by specific probiotic microorganisms such as prevention of gastrointestinal tract infections, immune stimulation, and balancing of the intestinal microflora have been established in numerous clinical trials.

The hypocholesterolemic effect of fermented milk products was discovered more than 30 years ago during studies conducted in Masai tribesmen in Africa. The Masai have low levels of serum cholesterol and clinical CHD despite a high-meat diet, but they consume daily 4–5 l of fermented whole milk. More evidence supports the role of probiotics in cancer-risk reduction, particularly colon cancer. This observation may be due to the fact that lactic acid cultures can alter the activity of fecal enzymes (e.g., β-glucuronidase, azoreductase, nitroreductase) that are thought to play a role in the development of colon cancer. Some evidence also suggests that probiotics play a role in reducing the risk of rotavirus-induced diarrhea. The increase in the growth of *Bifidobacterium* sp. is also accompanied by the production of nitrogen derivatives, such as ammonia, indole, phenol, and skatole, and by the elimination of carcinogenic substances during fermentation.

Prebiotics and probiotics must be seen as complementary in many aspects, because often a combination of both may prove to be an important clinical method of treating intestinal disorders. A mixture of probiotics and prebiotics may improve the survival

and implantation of live microbial dietary supplements in the gastrointestinal tract. It has been suggested that such an approach may produce the following nutritional benefits:

- improved survival of live bacteria in supplementary or food products and consequently prolonged shelf-life;
- an increased number of ingested bacteria reaching the colon in viable form;
- stimulation in the colon of the growth and implantation of both exogenous and endogenous bacteria; and
- activation of the metabolism of these bacteria (only metabolically active bacteria can promote health).

A new symbiotic concept, or combination of both pre- and probiotics, has been proposed to obtain the healthy benefits of both pre- and probiotic and in addition other new benefits, but this is an attractive concept that needs to be tested in clinical conditions.

Minerals

Minerals play an important role in maintaining muscle and nerve function, regulating water balance and metabolism, mineralization of the skeleton, and transformation of energy. Selenium functions as an antioxidant and is a component of another antioxidant, glutathione peroxidase. It also helps to maintain adequate levels of coenzyme Q in heart muscle. Similar to selenium, several other metalloenzymes are directly involved in immunity and antioxidant defenses, including copper/zinc superoxide dismutase and iron-catalase. Zinc is essential for normal growth, appetite, and immune function. Recommendations for an increased daily dietary intake of calcium have been made in many countries, so the dairy industry has developed different milk products enriched in calcium, up to about 25% on a product basis. It has recently been shown that food products enriched with a milk calcium extract may increase the rate of bone-mass accumulation in prepubertal girls by 1.5% per year.

Polyunsatured Fatty Acids

Dietary polyunsaturated fatty acids (PUFAs) are classified into two families: ω-6, or *n*-6, and ω-3, or *n*-3. Each has different functions in the regulation of physiological processes in the human body. *n*-6 PUFA, but not arachidonic acid, is found primarily in plants; *n*-3 family linolenic acid (18:3*n*-3) is similarly converted into eicosapentaenoic acid (EPA) (20:5*n*-3) and docosahexaenoic acid (DHA) (22:6*n*-3); linolenic acid is found in plant sources, whereas EPA and DHA occur in marine oils.

Research has shown that polyunsaturated fatty acids can play a key role in reducing the risk of cardiovascular diseases by lowering serum triglycerides, and reducing the development of thrombosis and arteriosclerosis.

There is good scientific evidence to indicate that the composition of dietary fatty acid is involved in the etiology of many diseases. Increasing the supply of *n*-3 PUFA may reduce the risk of CHD. In terms of disease status, epidemiological studies have demonstrated that the incidence of CHD is inversely associated with consumption of *n*-3 PUFA. However the cardioprotective effect of fish consumption has been observed in some prospective investigations but not in others. Negative results could be explained by the fact that although *n*-3 fatty acids have been shown to lower triglycerides by 25–30%, they do not reduce low-density lipoprotein (LDL) cholesterol. In fact, a recent review of 72 placebo-controlled human trials showed than *n*-3 fatty acids increased LDL cholesterol. PUFA are derived primarily from fish oils. Therefore, increasing fish intake is the most obvious way of increasing *n*-3 PUFA intake. However, a large percentage (up to 65%) of the population do not eat fish. Thus, there is a need for alternative sources of *n*-3 PUFA, such as functional foods, whose unique fatty acid composition could fortify staple foods, thereby promoting optimal levels of *n*-3 PUFA intake.

Furthermore, an anticarcinogenic fatty acid known as conjugated linoleic acid (CLA) was first isolated from grilled beef in 1987. CLA is a mixture of positional and geometric isomers of linoleic (18:2 *n*-6) in which the double bonds are conjugated instead of existing in the typical methylene interrupted configuration. Nine different isomers of CLA have been reported as occurring naturally in food. Over the past two decades, CLA has been shown to be effective in suppressing forestomach tumors in mice, aberrant colonic crypt foci in rats, and mammary carcinogenesis in rats. More recently, CLA has been investigated for its ability to change body composition, suggesting its role as a weight-reduction agent.

Other (e.g., Phytochemicals and Antioxidants)

Recent epidemiological studies have indicated that a high intake of fruit and vegetables is associated with a reduced risk of a number of chronic diseases. This is attributed to the fact that these foods may provide an optimal mix of phytochemicals, such as natural antioxidants, fibers and other bioactive compounds.

Experts from the US Food Administration have defined phytochemicals as substances found in edible fruits and vegetables that may be ingested by humans daily in gram quantities and that exhibit a potential for modulating human metabolism in a manner

favorable for cancer prevention. Most recently, other beneficial properties, such as cardiovascular-protective properties, have been considered.

Phytochemicals could provide health benefits, such as: (1) substrates for biochemical reactions; (2) cofactors of enzymatic reactions; (3) inhibitors of enzymatic reactions; (4) absorbents/sequestrants that bind to and eliminate undesirable constituents in the intestine; (5) ligands that agonize or antagonize cell surface or intracellular receptors; (6) scavengers of reactive or toxic chemicals; (7) compounds that enhance the absorption and or stability of essential nutrients; (8) selective growth factors for beneficial gastrointestinal bacteria; (9) fermentation substrates for beneficial oral, gastric or intestinal bacteria; and (10) selective inhibitors of deleterious intestinal bacteria. Nutraceuticals have been defined as bioactive phytochemical compounds that have disease-preventing, health-promoting and/or medicinal properties.

Free radicals are unstable molecules that have an unpaired electron, which makes them highly energized and reactive, and which can damage DNA and induce cancer. Food ingredients capable of quenching or stabilizing free radicals are referred to as antioxidant ingredients. There are many antioxidants in foods, but the primary antioxidants that play this very important role in the human body are vitamin C, vitamin E, and carotenoids such as β-carotene, lycopene, lutein, or zeaxanthin. In addition to preventing cancer, some antioxidants such as vitamin E may help to prevent heart disease by preventing oxygen in the blood from combining with LDL cholesterol (oxidized LDL cholesterol is one of the contributors to plaque in the coronary arteries).

Several crops, including grains, oilseeds and horticultural crops, are rich sources of phytochemicals. Cereals such as wheat, barley, and oats, oilseeds such as canola, flaxseed, and mustard, and horticultural crops such as grapes are good sources of phytochemicals. Anthocyanins are flavonoids (pigments) present in fruits such as blueberries and also have antioxidant properties. Isoflavones are a group of phytochemicals that can reduce the risk of heart disease and several cancers, including breast, lung, and prostate cancer. Polyphenols, which are said to be present in large quantities in tea, coffee, red grapes, kidney beans, prunes and red wine, display anticarcinogenic, antioxidant, antibacterial, and antiviral action. Most clinical studies have been carried out on tea; catechins are the predominant and most significant of all tea polyphenols, and the four major green tea catechins are epigallocatechin-3-gallate, epigallocatechin, epicatechin-3-gallate, and epicatechin. Recent studies suggest that benefits from tea consumption are restricted to high intakes in high-risk populations. This hypothesis supports the recent finding that the consumption of five or more cups of green tea per day was associated with a reduced recurrence of stages I and II of breast cancer in Japanese women. Saponins, also known as triterpenoids, are classified as polyphenols, and are abundant in soyabeans more than in any other legume, including various beans and chickpeas. Saponins have a modest hypocholesterolemic effect. Citrus fruits contain particularly high contents of one class of phytochemical known as limonoids, and over the last decade, evidence has been gathered to support the cancer-preventive effect of limonene. Based on these observations, and because it has little or no toxicity in humans, limonene has been suggested as a good candidate for human clinical chemoprevention trial evaluation. Phytosterols (plant sterols), structurally related to cholesterol, reduce blood cholesterol and lower LDL cholesterol levels, possibly by either inhibiting cholesterol absorption by displacing cholesterol from intestinal micelles or altering the activity of enzymes involved in cholesterol metabolism and excretion. The most abundant plant sterol is β-sitosterol (sitosterol), whereas sitostanol, the saturated derivative of sitosterol, occurs at negligible levels in plant lipids.

FUNGICIDES

N A Smart, Harpenden, Hertfordshire, UK

Introduction

A fungicide is any substance, preparation, or organism intended for destroying or controlling any fungal species during production, storage, or distribution of an agricultural commodity or food, in ornamental plants, or in situations endangering the health of animals or humans. Numerous organic chemicals, as well as some inorganic ones, are formulated for use as fungicides in agriculture and food storage. Fungicides help to increase efficiency of production, by preventing or reducing damage to the growing crop or stored commodity, and to improve the quality of the product, by preventing rotting and a damaged appearance. These chemicals are closely scrutinized for any toxic hazard before they are marketed. Plant breeders can produce cultivars of plants, fruits, and vegetables that are resistant to attack by specific diseases so that a fungicide may not be required. The damage done by fungi (pathogens) depends on the host plant–pathogen–fungicide interaction. Different mechanisms of fungitoxicity can operate in different hosts and environments so that standard measures may not work in every situation. More information on mechanisms that influence host–pathogen interactions, predictive tools for use in the field, and wider options of treatment are desirable to obviate development of resistance to fungicides.

Types of Compound

Fungicides used for preharvest control of fungal and bacterial infections of commercial crops at the beginning of the 20th century were simple inorganic compounds. Organic chemicals began to be developed for use as general agricultural fungicides during the 1950s and many organic compounds, which often have a specific biological action, have been marketed since then. The structural types of chemicals used as fungicides have changed as newer molecules have been found to give more effective control than the earlier ones, and better technologies have been developed for manufacture, making them more cost-effective. However, a significant proportion of inorganic (probably over a third of the total) and older organic compounds (probably about a quarter of the total) are used worldwide.

Fungicides used in agriculture and food storage may be systemic or nonsystemic, eradicant, curative, or protectant, or a combination of these effects. Eradicant fungicides are only active against the later, visible stages of the fungal life cycle. Curative fungicides are active against the early but postpenetrative effects of fungal action. Protectant fungicides prevent infection and are active against spore germination, germination development, and growth.

Although about one-third of organic fungicides can exist in more than one stereochemical form, i.e., can be chiral, only about 1–2% of the products marketed are sold as single isomers. Most of such formulations are mixtures of isomers.

This entry outlines the subject at the end of 1999 and some more recent material has also been included. International common names are used. Fungicides are grouped mainly in terms of their biochemical mechanism of fungicidal action (in as far as this is known):

1. General cell toxicants
2. Inhibition of biosynthesis of microtubules

3. Inhibition of methionine biosynthesis
4. Inhibition of ribosomal RNA synthesis
5. Inhibition of sterol biosynthesis
6. Inhibition of melanin biosynthesis
7. Glutathione system targeting
8. Uncoupling oxidative phosphorylation
9. Inhibition of respiratory chain in the mitochondria
10. Inhibition of mitochondrial electron transport
11. Inhibition of fungal biosynthesis of nucleic acids
12. Inhibition of glycerophospholipid biosynthesis
13. Inhibition of protein synthesis
14. Acquired systemic resistance
15. Biological control
16. Unknown or very uncertain mechanisms of action

This list is not exhaustive and it should be realized that a fungicide may exhibit control by more than one mechanism. Grouping in terms of chemical structure so as to cover most known agricultural fungicides can be arranged within this framework. The chemical structures of some representative organic fungicides within each type are given in Table 1; again, the lists are not exhaustive. Only a few of the many possible compounds of a chemical structural group listed will show sufficient fungicidal activity and be of practical use in the field.

A significant number of fungicides are now generic and off-patent. Such chemicals can be manufactured by any company provided that the manufacturing process satisfies the legal requirements of the country in which it is situated. Health and safety regulations of any country in which the fungicide is then used will, of course, still need to be complied with (see below).

Use

Pathogens Controlled

Fungicides of various types have been successful in controlling most major diseases in growing crops intended for market. The commercially important diseases are (in an order of relative importance): leaf spot diseases, late blight/downy mildew, rice diseases, fruit rots, cereal seed-borne diseases, powdery mildews, cereal stem diseases, rusts, and smuts. Diseases in particular crops which it is commercially essential to control with fungicides are given in Table 2.

Fungicides are also used to control many postharvest diseases that cause rapid and extensive breakdown of high-moisture commodities and pose serious problems. Some infections, such as *Monilinia fructicolis* in stone fruits, will have started in the field. Storage rots in potatoes may be controlled with suitable fungicide treatment in store, e.g., 2-butylamine.

Some crop diseases caused by fungi are still difficult to control with chemicals, e.g., eyespot of cereals can only be partially controlled and a fungicide has only very recently been developed that is effective against take-all of wheat.

Mode of Action

Fungicidal action is not simply interaction between fungicide and fungus; it involves the host (plant) and its environment. Hence plant variety, temperature, humidity, cultivation regime, and several other factors play a part in the control of fungal attack. For effective action, careful timing of fungicide applications in relation to the stages of development of infection is essential. The persistence of a fungicide on the surface or within the plant is an important factor in deciding whether to use that chemical.

Many older-type fungicides, e.g., copper and dithiocarbamates, are surface-acting and protectant in action; they are fungistatic and do not prevent infection. They are also multisite in action.

The highly effective, modern, systemic fungicides are often curative and protectant as well as eradicant, i.e., they are fungitoxic. Systemic fungicides are often selective in the range of pathogens they effectively control: they act on a specific receptor or process, e.g., are sterol C14-demethylation inhibitors. However, there are some uncertainties about the mechanism of action of some fungicides and different mechanisms can operate in different hosts/environments, e.g., carpropamid has two different modes of action.

The build-up of resistance to some groups of fungicides, further discussed in the next section, is considered to be related to single-site attack on the mechanism of fungal cells. Detailed discussion of the biochemistry of the mechanism of action of individual fungicides and of resistance of diseases to control by fungicides is beyond the scope of this article and may be followed up elsewhere (see Further Reading).

The systemic activity of fungicides takes place almost entirely through the xylem. Fungicides are usually applied to the foliage/leaves of plants, although some are effective through root uptake. Attempts have been made to design fungicides that will translocate through the phloem but without success. Systemic fungicides are generally longer-lasting than the older surface-acting chemicals.

The mode of action of the groups of fungicides listed above is now discussed in outline:

1. General cell toxicants. Numerous multiple-site, nonselective older chemicals are widely used. This is particularly the case in some less well-developed countries as these chemicals cost less than more recent selective and systemic fungicides. Their

Table 1 Grouping of fungicides in terms of their biochemical mechanism of fungicidal action and chemical structure

Mechanism of action	*Chemical structural group*	*Example(s) with chemical formula*	
Multisite nonselective		Diverse	Copper (Cu^{2+}) Sulfur (S)
			Dichlofluanid
		Alkylenebisdithiocarbamates	 where x is large and $= y + z$ (polymeric) Mancozeb
Inhibition of biosynthesis of microtubules		Benzimidazoles	 Carbendazim
		N-arylcarbamates	 Diethofencarb
Inhibition of methionine biosynthesis		Anilinopyrimidines	 Pyrimethanil
Inhibition of ribosomal RNA synthesis		Acylalanines	 Metalaxyl
Sterol biosynthesis inhibition 14α-demethylation inhibitors		Triazoles	 Propiconazole (4 stereoisomers)
		Imidazoles	 Imazalil

Table 1 Continued

Mechanism of action	*Chemical structural group*	*Example(s) with chemical formula*
Inhibition of mitochondrial electron transport	Hydroxypyrimidines	 Ethirimol
Inhibition of fungal biosynthesis of nucleic acids	Carboxanilides (oxazolidinones)	 Famoxadone
Inhibition of glycerophospholipid bisynthesis	Diverse	 Edifenphos
Inhibition of protein synthesis	Microbiological origin	 Blasticidin S
Acquired systemic resistance		 Probenazole
Biological control Unknown or very uncertain mechanisms of action	Organophosphorus compounds	 Pyrazophos
	Aromatic hydrocarbons	 Quintozene

Table 2 Important diseases controlled by fungicides in the field

Crop	*Important diseases against which fungicides are used*
Barley	Loose smut (*Ustilago nuda*), stripe (*Puccinia striiformis*)
Rice	Rice blast (*Magnaporthe grisea*, anam. *Piricularia oryzae*), sheath blast (*Rhizoctonia solani*, anam. *Thanatephorus cucumeris*)
Wheat	Rusts (*Puccinia* spp.), bunts (*Tilletia* spp.), loose smut (*Ustilago* spp.)
Potato	Late blight (*Phytophthora infestans*)
Cocoa	Black pod (*Phytophthora palmivora*)
Coffee	Leaf rust (*Hemileia vastatrix*), berry disease (*Colletotrichum coffeanum*)
Banana	Black and brown (yellow) Sigatoka (*Mycosphaerella* spp.), Panama disease (*Fusarium oxysporum*)
Grapes	Powdery mildew (*Uncinula necator*), downy mildew (*Plasmopora viticola*), *Botrytis cinerea*
Top fruit	Apple scab (*Ventura inaequalis*), pear scab (*V. pirina*), powdery mildew (*Podesphaera leucotricha*)
Cotton	Macrosporiosis (*Alternaria macrospora*), seedling disease complex
Vegetables	Powdery mildew (*Sphaerotheca fuliginea*), early blight (*Verticillium* spp.),damping off (*Pythium* spp.)
Sugar beet	Leaf spot (*Cerospora* spp.)

preventive action is mainly due to inhibition of spore germination related to the blocking of several thiol-containing enzymes involved in spore respiration. Copper (Cu^{2+}) fungicides are among the oldest known fungicides (e.g., as Bordeaux mixture, with lime) and are simply protectant. Sulfur and lime sulfur are also protectant. The alkylenebisdithiocarbamates (EBDCs), e.g., mancozeb, became commercially viable in the 1960s and are essentially surface-acting protectant fungicides. However, in recent years they have been closely scrutinized on toxicological grounds and their use is now restricted in some countries. Dichlofluanid, tolylfluanid, and captan are likewise contact multiple-site fungicides and have protectant and curative action. Orthophenylphenol is used as a dip and on wrapping paper to control storage diseases in citrus fruit.

2. Inhibition of biosynthesis of microtubules. Several benzimidazoles, e.g., carbendazim, benomyl, inhibit biosynthesis through forming complexes with β-tubulin leading to increased acid production and polymerization of tubulin. Some *N*-arylcarbamates, e.g., diethofencarb, are also multiplication inhibitors. These are systemic fungicides having a wide range of action and are both protectant and curative.
3. Inhibition of methionine biosynthesis. Anilinopyrimidines, e.g., pyrimethanil, cyprodinil, can inhibit methionine synthesis. These chemicals are systemic and both protectant and eradicant. They act primarily on the process of penetration of fungi into their host so that the excretion of hydrolytic enzymes is blocked.
4. Inhibition of ribosomal RNA synthesis. Several acylanilines, e.g. metalaxyl, oxadixyl, and related compounds, are systemic, eradicant, and protectant fungicides which are selective and good for controlling *Oomycetes* and *Phytophthora* spp. diseases. (Carboxanilides, although of an acylalanine structure, have a different mode of action from the above and are considered separately below.)
5. Sterol biosynthesis inhibitors (SBIs). There are two groups:
   a. C14α-demethylation inhibitors (DMIs) which interfere with cytochrome P-450_{DM}. The chemical structural types present in these compounds are: triazoles, e.g., bitertanol, propiconazole; imidazoles, e.g., imazalil, prochloraz; and some 6-membered heterocyclics, e.g., fenarimol, triforine. They are systemic, being translocated in the xylem, and have protectant and curative action; some have an eradicant action. They are effective against *Ascomycetes*, *Basidiomycetes*, and *Fungi imperfecti* spp., but are not effective against *Oomycetes* spp.
   b. Δ^{14}-reductase and $\Delta^8 \rightarrow \Delta^7$ isomerase inhibitors. Several morpholines, e.g., tridemorph, and piperidines, e.g., fenpropidin, are systemic fungicides of this type and have eradicant action while affording some protection. The use of tridemorph has been revoked in the UK.
6. Melanin biosynthesis inhibitors (MBIs). These fungicides, e.g., carpropanid or dithianon, are protectant and partly eradicant in action.
7. Glutathione system targeting. Some dicarboximides, such as iprodione, which is a contact fungicide with preventive and eradicant action, and vinclozolin, which is again nonsystemic with protectant action, are effective in controlling *Botrytis* spp. and *Sclerotonia* spp.
8. Uncoupling of oxidative phosphorylation. Fluazinam, which is protectant with good residual effect but little eradicant and systemic activity, acts as a potent uncoupler of oxidative phosphorylation leading to disorder of the mitochondrial membrane (other factors may also be involved). Fenpiclonil, a phenylpyrrole, and fentin fungicides also inhibit oxidative phosphorylation.
9. Inhibition of respiratory chain in the mitochondria. A number of *E*-β-methoxyacrylates are specific inhibitors of the cytochrome bc_1 complex (complex III) in the mitochondrial respiratory chain. Azoxystrobin has protectant, eradicant, translaminar, and systemic properties. It is broad-spectrum in action against the major groups of pathogenic diseases that attack crops and is a

good fungicide for control of downy mildews. This class of fungicide (strobilurins) was derived from the study of edible woodland mushrooms.

10. Inhibition of fungal biosynthesis of nucleic acids. Some hydroxypyrimidines, e.g., ethirimol, were developed during the 1960s and are thought to inhibit fungal biosynthesis by inhibiting adenosine deaminase in the purine reutilization pathway. They have systemic action and are protectant and eradicant.
11. Inhibition of mitochondrial electron transport. Cytochrome bc_1 is involved as the fungicide inhibits electron transport in oxidative phosphorylation in the fungal mitochondria and energy production. Several aryl carboxanilides (oxazolidinones) inhibit succinate ubiquinone reductase and hence fungal respiration. This group of fungicides are specifically effective on *Basidiomycetes*. They are systemic, protectant, and residual. Carboxin is an older example of this class while famoxadone has much more recently reached the market.
12. Inhibition of glycerophospholipid biosynthesis. Edifenphos and validamycin A have this mode of action. Edifenphos is used as a protectant and eradicant fungicide for the control of rice blast.
13. Inhibition of protein synthesis. Some fungicides of microbial origin are used commercially to control disease, e.g., blasticidin S by foliar application to control rice blast, and jinggangmycin to control sheath blight of rice. Since these 'biochemicals' are made biologically, they may well be specific for target organisms. They are also likely to degrade *in vivo* and so be safer than synthetic chemicals.
14. Acquired systemic resistance in the plant and increase in the effectiveness of its defense mechanism. Some chemicals act not by killing the fungal disease but by affecting the defense mechanisms in the metabolism of the plant so that it is more resistant to attack and so continues to develop and function normally; endogenous salicylic acid is believed to play a crucial role in the induction process. Probenazole is a systemic compound used to control rice blast and can be absorbed by the roots. Some antifungal proteins have been found to increase the defense mechanism of the plant, although these have yet to impinge on the commercial market.
15. Biological control using bacteria, virus, and other fungi can work, although its commercial exploitation to date has not been successful. However, this approach can be a useful tool in integrated pesticide management (IPM) – and has been operative in natural systems for millions of years!
16. Unknown or very uncertain mechanism of action.
    a. Certain organophosphorus compounds have been widely used for particular crops for some time without any definitive understanding of their mode of action, although they are now believed to interfere with fungal choline biosynthesis. Pyrazophos is used as a protectant and eradicant fungicide for the control of rice blast. Tolclofos-methyl is a nonsystemic compound of a different type used, for example, on vegetables and fruits.
    b. Aromatic hydrocarbons. Quintozene can be used in dressing seed. Chlorothalonil has a nonsystemic and protective action, giving good control of *Oomycetes*. This group of fungicides has become increasingly suspect toxicologically, e.g., chlorothalonil is now banned in some countries.
    c. Pencyuron is also nonsystemic and protectant and controls rice sheath blight.
    d. Dicloran is protectant for control of *Botrytis*, *Sclerotonia*, and *Monilinia* spp. in fruits.
    e. Cymoxanil, a cyanoacetamide, is protectant and curative in action and is usually used in combination with compounds having contact or local systemic activity.

Resistance

Problems can arise from the build-up of resistance of fungi to control by a fungicide or, more often, by a group of fungicides.

Before 1970, resistance to the effects of the multisite inhibitor fungicides then mostly used was infrequent and only occurred after prolonged use, e.g., in vineyards. Where resistance did occur it was probably nonspecific in nature, e.g., from reduced uptake on the foliage surface.

With the introduction of site-specific systemic fungicides, the incidence of resistance problems became much more frequent and problems emerged more quickly. The risk of resistance from site-specific fungicides may have been increased through selection pressure resulting from their greater effectiveness and eradicant action.

To resolve a resistance problem, a systemic chemical may have to be formulated alongside another active ingredient of a different type, such as a dithiocarbamate, because of a partial loss of effectiveness in controlling fungal infections. Resistance problems with sterol biosynthesis inhibitors can sometimes be overcome by switching to another sterol biosynthesis inhibitor with a low level of cross-resistance or by changing the application method. Growers will also look to plant breeders for cultivars of plant, fruit, or vegetable that are more resistant to attack by disease.

The Groupement International des Associations Nationales de Fabricants de Produits Agrochemiques (GIFAP) has a Fungicides Resistance Action Committee (FRAC) which has working groups covering the six main classes of fungicide for which resistance is a problem: sterol biosynthesis inhibitors, phenylamides, dicarboximides, benzimidazoles, anilinopyrimidines, and strobilurins. Information and recommendations on fungicide resistance are available from this source.

A serious resistance problem has occurred with the control of late blight in potatoes. Aggressive populations of the A2 mating type of *Phytophthora infestans* have developed so that severe losses have occurred. Strategies that have been developed to cope with the problem include using nonsystemic protectant fungicides, translaminar fungicides, and a single *R*-enantiomer formulation of metalaxyl. Resistance to the systemic fungicides normally used has been marked and these failed to control the situation effectively.

Only a limited number of field trials with genetically modified plants have involved resistance to fungi.

Effective fungicide resistance management is crucial. Much management is based on experience but there is a need to develop predictive tools based on mechanistic and other knowledge and data. Many countries have national programs to monitor fungicide resistance.

Extent of Use

The Food and Agriculture Organization gives the world trade in fungicides in 2000 to be worth nearly US$ 3 billion (about 20% of the total pesticide market). This is probably an underestimate of the amounts actually used. The proportion of total fungicide sales, as an estimate of use, by region worldwide in 1995 is indicated in Table 3. In the same study, the total sales of fungicides among various crops worldwide were assessed, as shown in Table 4.

Table 5 shows the sales of fungicides on vegetables and cereals by region worldwide. It should be noted that all global figures for pesticide sales/use are approximate as reliable data may not be obtainable from China or some other South-east Asian countries. Seed treatments are estimated to account for about 10% of the total fungicide market. Although an increasing awareness of the advantages of IPM is evident, use of fungicides globally continues to increase.

Fungicides are available for home garden use on soft fruit, legumes, and other vegetables as well as on ornamentals.

Table 3 Fungicide sales by region in 1995

Region	*Percentage of total worldwide fungicide sales*
Western Europe	41
East Asia	35
North America	10
Latin America	8
Eastern Europe	3

Methods of Application

Fungicides are applied to growing crops in a wide variety of ways. The active ingredient(s) may be formulated with added wetter, emulsifier, filler, etc. as an emulsifiable concentrate, a suspension concentrate, a fungicidal dust, as granules, or as a wettable powder. Microencapsulated systems are now widely used and have advantages such as reduction in operating hazards, controlled release, and protection of the active chemicals against degradation in the field. Microemulsions are now being developed and offer an advantage of being thermodynamically stable. Reference should be made to the article on pesticide types for detailed information on techniques of application.

Applications to harvested produce are closely linked with procedures for storage and marketing the particular commodity. For example, dipping citrus fruit in a solution of an appropriate fungicide may be

followed by wrapping the individual fruits in fungicide-impregnated paper before packing in trays or boxes for transport.

To control some diseases, the seed is treated before planting by dressing with a dust or liquid or by encapsulating the seed with a nutrient coat which includes fungicide, e.g., sugar beet is normally sown in this way. Fungicidal seed bed drenches are also used.

Surface biocides are applied to empty animal houses and buildings for control of fungal and bacterial infection.

Significant developments in product packaging and pesticide delivery systems have taken place in recent years. Successful development of refillable containers of all sizes, water-dissolvable films or gel tablets, and microencapsulated pesticides substantially reduce or eliminate the need for recycling or disposal of packaging that has been exposed to pesticide and hence potentially may leave hazardous residues.

Examples of Benefits in using Fungicides

1. The quantity, or yield, of the crop or foodstuff is increased, making marketing more commercially viable. Globally, potential losses in crops because of disease are estimated to be about 17% and these are reduced by about a quarter to about 13% by using fungicides. (This averages out the effects of epidemics in which entire crops are lost.) Table 6 shows some of the global advantages of using fungicides in growing rice.

   Work carried out in Germany on the wheat harvests in 1991–93 indicated that the average yield would drop from 6.4 t ha^{-1} to 4.2 t ha^{-1} without the use of fungicides. Furthermore, in a no-pesticide scenario (no herbicides or insecticides either) the loss rate for diseases would increase from 6% to 11%.

   Infestation is related to air temperature and humidity and modern methods can forecast when a fungal infection is likely so that growers can apply fungicides to control proliferation of spores. Forecasting rapid spread of disease and advising on the timing for fungicide treatment was pioneered for the control of potato blight.
2. The quantity of the commodity is increased to obtain a wider market and a better value. Without fungicide dips with citrus fruit for export and of impregnated packing for transport, infections latent from the preharvest environment would severely reduce the proportion of a consignment that would be marketable and lower financial returns markedly. People prefer to buy apples without unsightly apple scab lesions in the skin and will refuse to buy inferior produce.
3. A disease may be eliminated. Bunt or stinking smut (*Tilletia caries*) of wheat now rarely occurs in the UK. It is probable that such diseases have been very efficiently controlled rather than eradicated.

Financial considerations of these benefits have to offset the cost of buying and applying fungicides.

Table 6 Potential losses and actual losses to diseases in rice in 1991–93, by region

Region	*Potential loss from diseases (% of yield)*	*Actual loss to diseases (% of yield)*
Western and southern Europe	21	9
North America and Oceania	24	8
East Asia	22	12
Rest of the world	18	17

These estimates are made alongside estimates of losses to other pests. Based on data from Oerke E-O at the 12th International Symposium on Modern Fungicides and Antifungal Compounds.

Safety Implications and Toxicology

Before a fungicide can be marketed, the manufacturer submits information on the biological, chemical, and physical properties of the active ingredient and of its formulations to pesticide registration authorities of the countries concerned. Possible effects on the operator, the consumer and on the environment are carefully evaluated and registration authorities have to be completely satisfied of the safety of the proposed chemical, its formulations, and the labeling directions for its use, as well as of safety arrangements in transport and storage.

Where sufficient information is available, the Joint FAO/World Health Organization (WHO) Meeting on Pesticide Residues (JMPR) has estimated acceptable daily intakes (ADIs) for pesticides. They are expressed in milligrams of the chemical per kilogram of body weight. Table 7 gives ADIs for some common fungicides.

Nevertheless, some adverse effects on wildlife and the environment have been attributed to fungicides. For example, investigations have suggested that iprodione has altered bird behavior, reduced egg production, reduced hatching rate, and impaired mysid reproduction. Azole fungicides, however, are known to have a low persistence in the environment and a low acute toxicity to birds. Triorganotin compounds are, expecially toxic to aquatic life.

Some fungicides once widely marketed are now withdrawn on toxicological grounds and their movement in trade between countries required prior informed consent (PIC). Organomercury compounds and hexachlorobenzene (HCB) are essentially banned

internationally, having a high toxicological risk to humans. Dinoseb and binapacryl are also suspect on toxicological grounds.

Maximum Residue Limits (MRLs)

The Codex Committee on Pesticide Residues (CCPR) recommends, on the advice of the JMPR, maximum residue limits for pesticides in foodstuffs, whether they are derived from preharvest or postharvest use, where such limits are necessary and whether sufficient information is available. MRLs generally apply to the raw commodity, although (separate) MRLs can be established for foods that have been processed, fabricated, or manufactured, if necessary. Codex MRLs for fungicides are listed in Table 8.

Maximum levels have also been fixed for residues of some fungicides by the European Community and the values corresponding to those of the Codex, where they occur, are given in Table 9. It will be seen that the European limits do not exactly correspond with those of the Codex, although they are generally of the same order of magnitude. This is because the different limits were the result of evaluations at different times, based on different data and by different experts. Some countries also have limits of their own covering particular interests. The overall lack of convergence of pesticide residues limits in foods is less than satisfactory.

Table 7 Acceptable daily intakes (ADIs) of some fungicides used in agriculture and food storage

Fungicide	*ADI (mg kg^{-1} body weight)*
Bitertanol	0.01
Carbendazim	0.03

Analysis of Residues

Methods

A necessary precursor to determining any fungicides in a sample of a food is a satisfactory, and in as far as is possible representative, method of sampling. Both the CCPR and the European Community have recently addressed this issue and have revised their recommendations. Many fungicides are one of a small group of compounds having similar chemical structures and/or physical properties. A group, or groups, can often be analyzed using a 'multiresidue' method rather than by employing individual procedures for each possible fungicide.

If present, residues can be identified and quantified using a range of gas chromatographic (GC) columns and detectors, especially mass spectrometric detectors for enforcement purposes. Fungicides not amenable to GC are often determined using high-performance liquid chromatography with ultraviolet or fluorescence detectors. Dithiocarbamates are usually determined as carbon disulfide by a GC head-space procedure. Some fungicides, e.g., chlorothalonil, are

The EU has not as yet fixed maximum levels in foodstuffs for many of the fungicides discussed in this chapter.
Where two figures are entered, these are values for different commercial commodities, e.g., table grapes, wine grapes.
[a]Lower limit of analytical determination.

difficult to analyze accurately as they are unstable and degrade during analysis. Sensitive immunoassay techniques have been developed for determining a number of fungicides: benomyl, chlorothalonil, fenpropimorph, metalaxyl, triadimefon, and other compounds. Such approaches have not, as yet, superseded the instrumental chemical approaches for definitive work, although they are increasingly useful for screening purposes.

Monitoring Data

It is not possible to summarize adequately all the selective monitoring data for fungicide residues in foodstuffs in those countries that report their work in the scientific or official publications. However, it appears that of the order of 1% of retail samples may contain residues above a residue limit. In an EU survey of 9700 samples, dithiocarbamates and benzimidazoles were the fungicides occurring most often as residues in foods and exceeded maximum limits the most frequently.

The relatively low toxicity, together with the small amounts, of copper and sulfur formulations likely to be in foods renders residue analysis for these moieties unnecessary. Significant traces of fungicides used for seed dressing, seed bed drenching, or as surface biocides in buildings are unlikely to be found in foodstuffs at market.

G

GALACTOSE

C A Williams, Kingswood, Wotton-under-Edge, UK

Occurrence

Galactose is a monosaccharide and has the same chemical formula as glucose, i.e., $C_6H_{12}O_6$. It is similar to glucose in its structure, differing only in the position of one hydroxyl group. This difference, however, gives galactose different chemical and biochemical properties to glucose.

The major dietary source of galactose is lactose, a disaccharide formed from one molecule of glucose plus one of galactose. Lactose is found only in milk; after weaning, significant quantities of dietary lactose are found only in dairy products (Table 1). Lactose levels are lower than expected in some dairy products, where it has been used by the microbes involved in processing the food.

Lactose, a byproduct of the dairy industry, can be hydrolyzed to produce lactose hydrolysate syrup, which contains lactose, galactose, and glucose. This syrup is used as a sweetener in biscuits, confectionery, and some dairy desserts. Thus, small amounts of lactose and galactose can appear in nondairy foods. (*See* **Lactose.**)

Apart from its presence in lactose hydrolysate syrup, the monosaccharide galactose is seldom found in the diet, although it has been identified as a trace component of some seeds and pulses.

Absorption

It has been established that the monosaccharides are absorbed at different rates from the small intestine. Initial studies, using animal models, showed that glucose and galactose are absorbed at a much faster rate than the other monosaccharides, and galactose is absorbed at a slightly faster rate than glucose. This finding has been confirmed in humans. (*See* **Glucose:** Function and Metabolism.)

In the brush border of the small intestine, there is a carrier that is shared by glucose and galactose; interaction between the carrier and an adjacent sodium pump allows the monosaccharides to be actively accumulated in the intestinal cell prior to their removal into the circulation.

Galactose absorption is an active process in that it requires energy (in the form of adenosine triphosphate, or ATP) and it can be stopped by the presence of metabolic inhibitors. The common carrier system concept is supported by knowledge of a rare clinical condition of glucose–galactose malabsorption, in which neither monosaccharide can be absorbed efficiently because of the absence or impairment of the common carrier.

Prior to absorption, galactose has to be released from lactose. This occurs in the presence of lactase, a disaccharidase, found in the brush border of the mucosal epithelial cells of the small intestine.

Human lactase has a pH optimum of 5.5–6.0, and its highest levels of activity are found in the jejunum, with lower levels occurring in the duodenum and ileum. It is thought that the enzymes that hydrolyze sucrose and maltose are closely aligned with their monosaccharide carriers. This may not be so for lactase. However, in reality, the rate of lactose hydrolysis does not appear to limit the quantity of galactose or glucose absorbed from lactose.

Lactose intolerance occurs when the mucosal cells do not produce sufficient quantities of lactase to hydrolyze ingested lactose. As a result of this insufficiency, undigested lactose remains in the small intestine and, because of its osmotic potential, draws water into the intestinal lumen. On arrival at the large intestine, the lactose can then be fermented by the microflora present to produce various gases and acids. The symptoms produced can range from a mildly bloated feeling to watery, explosive diarrhea. There are three kinds of lactose intolerance:

1. Congenital lactase deficiency is an extremely rare disorder in which lactase is absent from birth. As lactose is a major constituent of the neonatal diet, early diagnosis and instigation of a lactose-free diet are essential if the condition is not to be fatal.
2. Secondary lactase deficiency occurs as a result of damage to the intestinal mucosa, caused, for

Table 1 Lactose content of milk and dairy products

Food	*Lactose content (g per 100 g)*

example, by an infection or disease. Lactase levels return to normal on successful treatment of the primary disorder.

3. In primary lactase deficiency, lactase levels are normal at birth but have declined by adulthood. A fall of lactase levels by adulthood has been noted in other mammals, but it was in the early 1960s that the condition was described in humans. Subsequently, it has been found that primary lactase deficiency is the normal state in most races, and with few exceptions, it is only in white Caucasians that lactase levels remain high in adulthood. Most lactose-intolerant individuals do not abstain totally from milk and can take small quantities regularly, but large quantities of milk are to be avoided. The absorption of other nutrients is not affected by drinking small quantities of milk. (*See* **Food Intolerance**: Lactose Intolerance.)

Metabolism of Galactose

The main route of galactose metabolism – the Leloir pathway – results in its conversion to glucose 1-phosphate, which can enter the glycolytic pathway (Figure 1). Intermediates of this pathway be used in glycogenesis, or mucopolysaccharide and glycoprotein synthesis. The pathway exists in the cytoplasm of the cells and is most active in the liver.

The Isselbacher pathway exists as an alternative route for metabolism of galactose 1-phosphate (Figure 1), a potentially toxic metabolite of galactose.

Pathways exist for the reduction of galactose to galactitol and for dehydrogenation to galacturonic acid.

There are two forms of clinical galactosemia, in which an enzyme concerned with galactose metabolism is absent from birth. Classical galactosemia is the result of a deficiency of galactose-1-uridyltransferase, so that galactose is phosphorylated to galactose 1-phosphate (gal 1-p) and no further. If the condition remains unchecked, gal 1-p and galactose accumulate in the tissues and can result in liver malfunction, cataract, mental retardation and failure to thrive.

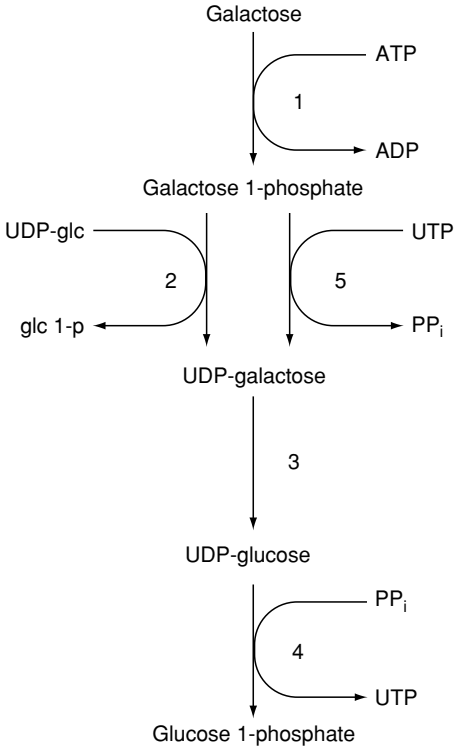

Figure 1 Galactose metabolism – the major pathways. The Leloir pathway: 1, galactokinase; 2, galactokinase 1-phosphate uridyl transferase; 3, UDP-galactose 4-epimerase; 4, UDP-glucose pyrophosphate. The Isselbacher pathway: 5, UDP-galactose pyrophosphorylase. *Note*: although unidirectional arrows have been drawn, most reactions are reversible. ATP, adenosine triphosphate; ADP, adenosine diphosphate; UTP, uridine triphosphate; UDP, uridine diphosphate; glc, glucose; glc 1-p, glucose 1-phosphate; PP_i, inorganic diphosphate. Reproduced from Galactose, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Early diagnosis and initiation of a galactose-free diet are essential. The second type of clinical galactosemia is galactokinase-deficient galactosemia, and this results in the accumulation of unphosphorylated galactose in the tissues. It is characterized by the development of cataracts in the first or second decade of life. Cataracts in both types of condition are caused by an accumulation of galactitol in the lens of the eye.

Metabolic Response to Galactose

The liver is the major site of galactose uptake and metabolism in humans, and practically all circulating galactose is removed by the liver. At one time, the disappearance of galactose from blood following an oral load was used as a test of liver function.

Normally, serum galactose levels are negligible in a healthy fasting individual. It is only after ingestion of galactose or lactose that they increase. The change

in blood galactose levels after ingesting galactose is directly related to the amount of galactose taken. The maximum blood galactose level achieved and the duration of elevated blood galactose levels increase with increasing galactose load. This is in marked contrast to the blood glucose response to differing glucose loads, which is highly controlled, primarily through the action of insulin.

Blood glucose levels increase after galactose ingestion, which is not surprising considering that the major metabolic route for galactose metabolism results in glucose production. Metabolic studies have found the rate of conversion of galactose to glucose to be very efficient in humans. Excretion of $^{14}CO_2$ after ^{14}C-1-galactose is only slightly less than after ^{14}C-1-glucose (galactose would need to be converted to glucose prior to excretion as CO_2). (*See* **Glucose**: Maintenance of Blood Glucose Level.)

A number of studies have reported that galactose metabolism to glucose, as reflected by blood glucose response to oral galactose, is more efficient in young infants than in older children or adults. These findings are, however, disputed.

In humans, oral galactose results in a slight increase in serum insulin levels, although animal studies have found galactose to be incapable of stimulting insulin release from the pancreas. It is believed to be the increase in blood glucose levels after galactose ingestion that brings about the increase in blood insulin levels. In galactosemic subjects, when galactose cannot be converted to glucose, oral galactose does not produce an increase in blood insulin levels.

Various carbohydrates have been found to have differing effects on metabolic rate (MR) and the respiratory quotient (RQ). Equivalent meals of galactose, galactose with glucose, and lactose produced similar changes in MR but had different effects on RQ in man. Galactose alone produces a greater and more rapid increase in RQ than after the other test meals mentioned, or after glucose alone. A larger RQ suggests that a greater level of glucose oxidation is occurring. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism; Metabolism of Sugars.)

Galactose, lactose, and glucose given with galactose loads have been shown to produce an increase in blood lactate levels in fasting subjects. This is not found after glucose loads. This result suggests a greater increase in glycolysis after galactose-containing meals, as is also suggested by RQ changes.

If glucose is ingested with galactose, either as a monosaccharide mixture or as lactose, the subsequent blood galactose levels are much lower than if galactose had been taken alone. It has been established that this effect is not due to changes in the rate of absorption of galactose, and it cannot be brought about by fructose. Intravenous insulin given at the same time as oral galactose does not influence the blood galactose response to oral galactose, even though the blood glucose levels are low during such a procedure. Intravenous glucagon reduces the blood galactose response to oral galactose and is accompanied by a large increase in blood glucose. It would appear that, in the presence of an elevated blood glucose level, blood galactose levels are lower after a galactose load.

Blood galactose, glucose, and insulin responses to a galactose and glucose mixture are the same in lactose-intolerant and lactose-tolerant individuals.

Alcohol has the opposite effect to glucose on blood galactose levels. Alcohol ingestion with oral galactose increases the blood galactose response to galactose. It is thought that the oxidation of alcohol in the liver increases the level of reduced nicotinamide adenine dinucleotide, which is essential for uridine diphosphate-galactose epimerase activity. Hepatic metabolism and uptake of galactose are therefore inhibited.

The blood galactose, glucose, and insulin levels after lactose are the same as after the equivalent mixture of glucose and galactose. The blood galactose response to lactose is increased if alcohol is taken with the lactose.

Long-term Ingestion of Galactose

Lactose hydrolysate syrup fed at levels of 5–7% of total energy intake for 10 weeks to men and women caused a slight, but insignificant, increase in fasting blood triglyceride levels in males but not females. There are conflicting reports concerning the long-term effects of feeding lactose on serum triglyceride and cholesterol levels.

For many years, dietary lactose has been associated with improved calcium absorption in humans and animals. It would seem that in lactose-tolerant individuals, lactose and glucose given with galactose can increase calcium absorption. It is not known how this effect occurs. (*See* **Calcium**: Physiology.)

GALLBLADDER

A Madden, London Metropolitan University, London, UK

Introduction

The gallbladder is located under the right lobe of the liver. It is a pear-shaped sac, usually measuring about 9 cm in length, but varying between 4 and 14 cm. Its average volume in health is 50 ml but this may treble in disease conditions. The thin and easily distended walls consist of undifferentiated muscle layers covered by a partial or complete covering of peritoneum. The mucosa is deeply folded and these indentations penetrate the muscle layer.

Structure

The anatomy of the gallbladder and biliary tract, shown in **Figure 1**, may vary between individuals. These variations have little clinical significance except during surgery or radiological investigations.

The fundus, which is the wide end of the gallbladder, may be palpable on physical examination. The body of the gallbladder joins the cystic duct at the neck, where there is an indentation – Hartmann's pouch. The cystic duct, with its spiral mucosal folds, joins with the common hepatic duct to form the common bile duct, which is 5–10 mm in diameter. This passes behind the duodenum, where it is joined by the pancreatic duct before reaching the ampulla of Vater. Around the duct, as it passes through the duodenal wall and ampulla, is a ring of circular muscle fibers called the sphincter of Oddi, which is responsible for controlling bile flow into the duodenum.

The cystic artery, a branch of the hepatic artery, supplies the gallbladder with blood which returns to the portal venous system via the cystic vein. The gallbladder is well innervated by both the sympathetic and parasympathetic nervous systems.

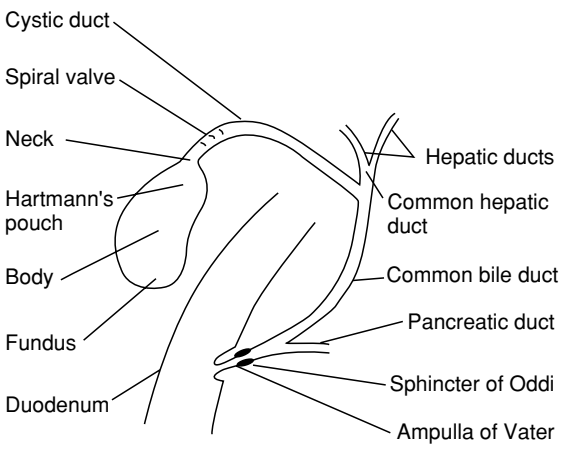

Figure 1 The gallbladder and connecting biliary ducts. Reproduced from Gall Bladder. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Function

The role of the gallbladder is to concentrate and store bile produced by the liver. When the gallbladder contracts, bile passes into the duodenum. Contraction of the muscles in the gallbladder is under both humoral and neurological control. The presence of food, especially fat, in the duodenum and jejunum causes local secretion of cholecystokinin (CCK) by the mucosa; CCK is carried via the blood to the gallbladder, where it stimulates muscle contraction. This contraction may also be brought about by vagal stimulation, which causes a simultaneous relaxation of the muscle in the sphincter of Oddi. In the duodenum and small intestine, bile is essential for the emulsification of dietary fat.

Gallstones (Cholelithiasis)

The most common disorder affecting the gallbladder is the formation of stones. This occurs predominantly in populations consuming a western-style diet, with an incidence of 12–20%.

Gallstones are composed most commonly of a mixture of cholesterol, various calcium salts, phospholipids, and bile pigments. Cholesterol-rich (up to 98% in some cases) stones are the most common, but occasionally stones may be composed almost entirely

of bile pigments. The latter are smaller and colored brown or black.

The differing composition of stones is determined by the factors influencing formation. Stones containing cholesterol occur when the bile stored in the gallbladder is supersaturated with cholesterol. This precipitates out into solid crystals, which settle on a nucleus of mucoprotein or bacteria and gradually increase in size. Stones made predominantly from pigment are more prevalent in individuals suffering from chronic hemolysis, as in sickle-cell disease or thalassemia.

Etiology of Gallstones

Although cholesterol supersaturation of bile is a prerequisite for the formation of cholesterol gallstones, this does not automatically lead to the production of stones. There are several other etiological factors.

Biliary Factors

Bile acids are required for the formation of micelles containing cholesterol and phospholipid in bile. If the concentration of bile acids is low, there may be precipitation of cholesterol. An increase in glycoprotein content may also encourage stone formation. Although bile is often sterile, repeated infections of the gallbladder can promote stone formation by deconjugating bile salts and providing nuclei for cholesterol deposits. Stones are more likely to form in a diseased gallbladder which does not empty fully on contraction, leaving residual bile susceptible to cholesterol precipitation.

Age, Sex, and Family History

Although gallstones may be found in either sex and at any age, the prevalence is twice as common in women as men, and increases with age in both sexes. Women who have never had children are less likely to develop stones than multiparous women. In late pregnancy the gallbladder does not empty completely, leaving residual bile to promote stone formation. Estrogens reduce bile acid secretion, again encouraging stone formation, and there is a higher incidence of their formation in women taking oral contraceptives. The risk of developing gallstones is greater in relatives of gallstone sufferers than in families with no history of the condition.

Physical Activity

Epidemiological studies suggest that the incidence of gallstones is inversely proportional to physical activity. A sedentary lifestyle is a significant risk factor for gallstone formation, independent of obesity, which is frequently associated with a lack of activity. It has been suggested that 30 min of endurance-type activity undertaken five times per week could prevent up to a third of symptomatic gallstone disease in men. Further studies are required to quantify the potential benefits of exercise in women.

Nutritional Factors

Obesity Obese individuals may have slightly raised plasma cholesterol levels, but excretion of cholesterol in their bile is usually greatly increased. As a result, gallstones are more commonly found in individuals weighing above the ideal weight range for their height.

Ironically, bile becomes supersaturated with cholesterol during weight loss and the risk of gallstone formation increases; this is particularly apparent in individuals following very-low-calorie diets. However, once a stable reduced weight has been achieved, cholesterol levels become unsaturated again, so reducing the risk of stone formation.

Western diets The varying geographical prevalence of gallstones supports the suggestion that there is a strong dietary factor involved in their etiology. Africans have a very low incidence of stones, while in western Europe and the USA they are much more common. Worldwide, the incidence is increasing as western-style diets are adopted in developing countries. The dietary characteristics which appear responsible for promoting gallstone formation include a high intake of refined carbohydrate and a low intake of dietary fiber. In experimental animals, gallstone formation may be induced by diets rich in refined carbohydrate which suppress bile acid production.

Fiber If a high-fiber diet is consumed there is a greater excretion of bile acids in the feces and, as a result, less is reabsorbed in the terminal ileum and less reaches the liver for resecretion. This stimulates an increase in hepatic synthesis of bile acids. When less fiber is consumed, an increased transit time allows dehydroxylation in the colon of the bile salt cholic acid to deoxycholic acid. This secondary bile acid is reabsorbed and suppresses hepatic synthesis of further primary bile acids, so reducing the bile acid pool and promoting cholesterol precipitation and thus gallstone formation.

Vegetarians Epidemiological and case-control studies have shown a reduced incidence of cholelithiasis among vegetarians. A high intake of vegetables among women eating mixed diets may be protective. These effects appears to be independent of body weight.

Cholesterol The cholesterol content of bile is only influenced by dietary cholesterol if more than

1000 mg is consumed daily for at least 3 months. This intake is unlikely under normal circumstances and for most individuals the risk of gallstone formation can be considered to be independent of dietary cholesterol intake.

Unsaturated fat There is evidence to suggest that subjects consuming a diet low in saturated fat and cholesterol but high in unsaturated fat may be more susceptible to gallstones. One possible mechanism is that such diets encourage the mobilization of cholesterol from plasma and tissue and, therefore, its excretion in greater quantities in the bile.

Fasting There is diurnal variation in the composition of bile, with cholesterol levels being higher in bile produced at night. This is more likely to influence stone formation if the more lithogenic nocturnal bile is retained in the gallbladder for long periods. As food intake stimulates gallbladder contraction, long intervals of 8–15 h between meals will result in bile stagnation and the increased risk of stone formation.

Alcohol A moderate intake of alcohol may protect against gallstone formation.

Caffeine There is limited epidemiological evidence to suggest that consuming four or more cups of regular coffee per day may help prevent symptomatic gallstone disease in men. This effect has not been observed with decaffeinated coffee.

Clinical Factors

Patients with certain medical conditions are more susceptible to gallstone formation. Approximately 30% of individuals with cirrhosis of the liver have gallstones, predominantly composed of pigment. Resections of the ileum also increase the risk of stone formation as bile acids are not reabsorbed, resulting in a reduced total bile salt pool.

Cholestyramine and clofibrate, prescribed to lower plasma lipid concentrations, may also increase the risk of gallstone formation. Cholestyramine acts by binding bile acids, preventing reabsorption, while clofibrate increases biliary cholesterol excretion.

Long-term parenteral nutrition may result in stone formation in adults and children because in the absence of oral intake there is reduced stimulus for gallbladder, thus stagnant, lithogenic bile is retained.

Treatment

Once gallstones have formed they may remain asymptomatic or cause cholecystitis, discussed below. If an individual has no symptoms, and the stones are diagnosed incidentally, then no treatment may be required. Approximately 15% of asymptomatic stone carriers will develop symptoms during a follow-up of 10–15 years, and a policy of whether or not to treat them while they remain asymptomatic varies from center to center.

Dietary Management

It would be prudent for obese individuals with gallstones to lose weight with a moderate calorie restriction. For those within the ideal weight range, a healthy diet along the lines recommended by the Committee on Medical Aspects of Food Policy would be suitable. This advised that fat in the diet should provide a maximum of 35% of food energy and that fiber intake should be increased. In the UK in 1997 the average diet provided 39% of total calories from fat, and only 12 g of fiber (measured as non-starch polysaccharide) per day. A reduction in fat towards a maximum of 35% energy and an increase in fiber intake to approximately 18 g day^{-1} would be suitable for individuals with gallstones, as well as for the healthy adult population. There is no evidence that a lower fat intake would be beneficial for individuals with gallstones.

A regular intake of three meals a day, including breakfast, which will insure periodic emptying of the gallbladder, may also be helpful.

Cholecystitis

Once gallstones have formed they may not give rise to symptoms, unless they move into the neck of the gallbladder, cystic duct, or common bile duct. Here they can obstruct the release of bile, so that when the gallbladder contracts the pressure rises, causing pain. In addition, the retained bile acts as a chemical irritant on the mucosal wall and makes the area susceptible to bacterial infection. Bile salts may be deconjugated by bacteria to produce further irritation and injury to the mucosa. In severe cases the pressure rise compresses small blood vessels, producing infarction and gangrene.

Cholecystitis is classified as acute or chronic. An acute attack can develop where there is already underlying chronic disease. It may also occur where there has been no previous history of gallbladder disease.

Acute Cholecystitis

This is characterized by severe pain in the right upper abdomen or epigastrium, lasting up to an hour without relief. Nausea may be present and the patient may become pyrexial. If a gallstone has escaped from the gallbladder and lodges in the common bile duct, the

patient may become jaundiced. Eighty-five percent of patients recover spontaneously from acute cholecystitis. However, further attacks are common, although there may be long intervals between them. Complications of acute cholecystitis include gangrenous cholecystitis, liver abscess, peritonitis, and the formation of fistulae to the bowel.

Treatment

The patient is treated with antibiotics to control the infection, usually caused by gut organisms such as *Escherichia coli*, *Streptococcus faecalis* or *Klebsiella* sp. Analgesia and intravenous fluids are also required in the acute phase as the patient may be severely ill and may be unable to take oral fluid.

After the acute attack has subsided, surgical removal of the gallbladder (cholecystectomy) is recommended to prevent further episodes of pain or progression to the complications of empyema. The mortality of cholecystectomy carried out within the first 3 days of acute cholecystitis is 0.5%.

Dietary Management

Traditionally, when the severe pain of cholecystitis has subsided and the patient is able to eat, a light, usually low-fat diet is recommended. However, an evidence-based reevaluation of this practice is required. Dietary fat is a potent stimulator of CCK secretion which causes gallbladder contraction and possibly exacerbates pain. However, CCK is also secreted in response to dietary protein, mixed meals, elemental diets, and both regular and decaffeinated coffee. In addition, the gallbladder will contract in response to sham feeding without any gastric, duodenal, or jejunal stimulation. This cephalic phase of gallbladder contraction is independent of CCK secretion and possibly mediated through a cholinergic mechanism. If a gallbladder is able to contract in the absence of ingested food, there is little evidence to support the avoidance of dietary fat. A study of gallbladder dynamics in patients with gallstones measured the effect of test meals containing varying amounts of fat on the postprandial gallbladder volume. The response was shown to be independent of the fat content in the meals. Most studies of gallbladder contraction have been carried out on subjects with functioning gallbladders but it is unlikely that the response to food stimulation would be greater after acute cholecystitis, if it is changed at all. In the absence of any evidence to the contrary, it would be justified to advise patients to try to eat a normal healthy diet after acute cholecystitis. There is no justification for imposing a virtually fat-free regime in an attempt to avoid pain. If certain foods cause distress to an individual it is reasonable to avoid them. This should not cause nutritional problems if the diet is varied and balanced. Reassurance about eating in general may be needed, as many people are afraid to eat after the severe pain they have experienced. If they remain unwell, supplementary drinks or nutritious 'between-meal snacks' would help to insure that their total nutrient intake is adequate.

Chronic Cholecystitis

This may arise with or without a previously documented attack of acute cholecystitis. The symptoms may be vague, with epigastric discomfort, particularly after eating, and distension of the abdomen. There may be nausea and flatulence which is often relieved by belching or taking antacids. Diagnosis may be difficult because of ill-defined symptoms. Moreover, dyspepsia may be associated with other gastrointestinal diseases. Ultrasound is used to diagnose gallstones and gallbladder disease. Endoscopy may be necessary to rule out peptic ulceration, hiatus hernia, or gastritis.

Treatment

Elective cholecystectomy is recommended if the patient suffers repeated attacks of pain. The mortality is 0.1% in patients less than 50 years old and 0.5% if the patient is over 50 years old.

If patients are unable to undergo surgery because of age, poor general health, or other conditions, they may be treated medically. Dissolution of gallstones using oral bile salts may be attempted if the cystic duct is patent and the stones are radiolucent (i.e., predominantly cholesterol-containing). Patients must be compliant and prepared to follow the treatment for at least 2 years. The aim of dissolution therapy is to expand the total bile salt pool and increase the concentration of bile salts in the bile by giving oral cheno- or ursodeoxycholic acid. Successful dissolution occurs in 14–30% of patients after 2 years of treatment, but side-effects include diarrhea and increased plasma cholesterol. Multiple stones may also be dissolved by topically applying methyl tertbutyl ether. Small numbers of medium-sized stones may be fragmented using extracorporeal shock-wave lithotripsy. However, stone recurrence within 5 years is a problem in approximately 50% of patients undergoing nonsurgical treatment. These results compare unfavorably with cholecystectomy, but should be considered in patients for whom surgery is too great a risk.

Dietary Management

As with asymptomatic gallstones, the first priority for obese patients is to lose weight to within the ideal range for their height. As well as ultimately reducing the cholesterol level in bile, gentle weight reduction

will make potential surgery easier and less hazardous. When normal weight is attained, a healthy diet should be continued, in line with recommendations for the general population: a maximum of 35% of energy from fat and 18 g fiber day^{-1}.

Patients with chronic cholecystitis frequently describe dyspepsia associated with certain foods but there is little evidence to incriminate any particular cause. When subjects describing fat intolerance were challenged with fat without their knowledge, only 8% suffered dyspepsia. Symptoms therefore appear to relate more to preconceived ideas about dietary fat than the fat itself. If particular foods are thought to provoke gastrointestinal symptoms the individual may wish to avoid them, but otherwise a liberal but healthy diet should be recommended.

After Cholecystectomy

Although up to one-third of patients have symptoms after surgical removal of the gallbladder, this is probably because they did not have cholecystitis in the first place: 95% of patients found to have gallstones at surgery suffer no further symptoms afterwards. With the removal of the gallbladder and its function as a bile reservoir there is a redistribution of the bile acid pool. Increased bile acid cycling in the enterohepatic circulation results in greater cholesterol solubility. After surgery, patients should eat a normal healthy diet.

Obstructive Jaundice

Obstructive jaundice may be caused by a gallstone lodged in the common bile duct, carcinoma of the pancreas, bile duct or ampulla and, rarely, benign biliary strictures. A patient presenting with obstructive jaundice will need medical investigation to determine the cause of the obstruction and the treatment required. Ultrasound scanning and cholangiography are needed.

Typically, the patient with a common duct stone has epigastric pain, jaundice, dark urine, and fever. Malignant bile duct obstruction is usually painless and without fever. Once the cause is confirmed, medical or surgical treatment is selected.

Dietary Management

Dietary advice should include both basic nutritional support in patients who may be ill, frail and cachexic, and symptomatic help for those with fat intolerance. Depending on the degree of obstruction, little or no bile may enter the duodenum, so that dietary fat may be inadequately emulsified, resulting in fat malabsorption (steatorrhea). If the obstruction is at the lower end of the biliary tract, e.g., at the ampulla of Vater, the pancreatic duct may also be obstructed, and the lack of pancreatic lipase will exacerbate steatorrhea. If steatorrhea is present, dietary fat should be reduced to levels tolerated by the individual and, if appropriate, pancreatic enzyme supplements prescribed. The calorie deficit from the reduced fat must be made up with an increased carbohydrate and protein intake. Medium-chain triglycerides may be useful as an additional source of calories as these are partially water-miscible and do not require bile for emulsification. When steatorrhea is present, fat-soluble vitamins should be given by intramuscular injection as enteral absorption is unreliable. If a patient does not have steatorrhea there is no benefit from restricting dietary fat, and such a diet should not be recommended prophylactically because of its negative impact on palatability and energy intake.

If obstructive jaundice is accompanied by recurrent infections (cholangitis) and the situation cannot be improved by surgical or medical treatment, for example in primary sclerosing cholangitis, it is essential that adequate nutritional support is given since weight loss and cachexia are commonly seen. Palatable supplements and plenty of encouragement to eat may be needed to help a patient achieve an acceptable nutritional intake and prevent further malnutrition.

Role of Low-fat Diets in Gallbladder Disease

It is a commonly held misconception among both the general public and some professionals that disorders of the gallbladder should automatically be treated with a diet restricted in fat. If this is taken to extremes and continued for long periods (over 3 weeks), several problems may arise. A very-low-fat diet is unpalatable and may require a large bulk of food to be eaten in order to provide sufficient calories. If the low-fat diet results in an inadequate energy intake, undesirable weight loss may occur. Clinical deficiencies of the fat-soluble vitamins, A, D, E, and K, may also eventually arise if the dietary intake is deficient and supplements are not given. An adequate intake of essential fatty acids, linoleic and linolenic, is unlikely to cause the characteristic skin changes associated with deficiency unless a severely fat-restricted diet is followed for several months but, even for shorter periods, such a diet will result in a suboptimal and unacceptable nutritional state.

There is insufficient evidence to support the widespread use of fat restriction in the avoidance of pain in gallbladder disease. However, when pain is associated with fat intake in an individual, a reduced fat intake may help, provided that the total diet remains adequate.

Fat restriction may be beneficial for some patients with obstructive jaundice accompanied by diarrhea. In this case, it should be followed only on medical advice and with the guidance of a state-registered dietitian.

GAME

Contents

Birds

P J Hudson, University of Stirling, Stirling, UK

Introduction

Game bird production and harvesting are undertaken principally for the financial and social benefits that accrue from shoot-letting rather than as a source of nutrition. However, since the regulations that relate to private property rights vary between countries, so the relative importance of game birds as a food source and as an important form of financial income varies around the world.

Game Bird Production and Revenue

Within the British Isles, the laws relating to hunting season are liberal and restrictions on the level of the harvest are left to the individual who owns the rights to take game from the property, usually the land-owner or, on common ground, the Lord of the Manor. Since game production can result in a profitable harvest, the land-owner has an incentive to manage the land in a manner sympathetic to game production and, when possible, to rear and release game birds to supplement wild birds. People with an interest in shooting then pay for the privilege of shooting the birds, usually on a daily basis, and the dead birds remain the property of the land-owner.

The financial return from the letting of game shooting can provide a significant income to many British

estates. Consider the financial aspects of grouse shooting in Britain. The red grouse is a wild game bird restricted to the heather moorlands of the British Isles; numbers are not supplemented through rearing or releasing but are increased through the care of the heather habitat and the control of harmful predators and parasites. The revenue generated from the letting of grouse shooting depends on the type of shooting undertaken. Driven shooting, where a group of 16 people drive the grouse to a line of 8–10 people standing with guns, can only occur when August grouse densities are sufficiently high and usually only when they exceed 60 birds per square kilometer. During 1991, driven grouse shooting was let at £70 per brace (one brace = two birds) and daily grouse bags of up to 500 and 650 brace per day were recorded. However, this level of harvesting is unusual and a productive day's driven grouse shooting is normally in the region of 100 brace per day. Even so, a day's let grouse shooting which generates £7000 gross per day forms an important source of financial return for upland estates which would otherwise have to depend on poor returns from sheep farming or commercial afforestation.

The sale of the game from these commercial shoots is an insignificant return. During 1991, old grouse were selling at £1 per brace and young grouse at £3.50 per brace, which amounted to approximately 5% of gross margin. Traditionally, each sportsman receives a brace of birds at the end of a day's shooting and the remainder are sold to game dealers who export the meat as a delicacy to continental Europe.

The revenue gathered from game shooting can be significant; within Scotland, the direct and indirect revenue of grouse shooting alone in 1989 generated a total of £10.3 million to the Scottish gross domestic product and created the equivalent of 2323 full-time jobs. These jobs were often in remote rural areas in which alternative opportunities were limited.

The financial returns from birds reared and released provide a much lower net return since the costs of rearing and subsequently feeding are high. In 1991, pheasant rearing costs almost equalled the £15 per bird return at which pheasant shooting is let. Once again the carcass value is low, at only £1 per bird or 7% of the gross margin.

In contrast to the British system, North American hunters have free access to vast areas of land and the game that it may contain and generally must purchase a license to take a limited number of game. Consequently the shooting season is shorter, but more intense, with a limited annual bag for each quarry species. Financially the system is designed so that the money generated from licenses and from taxes on guns and sporting equipment is used to finance the state Fish and Wildlife Services. Unlike the British intensive system of game production, the American system provides an incentive for a larger proportion of the population to be involved in the sport and have access to the game as a source of food.

Harvesting Strategies

The objective of most harvesting strategies is to produce the maximum long-term yield of game from a population (known as the maximum sustainable yield or MSY), be it for economic revenue, quantity of food produced, or even the esthetic benefits arising from the conservation of the game bird resource. The size of the MSY that can be obtained from a population can be estimated through mathematical models using a number of approaches.

The simplest is to consider a population that increases according to a logistic growth curve where the per capita rate of increase falls linearly as the population rises; when this reaches zero the population has reached its carrying capacity. Harvesting this population will result in the size of the population falling to a level where the harvesting rate is equal to the population growth rate. The MSY is reached when the harvest rate equals the maximum growth rate of the population, and for the logistic model this is when the density is at half the carrying capacity. Higher harvesting rates will result in the final extinction of the population, whereas lower harvesting rates allow the population to rise until harvesting rate equals the growth rate of the population.

For any regulated population it is important to realize that any sustainable yield, including the MSY, lies at a level below the carrying capacity of the environment. This point is rarely appreciated by managers of wild animal populations or even by many biologists who are frequently concerned with keepering a breeding population as high as possible in the misplaced belief that this will increase the quantity of the resource available for harvesting. MSYs have been estimated for a number of game bird populations; for example, MSY for bobwhite quail is 55% of the autumn population, which reduces the size of the population to 72% of the unharvested state. For gray partridges the MSY is about 37%, mallard 29%, and pheasants 20% of the female population. For other species MSYs may not be easily calculated since numbers may fluctuate greatly and the optimal solution may depend on whether the population is increasing or decreasing.

The release of reared birds provides a supplement to the wild population but may result in overharvesting of the wild population and in the long term the loss of a wild breeding population. For example,

in Italy, 275 000 gray partridges are reared and released annually and approximately 65% are subsequently shot. Such a level of harvesting is far too high for the wild population to be sustained and yet this is not apparent to the hunters, since the rearing has maintained the size of the harvest. The released birds have a poor survival rate and rarely breed well, so there is insufficient recruitment into the wild population.

Environmental Benefits of Game Bird Production

One of the major benefits of wild game bird shooting are the indirect benefits of game management to the environment. Game management has frequently resulted in the amelioration of the harsher effects of agriculture and commercial afforestation on the environment.

Inevitably farming has produced major ecological changes to the environment, particularly in recent years through the mechanization of farming methods and the application of pesticides, fertilizers, and other chemicals which may have both direct effects in reducing nontarget species and indirect effects through the loss of food species utilized by other organisms. Perhaps the most obvious effect has been the dramatic decline in biodiversity associated with the cereal ecosystem. The effects on game birds (Table 1) have been dramatic but have also included a large number of other species such as the almost total demise of the once-abundant corn crake. Even in the uplands of Britain one of the most important impacts has been the overutilization of the seminatural habitat by domestic stock, which has directly destroyed habitats and in so doing reduced the abundance of the invertebrate food taken by immature game birds (Table 1).

The simple answer to reducing environmental damage and problems of agricultural intensification is to change the direction of the system towards one of extensification. Reduction of the impact of pesticides on cereal fields without significantly reducing the yield can be achieved through the use of conservation headlands, where limited application of pesticides results in the maintenance of beneficial broad-leaved weeds and the invertebrate fauna associated with them.

Large areas of the British countryside are planted with woodland specifically with the objective of producing pheasants. The maintenance of these woodlands, production of rides, and other management activities have proved highly beneficial to song birds, butterflies, and other animals. Similarly, heather moorlands are a habitat of international importance, a large proportion of which is centered in the uplands of Britain and maintained principally through the management activities of estates interested in grouse shooting.

Wise Use of Gamebird Resources

The concept of wise use of renewable resources has a number of interpretations and has yet to be defined in detail. The principle is that the management of the resource, game birds in this case, encourages harvesting at a sustainable level which provides benefits to the conservation of the species harvested and has additional benefits to human society and conservation of other species without exploitation.

One example of this wise use has been in the production of red-legged partridge shooting in the Ciudad Real province of Spain. After the revolution, few partridges existed, but the population was subsequently increased to a level where the population could be harvested through careful management and the cooperation of the local farmers. A harvest is produced which is of value to the whole rural community and provides the farmers with an economic interest in the care and habitat protection of the birds. Two brothers acquired shooting rights over the ground owned by more than 2000 individuals and produced a commercial partridge shoot bringing in nearly $3 million annually. Half of this money is

Table 1 Population size, harvest, and management recommendations for British game bird species

Species	*Number prior to harvest*	*Harvest*	*Status*	*Problem facing population*
Red grouse	1 500 000	30%	Stable after decline	Overgrazing, predation, and disease
Ptarmigan	35 000	5%	Stable after decline	Overgrazing and predation
Black grouse	40 000	5%	Stable after decline	Overgrazing and predation
Capercaillie	2 500	0%	Declining	Overgrazing and predation
Red-legged partridge	1 500 000	30%	Decline after increase	Release of chukar partridges
Grey partridge	1 250 000	15%	Declining steeply	Predation and intensification of cereals
Pheasant	20 000 000	50%	Slight decline	Predation and intensification of cereals
Woodcock	1 000 000	10%	Stable after increase	
Common snipe	720 000	5%	Stable after decline	Drainage
Woodpigeon	13 000 000	18%	Increase after decline	

distributed locally each year by paying a set amount per hectare to the local farmers, an amount for each partridge clutch hatched on the ground, and compensation for any damage. Local taxes are alsopaid which have resulted in local community benefits such as street lighting. The wise use in the development of partridge shooting has had clear economic benefits to the local community and, with a financial interest in each brood produced, encourages farmers to create habitat and reduce intensification of marginal agricultural land.

Scent, Taste, and the Significance of Hanging Game

Game birds have a characteristic taste which can be accentuated through the effects of hanging the dead birds for a period prior to eating. This is a habit developed in colder climates where the daily temperatures during the winter hunting season are usually less than 10 °C. At higher temperatures, and particularly in damp conditions, hanging game can lead to bacterial development and the rotting of game even when care is taken to avoid fly strike.

In Britain, the technique is to examine shot birds, often plucking the lower abdomen to determine that the guts have not been badly punctured. The birds are then hung in a cool game larder with air circulating, away from direct sunlight and so that the birds are not touching each other. The time the birds are left to hang depends on the age of the bird, size of the species, and the weather conditions. In August, young grouse are usually eaten immediately, whereas older birds are left for 2–4 days. Young partridges shot in September are also only hung for a short time so as not to lose the delicate taste of young birds. Young pheasants in October are usually hung for about 3 days, although by January when the temperature is cool the birds can be hung for 14–18 days. Usually birds are examined regularly until the skin below the breast bone turns bluish and produces a slight smell.

One of the characteristic of game birds is the strong scent and taste they emit. The scent is frequently so strong that a pointing dog can locate a bird 50 m downwind and on occasions even further, up to 200 m. Occasionally the scent can be so strong a human observer can smell a grouse at 10 m. One interesting characteristic for most game birds is that scent emission falls and almost ceases once incubation commences, so that trained pointing dogs have problems locating an incubating hen from distances greater than 0.5 m. This change in scent emission coincides with the birds ceasing to produce cecal feces, a brown glutinous feces produced daily from the ceca of the bird which contrasts with the more familiar fibrous feces. It seems likely that much of the scent and taste of the game birds may derive from the birds' ceca.

Most red grouse carry a burden of the cecal nematode *Trichostrongylus tenuis*, which burrows into the cecal wall and causes internal bleeding. Heavily parasitized birds frequently have a stronger taste and may emit more scent. This was demonstrated through a simple experiment. Trained pointing dogs and human observers were used to locate two groups of incubating females, one which had been treated with an anthelmintic to remove the parasitic nematode and a second control group that had received water. Observers and dogs searched for nests, the dogs searching by scent and the human observers by sight. The human observers found the treated birds in the proportions expected but the dogs located relatively few of the treated birds, presumably because they emitted less scent since they carried few parasites. The suggestion is that scent and taste of grouse may be determined by the birds' ceca.

The role of the ceca in digestion is not clear. They were originally thought to function primarily as a suitable environment for the fermentation of plant fiber, but such a hypothesis has been rejected. Ceca are now thought to separate soluble and suspended particulate food components from insoluble material. The adaptive significance is to maximize the rate of

throughput for birds feeding on a high-fiber, low-nutrition diet.

Nutrient Composition

Compared with other forms of poultry, relatively little information has been published for game birds. However, a comparison of the data available with comparable data for chicken shows that the nutrient compositions are not dissimilar (Table 2). In general, meat from game birds is somewhat richer in the sense that it has a higher protein and fat content than chicken. The increased fat content affects the texture of the meat and also its stability on storage. No significant body of data is available to compare the nutritional value of wild birds with those bred in captivity.

The limited information available on micronutrients (minerals and vitamins) shown in Table 3 would also suggest that there are no major differences between the meats of game birds in this respect. (*See* **Meat**: Nutritional Value.) Refer to individual nutrients.

Mammals

R J McCormick, University of Wyoming, Laramie, WY, USA

Introduction

Humans obtained food of animal origin exclusively from wild animals before the domestication of goats and sheep which probably began some 8000–9000 years ago. Today, only a small fraction of the meat consumed worldwide comes from nondomesticated or game animals. Utilization of game animals for food continues to varying degrees throughout the world. Hunting for sport, subsistence, or commercial purposes and herding and harvesting are traditional methods of obtaining game meat. Hunting and systematic harvesting of wild populations have been replaced in some locations with the intensive farming of wild ungulates for meat production. The compositional and organoleptic properties of game meat have resulted in increased interest in production of game animals for food. The variable conditions under which game animals are produced, harvested, and marketed often dictate special processing considerations.

Classification

Meat-producing large game species are largely ruminant ungulates which are members of the Cervidae or Bovoidea families (**Table 1**). Wild pig or boar (*Sus scrofa*) and rabbits (*Sylvilagus* spp.) hares (*Lepus* spp.), and other small mammals are also important sources of game meat. The Cervidae family encompasses the various deer species which are characterized by deciduous, solid antlers and generally the absence of a gallbladder. The superfamily Bovoidea includes all the true antelope, pronghorn, sheep, goats, and large wild bovids, such as bison and muskox. They possess hollow permanent horns, with the exception of pronghorn whose horns are deciduous, and the presence of a gallbladder is nearly universal. Indigenous populations of deer are notably absent from Africa and true antelope from North and South America.

Hunting – Sport and Commercial

Large numbers of indigenous and introduced game animals are harvested by hunters worldwide. Estimates

Caribou or reindeer (*Rangifer tarandus*)	Eland (*Tarrotragus* spp.)

of the numbers of wild game animals harvested annually in North America, Central Europe, the former Soviet Union and Norway, Sweden, and Finland (Fennoscandinavia) are summarized in Table 2. The most prevalent large game species, both in distribution and numbers harvested, is the white-tailed deer. In some areas the actual harvest may be 50–100% greater due to illegal or unreported kills. The game animal harvest in North America is almost exclusively the product of sport hunting. In general, indigenous game animals are considered part of the public domain and private ownership of game animals and the sale of game meat obtained by sport hunting are largely prohibited by law. In Alaska, the western provinces of Canada and the Rocky Mountain region of the USA, game obtained through hunting comprises a significant fraction of the dietary meat.

In Central Europe and Scandinavian regions, with long traditions of sport hunting, significant numbers of ungulate game animals (primarily roe and fallow deer, wild boar, and moose) are harvested annually. A large fraction of the game meat is sold by the hunters to markets and restaurants. In other areas of the world, notably the former Soviet Union and the southern third of Africa, traditional sport and subsistence hunting are distinguished from commercial hunting. In these areas, increasingly larger numbers of game animals are harvested by relatively few hunters, often working in teams with the benefit of all-terrain vehicles, helicopters, or fixed-wing aircraft. In the former Soviet Union, saiga and wild reindeer comprise the bulk of the game animals harvested commerically. In Africa the antelope species, including blesbok, springbok, impala, kudu, and eland, account for the vast majority of wild game cropped for commercial purposes. Commercial hunting of red deer was practiced in New Zealand from the 1930s through the 1970s as part of the effort to control the expanding deer population. In one year (1970–71) an estimated 140 000 red deer were harvested; by 1985 approximately 1.5 million red deer carcasses obtained by hunting had been processed and exported from New Zealand.

A substantial fraction of the wild game harvested by sport hunting or commercially is comprised of small game, primarily rabbits and hares. Argentina exports 10 000–14 000 tonnes of meat from the brown hare (*Lepus capensis*) per year, making it the largest single exporter of game meat in the world. The annual harvest of small game animals in North America and Europe,

Table 2 Annual hunter harvest of game animals in selected locations

mostly rabbits and hares, is in the millions. Australia exports kangaroo meat, although the quantity has declined over recent years. Of the total game meat marketed internationally, it has been estimated that less than one-half the tonnage is from ungulate species.

Game Farming

Game farming has existed for centuries: reindeer husbandary in Fennoscandinavia and deer farming in China are ancient practices. Herds of bison have been maintained on farms and ranches in North America for most of this century and game ranching in southern Africa involves enclosure of wild species to control numbers and facilitate harvesting. In the thirty years intensive game-farming systems have developed which involve careful reproductive and nutritional management, and rather strict containment of a group of animals. Intensive farming systems exist throughout the world to raise, manage, and process game animals, primarily for meat production or velvet antlers, or both (Table 3).

The greatest number of farmed game animals, mainly red and fallow deer, exists in New Zealand. The farmed deer population is approaching 1 million animals with about 10% slaughtered for meat annually. China, the former Soviet Union, Australia, Korea, and Ireland also have large populations of farmed deer, although in Asia, deer production is mainly for velvet antler used for medicinal purposes, rather than meat. Whenever cervids are intensively farmed, however, velvet antler production is an important byproduct. A large bison population exists in North America with over 70 000 animals in the USA and 5000 in Canada on farms and ranches. Approximately 11 000 bison were slaughtered in 1985 for meat.

The intensive New Zealand deer-farming system evolved in barely two decades from the successful commerical hunting, processing, and export practices of prior years. Capture and containment of free-ranging red deer allowed selection and reproductive management, development of a breeding herd and controlled, but rapid, expansion of the farmed-deer population. The processing and export of deer meat have been facilitated in New Zealand by construction of specially designed deer slaughter and processing plants. Ante- and postmortem inspection of animals and carcasses, and fabrication and packaging of meat are accomplished in a manner similar to that used for domestic livestock. In many other areas where game animals are bred or managed for meat production, notably Africa, animals are often still harvested by shooting with processing of the carcasses carried out by mobile processing units. Absence of suitable handling and processing facilities for bison is a major factor constraining wider development of the bison-meat industry in North America. (*See* **Meat: Slaughter.**)

Processing Considerations

Game is generally subject to handling and treatment different from that of domestic livestock because of the conditions under which carcasses are obtained. Carcass weight and the composition of meat from some common large game and domestic species are shown in Table 4.

Carcass and Meat Characteristics

Most game animals (Cervidae and Bovoidea families) produce carcasses significantly lighter than beef cattle; exceptions are moose, bison, and eland. The most obvious differences between game and domestic species are the lower fat and metabolizable energy levels in cuts of meat from the game species. Differences in leanness between game and domestic species are even larger when whole carcass composition is determined. Carcass fat content of market lambs, for example, may exceed 30% but the carcass fat content of game animals is usually below 10% and often substantially lower. There can be wide seasonal,

age-, and gender-related variations in the leanness of game animals. Males postrut are generally much leaner than prerut and older animals often contain more fat than younger.

Game meat is often much darker red in color than the meat from domestic species. The darker color may be due to increased muscle myoglobin concentration decreased intramuscular fat content (marbling), elevated muscle pH, or a combination of all these factors. Myoglobin concentration is a function of animal age and muscle fiber type and muscle from game animals generally possesses a higher proportion of fibers of the red, aerobic type geared to oxidative metabolism than does muscle from domestic species. Red, aerobic fibers contain more myoglobin and are smaller in diameter than less oxidative fiber types. In all species, myoglobin content in muscles increases with age.

Hunter-harvested game animals are particularly subject to excitement and stress which may result in depletion of muscle glycogen levels prior to death. Postmortem lactic acid production in the muscle is decreased, resulting in a higher than normal ultimate muscle pH (5.4–5.7) and a dark appearance. Muscle pH of hunter-harvested pronghorn, mule deer, and white-tail deer when determined ranged from somewhat elevated (5.8–6.0) to normal (5.4–5.6). Both hunter-harvested elk (wapiti) and farmed red deer showed normal ultimate meat pH (< 5.7). (*See* **Exercise**: Muscle.)

Texture and tenderness of meat are primary quality characteristics and are related to muscle connective tissue content and maturity, muscle fiber diameter, and degree of postmortem muscle proteolysis. There can be wide variations in the tenderness of game meat, due primarily to the wide range of ages at which individuals are harvested and to seasonal fluctuations in growth rate. Increasing age results in muscle connective tissue maturation, increased collagen cross-linking, and decreased meat tenderness. Variable growth rate alters collagen synthesis rate and may similarly affect muscle collagen quality and meat tenderness, especially in males during and after the rut. Variable carcass chilling rates and aging temperatures also contribute to differences in tenderness. (*See* **Meat**: Preservation.)

The smaller ungulate game species, particularly fallow deer, produce a fine-textured meat that is highly valued. The fine texture of meat from the smaller game species is due in part to decreased muscle fiber diameter. Both pronghorn and deer can develop an objectionable, mushy texture with increased postmortem hanging time. A comparison of endogenous muscle protease activity and postmortem myofibrillar protein degradation, however, revealed no differences between pronghorn and beef muscle.

Aging

The major differences between processing of conventionally slaughtered domestic livestock and game are the recommendations for reduced length of postmortem refrigerated storage time (aging) for game prior to freezing or consumption. Aging of carcasses with little or no fat results in excessive carcass dehydration, weight loss, and discoloration of the lean meat. The vast majority of game carcasses and meat are not subject to the rigid inspection and slaughter standards applied to conventionally slaughtered animals. With game, high levels of microbial contamination, slow carcass chilling, and elevated muscle pH often result in rapid microbial proliferation. Higher bacterial counts in ground meat from deer and pronghorn than from elk carcasses occur because of the increased carcass surface area relative to total meat in the smaller animals. Intensive game-farming systems and the slaughter and processing of game in specially designed facilities reduce or eliminate many of the difficulties associated with processing and handling hunter-harvested animals. Bacterial counts and refrigerated shelf-life of meat from farmed New Zealand red deer are comparable to values obtained for conventionally processed domestic livestock. Meat from game carcasses often requires addition of fat to enhance palatability.

Species Identification

Substitution of less valuable meat for game or illegal trade in game species meat poses worldwide concern. Methods for the identification of raw (uncooked) game meat based on protein differences detected by electrophoresis are well established for most species. Heating or cooking denatures and inactivates meat proteins and enzymes, greatly reducing solubility and extractability. Specialized techniques for the identification of game species in processed and cooked meat products based on protein or immunological variations have, therefore, been developed in recent years.

Dietary Significance

Medical and nutritional dietary recommendations currently emphasize decreased overall dietary fat intake and lower saturated fat consumption. There is generally significantly less total lipid associated with meat from game animals than from domestic livestock (Table 4). Substitution of game for meat from domestic livestock in the diet often provides consumers with a means of decreasing dietary energy supplied by fat. At the same time, nutrient intake associated with red meat consumption, including B-vitamins, minerals, and high-quality protein, is maintained. Refer to individual nutrients.

The fatty acid composition and cholesterol content from game animal and beef lean muscle are shown in Table 5. Species differences exist in amounts and proportions of saturated, monounsaturated, and polyunsaturated fatty acids in meat. Decreased dietary intake of saturated fatty acids, particularly myristic and palmitic acids, are associated with lower blood serum cholesterol and, therefore, diminished risk of cardiovascular disease development. Consumption of ω-6 and ω-3 polyunsaturated fatty acids may lower blood serum cholesterol and protect against coronary heart disease development. Game meat is lower in saturated and higher in polyunsaturated fatty acids than grain-fed beef. There are no wide species-related difference in muscle cholesterol content because cholesterol is present in both fat and lean tissues as a component of cellular membranes. Meat from small species is somewhat higher in cholesterol partly because the decreased muscle fiber (cell) diameter in these species favors increased cell membrane mass relative to total muscle mass. (*See* **Fatty Acids**: Properties.)

GARLIC

H Amagase and B L Petesch, Wakunaga of America Co Ltd, Mission Viejo, CA, USA

Introduction

Garlic is a very well-researched herb with centuries of culinary and medicinal uses. This powerful herb appears in the historical writings of numerous cultures. This article touches on the cultivation, history, chemistry, pharmacology, and safety of garlic.

Cultivation

Garlic, or *Allium sativum*, is a member of the lily family. It is a perennial, which is usually grown as an annual. A typical plant consists of one large bulb made up of numerous small cloves. The word 'clove' came from the word 'cleave' which means both to cling together and to divide along natural lines. Garlic is typically planted in autumn and harvested about 8 months later in the summer. Various cultivars can grow under an array of climates, temperatures, rainfall, and soil types.

Historical Effects

Garlic has been utilized as a medicinal for centuries. References to this herb have been recorded in the Old Testament of the Bible, the *Codex Ebers*, an ancient Egyptian medical volume, *Shin ching*, the Chinese *Book of Songs*, and in medical texts of Sumeria, considered to be the world's oldest pharmacopeia. From pharaohs to pharmacies, it is known as the king of the herbs and with more than 2000 scientific publications in the last century alone, it has rightly earned and maintained such a title. A plethora of recent research has confirmed many of the empirical usages of garlic for medicinal purposes. Some of the historical usages of garlic have included remedies for heart problems, headaches, coughs and colds, snake and insect bites, asthma, arthritis, hair growth, worms, respiratory ailments, digestive disturbances, toothaches, and tumors.

Garlic has been used as a poultice to treat respiratory conditions. Since many of its sulfur compounds are modified in the intestinal tract, this was a means of introducing salubrious compounds into the blood stream, as confirmed by garlic breath noted after topical administration. However, careless administration without an adequate vehicle (thick layer of Vaseline) added to the feet prior to administration has led to severe secondary chemical burns.

Tales of garlic as a cure for the great plagues were passed along and written about for several centuries. It was recommended more for protection rather than for actual treatment of the disease. Garlic was coined as 'Russian penicillin' due to its potent antibiotic effects. During both world wars it was used to prevent wounds from growing gangrenous. However, since it can also induce chemical burns, and more practical and effective antibiotics have since been developed, this usage has mostly been abandoned.

Historical interest in garlic has led to extensive research to test its pharmacological effects, resulting in more than 1000 publications over the past decade alone.

Garlic Chemistry

Garlic is quite a complex herb. It is well known with its characteristic odor. Garlic has many intrinsic specific enzymes and chemical constituents that cause a specific odor by crushing the garlic cloves. This odor comes from allicin and decomposes to other compounds instantly. Allicin thus appears to be a transient compound to many of the other sulfur compounds in garlic. It has shown potent antimicrobial effects against even pathogenic and resistant microorganisms in testtubes. However, it is extremely unstable and not bioavailable, absorbed from the intestinal tract, so its testtube effects may not be demonstrated in the body upon consumption. Further, its toxicity is rather high (LD_{50} in $mg\,kg^{-1}$ body weight in mice is 309 in males and 363 in females). It is converted mainly into diallyl disulfide and allylmercaptan in the body. Diallyl disulfide, an oil-soluble compound, has shown remarkable anticancer potential in an array of studies; however, its toxicity is even higher (LD_{50} in $mg\,kg^{-1}$ body weight in mice is 145 in males and 130 in females) than allicin. Chemically garlic is best known for its characteristic sulfur compounds, possessing more than 200 kinds, many of which have scientifically documented pharmacological effects. The water-soluble sulfur compounds derived from γ-glutamyl cysteine, such as *S*-allyl cysteine (SAC), have shown diversified pharmacological activities with little or no toxicity (LD_{50} of SAC in $mg\,kg^{-1}$ body weight in mice is 8890 in males and 9390 in females). Further, they are much more stable and have demonstrated bioavailability in both preclinical and clinical

studies. Garlic also contains nonsulfur compounds with pharmacological effects. A protein fraction, identified in aged garlic extract, has been shown to enhance immune function, nerve growth, to combat cancer, and enhance the growth of friendly bacteria. Steroidal glycosides or saponins in garlic have demonstrated cardioprotective and antifungal activities. And various minerals, such as selenium, germaninum, calcium, copper, iron, and vitamins such as A, B_1, and C, are found in this herb. In fact, garlic is one of the richest sources of selenium. Though garlic is not a rich source of protein, it does contain an array of amino acids.

Pharmacology

Cardiovascular Effects

Extensive research has suggested that garlic intake may reduce various cardiovascular disease risk factors. Randomized, placebo-controlled, double-blind clinical studies have shown modest reductions in elevated blood lipids or fats, such as serum cholesterol, low-density lipoprotein (LDL) cholesterol and triglycerides, and elevated blood pressure. Though the effects are not as pronounced as those of medications designed specifically for such ailments, the side-effects are also nominal or nonexistent, unlike their drug counterparts. Further, garlic is more versatile in its effects on the heart than drugs designed merely to lower blood pressure or lower blood lipids. Garlic has been shown not only to reduce elevated blood lipids, but some studies have even shown an improvement in high-density lipoprotein (HDL)-cholesterol. However, some recent studies utilizing garlic powders and oil have shown no effect on cholesterol, so that standardization of garlic products for effective active ingredients appears to be relevant. Of greater concern than elevated lipids may be their oxidation. Recent work has shown that extracted garlic may prevent the oxidation of blood fats, reducing their ability to adhere to and damage the veins. Garlic has also been shown to reduce the build-up of plaque in the arteries induced by a high-cholesterol diet, as shown in atherogenic models.

Garlic has shown blood-thinning effects, such as inhibiting platelet aggregation and adhesion. These effects have been demonstrated in testtubes and in humans. Thermography has confirmed the ability of garlic to enhance peripheral circulation in humans within 90 min of its intake.

Garlic has also recently been reported to suppress the elevated level of homocysteine, a strong indicator of atherosclerosis, further heart attack, stroke or any kind of stenosis. Thus, garlic has many beneficial effects on the cardiovascular system to reduce multiple risk factors of this disease.

Immune-Enhancing Effects

Garlic has been shown to mitigate infectious diseases through enhancement of the immune system. It has been found to enhance various immune factors such as the phagocyte (cell-killing) activity of macrophages, T-lymphocyte activity, natural killer cell activity, and antibody generation. It has also demonstrated antiviral and antifungal activities. Further, it has been shown to modify, both directly and indirectly, the function of immune cells which play a leading role in allergic cascade reactions, including inflammation. Garlic has also been shown to improve age-related deterioration of the immune response.

Clinical studies have shown that both raw garlic and especially aged garlic extract significantly enhance natural killer cell activity in normal subjects. In a clinical study done on acquired immunodeficiency syndrome (AIDS) patients, who have poor immune function, aged garlic extract was shown to bring natural killer cell activity to normal within only 6 weeks of oral intake. Subjects also experienced improvement in subjective symptoms such as candidiasis and pansinusitus.

Antimicrobial Effects

In testtubes, garlic and some of its constituents have shown potent antimicrobial effects against even pathogenic and resistant microorganisms. Fresh raw garlic and its constituents have been shown to kill *Escherichia coli, Salmonella enteritidis, S. typhimurium, Staphylococcus aureus* and *S. vulgaris, Shigella dysenteriae, S. flexneri, S. sonnei, Mycobacterium tuberculosis, Giardia lamblia, Helicobacter pylori, Entamoeba histolytica*, and other organisms. However, few clinical studies have been done in regards to such antiinfectious effects and some of the effective compounds may not be absorbed from the intestinal tract. Quality research still needs to be done in this area to confirm an effect in humans.

Garlic has demonstrated antifungal effects against *Candida albicans, Aspergillus niger, Cryptococcus neoformans, Coccidiodes immitis, Epidermophyton, Trichophyton*, and other fungi. *Candida albicans* is responsible for secondary yeast infections that often occur after intake of antibiotics. Aged garlic extract was shown to reduce candidiasis, or systemic *Candida albicans* infections, in AIDS patients.

Antiviral effects have also been noted against herpes simplex and influenza. Orally and topically, aged garlic extract has been utilized for genital herpes.

Anticancer Effects

A great deal of epidemiological, chemopreventive, and other research has been done in the area of cancer. Various epidemiological studies conducted in China, Italy, and the USA have shown an inverse relationship between garlic intake and stomach and colon cancer. Various cell culture studies have suggested that compounds in garlic may inhibit the growth of human breast cancer cells, several human melanoma cells, and neuroblastoma cells. Aged garlic extract has been shown to inhibit the growth of breast cancer, bladder cancer, skin cancer, colon cancer, the development of esophageal tumors, and stomach and lung tumors in animal models. The anticarcinogenic effects of garlic are believed to be due to its ability to reduce the rate of activation of chemical carcinogens, that is, preventing the conversion of inactive cancer-causing agents into active ones; its ability to enhance the rate of chemical carcinogen excretion, to protect DNA from carcinogen-DNA adduct formation, to enhance enzymes that detoxify carcinogens, and to suppress tumor cell growth through stimulation of immunoresponder cells. Garlic compounds, injected into cancerous tumors, have resulted in immune cells more aggressively attacking the tumor. Oral intake of garlic has been shown to enhance the activity of various immune cells.

Studies have also suggested that garlic may be a promising adjuvant to cancer therapy. Aged garlic extract was shown to reduce side-effects such as fatigue and anorexia in head-and-neck tumor patients on radio- and chemotherapy and to reduce the cardiotoxicity of the potent anticancer drug doxorubicin/Adriamycin. Aged garlic extract has also been shown to reduce the intestinal damage caused by the anticancer drugs 5-fluorouracil and methotrexate, suggesting that garlic should be included in an overall strategy to reduce/prevent cancer.

Liver Protection

Aged garlic extract and some of its water-soluble compounds, including *S*-allyl cysteine and *S*-allyl mercaptocysteine, have shown significant liver-protective effects against an array of liver toxins, including carbon tetrachloride, aflatoxin B_1, acetaminophen (paracetamol), and others. The protective effects appear to be due to the enhancement of detoxifying phase II enzymes, such as the glutathione-related enzymes. Enhancement of glutathione level by aged garlic extract has been demonstrated in both testtubes and humans.

Other Potential Effects

Recent research has demonstrated antiaging and neurovascular support from garlic and its constituents. Compounds in garlic have been shown to enhance memory in genetically age-accelerated rodents with learning deficits (used for Alzheimer models). Garlic has also been shown to prolong their life span. Enhanced nerve growth and branching have been demonstrated in culture. Garlic, specifically aged garlic extract, has been shown to protect nerve cells from oxidative damage caused by the accumulated neurotoxin beta-amyloid (Aß), which is a hallmark for Alzheimer's disease. One of the water-soluble sulfur compounds, *S*-allyl cysteine, is found in the brain after the consumption of garlic. This may suggest that bioavailable compounds such as *S*-allyl cysteine may work at the target sites of the body and can pass the blood–brain barrier. Moderate but significant ergogenic or energy-enhancing and antistress effects have been noted in athletes following intake of garlic. Garlic has also been shown to reduce stress-induced suppression of immune function and adrenal hypertrophy.

Dosages

Various forms of garlic have shown health-enhancing effects – from fresh garlic, cooked garlic, garlic oils, garlic powders, to aged garlic extract. More than 250 studies have been conducted on aged garlic extract. Some clinical studies have been done on garlic powders that have shown both positive and no effects. Thus, the efficacy of garlic powders, especially in regard to cholesterol reduction, is controversial. The following are dosages used in various studies:

Raw garlic	1–2 cloves (3000–6000 mg)
Garlic oil	2–5 mg
Garlic powder	600–900 mg
Aged garlic extract	4 ml
	1000–7200 mg (as dried form)

Safety

For the most part, garlic is quite a safe herb when taken in reasonable amounts by appropriate means. However, taking garlic as a preventive involves long-term supplementation, which leads to the necessity of consideration of the issue of toxicity. One of the greater concerns associated with long-term garlic supplementation is the general attitude of the public that if a little of something is good for the body, a larger quantity must be even better.

Although garlic has been safely used in cooking as a popular condiment/flavoring and used traditionally for medicinal purposes, it is commonly known that excessive consumption of garlic can cause burning

sensations and diarrhea. Excess intake of raw garlic or garlic powders can cause the following adverse effects/toxicity: stomach disorders and diarrhea; decrease in serum protein and calcium; anemia; bronchial asthma (via inhalation, seen from factory workers); contact dermatitis (skin burns); and inhibition of spermatogenesis. It appears that allicin and some of its degraded compounds may be responsible for some of the harmful effects of garlic, such as anemia and skin burns. The oil-soluble sulfur compounds in garlic have been shown to be much more toxic than water-soluble compounds.

Cooking can reduce the toxicity of garlic but also eliminates its antimicrobial effects. Aging garlic by long-term extraction, by reducing oil-soluble compounds and increasing water-soluble compounds, greatly reduces the toxicity of garlic so that even large amounts can be and have been consumed safely. Further, aging garlic improves its pharmacological activity.

Since garlic has shown potent antiplatelet or blood-thinning activity, it is typically contraindicated with Coumadin (sodium warfarin) or other anticoagulant medications. However, a clinical study has shown that aged garlic extract does not worsen the side-effects of Coumadin in patients. Thus, unlike fresh garlic or other forms of garlic, such as dehydrated garlic powder, aged garlic extract does not have a contraindication with medication.

It may not be suitable for pregnant and nursing women to consume a large amount of garlic products, except aged garlic extract that is approved for those women in Japan as a medication for nourishment pregnant and nursing women.

Conclusions

Garlic is a unique herb loved the world over for centuries. The odorous compounds were formerly believed to be responsible for its beneficial effects. However, recently numerous nonodorous compounds in garlic have been discovered which have potent pharmacological activity. Recent clinical studies support many of the historical usages of garlic, suggesting that its long-term intake may reduce many risk factors for various diseases.

GELATIN

P Harris, V Normand and I T Norton, Unilever Research Laboratory, Sharnbrook, Bedford, UK

Introduction

Gelatin is a nutritious protein containing essential amino acids and is derived from collagen present in the skin and bones of animals. The main food use for gelatin is as a gelling agent for ready-to-eat products residing in the refrigerator (e.g., mousse, trifles, etc.). Other uses are as a dry ingredient (crystal table jellies) or in a highly concentrated gel form (fruit pastilles, marshmallow). More gelatin is sold to the food industry than any other gelling agent; it is relatively cheap to produce in quantity, and there is a ready supply of suitable raw material. This article will review the source, manufacture, and properties of gelatin.

Collagen

Occurrence

Collagen is an important component of skin and bones, and constitutes as much as 30% of total human protein, with similar proportions being found in many other animals. It is widespread in both vertebrates and invertebrates, differing somewhat in amino acid composition, but providing the same function-strength and support for the tissues and organs of the animal concerned.

Structure

The collagen molecule exists as a triple helix comprising three discrete α-chains stabilized by hydrogen bonding. It is characterized by high percentages of glycine (33%), and the imino acids proline and hydroxyproline (22%).

At least 10 collagen types have been identified and another four tentatively recorded on the basis of differences in the three α-chains; the best known are types I and III, from which all commercial gelatins are produced.

The molecular weight of collagen is around 285 kDa, and that of the α-chains 95 kDa.

In most tissues, collagen is arranged in bundles of four or five molecules to form structures known as fibrils. These are further associated with other fibrils nearby to form further bundles of larger diameter. These fibrils are stabilized by the formation of intermolecular cross-links formed from lysine or hydroxylysine residues; the degree of this cross-linking increases with maturity of the animal.

Gelatin

Manufacture

Three types of gelatin are available commercially – ossein (from bones), bovine hide, and pigskin. Gelatin is extracted from collagen by a controlled acid or alkali hydrolysis. The source, age, and type of collagen each influence the properties of the gelatins derived from them. The following steps make up the manufacturing process:

Washing Initial washing of the starting raw material removes impurities; this step also includes degreasing and demineralization of bones to produce ossein.

Pretreatment The pretreatment process is designed to convert collagen into a form suitable for extraction. To achieve this, a sufficient number of covalent cross-links in the collagen must be broken in order to enable the release of free α-chains. The process is also designed to remove other naturally occurring organic substances such as proteoglycan, blood, mucins, and sugars. Pretreatments are optimized by each manufacturer to give the required physical and chemical properties to the gelatins that are produced. The degree of collagen cross-linking governs the pretreatment process required for gelatin manufacture. In young fetal tissues, the concentration of cross-links is at a minimum, and much of the collagen is soluble in mild acid or salt buffer. As collagen matures, the proportion of soluble fraction (procollagen) reduces markedly as cross-linking progresses. To convert insoluble collagen into soluble gelatine three processes are in current use:

1. Acid pretreatments leading to acid process type A gelatins.
2. Alkaline or basic pretreatments leading to alkaline process or type B gelatins.
3. Acid pretreatment processes, which are less aggressive than those using alkali, are applied to pigskin and fresh ossein from young animals. Alkaline pretreatment processes are normally applied to bovine hide and ossein.

Extraction The extraction process is designed to obtain the maximum yield by optimizing the balance between pH, temperature, and the extraction time. In practice, gelatin is obtained from the raw material in three or four separate extractions, each at an increasing temperature. Typical values are 55 °C for the first extraction, 60 °C for the second, 70 °C for the third, and 80–90 °C for the final extraction, each giving gelatins of decreasing gel strength, viscosity, and increasing color. The simplest result of the denaturation is solubilization of the α-chain, however, the denaturation process also leads to secondary products due to random cleavage of single collagen molecules (small units). The other important point to remember is that hydrolysis is sometimes incomplete, leaving covalent bonds between molecules. When two or three α-chains are linked together they are commonly called β- and γ-chains, and when more then three chains are covalently linked, the macromolecules form what are known as microgels. The molecular distribution produced from any extraction can be divided into three broad molecular weight classes: small units, $\alpha + \beta + \gamma$, and microgels. As the extraction number increases, the fraction of $\alpha + \beta + \gamma$ chains decreases, the fraction of small units increases, and the fraction of microgels decreases.

Purification Following extraction, the gelatins are filtered to remove suspended insolubles such as fat or unextracted collagen fibers. The gelatin is further purified by deionization which both removes inorganic salts left from pretreatment and also adjusts the pH to that suitable for sale. Most commercial gelatins are sold in the pH range 5.0–5.8.

Concentration The final stage is evaporation, sterilization, and drying. These are performed as quickly as possible to minimize loss of properties; after this the gelatins are subjected to laboratory testing for their physical and bacteriological characteristics.

Structure

The primary structure of gelatin closely resembles the parent collagen. Small differences are due to raw material sources together with pretreatment and extraction procedures.

These can be summarized as: (1) Partial removal of amide groups of asparagine and glutamine resulting in an increase in the aspartic and glutamic acid content; and (2) conversion of arginine to ornithine during prolonged alkali pretreatment processes. Typical amino acid composition data of gelatins are shown in Table 1.

Table 1 Average amino acid distribution for the three α-chains found in the collagen precursors of gelatin

Residue	*Residues per 1000 residues*
3-Hydroxyproline	1
4-Hydroxyproline	108
Proline	115
Lysine	25
Hydroxylysine	9
Glycine	340
Cysteine	0
Serine	34
Alanine	104
Histidine	7
Valine	23
Methionine	7
Isoleucine	11
Leucine	24
Arginine	49
Phenylalanine	11
Aspartic acid	42
Threonine	16
Glutamic acid	71
Tyrosine	3

Properties

Commercial gelatins consist of gelatin protein in a high state of purity; the nonproteinaceous matter present is mainly mineral ash and residual moisture. The only additive sometimes incorporated during manufacture is sulfur dioxide, used as a color inhibitor during extraction and evaporation and not as a preservative. There is also a small proportion of carbohydrate (1–1.5%) in the form of glucose and galactose bound to gelatine at hydroxylysine residues.

The main gelatin properties of interest to food users are:

1. Bloom value, which is a function of the gel strength.
2. Viscosity, which gives a measure of the solution properties.
3. Surface activity or polyelectrolyte properties.

These main properties will be discussed in more detail later.

Other properties which are important are as follows.

Particle size and solubility Gelatin, although insoluble in cold water and other liquids such as milk, sugar solution, dilute food acids, etc., will swell and absorb up to 10 times its weight in water, the rate of which is dependent on particle size. Swelling characteristics in cold water are determined by temperature and salt or sugar content of the liquid, all of which can affect the rate of water uptake.

Isoelectric and isoionic points The isoelectric point is defined as the pH at which no net migration takes place in an electric field, while the isoionic point is defined as the pH at which there is no net charge on

the molecule. In a deionized solution, the isoelectric and isoionic points are for most purposes identical.

The isoelectric point of gelatine is dependent on the type of pretreatment applied during manufacture. Type A or acid-processed gelatins have isoelectric points that can vary from 6.5 to 9.0. Acid ossein gelatins are at the lower end of the range with isoelectric point values of 6.5–7.5, while acid pigskin is more likely to have values from 7.5 to 9.0.

Many physical properties of gelatine have either a minimum or a maximum at the isoelectric point. This means that acid- and alkali-derived gelatines can sometimes perform quite differently in the same system.

Solution Properties

Typical commercial gelatins tend not to find use as thickening agents due to their relatively low specific viscosity ($\eta_s < 60$ m.ps., @ 6.66) as there are more efficient polysaccharides available for this purpose. Instead, gelatins in the liquid phase can be used for their surface-active properties, either as a stabilizer and emulsifier or as a polyelectrolyte.

Higher-viscosity gelatins will give higher melting temperatures and somewhat quicker setting times, while those of lower viscosity can be prepared in a much higher concentration without causing problems due to tailing when depositing in molds.

A solution of gelatin in water will possess a viscosity or thickening power proportional to its concentration, pH, ionic strength, and the specific viscosity of the gelatin itself. The relationship of viscosity with concentration is not directly proportional but is approximately logarithmic. There is a straight-line dependence for log viscosity with the reciprocal of absolute temperature. The viscosity is always at a minimum at the isoelectric point, and increases as the overall charge on the molecule is increased.

Gel Properties

Preparation of a gel The gelatin is first dispersed in cold water (never the reverse) and allowed to swell. The dispersion is then heated to 50–60 °C and the resultant solution allowed to cool without agitation. A gel is formed at temperatures below about 25 °C depending on the type of gelatin used and its concentration. The critical concentration for a gelatin gel to form is approximately 1% w/w.

Mechanism of gel formation When a solution of gelatin is hot (> 65 °C), it exists as near to random coil chains. As the solution is cooled, the chains lose some of their mobility and start to order locally as segments: on further cooling, these ordered segments associate into triple helices. The site where this association takes place is referred to as cross-link or junction zone. The structure of these junction zones is similar to that of the native collagen. When sufficient junction zones are formed, a three-dimensional network or gel is produced. The gelation kinetics can be divided into two phases:

1. During the first hour, the gel strength increases rapidly. The reinforcement of the network is believed to be mainly due to formation of new cross-links.
2. From 1 h to several hundred hours, the gel strength increase slows down and is linear with the logarithm of time. The reinforcement of the network is believed to be due to the extension of existing cross-links rather than the formation of new ones.

The exact nature of the junction zones is still under investigation, although it has been shown that (GLY-PRO-HYP) triplets are involved. Hydrogen bonding takes place between the amino acids and nearby C–H groups, e.g., on glycine found on adjacent chains. (It is well known that hydrogen bond breakers, such as thiocyanate or urea, can prevent gelation.)

The equilibrium of junction zone formation and breakage moves to create a dynamic gel structure as the temperature of the solution approaches the setting point. At this stage, the larger branched molecules (microgels) begin to grow via junction zone formation with other smaller α- + β- + γ-chains. The condensation reaction corresponds to a second-order reaction, even if triple helices are formed. This has been visualized microscopically, which suggests that an α-chain loops back on to itself and then reacts with a second α-chain to form a triple helix involving just two chains and the junction zone has four free ends. The current thinking is that the elasticity of gelatin gels comes from the relatively free rotation of the segments before these junction zones.

Measurement of Gel Strength

The gel strength of gelatin is nearly always quoted commercially as the Bloom strength. The Bloom value of gelatin is defined as the weight required to push a cylindrical plunger of 12.7 mm diameter 4 mm into a previously prepared gel of 6.66 w/w concentration matured at 10 °C for 16–18 h. Gel strength determinations not performed under these strict conditions cannot be quoted as Bloom strength.

To determine the gel strength, one of the following three instruments can be used:

1. The lead shot gelometer, also known as the Bloom gelometer.
2. The Boucher gelometer.
3. The Stevens-LFRA texture analyzer.

Large Deformation and Failure Behavior

As the requirements of users of gelatin have become more complex, the gel properties are now commonly determined in other ways. Gelatin gels are viscoelastic and incompressible materials (Poisson's ratio close to 0.5). When submitted to large strains, they always present a strain-hardening behavior before failure. The strain at failure is always greater than 50% of strain and can reach 200% of strain in appropriate conditions of concentration and deformation rate. These properties can be linked to the dynamic nature of the cross-links which are melting and reforming under stress, leading to alignment of the elastically active chains. As might be expected, the strain, stress at failure, and the Young's modulus increase when the concentration increases.

Factors Affecting the Properties of Gelatine Gels

Concentration and temperature The exact relationship between concentration and gel strength depends on the type and origin of the gelatin itself, but using gelatins commonly found in the food industry, i.e., 100–250 Bloom, the relationship becomes $(C_2)^n \times (B_1) = (C_1)^n \times (B_2)$ where C is the concentration of the gel concerned; B, the Bloom of the gel concerned; n is equal to 1.7 for high-Bloom gelatins and 1.8–1.9 for lower-strength gelatins of 150–100 Bloom. More precisely, for well-characterized gelatins, a correspondence between the elastic modulus, the measurement temperature, and the concentration in α- + β- + γ-chains has been introduced at any time of the gelation process (master curve). Two equations are necessary for this model:

$$(C_2)^2 \times (T_1) \times (G_1) = (C_1)^2 \times (T_2) \times (G_2)$$

$$\text{and } (C_1) \times (T_2) \times (\tau_1) = (C_2) \times (T_1) \times (\tau_2)$$

where G is the elastic modulus, T the temperature in degrees Celsius, and τ the time scale.

In principle, this model, together with a single elasticity measurement at one temperature and one concentration, can be used to calculate the whole gelation kinetics of a sample. This includes setting to several months, storage, at concentrations between 3 and 10% w/w and temperatures between 5 and 20 °C. The Bloom value is directly proportional to the elastic modulus at a concentration of 6.66% after 16 h at 10 °C.

Effect of pH The gel strength is only seriously affected by solution pH at extremes of the range; from pH 4 to pH 9 it is not affected to any significant extent. Dilute gels (< 2%) are more affected while stronger gels (> 10%) are relatively insensitive to pH.

Time and temperature of set The gel strength will depend on the time and temperature of set. This will vary from gelatin to gelatin and is also dependent on the proportions of molecular fractions present and thus the viscosity. When a gel is in the process of formation, the more the coils can align themselves, before or during maturation, the greater the number of junctions that will form. This becomes apparent if gelatins are snap-chilled as they are found to have significantly lower gel strengths than expected. The sites involved in hydrogen bonding cannot align themselves efficiently enough to produce the expected number of junctions, whereas if gels are 'tempered' at a temperature just above the setting point, the gel strength is above that which could be expected.

Effect of melting point The unique organoleptic qualities exhibited by gelatin are strongly dependent on its melting point, which in turn is influenced by:

1. The bloom value and viscosity of the gelatin.
2. The concentration of the gel.

These in turn can be altered by other ingredients incorporated in the food concerned e.g., salts, sugars, and other gelling or thickening agents.

Effect of low-molecular-weight compounds The effect of other dissolved ingredients in the gel can be either to weaken the gel or to strengthen it. Most simple sugars, glycerol, and other nonelectrolytes can contribute to an increase in gel strength (fructose and sorbitol being an exception) while the addition of most electrolytes has the opposite effect. It has been shown that these components affect the number and size of the junction zone as they impact on the quantity of the solvent (i.e., in sucrose, the number of cross-links increases and the size of each junction zone decreases).

Compatibility with other food biopolymers Gelatin is incorporated as a functional ingredient in a wide variety of foods. When doing so, it is important to have a knowledge regarding its compatibility with other substances with which it is likely to be blended in order to form the final food product.

Food biopolymers can be classified into two main groups depending on their structural features. Gelatin solutions will either interact constructively or destructively depending on the environment.

Noncharged biopolymers, e.g., locust bean gum, guar gum, starches, agarose This class of hydrocolloid can be added in low concentrations (separately from the gelatin) to most food systems without significantly impairing the gelling properties of the gelatin.

However, as the concentration is increased, phase separation of the two will often occur.

When composites are prepared in the liquid state at high temperature, gelatin is compatible with the other biopolymer molecules. This compatibility is reduced when the temperature decreases. The incompatibility between the two biopolymers is revealed by an increase in turbidity of the solution and by the appearance of two separated phases (droplets). The two phases have different compositions: one phase is enriched in gelatin while the other is enriched in the other biopolymer and a phase diagram and tie-lines can be constructed (Figure 1). Ultimately, when the densities of the two phases are different, the hot solution evolves into two physically separate layers, with creaming of one phase and sedimentation of the other (Figure 2).

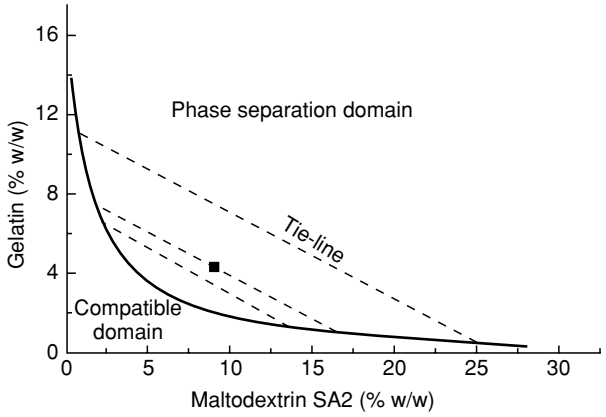

Figure 1 Phase diagram of gelatin (lime hide), maltodextrin SA2 (degraded potato starch), measured at 60 °C. The binodal line separates compatibility and incompatibility domains.

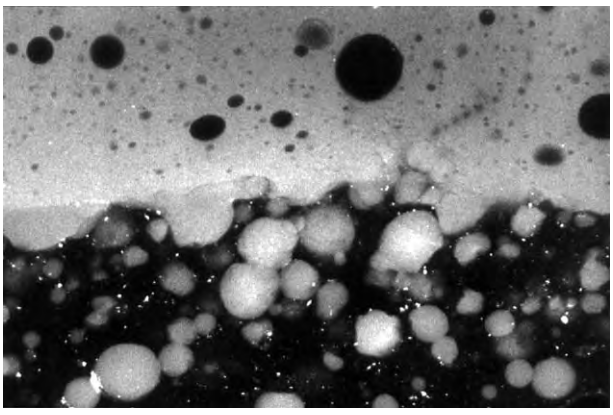

Figure 2 Confocal laser scanning microscopy image of the boundary between two phases in equilibrium. Gelatin is clear and maltodextrin is dark. The composition of the system corresponds to the solid square presented in **Figure 1**. The composition of each phase is determined by the end points of the tie-line (20 mm = 100 μm).

The composite gel formed after cooling of the mixed solution has properties which depend on the microstructure produced. For instance, whether the gelatin forms the included or continuous phase for the same initial system composition, different trapped microstructures can be achieved depending on the processing conditions (i.e., temperature profile, shear, etc.). This can even result in phase inversion of the two biopolymer phases.

Charged biopolymers, e.g., pectins and alginates, agar, carrageenan, and gum arabic This class of hydrocolloid with its negative charge will interact with gelatin, coacervating in a joint phase from solution when the gelatin has a net positive charge and acting synergistically when the gelatin has a negative charge. The degree of synergism is dependent on the negative charge density, and its distribution on the hydrocolloid. However, when the saturation of the charges has been reached, similar behavior as above is reached involving compatibility, incompatibility, and microstructure trapping.

Effect of processing conditions Gelatin will degrade and lose its gelling properties when subjected to conditions of heat, extremes of pH, and exposure to enzyme attack. This has been studied in some detail and modeled.

Also, when gelatin gels under physical disruptions (shear), the final properties of the gel can be very different. For instance, constant shear stress conditions which modify the linear rheological properties at short times of the gelatin gels still result in gels with similar linear properties at long times, but in which the resistance against fracturing is weaker. The model proposed involves particles of gelatin that connect one to the other by cross-link formation to form a network with the same characteristics as the quiescent gel. However, the last cross-links formed are weaker than the earliest and therefore are the first to melt when the gel is submitted to large strains. This highlights the healing properties of the gelatin. Moreover, if constant shear strain is used, instead of a rubber-like material, the final product is more fluid or paste-like as fluid gel particles are produced.

Polyelectrolyte Properties

The gelatin molecule, with its mixture of acidic and basic amino acid side chains, has polyelectrolyte characteristics and is described as amphoteric. At pH levels lower than the isoelectric point the molecule will have a net positive charge, and above this point a net negative charge. Since the isoelectric point in gelatin can vary considerably, the extent of net charge is dependent on the environment pH.

Surface Activity and Related Sol Properties

Gelatin is often used for its surface-active properties, altering the rate of crystal growth in supersaturated solutions, e.g., marshmallow and icecream, where sugar and ice crystal growth are suppressed, giving the desired product. It also finds applications in stabilizing other emulsions such as mayonnaise, pâté, and meat homogenates. Gelatin is added to various types of yogurt formulations, stabilizing the product. It forms a weak gel structure, which imbibes free water, thus inhibiting separation of whey, especially after pasterurization.

The polyelectrolyte behavior of gelatin solutions is widely used for clearing wine and apple juice musts of yeast suspensions, tannins, and other polysaccharides formed during fermentation. It can also be used in the modern 'hot fining process' designed for improved cider and apple juice production. These properties are related on the molecular level to three parameters:

1. Overall charge, and its distribution along the chain.
2. Distribution of nonionic groups.
3. Molecular weight (mean chain length).

Applications

Uses of gelatin in food production Gelatin is widely used as an ingredient in the food industry, due to the following functional properties:

1. It forms high-quality gels in dilute solution with typical clean, melt-in-the-mouth textures.
2. It forms elastic gum-type textures in the concentrated gel, slowly dissolving in the mouth.
3. It forms stable gels on cold storage.
4. It produces emulsification and stabilization of immiscible liquid/liquid, liquid/air or liquid/solid mixtures.
5. It acts as a polyelectrolyte to flocculate suspended particles or unstable colloids from dilute solutions.
6. It acts as a water retainer (it swells easily and there is no syneresis).
7. It acts as an efficient tableting aid and binder.

Gelatin is sold to many sections of the food industry. The major areas of use are in table jellies, confectionery, meat products, icecreams, low-fat and very-low-fat spreads, and chilled dairy products.

Other applications are in the pharmaceutical industry for hard and soft capsule manufacture, and in the photographic industry, which exploits the unique combination of gel formation and surface activity to suspend particles of silver chloride or light-sensitive dyes, without any agglomeration.

Gelatine Derivatives

Cold-Water-Soluble Gelatin

When gelatin solutions are dried without passing through the gel phase, they are of amorphous structure, and do not show any crystalline character, as do gelatins dried from the gel phase. When these dried solutions are rehydrated at a temperature below the gelling point, they will set and form a rigid gel identical in every way to that of a normal gelatin. Unfortunately, when dehydrated, gelatin is extremely hygroscopic and it is difficult to form gels of moderate concentration. In order to overcome this difficulty, mixtures of gelatin and certain carrier substances are available. Glucose syrup and starch are the most popular, as they are ingredients in many of the products for which the gelatin is intended. Drum-dried instant gelatin is also available, but still has to be intimately mixed with other ingredients to insure complete solution.

Hydrolyzed Gelatins

Hydrolyzed gelatins differ from normal gelatins in that they are soluble in cold water, but possess no gelling power.

The hydrolysis of gelatin is complex. There must be strict control of the reaction to avoid the formation of undesirable products such as bitter peptides. Collagen itself is sometimes used, thereby avoiding the gelatin extraction stage. Several manufacturers market a range of hydrolyzed gelatins, each with controlled molecular weight ranges, which can vary from < 1000 to 15 000 molecular weight.

They can be used in tablet binding and granulation agents replacing gelatin, which is not cold-water-soluble under normal conditions of use. Hydrolyzed gelatines give the tablet a better rate of dissolution and disintegration. They are also used as emulsifiers in meat/fat emulsion and as an encapsulation agent for flavor concentrates, taking advantage of its low carbohydrate content.

Hydrolyzed gelatin can be kept as a concentrated solution in a bulk pack after ultrahigh-temperature treatment, or more commonly with preservative added. These are often supplied to the wine industry as ready-to-use fining agents. Hydrolyzed gelatins still possess many of the useful properties of gelatin, e.g., emulsion stability, colloid protection, and flocculation promotion. Much of the production is destined for the cosmetic market where it is added to shampoos as 'protein' and to creams and lotions as 'hydrolyzed collagen,' where use is made of its skin and hair absorption characteristics.

The price of food-grade hydrolyzed gelatine is roughly that of a high-grade gelatin, partially due

to the cost incurred in spray-drying the processed materials.

Analysis of Gelatin Content

The gelatin content of foods can be determined in several ways, each depending on other known constituents present. Kjeldahl nitrogen digestions or biuret reagent determinations can only be applied if it is certain that there are no other proteinaceous compounds present. The procedure for Kjeldahl determinations is well known and suitable conditions have been published. The conversion factor for gelatin determinations is considerably lower than for most other proteins (5.36 for collagen, 5.51 for type B gelatin, and 5.46 for type A gelatin). Hydroxyproline analysis is the definitive method which is applicable in nearly all situations with a high degree of accuracy.

Nutritional Aspects

Because gelatin does not contain any tryptophan, it cannot be used as a 'complete protein;' however it has increased proportions of certain amino acids (e.g., lysine). It can therefore be used to supplement other proteins, to give a mixture with a higher protein value than each component. When mixed with beef protein, the net protein value can rise from 84% to 99%.

The calorific value of gelatin is only 3.5 kcal g^{-1}, which explains its use in low-calorie and diet foods.

GENE EXPRESSION AND NUTRITION

P Trayhurn, University of Liverpool, Liverpool, UK
J E Hesketh, University of Newcastle, Newcastle upon Tyne, UK

Introduction

Molecular biology has provided a detailed description as to how genes are organized and expressed. A number of technologies have been developed in the period since the late 1970s which enable the factors which influence the expression of genes to be readily investigated. In particular, these techniques permit study of the interaction between nutrients and the genetic information in an organism. This article summarizes some of the key concepts and techniques of molecular biology, and their application to nutritional science.

Structure of DNA and RNA

The two fundamental molecules involved in the transfer and translation of genetic information are DNA and RNA. These polymeric macromolecules are composed of a chain of nucleotides. Each nucleotide consists of a sugar moiety, a phosphate group, and either a purine or a pyrimidine base. In the case of RNA the base is ribose, while in DNA it is deoxyribose. The nucleotides in DNA contain one of four bases – the purines adenine (A) and guanine (G), and the pyrimidines cytosine (C), and thymine (T). Both the purines A and G are also present in RNA, as is the pyrimidine C. However, the second pyrimidine in RNA is uracil (U) rather than T.

The nucleotides in DNA and RNA are linked by phosphate bridges to form a sugar–phosphate backbone. Each base is attached to the sugar moiety. DNA consists of two polynucleotide strands arranged in the double helix structure elucidated by Watson and Crick. The sugar–phosphate is on the outside of the helix, with the bases in the center. The two strands of the helix are held together by hydrogen bonding between specific base pairs. Each base pair consists of a purine and a pyrimidine, the pairings being A–T (two hydrogen bonds) and C–G (three hydrogen bonds).

The information necessary for the synthesis of each individual protein in an organism is encoded by lengths of DNA, termed genes. Large numbers of different genes are linked together linearly, and assembled with specific histone proteins, to form chromosomes, the number of which varies from species to species (e.g., 46 in humans and 8 in fruit flies). In eukaryotes, the chromosomes and the genes within them are localized in the nucleus of the cell. The number of human genes is thought to be between 30 000 and 50 000, but the full realization of the Human Genome project will provide a definitive assessment.

Gene Expression

The precision of base pairing allows the nucleic acids to act as templates for the synthesis of strands containing complementary sequences (Figure 1). This is the critical feature of the transfer of genetic information in all organisms. The sequence of the four bases in DNA is transcribed into a complementary strand of RNA, messenger RNA (mRNA). This transcription process uses the same base pairings as in the two strands of DNA, except that mRNA contains U rather than T. Thus A in DNA codes for U in mRNA.

Genes are now recognized to consist of coding regions (exons), regulatory sequences (promoters), and internal noncoding regions (introns); only a small part ($\sim$2%) of the mammalian genome actually codes for protein. Transcription produces an RNA molecule which is complementary to both coding and noncoding regions. However, sequences corresponding to the introns are removed from the primary transcript to produce the functional mRNA molecule.

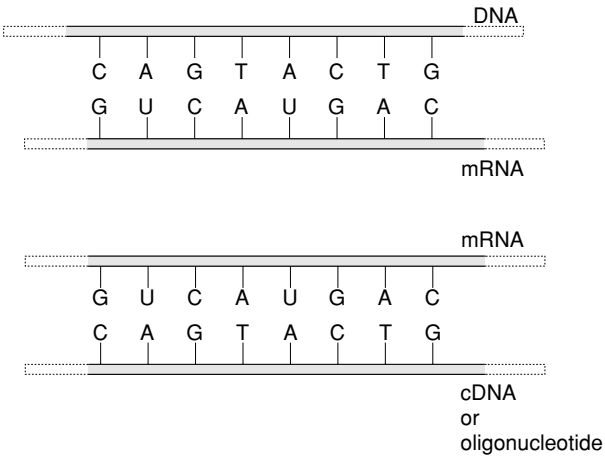

Figure 1 Coding of messenger RNA (mRNA) and complementary DNA (cDNA) molecules.

In eukaryotic cells mRNA is transferred from the nucleus to the cytoplasm, where it becomes associated with ribosomes. The ribosomes, which consist of ribosomal RNA (rRNA) and protein, read the sequence of bases in mRNA and translate this into a sequence of amino acids specific for each individual protein. Not only does the ribosome read the sequence of bases, but it also assembles the amino acids into the protein through the intervention of a further form of RNA, namely transfer RNA (tRNA).

Each amino acid in a protein is coded by a sequence of three bases, and this triplet code is the same in all organisms (universality of the genetic code). The code has some degeneracy in that certain amino acids are coded by more than one triplet.

It is evident from the above that DNA sequences direct the synthesis of protein through the medium of mRNA. Modern molecular biological techniques allow the detection of specific mRNAs, and in practice the expression of a particular gene in a tissue is assessed by identifying the presence of the corresponding mRNA. Strictly, the protein itself should also be identified since an mRNA could, in principle, remain untranslated.

Technology

The ability to detect specific mRNAs depends on two broad types of methodology, one depending on the preparation of DNA sequences which are complementary to part, or all, of the sequence of the mRNA of interest. This is achieved through the application of recombinant DNA technology. Once obtained, a complementary DNA (cDNA) probe will bind, or hybridize, with the corresponding mRNA through the specificity of the base pairings. By tagging the cDNA molecule with a marker, the cDNA–mRNA complex can be readily detected.

The other methodology is dependent on the conversion of the mRNA sequence to DNA using reverse transcriptase (see below) and the subsequent amplification of this DNA by the polymerase chain reaction (PCR).

Isolation of RNA

In order to obtain RNA, tissues and cell membranes must first be disrupted in a denaturing medium, and nucleic acids selectively solubilized. Precautions should be taken throughout to avoid degradation by endogenous and exogenous ribonuclease enzymes. Most procedures yield total RNA, from which mRNA can be obtained by exploiting the characteristic poly(A)$^+$ sequence; this sequence can be bound by synthetic poly(T) oligonucleotides. By linking oli-

go(T) to supports, such as cellulose or magnetic beads, mRNA may be readily isolated.

cDNA cloning

The production of a cDNA probe utilizes the total mRNA complement of a tissue as the starting material. The process requires the synthesis of complementary DNA sequences, their linking to DNA from a plasmid (vector), multiplication of the plasmids in host bacteria, and subsequent screening and selection of clones containing the cDNA of interest (Figure 2).

cDNA sequences are synthesized from mRNAs using the prokaryotic enzyme reverse transcriptase; this involves a fundamental reversal of the normal flow of genetic information. Each cDNA will be an exact replica of parts, or all, of the coding regions of the original DNA from which the mRNA was derived (Figure 1). Since the starting material is invariably a complex mixture of some hundreds or thousands of mRNAs, a wide range of cDNAs will be obtained by the action of the reverse transcriptase.

In the next stage the cDNAs are joined (ligated) to a plasmid DNA (e.g., pBR322), thus generating a recombinant DNA molecule. The plasmids are incorporated into a host bacterium, such as *Escherichia coli*, which is then grown using standard microbiological procedures, resulting in the production of large quantities of the cDNAs. Using appropriate vectors, the cDNAs will direct the synthesis of encoded proteins. Traditionally, clones containing the required cDNAs are identified using antibodies raised against the protein product of the mRNA of interest. Appropriate clones are maintained in culture, and the cDNA excised from the plasmid DNA within the bacteria, using selective restriction enzymes (endonucleases).

Hybridization

A cDNA will bind, or hybridize, specifically to its corresponding mRNA, and this complex can be detected if the cDNA is first tagged with a radioactive (^{32}P) or other label (e.g., enzyme-linked systems which generate chemiluminescence). Hybridization

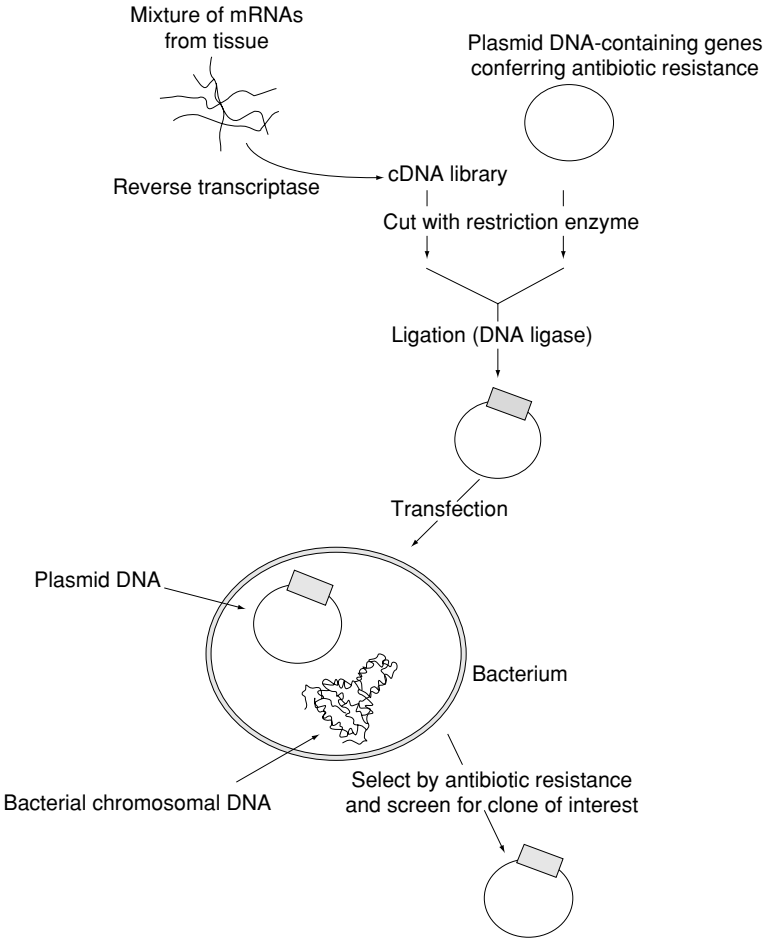

Figure 2 A schematic representation of the application of recombinant DNA technology to produce a cDNA probe.

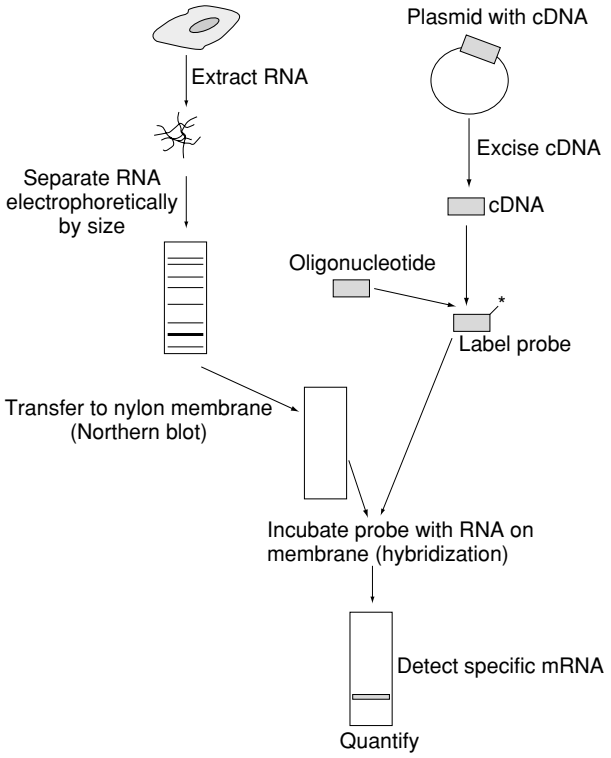

Figure 3 A schematic representation of the detection and measurement of mRNA.

is carried out on solid supports such as nitrocellulose or nylon membranes. This can be achieved by direct application of a mixture of total RNA, or purified mRNA, on to a membrane (dot blot). Alternatively, and more usually, the RNA species are first separated electrophoretically according to size (using agarose gels), followed by transfer to a membrane (Northern blotting); see Figure 3.

Identification of mRNA–cDNA complexes is made by autoradiography, film, or colorimetry, according to the nature of the label attached to the probe. In each of these cases quantification can be achieved by densitometry, or image analysis. A membrane may be sequentially reprobed for the analysis of different RNA species, and this is particularly important in quantitative studies in that it allows the level of a specific mRNA to be related to reference RNAs. In addition, and of special relevance to nutritional studies, the effects of a defined manipulation can be assessed with respect to the expression of different genes associated with linked metabolic processes.

Oligonucleotides

Once the sequence of a gene, or a cDNA probe, is known, computer databases of gene and cDNA sequences can be scanned, so as to design an oligonucleotide probe which will specifically recognize a particular mRNA. Such oligonucleotides provide a convenient alternative to cDNA probes for the detection and measurement of mRNAs (Figure 1). Automated oligonucleotide synthesizers are widely available, and in general an oligonucleotide of 25–30 bases has sufficient specificity to provide a unique probe for each mRNA.

Polymerase Chain Reaction

An alternative to mRNA detection by Northern hybridization is detection by a combination of reverse transcriptase and polymerase chain reaction (RT-PCR). This approach uses short, complementary sequences (primers) to make a cDNA sequence from the mRNA and then, using PCR, to amplify the DNA to produce copies of this DNA sequence. Since PCR uses primers specific to the DNA sequence only the cDNA produced from the original RNA is amplified and produced in sufficient quantity to be detectable after subsequent electrophoretic separation. The method is more sensitive than Northern blotting and more suitable for dealing with large numbers of samples. However, care needs to be taken to make the method quantitative.

In situ hybridization

A further methodology for examining gene expression is *in situ* hybridization, which utilizes probes (often oligonucleotides) for detecting mRNAs in tissue sections. *In situ* hybridization is particularly valuable for identifying the specific region(s) of a complex organ, such as the brain, in which expression of a particular gene occurs. Similarly, the cell types in which expression is taking place within a tissue can be determined.

DNA microarrays

A recent, and rapidly evolving innovation comes from the development of DNA microarrays. One such technique involves the use of arrays of single-stranded cDNA targets immobilized on nylon or glass supports. Each array can contain thousands of cDNA target sequences. Gene expression is monitored by isolation of RNA from a given material, followed by conversion of all the mRNA species in the sample to fluorescently labeled single-stranded DNA probes (using reverse transcriptase) and then hybridization of the labeled probes with the immobilized target. This methodology allows the analysis of the expression of hundreds – or even thousands – of genes in parallel; it offers considerable potential for investigating the integrated effects of a given stimulus or intervention on gene expression.

Nutrition

An appropriate quantity and balance of nutrients is essential for the genetic potential of each individual to be fully realized. Nutrition represents a major interaction with the environment, and an organism has to exhibit both acute and long-term adjustments to changes in nutrient availability. For mammals, these changes are especially marked both at birth, when feeding by the oral route is initiated with the periodic consumption of milks that are characteristically of high fat content, and at weaning when there is normally a switch towards a diet with a lower ratio of fat to carbohydrate.

Gross Nutritional Changes and Gene Expression

Changes in diet induce alterations in the flux of substrates through individual metabolic pathways. Such adaptations are regulated by alterations in hormonal status, and require, on a long-term basis, changes in the amount of associated enzymes. Adjustments in enzyme synthesis generally involve changes in gene expression – either by switching genes 'on' or 'off,' or by 'up' or 'down' regulation of genes that are already being expressed. The genes that code for hormones and their receptor proteins, as well as for transport and carrier proteins, are often also subject to nutritional modulation.

The expression of individual genes is affected by changes in both the quantity and quality of the diet. Thus fasting and refeeding (which represent extreme changes in quantity) lead to alterations in the expression of a variety of genes, including those coding for enzymes of carbohydrate and lipid metabolism, and for receptor and transporter proteins. For example, fasting induces an increase in the level of the mRNAs for both the insulin and the insulin-like growth factor (IGF_1), while subsequent refeeding leads to a rapid fall. Such changes may be tissue-specific, as is the case with the glucose transporters where the level of the mRNA for the insulin-sensitive variety (GLUT 4) alters reciprocally in skeletal muscle and white adipose tissue in response to fasting.

Major changes in the macronutrient composition of the diet can provoke substantial alterations in the expression of particular genes. For example, switching from a high-fat to a high-carbohydrate diet leads to greatly increased levels of the mRNAs for lipogenic enzymes, such as fatty acid synthetase and acetyl coenzyme A carboxylase; in contrast, the levels of the mRNAs for enzymes associated with gluconeogenesis (e.g., phosphoenolpyruvate carboxykinase) are decreased.

It should be noted that, although changes in the level of an mRNA generally imply that the expression of a particular gene has altered, this is not always the case since variations in the stability of mRNAs may also occur.

Transcriptional and Posttranscriptional Control of Gene Expression

In many cases, such as those discussed above, dietary components do not themselves directly affect gene expression, the effects being mediated through changes in hormonal signals. However, in certain instances there is a more direct interaction between specific nutrients and gene transcription. This is especially clear in the case of some micronutrients. Zinc, for example, is required for the loop, or finger-like, structures present in a number of regulatory transcription factors (e.g., nuclear receptors for thyroxine and steroid hormones), and has also been implicated in the regulation of the level of the mRNA for thymidine kinase, an enzyme involved in DNA synthesis.

In addition, the expression of certain genes, notably those coding for proteins involved in the transport, or storage, of trace elements is sensitive to changes in the supply of specific micronutrients. This regulation occurs both at transcriptional and translational levels. Thus transcription of the gene for the metal-binding protein, metallothionein, is regulated by zinc. On the other hand, synthesis of the iron storage protein, ferritin, is controlled by binding of an iron-dependent protein to a specific sequence in an untranslated region of the ferritin mRNA, thereby inhibiting its translation into the protein.

Increasingly, it is being realized that nutrient–gene interactions involve not only the regulation of gene transcription but also posttranscriptional controls such as mRNA stability, translation, and mRNA localization.

Transgenics

Transgenics involve the insertion of genes from one species into the chromosomes of another. The use of transgenic animals has opened substantial opportunities both for the study of metabolic control and for biotechnological applications in agriculture and medicine. One of the earliest and most dramatic examples of the application of transgenics came from the insertion of the gene for growth hormone into mice – such transgenic mice are substantially larger than normal animals. From a nutritional standpoint transgenic animals may have altered nutrient requirements, which will depend in part on the nature of the incorporated gene(s) and the physiological consequences of the change.

Biotechnological applications of transgenics to livestock production include the possibility of inserting genes coding for enzymes associated with the synthesis of essential amino acids, such as lysine, which may be rate-limiting in protein deposition. In medicine, transgenics allows the insertion of genes coding for proteins of therapeutic or pharmaceutical interest. Production of such proteins in milk, through expression in the mammary gland, is likely to provide a particularly potent route for harvesting large quantities of substances such as growth factors and hormones.

Glossary

cDNA

A DNA sequence complementary to part, or all, of the sequence of a particular messenger RNA

Gene Transcription

Conversion of the base sequence of a gene into the corresponding complementary RNA sequence (messenger RNA)

Gene Translation

Conversion of the base sequence in messenger RNA to the corresponding sequence of amino acids in a protein

Hybridization

Formation of duplexes between complementary RNA and/or DNA sequences

Northern Blotting

Transfer of RNA, following separation by molecular size using agarose gel electrophoresis, to a nylon or nitrocellulose membrane

Plasmid

A piece of circular, extrachromsomal DNA which replicates independently; used for the amplification of inserted cDNA sequences

GENETICALLY MODIFIED FOODS

R L Fuchs and M A Mackey, Monsanto Company, St Louis, MO, USA

Background

Food crops have been genetically improved since the beginning of agriculture by selecting and breeding seeds from superior plants. These traditional breeding methods resulted in significant increases in crop productivity and food and feed quality. More recently, it has become possible to introduce DNA directly into crop plants to produce specific genetic modifications; the techniques used are commonly referred to as plant biotechnology, genetic engineering, or recombinant DNA methodology. The introduced DNA can code for proteins that provide plants with the ability to protect themselves against insect damage and fungal, viral, or bacterial diseases; tolerate preferred herbicides; increase yield and nutritional value; reduce naturally occurring toxicants or allergens; modify the ripening process; and provide fruits or vegetables with superior flavor, and other desirable qualities.

Plant biotechnology is a tool to help address the challenge of producing more food, and more nutritious food, more effectively than was previously possible. Global demand for food is projected at least to double in the next 50 years as the world population increases from the current 6 billion to 10 billion. The World Bank outlined a list of agricultural

improvements that can help meet future food needs, including improving pest control and soil conservation; developing new crop strains with increased yields, resistance to pests, and tolerance to drought conditions; and reducing dependence on pesticides and herbicides. Biotechnology must be integrated with the best crop germplasms and agricultural practices in the various geographies to help meet these future food demands.

Biotechnology Process

There are several ways to insert genes in plants, with the most popular being through use of specific bacterial plasmids or particle bombardment. Plasmids are rings of DNA found in bacteria, such as *Escherichia coli* and *Agrobacterium tumefaciens*, a soil bacteria. A gene coding for a desired trait from a donor cell is spliced into an appropriate plasmid using restriction endonucleases. Appropriate regulatory signals are added to enable the gene to function optimally in the host plant. The engineered plasmids are introduced into *E. coli*, then transferred to *A. tumefaciens* by a conjugation process. *A. tumefaciens* containing the engineered plasmids are incubated with tissue from the host plant under conditions which enable the gene(s) of interest to be transferred to and stably inserted into the genome of the host. The inserted gene(s) can then be transferred to related plant varieties using traditional breeding methods.

Particle bombardment is used to transfer DNA directly into cells by use of a 'particle gun.' Pellets of gold or tungsten are coated with the desired DNA and literally fired through the plant cell walls. As they pass through the cells, some of the DNA coating is left behind and stably incorporated into the plant genomic DNA to create a plant cell that will express the desired trait. This technique has been particularly valuable in plants for which the *Agrobacterium* transformation method was not effective or efficient.

Products on the Market

Since the initial reports of the production of the first genetically improved plants in 1983, almost all economically important plants have been genetically improved, and as of 2001 over 50 different products have completed regulatory review by the appropriate regulatory agencies for marketing in at least one country (Table 1).

Most of these initial products were developed either to be resistant to pests, such as viruses and insects (including potato beetles, cotton bollworm, or corn borers), or to tolerate specific herbicides, such as glyphosate, glufosinate, or bromoxynil. Making plants resistant to pests improves pest

Table 1 Plant biotechnology products that have regulatory approval in at least one country as of 2001

Company	*Trait*
AgrEvo	Phosphinothricin-tolerant canola, corn, soy, rice, sugar beets
	Male sterile/phosphinothricin-tolerant canola and corn
	Phosphinothricin-tolerant/ lepidopteran-resistant corn
	Fertility restorer/phosphinothricin-tolerant canola and corn
Agritope, Inc.	Modified fruit ripening tomato
	Delayed-ripening cantaloupe
Asgrow Seed Co.	CMV/WMV2/ZYMV-resistant squash
BASF	Sethoxydim herbicide-tolerant corn
	Canola with enhanced digestibility (animal feed use)
Bejo-Baden	Male sterility chicory
Calgene Inc.	Delayed-ripening tomato
	Bromoxynil-tolerant cotton
	Bromoxynil-tolerant/lepidopteran-resistant cotton laurate canola
China	Virus-resistant tomato and tobacco
Ciba-Giegy	Lepidopteran-resistant corn
Cornell U./U. of Hawaii	PRSV virus-resistant papaya
DeKalb Genetics Corp.	Phosphinothricin-tolerant corn
	European corn borer-resistant corn
	European corn borer-resistant/ phosphinothricin-tolerant corn
DNA Plant Technology	Improved-ripening tomato
DuPont	Sulfonylurea-tolerant cotton
	High-oleic-acid soybean
Florigene	Carnations with increased vase life and modified flower color
Monsanto	Glyphosate-tolerant soybean, cotton, corn, canola, sugar beet
	Improved-ripening tomato
	Insect-protected tomato
	Colorado potato beetle-resistant potato
	Lepidopteran-resistant cotton
	European corn borer-resistant corn
	European corn borer-resistant/ glyphosate-tolerant corn
	Colorado potato beetle-resistant PVY-resistant potato
	Colorado potato beetle-resistant PLRV-resistant potato
Mycogen	European corn borer-resistant corn
Novartis	European corn borer-resistant corn
	European corn borer-resistant/ phosphinothricin-tolerant corn
Northrup King	European corn borer-resistant corn
Rhône-Poulenc	Bromoxynil-tolerant canola
Pioneer Hybrid	Male sterile/phosphinothricin-tolerant corn
Seita	Bromoxynil-tolerant tobacco
Seminis	Virus-protected squash
University of Saskatchewan	Sulfonylurea-tolerant flax
Upjohn	WMV2/ZYMV virus-resistant squash
Zeneca/Petoseed	Improved-ripening tomato

CMV, cucumber mosaic virus; WMV2, Watermelon mosaic virus type 2; ZYMV, Zucchini yellow mosaic virus; PRSV, papaya ringspot virus; PVY, potato virus Y; PLRV, potato leaf roll virus.

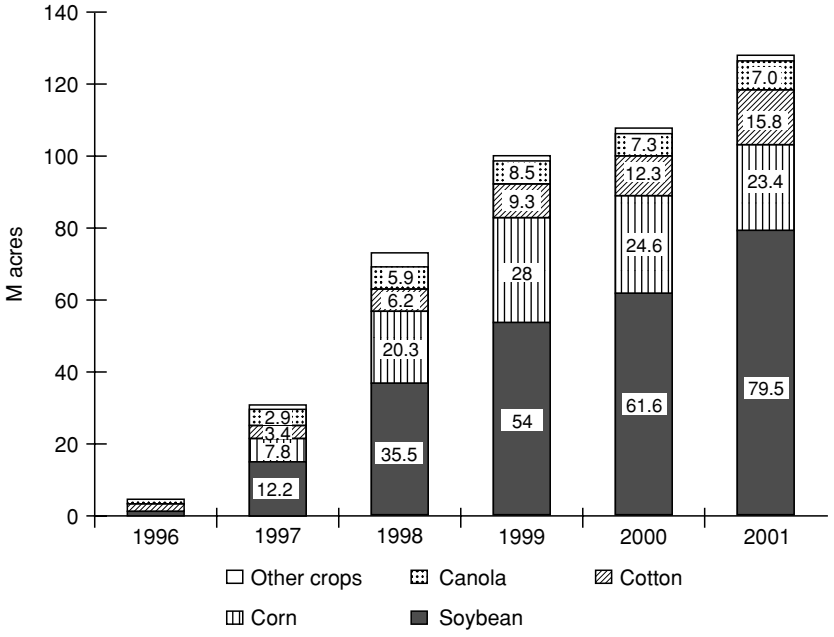

Figure 1 Worldwide acreage (millions) of genetically improved crops planted in 1996 to 2001. Information derived from James C (2001) *Global Review of Commercialized Transgenic Crops*: 2001 Preview ISAAA Brief 24–2001. Ithaca, NY: ISAAA.

management efficacy while reducing the farmer's reliance on and use of various pesticides and increasing crop yield. Herbicide tolerance in crops allows farmers to manage weeds more effectively and with the use of fewer herbicides.

Figure 1 shows the increase in acreage planted worldwide in genetically improved crops from 1996 to 2001. Thirteen countries (USA, Argentina, Canada, China, Australia, South Africa, Mexico, Spain, France, Portugal, Romania, Bulgaria, and Ukraine) grew nine crops (soybean, corn, cotton, canola, potato, squash, papaya, tomato, and tobacco) commercially in 2001. Over 65% of the soybeans, 65% of the cotton, and 25% of the corn grown in the USA in 2000 were genetically improved, while over 95% of the soybeans grown in Argentina were genetically improved (James 2001).

Safety Assessment Process and Regulations for Foods Derived from Genetically Improved Crops

As plant biotechnology products have been developed, so have national and international regulatory oversight measures for them. Appropriate scientific procedures to assess the safety of products from crop biotechnology have been developed over the past decade by scientists and regulatory agencies, including the United Nations (UN) Food and Agriculture Organization (FAO), the UN World Health Organization (WHO), the Organization for Economic Cooperation and Development (OECD), the US Food and Drug Administration (FDA) and others. There is general consensus among scientists on the approach used and information appropriate to assess the safety of foods and feeds from genetically improved plants. These procedures focus on the safety of the final product.

The majority of food and feed products from genetically improved plants introduced to date have been shown to be compositionally and nutritionally comparable (i.e., 'substantially equivalent') to the parent crops, with the exception of the introduced trait(s). Additional safety assessments have focused on the safety of the expressed protein and any products resulting from it. The safety of the protein conferring the desired trait is assessed via internationally accepted procedures, including characterization of the function, specificity, and history of consumption of the same or related proteins, estimation of the level of consumption of the protein, assessment of digestibility, and appropriate animal toxicology studies. Special attention is paid to insure that the introduced protein is not allergenic and does not share physicochemical properties of allergenic proteins. Once food or feed from a crop has been shown to be substantially equivalent to its traditional counterpart except for the introduced trait, and the trait has been shown to raise no safety concerns, the crop (following appropriate regulatory review) may be introduced into the marketplace with the same degree of safety assurance as those products derived from their traditional counterparts.

Table 2 summarizes the information typically provided to regulatory authorities to demonstrate the food, feed, and environmental safety of genetically improved plants and plant products.

In the USA three federal agencies have the authority to regulate biotechnology. The FDA maintains authority to insure the food and feed safety of the products of plant biotechnology; the US Department of Agriculture (USDA) has the authority to insure that these plants do not present any plant pest risks; and the Environmental Protection Agency (EPA) has the authority to assess the safety of plants that produce a pesticidal substance (e.g., plants protected against insects, fungi, or viruses). The EPA also maintains authority over herbicides used in conjunction with herbicide-tolerant plants.

In the FDA's 1992 document *Statement of Policy: Foods Derived from New Plant Varieties*, as well as in the international documents from the FAO, WHO, OECD, and other organizations, there is a general consensus that foods derived from genetically improved plants do not pose any unique safety concerns. The FDA regulates these products in the same way as food and feed products derived from traditionally bred plant varieties.

Other countries, such as Canada, Japan, Korea, South Africa, Switzerland, and Australia also have specific regulations for genetically engineered plant products. In the European Union, the primary control is Directive 2001/18 EEC, which regulates the release of genetically modified organisms (GMO) into the environment. The foods and feeds produced from these GMO are regulated via the Novel Foods Regulation, which requires that before a novel food is marketed, manufacturers must document that the new food does not present a new safety or nutritional risk. Other countries are also developing regulations for these products.

Resistance management (where appropriate)

Food Quality Enhancements

Although most of the initial genetically improved plant products have improved agronomic traits, the first plant biotechnology product marketed in the USA, the Flavr Savr tomato, was developed to allow the fruit to ripen longer on the vine and have an increased shelf-life. Many additional products with improved quality or nutritional properties are under development (Table 3).

Carbohydrates Modifications in the composition and total amount of starch have been achieved via

Table 3 Products from plants improved to contain improved nutritional or quality traits

High-oleic-acid vegetable oils
High-stearate vegetable oils to replace the hydrogenated oils and reduce *trans* fatty acids
Canola oil high in beta-carotene
Corn and soy with increased levels of lysine, tryptophan, methionine
Corn, rice, wheat, and potato with improved starch characteristics
Rice high in beta-carotene and iron
Sweet potatoes with improved protein quality
Ripening-controlled papayas, cherry tomatoes, bananas, strawberries, and pineapples
Tomatoes with increased lycopene
Soybean with increased vitamin E

biotechnology. For example, amylose-free, amylopectin-enriched potatoes have been produced by inhibiting the production of granule-bound starch synthase to produce starch preferred for specific industrial applications. It was recently reported that by introducing photosynthetic genes from corn into rice, yield increases of up to 25% were observed in new rice varieties. In addition, by redirecting the flow of carbon from starch biosynthesis, increases in sucrose content and production of new components like fructans or other sweeteners also can be realized.

Oils Plant biotechnology efforts have focused largely on altering the fatty acid composition of canola, soybeans, corn, and sunflowers, all major sources of dietary oils, to provide either more oxidatively stable oils or oils with enhanced nutritional characteristics. A genetically improved soybean with increased levels of oleic acid, a monounsaturated fatty acid, and reduced levels of polyunsaturated fatty acids has also been produced. Because this product is more stable, it does not require hydrogenation, thereby eliminating the production of *trans* fatty acids which have been linked to cardiovascular disease. Modification of other fatty acids, such as stearate, is also being evaluated for improved human health.

Proteins Foods that provide sufficient quantities of essential amino acids are critical to meet dietary needs, especially in developing countries where foods low in one or more of these amino acids are often relied upon as staples of the diet. Approaches to increase the amount of lysine in cereals and methionine in legumes are being assessed. For example, total lysine content of canola and soybean was increased two- and fivefold, respectively, by expressing non-feedback-inhibited forms of two key enzymes in lysine biosynthesis. A two- to threefold increase in the total lysine content of corn was also obtained using the same approach. These changes are important both from a human nutritional perspective as well as for improved animal feeds, eliminating or decreasing the need to provide supplemental lysine to animal rations.

Vitamins/minerals Research efforts to increase the levels of certain vitamins and minerals in genetically improved crops are ongoing. In developing countries where malnutrition is a major concern, enhancing these components in staple foods may improve nutritional status and reduce disease. These projects include increasing the levels of beta-carotene, the precursor of vitamin A, vitamin D, iron, lycopene, folate, and other nutrients. The most exciting of these research programs is the production of a variety of rice with significantly increased levels of beta-carotene and iron in a more bioavailable form. Consumption of a typical serving of $300\,g\,day^{-1}$ of this rice could help reduce both xerophthalmia and iron-deficiency anemia, which are devastating nutritional problems in the developing world. Over 2 million children die annually from vitamin A-related illness and over 3.7 billion people globally have a deficiency in iron intake. A canola variety with greatly increased levels of beta-carotene in the oil has also been developed.

Eliminating undesirable food components Plant biotechnology can reduce a number of undesirable food components, such as one of the major allergenic proteins in rice or the major allergens in peanut or soybeans. Other efforts to eliminate allergens in foods by modifying their amino acid sequences have also proven successful. Efforts to reduce or eliminate other undesirable components of foods, e.g., glucosinolates in canola meal, protease inhibitors in beans, glycoalkaloids in potatoes and mycotoxins in corn, are being evaluated. Components such as caffeine from coffee beans can be eliminated or reduced to provide a coffee with no or a very low caffeine level without using chemical extraction.

Impact of Genetically Improved Crops on Agriculture

Insect Protection

Insect pests, which can cause tremendous damage to agronomically important crops, typically have been controlled by a variety of chemical insecticides. Yet 20–30% of total crop product is still lost due to these pests. Thus, genetically improved plants containing insecticidal genes from microbes which have been used safely as microbial insecticides for over four decades were developed to improve the efficiency of pest management.

Approximately four million acres of insect-protected cotton varieties were grown in the USA in 1999 and 2000. Use of these varieties significantly reduced the use of chemical insecticides (by over two million pounds annually in the USA alone), significantly increased cotton lint production, and also increased the number of beneficial insects compared to fields treated with chemical insecticides due to increased specificity of the pesticidal protein. US farmers realized significant economic value, averaging about $40 per acre increase in income. Data from developing countries show even greater benefits; for example, insect-protected cotton in China allowed

reduction of chemical insecticide use by approximately 80% and reduced applications from an average of 15 to less than one per season and increased yields by approximately 25%.

Potato plants protected against Colorado potato beetle, the most damaging potato insect pest, were planted commercially in 1996. Growers used approximately 35% less insecticide to control this beetle compared to growers planting nongenetically protected varieties. In 1999, two new products were introduced which combined protection against the Colorado potato beetle with resistance to either potato leaf roll virus or to potato virus Y, two major viral diseases for potato. These products essentially eliminate the need for chemical insecticide use for potato production.

In 1999 and 2000 approximately 25% of the corn planted in the USA was genetically improved to resist pests. An additional advantage of this genetic modification is that the protection of corn ears from pests also drastically reduces the amount of secondary infection caused by the fungus *Fusarium*. The ability to control *Fusarium* results in up to 95% reduction of the level of the mycotoxin fumonisin under some environmental conditions. Fumonisin is known to cause adverse health effects in swine, horses, rodents, and humans. Significant reductions in fumonisin on insect-protected corn have been demonstrated in a number of countries, including the USA, France, Italy, and Argentina.

Virus Protection

Virus-resistant plants have been produced by using genes derived directly from the virus – so-called pathogen-derived resistance. The first genetically improved plant, tobacco with increased resistance to tobacco mosaic virus (TMV), resulted from the expression of the TMV coat protein in tobacco. This coat protein-mediated resistance has been used extensively to confer viral resistance to numerous food crops, including tomato, squash, melon, papaya, sweet potato, and potato. Squash varieties resistant to zucchini yellow mosaic virus (ZYMV) and watermelon mosaic virus (WMV) were approved in the USA in 1995 and marketed. These two viruses routinely reduce crop yields by 20–80% depending on production season and growing region. More recently, squash plants resistant to these two viruses plus a third destructive virus, cucumber mosaic virus (CMV), were developed. Marketing of these products will allow the more consistent production of squash varieties with significant reductions in the use of chemical insecticides that are typically required to control virus spread by insects. Coat protein genes have also been used to confer resistance to papaya ringspot virus (PRSV) in Hawaii, and to sweet potato feathery mottle virus (SPFMV) in Kenya. Resistance to PRSV has essentially saved papaya production in Hawaii, while resistance to SPFMV has the potential to increase yields in Kenya by up to 80%, based on reported yield losses attributed to this virus.

Selectivity to Herbicides

Weeds are one of the major agricultural pests that can devastate a crop. Weeds compete with crops and reduce yield, decrease harvest efficiency, decrease seed quality, and serve as a reservoir for pests. Agricultural practices used prior to World War II were labor-intensive and contributed to soil erosion. These processes have been replaced by the use of chemical herbicides that are the most effective, reliable, and economic method of controlling weeds on a large scale. Today herbicides are used on essentially 100% of the acreage of the major agronomic crops in developed countries.

Traditionally, herbicides are selected based on the weeds to be controlled and the natural resistance of the crop to the herbicide. Biotechnology provides an opportunity to modify crops so they tolerate selected herbicides with preferred environmental properties, such as glyphosate. These herbicide-tolerant crops allow the farmer to apply herbicide to planted fields, killing weeds but leaving the crop unaffected. This ability provides increased flexibility and cost savings to growers. In addition, farmers can move from using preemergent, soil-incorporated herbicides to postemergent herbicides that are applied on an 'as-needed' basis. This strategy can reduce the number and total amount of herbicides used and enables the application of herbicides that bind tightly to the soil and are less likely to enter the groundwater, thereby providing environmental benefits and encouraging the use of reduced-tillage agriculture.

Soybeans, canola, cotton, and corn tolerant to glyphosate, and canola and corn tolerant to phosphinotricin are examples of herbicide-tolerant crops (Table 1). When introduced in 1996, glyphosate-tolerant soybeans were planted on only 1.5% of the US soybean acres. Because of exceptional weed control and crop safety, these soybeans were rapidly adopted. Approximately 75% of the growers used only one herbicide application, providing a reduction in the amount and number of herbicides used compared to soybeans treated with conventional herbicide programs. By 1999 greater than 65% of the US soybeans, and over 95% of Argentinian soybeans in 2001, were glyphosate-tolerant.

Plants as Production Factories

Plants provide an unmatched capacity to produce products with a maximum efficiency and a minimum of energy – thus, cost-effectively. Plants can be bioengineered to produce insecticidal proteins using just carbon dioxide, water, and nitrogen, thereby reducing the need for expensive and energy-intensive chemical insecticide manufacturing. The potato which has been developed to produce proteins that protect it from both the Colorado potato beetle and the potato leaf roll virus is an excellent example. The combination of these two traits enables potatoes to be grown without the application of chemical insecticides and will result in environmental and economic savings. Approximately 5 million pounds of chemical insecticides are used to control these pests annually in the USA, and 2.5 million pounds of waste are generated in the production process. Less than 5% of the applied insecticide actually reaches the pest. Using the plant to produce these pesticides is more energy-efficient and environmentally acceptable.

One of the most exciting applications of plant biotechnology is the ability to produce edible vaccines in plants. For example, transgenic potatoes containing the nontoxic binding subunit of the *E. coli* enterotoxin as well as transgenic potatoes which express the capsid protein of Norwalk virus have been produced. The expressed proteins function as oral immunogens in humans which, if effective, could immunize people against the diarrheal diseases caused by these organisms. Efforts are under way to introduce such vaccines into banana, which would be eaten raw and thus serve as an ideal source to deliver this technology to developing countries, where inexpensive vaccines are urgently needed.

Improving crop yields is essential to meeting the increased food demands of an ever-increasing world population. Improving crop protection from pests and increasing crop yields through herbicide tolerance are two strategies that will help meet this need. Biotechnological enhancements of crops can insure that these changes occur quickly enough to meet global food needs. At the same time, agricultural biotechnology has advantages for the environment in terms of reductions in soil erosion and tilling, and less agricultural chemical use and run-off. The first generation of crops developed via biotechnology provides these agronomic and environmental benefits. The next generation of products is expected to provide greater direct consumer benefits, such as enhanced food quality and nutritional value.

GHEE

G S Rajorhia, National Dairy Research Institute, Karnal, India

Introduction

Ghee (synonyms: ghrit, ghritam, havi, rognezard, samn, samna, maslea) is a milk-fat product originally produced in India. The origin of gheemaking lies far beyond recorded history. Indian epics and Vedas relate it to third-century BC. Ghee is also marketed in Australia, Armenia, many African and Asian countries, Belgium, The Netherlands, New Zealand, the UK, and the USA. 'Ghee' is the Indian name for clarified butterfat, and it is usually prepared from cows' milk, buffalo milk, or mixed milks. Milk is separated into cream, which may be directly converted into ghee, or it can be first converted into butter and then into ghee. Milk of other mammals, such as goat, sheep, and camel, can also be used. Cream or butter is heated at a temperature sufficient to evaporate nearly all the moisture content, and to produce the characteristic flavor. Heating destroys most of the microorganisms and enzymes. Low water activity hampers the growth of organisms that survive heat treatment or those recontaminating the product. The suspended curd particles are either filtered off or removed by centrifugation. The clear butterfat is cooled to develop a special physical structure by a controlled crystallization process. (*See* **Buffalo**: Milk; **Milk**: Dietary Importance; **Sheep**: Milk.)

Mode of Ghee Utilization

The butterfat in milk is largely used in the form of ghee, as this method of utilization admirably suits the climatic conditions and food habits prevailing in the tropics and the subtropics. It does away with the need for elaborate arrangements which would otherwise be required for the manufacture and storage of table butter. It is an effective way of avoiding the risk of microbial and chemical deterioration incidental to holding butter at relatively high temperatures.

There are regional and seasonal variations in the mode of ghee utilization which can largely be influenced by local food habits, price structure, number of festivals, and image of the product as a nutritional supplement. A major portion of ghee is utilized for culinary purposes. This may cover its extensive use for the direct dressing of food articles, such as unleavened breads, cooked rice, and lentils (dhal), for flavoring, and as a cooking and frying medium. About 60–70% of the total ghee in India is used for direct dressing, and almost 15–20% for the cooking and frying of foods. A significant quantity of ghee is used by confectioners and bakers. Ghee is recognized as a sacred article, and approximately 5–7% is used in religious rites, such as the burning of ghee dips, lighting of the sacred fire in yaganas, preparation of sacred offerings and prasadam, and even for cremation of dead bodies. It is conjectured that ahutis (burning of ghee in religious functions) purifies the air. This practice is considered environmentally safe. Other usages of ghee of minor significance include ladies' hair dressing, body massage of wrestlers, athletes, and invalids, and in the formulation of indigenous pharmaceutical drugs. Ghee is also used for flavoring snuff by mixing and grinding to a very fine powder.

Method of Manufacture

The methods of ghee manufacture vary according to the base material used (milk, cream, butter), intermediate treatment of raw materials, and handling of the semifinished or fully formed ghee. There are four methods for the production of ghee which are essentially based on batch operation:

1. the indigenous milk–butter process
2. direct cream (DC) method
3. the creamery butter (CB) method
4. prestratification (PS) method

These methods are suitable for the different scales of production.

Indigenous Milk–Butter Process

The indigenous methods of gheemaking usually involve: (1) direct churning of raw milk; (2) lactic acid fermentation of heat-treated milk followed by churning; or (3) removal of thick clotted-cream layers (malai); from continuously heated milk at temperatures around 80 °C followed by grinding of clotted cream, its dispersal in water and, finally, churning. In methods (1) and (2), milk is churned every day. Hand-driven wooden beaters are usually employed for separating the butter. After accumulating sufficient quantity over a period of a few days, the butter is melted in a metal pan or earthenware vessel on an open fire until almost all the moisture has been

removed. The extent of frothing may be used as an index to judge when to terminate heating. After heating, the contents are left undisturbed. When the curd particles have settled at the bottom of the pan, the clear fat is carefully decanted off into ghee storage vessels.

The traditional gheemaking practice contributes about 90% of the total ghee production in India. This method leaves behind a large quantity of buttermilk of varying quality, and also leads to low fat recoveries (75–85%). This is why modern dairies do not use the indigenous method of gheemaking. However, village ghee constitutes the major share of the base material used for the blending operations at ghee grading and packing centers functioning under the Agricultural Marketing Grading (AGMARK) scheme in India. (*See* **Lactic Acid Bacteria**.)

Direct Cream Method

The small dairies use a technologically improved method for gheemaking which involves the separation of cream from milk by centrifugation. This process omits the need for production of butter because cream is directly converted into ghee. The fresh cream, cultured cream, or washed cream is heated to 115 °C in a stainless-steel, jacketed ghee kettle fitted with an agitator, steam control valve, pressure and temperature gages and a movable, hollow, stainless-steel tube centrally bored for emptying out the contents. Alternatively, provision can be made for a tilting device on the ghee kettle to decant off the product. Heating is discontinued as soon as the color of the ghee residue turns to golden yellow or light brown. One of the limitations of the DC method is that it requires a long heating time to remove the moisture. A high content of serum solids in the cream may also produce a highly caramelized flavor in the ghee, and lead to about 4–6% loss of butterfat in the ghee residue or during handling operations, depending upon the fat percentage in the cream. The use of plastic cream or washed cream with about 75–80% fat is recommended for minimizing both fat loss and steam consumption. The final product will have a less intense cooked flavor when low-solids not fat (SNF) cream is used.

Creamery Butter Method

Most dairies use unsalted CB or white butter as a raw material for gheemaking. A typical plant assembly for the CB method comprises the following: (1) a cream separator; (2) butter churn; (3) butter-melting outfits; (4) steam-jacketed, stainless-steel ghee kettle with agitator and process controls; (5) ghee filtration devices, such as disk filters or oil clarifier; (6) storage tanks for cream, butter, and ghee; (7) pumps and pipelines interconnecting these facilities; (8) crystallization tanks; and (9) product filling and packaging lines.

First, the butter mass is melted at 60 °C. The molten butter is pumped into the ghee boiler, and the steam pressure increased to raise the temperature to 90 °C. This temperature remains constant as long as the moisture is being driven off. The scum which collects on the top surface of the product is removed from time to time with the help of a perforated ladle. The temperature gradually rises and the heating at the last stage is carefully controlled. The endpoint shows the disappearance of effervescence, appearance of finer air bubbles on the surface of fat, and browning of the curd particles. At this stage, the typical ghee aroma is also produced. The final temperature of clarification is adjusted to 110 °C. In some cases, heating beyond this temperature is carried out in order to generate a marked 'cooked' flavor, relished by a sizeable section of consumers. The ghee is then pumped, via an oil filter or clarifier, into settling tanks which are cooled by recirculating water at 60 °C. The residue is packed in suitable containers at 60 °C.

Prestratification Method

The PS method consists of keeping molten butter undisturbed in a ghee boiler at a temperature of 80–85 °C for 30 min for stratifying the mass into three distinct layers. The top layer is composed of floating, denatured protein particles and impurities, the middle layer of almost clear fat, and the bottom layer of buttermilk serum. This division helps in mechanical removal of the bottom layer of buttermilk, carrying about 80% of the moisture and 70% of the SNF contained in butter. Removal of the buttermilk eliminates the need for prolonged heating for evaporation of the moisture, and results in the formation of a significantly low quantity of ghee residue, into which a portion of ghee can become absorbed and from where it is irrecoverable.

The middle layer of fat is heated, usually to 110 °C, along with some denatured curd particles floating on the top. This process is essential to promote development of a more chracteristic aroma. This method offers the advantages of economy in fuel consumption up to 35–50%, saving in time and labor up to 45%, and production of ghee with lower free fatty acid (FFA) levels and acidity. The provisions of pressure gage, safety valves, temperature regulators, and condensate outlet pipe make the PS process capable of producing ghee of better quality, and amenable to process controls. Stratification also helps in the production of ghee with a milder flavor. Its application is limited to batch-scale operation.

Continuous Gheemaking (Figure 1)

To overcome the problems of low heat transfer coefficients in batch methods of gheemaking, limitations of scale of operation and excessive exposure of the plant operators to the stresses of heat and humidity, a continuous gheemaking machine was designed using the principles of hydrodynamics and heat transfer in a horizontal, straight-sided, thin-film, scraped-surface heat exchanger. The rate of water evaporation is 75–80 kg h^{-1} m^{-2} of surface area at a steam pressure in the jacket between 450 and 500 kPa. The rotor is provided with four variable-clearance blades revolving at a speed of 2.45 m s^{-1}. The capacity of the prototype developed is 500 kg h^{-1} ghee.

Butter, heated in a tank to 75 °C, is pumped into the heat exchanger, with the flow rate adjusted with a rotameter. The rotor drive is switched on, and steam allowed to flow into the jacket. The centrifugal action of the rotor causes the product to spread uniformly as a thin film on the heating surface. The turbulence induced by the blade action causes rapid evaporation of water from the product film. The vapors removed via vapor outlets are used for preheating the butter in a tank. During the warm-up period, the partially concentrated fat is diverted into a balance tank. After attaining the desired temperature, ghee is collected in a tank and subsequently passed through a residue separator or clarifier.

Quality of Ghee

The quality attributes of ghee are affected by many factors, such as quality of base material, extent of lactic acid fermentation, time and temperature of heating, rate of cooling, package type, filling conditions, presence of oxygen and contaminants such as iron and copper, exposure to sunlight and temperature, and duration of storage. These factors should be controlled to produce ghee of premium quality.

The consumers of ghee always look for most desirable flavor, texture, and color, and freedom from suspended serum residues. They also want an assurance of purity, freshness, and wholesomeness. The above attributes are assigned relative weightings by consumers in the overall assessment of quality. A perfect score of 60 for flavor, 25 for texture, 10 for color, and 5 for freedom from suspended impurities is recommended for the judging of ghee. The preference for quality is also determined by the end use.

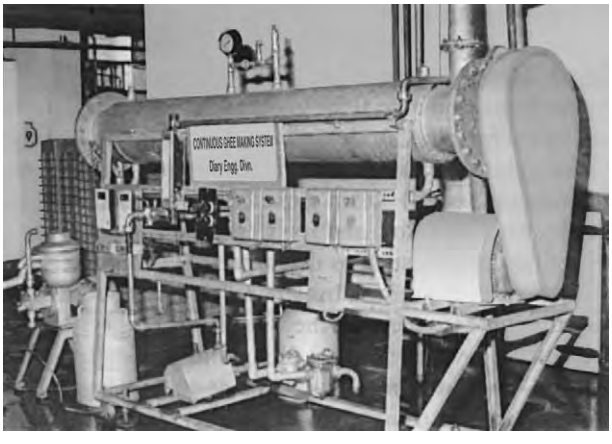

Figure 1 A continuous ghee plant. Courtesy of NDRI, Karnal, India.

Flavor

Aroma and taste constitute the flavor of ghee. A perfect ghee flavor is characterized by a multitude of sensory perceptions which are pleasant, enjoyable, and lingering in the mouth. Consumers always resist any change in the flavor of ghee as this is one characteristic which predominantly determines acceptability. There are regional preferences for flavor in ghee. The preferred ghee flavors range from 'slightly curdy' to 'pronounced curdy', cooked to caramelized and, at times, slightly oxidized in some quarters of the population. The village-produced ghee is characterized by a curdy flavor which lingers in the mouth. (*See* **Sensory Evaluation**: Taste.)

The quality and the amount of SNF present in the base material, as well as the intensity of heating separately and cumulatively, affect the flavor of ghee. Technologies have been developed in the author's laboratory to produce ghee with desired flavors of both 'curdy' and 'cooked' types.

The flavor of ghee is mainly contributed by the heat interaction products formed between the unfermented serum portion, comprising the native carbohydrate and protein system, and by metabolic products of the starter culture when ripened cream is used for gheemaking. The most important flavor components of ghee are as follows: FFAs, 6–12 mg g^{-1} fresh ghee; methyl ketones, 6–12 p.p.m.; a complex mixture of 44 lactones, both δ-lactones and γ-lactones, 29–43 p.p.m.; aldehydes, ketones, and alcohols. About 34 monocarbonyls were found in the flavor volatiles of ghee. The 'curdy' flavor in ghee could be produced by mixing of desi ghee with dairy ghee in varying proportions, by the addition of lactic cultures to butter at heating, by incubating the molten butter with a lactic culture, or by the addition of 'lassi' powder at the time of heating. 'Cooked' flavor could be simulated by clarifying butter at temperatures of 115 °C for 10 min, or 120 °C for 5 min, or 125 °C without any holding time. (*See* **Flavor (Flavour) Compounds**: Structures and Characteristics.)

Texture

Granulation of ghee is an important criterion for its selection; a good grainy texture is very much appreciated by consumers, and such a ghee develops a lower degree of rancidity than ghee kept in the liquid state. Milk fat has the unique property of forming grains because it is made up of a wide variety of complex triacylglycerol mixtures with varying melting points. The texture of ghee will depend on the source of the fat (animal species), method of preparation, temperature of clarification, rate of cooling, amount of FFAs, rate of seeding, and storage temperature. The presence of FFAs markedly increases the grain size, but the quantity of grains is only increased to a limited extent. Seeding with grains of ghee at the rate of 2% by weight of ghee improves grain formation. The grain shape becomes needle-like, in contrast to the spherical shapes obtained without seeding. The large number of fatty acid residues present in ghee results in a wide variety of crystallization patterns.

The maximum amount of solid fraction (about 74%) is obtained at 28 °C in 20–24 h from buffaloes' ghee, closely followed by cows' ghee (69.5%) and a distinct low in goats' ghee (30%). There can be significant differences in the melting curves of fat from the milk of buffaloes, cows, and goats. The changes in the conditions of cooling can have a pronounced effect on ghee texture. If ghee is cooled rapidly, a larger number of very fine crystals will be formed, all consisting of a mixture of high- and low-melting fats, leading to a smooth, grease-like character. Slow cooling of ghee from a temperature higher than the melting point will lead to the formation of few crystals with a high melting point. As cooling proceeds, more and more fat solidifies, forming a mass of large crystals suspended in liquid fat.

Color

Buffaloes' ghee appears whitish in color owing to the absence of carotene, which imparts a yellow color to cows' ghee. In the village method of gheemaking, the development of a greenish-yellow tinge in buffaloes' ghee is caused by the action of lactic acid bacteria. Ghee produced by the DC method has a brownish color compared to that prepared by the CB process. Stratification results in a light color. A more intense heating in the presence of a high SNF content will result in a darker color, especially if the raw material has been fermented. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Shelf-Life of Ghee

Although ghee has a better capacity to resist spoilage by elemental and microbial attack than any other milk product, it is common knowledge that, upon prolonged storage at ambient temperature, it undergoes oxidative changes. Reaction of oxygen with the 'unsaturated fat' is a major cause of spoilage. It gives rise to a typical, strong and disagreeable odor. Production of off-flavors accompanies the loss of nutritive value. (*See* **Oxidation of Food Components**.)

Autooxidation of ghee is aggravated by metallic contamination and sunlight. The 'acceleration' effect of light is dependent on its wavelength, and visible light accelerates the decomposition of hydroperoxides. The effect of ultraviolet light on ghee is more pronounced than the impact of other rays. High-energy radiations, such as β- and γ-rays, exert a pronounced acceleration effect because they split hydroperoxides and also generate free radicals from molecules of unoxidized substrate.

The durability of ghee is affected by the degree of unsaturation of the fat, the temperature at which the ghee is stored, the manner in which the milk for gheemaking was handled, uncontrolled fermentation during curdling, uneven heating during manufacture, and insanitary conditions of the vessels used for the production and storage of ghee.

A number of synthetic antioxidants, such as gallates (ethyl, propyl, octyl), butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), tertiary butyl hydroquinone (TBHQ), ascorbic acid, α-tocopherol, phospholipids, and some natural antioxidants, namely curry leaves, betel leaves, soya bean powder, safflower, and amla (*Phyllanthus amblica*), can be added in small amounts (permitted legally by different countries) with a view to either complete prevention or partial retardation of the oxidation of fat during storage. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

The antioxidative properties of curry and betel leaves are attributed to their phenolic compounds, predominantly hydroxychavicol. These leaves also contain ascorbic acid, which may act synergistically. Curry leaves and betel leaves also contain many amino acids which serve as antioxidants. Studies have proved that the age-old practice of boiling betel and curry leaves with desi butter at the time of clarification helps to improve the flavor, color, and shelf-life of ghee.

Increasing the Durability of Ghee

1. Ghee should be prepared from a good-quality cream or butter.
2. If possible, oxygen should be replaced by nitrogen gas.
3. Some permitted antioxidants should be added before crystallization.

4. Feeding of green fodders and cottonseeds to lactating cows or buffaloes helps to increase the keeping quality.
5. Transparent containers should not be used for packaging ghee.
6. Ghee should be stored in a cool, dark place, preferably at temperatures below 20 °C.

Packaging of Ghee

Ghee is generally packed in lacquered tin cans of various capacities ranging from 250 g to 15 kg. Tin cans protect the product against tampering, and allow transport to far-off places without any significant wastage; they can be printed with attractive and colorful designs. However, tin cans are very expensive. Some plants do pack ghee in metallized, polyester pouches, but these also work out to be expensive owing to the aluminum coating. High-density polyethylene and polypropylene are known to have low water vapor transmission rates and are inexpensive. Such films can be laminated with other suitable, basic packaging materials. Ghee packed in flexible pouches should be placed in cartons that contain some cushioning matter to absorb vibrations during transportation or rough handling. Ghee can also be packaged in polymer-coated cellophane, polyester, nylon-6, food-grade polyvinyl chloride (PVC) or various laminates.

Bulk transport of ghee in tankers, and distribution at the consuming centers in retail containers, could be ideal for interstate or intercontinental marketing. A suitable pumping device is needed to transfer the ghee from the bulk tank without affecting the texture and granular structure of the ghee. Bulk dispensing of ghee, as used for milk, could also become an alternative system for retailing.

Chemical Composition of Ghee

Ghee is largely made up of triacylglycerols (98%) and other minor constituents, such as (1) diacylglycerols (1–2%), (2) monoacylglycerols (0.1–0.2%), (3) FFAs (1–10 mg $100\,g^{-1}$), (4) phospholipids (0–80 mg $100\,g^{-1}$), (5) cholesterol (0.25–0.4%), (6) fat-soluble vitamins, (7) carbonyls (4–6 $\mu g\ g^{-1}$), (8) glyceryl ethers ($0.8\,\mu mol\ g^{-1}$), and (9) alcohol ($1.8–2.3\,\mu mol\ g^{-1}$). (*See* **Cholesterol**: Properties and Determination; **Fatty Acids**: Properties; **Phospholipids**: Properties and Occurrence; **Triglycerides**: Structures and Properties; **Vitamins**: Overview.)

The presence of about 500 fatty acids in milk fat has been reported and the majority possess even-numbered carbon chains, $C_{4–18}$. The total proportion of polyunsaturated fatty acids is only 3–4% in ghee. Buffaloes' ghee is richer in butyric, palmitic, stearic, tetraenoic, and pentaenoic acids than the fat of cows' milk. The levels of other short-chain fatty acids (caproic to myristic) are higher in cows' ghee than in buffaloes' ghee. The fatty acid composition greatly influences the fat constants and rheological properties, such as melting and crystallization behavior, solubility, surface activity, and ability to form emulsions. Table 1 shows the major analytical constants for buffaloes' ghee and cows' ghee.

Table 1 Average analytical constants of ghee

Constant	*Buffalo*	*Cow*
Butyrorefractometer reading	42.0	43.2
Saponification value	230.1	227.3
Reichert–Meissl value	32.3	26.7
Polenske value	1.41	1.76
Kirschner value	28.5	22.1
Iodine value	29.4	33.7
Melting point	32–43	28–41

Nutritive Value of Ghee

Milk fat performs many definite functions in the human diets. It is a rich source of fat-soluble vitamins, essential fatty acids, and other growth-promoting factors. It is believed that ghee improves mental power, physical appearance, and longevity. It increases the capacity to work and enhances the body's resistance to stresses such as cold and undernourishment. Ghee is used as a curative agent for wounds, ulcers, and eye ailments. The conjugated linoleic acid content of milk fat, which is known to be anticarcinogenic, increases substantially during the manufacture of ghee. Addition of ghee to foods improves the satiety value and consumers enjoy the feeling of eating. (*See* **Fatty Acids**: Dietary Importance.)

Anhydrous Milk Fat (AMF)

AMF (anhydrous butterfat, butter oil) is composed of the products exclusively obtained from prime-quality milk, cream, or butter, and resulting from the removal of almost the entire water and SNF contents. The highest-grade AMF suitable for the production of recombined milk and other milk products is produced from fresh milk or cream (rather than from butter) which has not undergone any appreciable microbiological or chemical changes. The moisture content, FFA level, and peroxide value must be very low to guarantee keeping quality. The essential compositional and quality factors for the different grades of AMF products are given in Table 2.

Anhydrous milk fat is obtained from prime-quality raw materials to which no neutralizing substances have been added. The maximum copper content is 0.05 p.p.m., and that of iron 0.2 p.p.m. The peroxide

Table 2 Composition of milk-fat products

Product	*Fat (%)*	*Moisture (%)*	*Maximum peroxide value per kg of fat*	*Fat-free dry mass*	*FFAs (maximum %)*
Anhydrous milk fat					
Grade I	99.8	0.1	0.2	0.2	0.3
Grade II	99.3	0.5	0.3	0.7	
Grade III (butter oil)	99.6	0.3	0.8	0.4	
Dry butter	96.0	0.3		4.0	
Ghee	99.5	0.5			3.0

FFAs, free fatty acids.

value (in mmd O_2 per kg fat) should not be greater than 0.2. Coliforms should be absent in 1 g of product. It must have a clean, bland taste with a smooth and fine-grained structure.

Methods of AMF Production

Only well-equipped dairy plants can produce pure milk fat to international standards, and the production methods, of which there are several, are classified in terms of three basic processes: (1) direct; (2) semidirect; and (3) indirect.

Direct process In the direct process, pure milk fat is made directly from milk. In a typical process, milk is pasteurized, using a regenerative process of heating, and separated into skimmed milk and cream (usually containing 35% fat). The cream is pumped through a plate pasteurizer, using a temperature of at least 75 °C for 15 s, and cooled by regeneration to 55–58 °C. It is then pumped to a clarifixator where it is concentrated to a very high fat content, and the emulsion breaks. The clarifixator has two outlets, one for skimmed milk and the other for oil. The oil phase (80–85% fat) is pumped, via a balance tank, to the fat concentrator, and, after preheating to 90–91 °C in a plate heat exchanger, is pumped to a vacuum chamber for dehydration to below 0.1% moisture. The finished product, extracted from the vacuum chamber, is cooled to 21 °C before packaging in large metal cans or drums. Nitrogen sparging of the AMF is carried out by injecting nitrogen gas at a pressure of 100–140 kPa into the oil-line after the final dehydration stage.

Semidirect process In a semidirect process, cream is fed, with the help of a positive displacement pump, to a continuous buttermaking plant. The butter granules then pass to a jacketed, hopper-dough pump, to a combination in order to condition the fat and make melting by a heat exchanger possible. Using a centrifugation system, desludging is carried out to remove all the solids and most of the aqueous phase. The semidry oil plus added water is returned to a heat exchanger for temperature adjustment. The contents are, thereafter, fed to another centrifuge which removes the last traces of solids and reduces the moisture content of the fat to less than 0.5%. Finally, the oil is passed through a vacuum vessel to reduce the moisture to less than 0.1%.

Indirect process In the indirect process, butter is used as a raw material. Butter is melted in steam-heated melting kettles or revolving plate-type 'melters.' The plate rotates at 150 rpm, throwing the molten butter on to the wall of the melter, where it drains into a collection trough. The molten butter is passed through a stainless-steel mesh filter to remove any extraneous matter, such as wrapping material, and is then pumped to the agitated, water-jacketed holding vats at 55–60 °C. Neutralization, if required, is carried out prior to separation in the holding vat and before pumping to centrifuge. Molten butter is pumped to a Sharples centrifuge for reduction of the total SNF and water content to about 0.5–0.8%. Fat from the centrifuge is washed with hot water at 82 °C. The fat–water mix is then passed to a battery of six Sharples vapor-type super centrifuges, or a set of oil clarifiers, to accomplish the complete removal of SNF and water. The oil is finally vacuum-treated to remove the remaining moisture.

Uses of AMF

AMF can be utilized in a number of ways. It is particularly suitable for use in warm climates and for export. It is used widely in making recombined milk and recombined milk products, and as an ingredient in many processed foods of commercial value. In addition, AMF can be converted into ghee or flavored with simulated ghee flavors.

Conversion of AMF into Ghee

In many countries, surplus milk fat is conserved in the form of butter oil, rather than butter, because of savings in cold storage capacity and the anticipated long shelf-life at ambient temperature. AMF lacks the characteristic flavor, aroma, and texture which are otherwise required in ghee, although the chemical composition is almost identical to that of ghee. A scheme has been suggested for producing ghee from butteroil by the addition of skim milk dahi (20% w/w) or dahi powder (5% w/w) to butteroil and heating the mixture to 120 °C for 3 min. It is also possible to incorporate ghee flavor concentrate in various proportions to butteroil. A synthetic flavor was

constituted to induce a ghee-like flavor in butteroil. The synthetic mixture consisted of δ-(G-10)-lactone (3 p.p.m.), δ-(G-12)-lactone (15 p.p.m.), decanoic acid (5 p.p.m.), and kenanone-2 (10 p.p.m.). The shelf-life of flavored butteroil was improved from 10 weeks to about 6 months by adding BHA (0.02%). A 'cooked' flavor can be induced by heating the ghee residue (10%) with butteroil at 120 °C for 30 min.

GIN

Contents

The Product and its Manufacture

R I Aylott, Tillyrie, Ramoyle, Dunblane, UK

Background

Gin is a distilled spirit drink. It is a colorless liquid containing at least 37.5% alcohol that has its flavor principally derived from juniper berries. It is usually mixed for drinking with tonic water, ice and lemon, or with other alcoholic beverages such as vermouth to make cocktails such as dry Martini.

Distilled gin is traditionally made by distilling alcohol in the presence of juniper berries and other botanical ingredients. Coriander seeds are usually included, together with ingredients such as angelica root, herbs, and orange and lemon peels. As the alcohol boils in the gin still, it extracts flavors from botanical materials, and these condense with the alcohol in the distillate. The alcoholic strength of the gin distillate simply has to be reduced with water down to the required bottling strength, and the gin is ready. There is no maturation process in wooded casks as is used with brown spirits such as whisky, brandy, and rum.

Gin as an English product dates back to the late seventeenth century. It was introduced into England by soldiers returning from wars in the Low Countries where wine and grain spirits were flavored with juniper to make 'jenever' (a corruption of the French word 'genievre'). In those days, the quality of the available alcohol was poor compared with modern alcohol, and the juniper flavor no doubt served to make the pungent alcohol more palatable.

When gin was introduced into England, the most popular alcoholic drinks, other than home-produced beers, were wines and brandies from France. The Dutchman William of Orange became King of England. Strong anti-French anti-Catholic interests at that time helped push the 1690 Distilling Act through Parliament. This act banned the import of French wine and brandy and encouraged the distillation of spirits from grain. Further changes in laws and fashion led to a vast increase in the production and consumption of gin.

The early eighteenth century was the time of a gin craze in England. Gin was often sweetened with sugar or glycerin and was known as 'Old Tom.' Consumption is reported to have increased from 0.5 million gallons in 1689 to 5 million gallons in 1727. By 1733, 11 million gallons were produced in London alone – that was 14 gallons a year for each resident.

Production in London, whose population was 500 000, increased to 20 million gallons by 1743. This enormous consumption of cheap liquor obviously had major social effects, especially on the poor people who already lived under bad conditions. Parliament tried to control consumption with the Gin Acts of 1736 and 1743. Prices rose, and this had the effect of reducing demand.

Quality started to increase, and the end of the eighteenth century/early nineteenth century was the time of the foundation of many of the firms carrying the popular brand names of today. Gin became socially acceptable, being drunk by the servants of the British Empire. Export trade developed, later involving overseas distilling and packaging operations.

Modern neutral alcohols are much purer than their equivalents in earlier centuries and now enable the sensory characteristics of juniper berries and other gin botanicals to be the primary source of gin flavor. These unique qualities help to make gin the internationally popular spirit it is today.

Definitions and Regulations

Gin and other major distilled spirits are defined in law. These definitions serve to protect the interests of consumers, protect gin as a generic product, and protect the interests of the gin distiller.

The law within the European Union (Council Regulation No. 1576 of 1989) is particularly important, as that is the definition where the generic product originated. In summary, a drink may be called *gin* if it is produced by flavoring *ethyl alcohol of agricultural origin* with natural and/or nature identical flavoring substances so that the taste is predominantly that of juniper. *Distilled gin* is produced by redistilling the alcohol in stills traditionally used for gin in the presence of juniper berries and of other natural botanicals provided that the juniper taste is predominant. The term *distilled gin* also applies to mixtures of distilled gin and similar alcohol of agricultural origin. Natural and/or nature identical substances may also be used. *London gin* is a type of distilled gin (and not a geographical location of manufacture), whereas *Plymouth gin* is a geographical designation. Gin simply made by adding essences or flavorings to alcohol may not be called distilled gin – this product is known in the industry as a compounded gin. The minimum bottling strength for all gin is 37.5% vol.

The regulations of other countries reflect much of the European law. The United States Bureau of Alcohol, Tobacco and Firearms distilled gin definition requires all the alcohol to be distilled with the botanical materials and the minimum bottling strength to be 40% vol. (80° US proof). Canada also has a 40% minimum bottling strength, whereas in Australia, it is 37% vol.

Materials for Gin Distillation

The three key ingredients for gin distillation are botanical materials, alcohol, and water. Each gin distiller has a specific botanical recipe for each brand and will have exacting quality requirements.

Figure 1 (see color plate 78) Juniper berries, the essential botanical ingredient in gin, together with commonly used coriander seeds.

Gin botanical ingredients are subject to rigorous quality assessment before purchase, are often stored for 2 years before use, and are carefully blended to ensure minimal seasonal and batch to batch variation. The essential ingredients are juniper berries (*Juniperus communis*). Although juniper is dispersed widely, it is usually harvested for distilling in Italy and the Balkans. Coriander seeds (*Coriandrum sativum*) are sourced from Morocco and Russia, angelica root (*Archangelica officinalis*) from Germany, and orange and lemon peels from Mediterranean countries. Drawings of juniper and coriander are shown in Figure 1. Other botanical materials used in the recipes of specific gins include aniseed, calamus root, caraway seed, cassia bark, cardamom seeds, cinnamon, fennel seed, liquorice root, nutmeg, orris root, and herbs.

The alcohol used for gin distilling is known as neutral alcohol. It is of agricultural origin and is commonly fermented from cereals or molasses. Gin distilled from grain neutral spirits is often sold at a premium. Neutral alcohol is produced on continuous distillation columns and is highly rectified. The resulting distillate is essentially very pure ethanol with only very small traces of congeners (that is, other compounds from the fermentation). The characteristics of ethyl alcohol of agricultural origin are defined within Annex 1 of regulation 1576/89, and the minimum alcoholic strength after final rectification is 96% vol. Production of the neutral alcohol is a separate process from gin distilling and is often conducted at separate distilleries and by different producers.

Water is used in two stages of gin production. First, it is added to the neutral alcohol in the still prior to the start of distillation, and second, it is added to the distillate in order to bring the gin distillate down to the required bottling strength. In both cases, high-purity water is required. It must be clear, odorless, and low in trace dissolved minerals. It is common for such water to be taken from a local supply and purified by demineralization and carbon treatment processes. Historically, many of the London gin distilleries were sited where wells could provide good sources of water.

Gin Distillation

Distilled gin is produced in a batch process in a traditional copper still similar to those used for Scotch malt whisky. Figure 2 shows a schematic diagram of

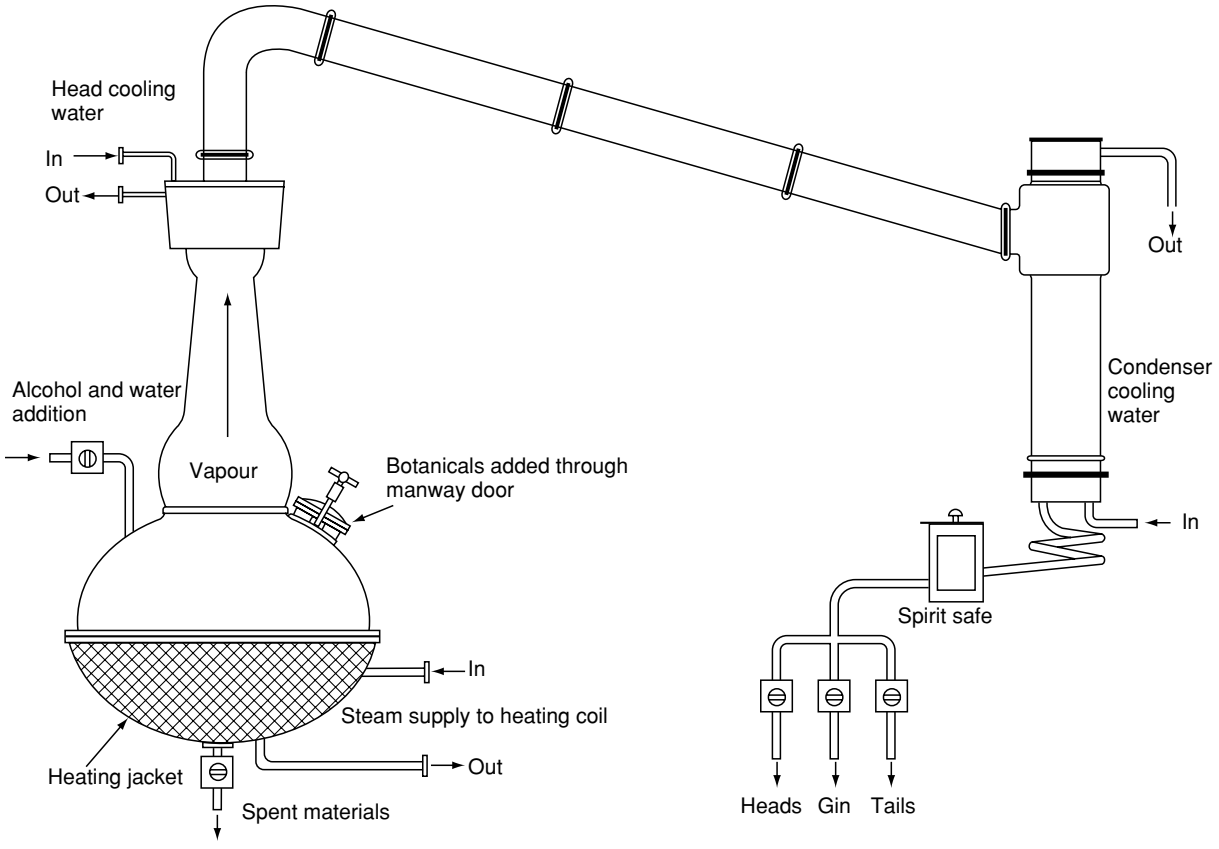

Figure 2 Schematic diagram of a typical gin still.

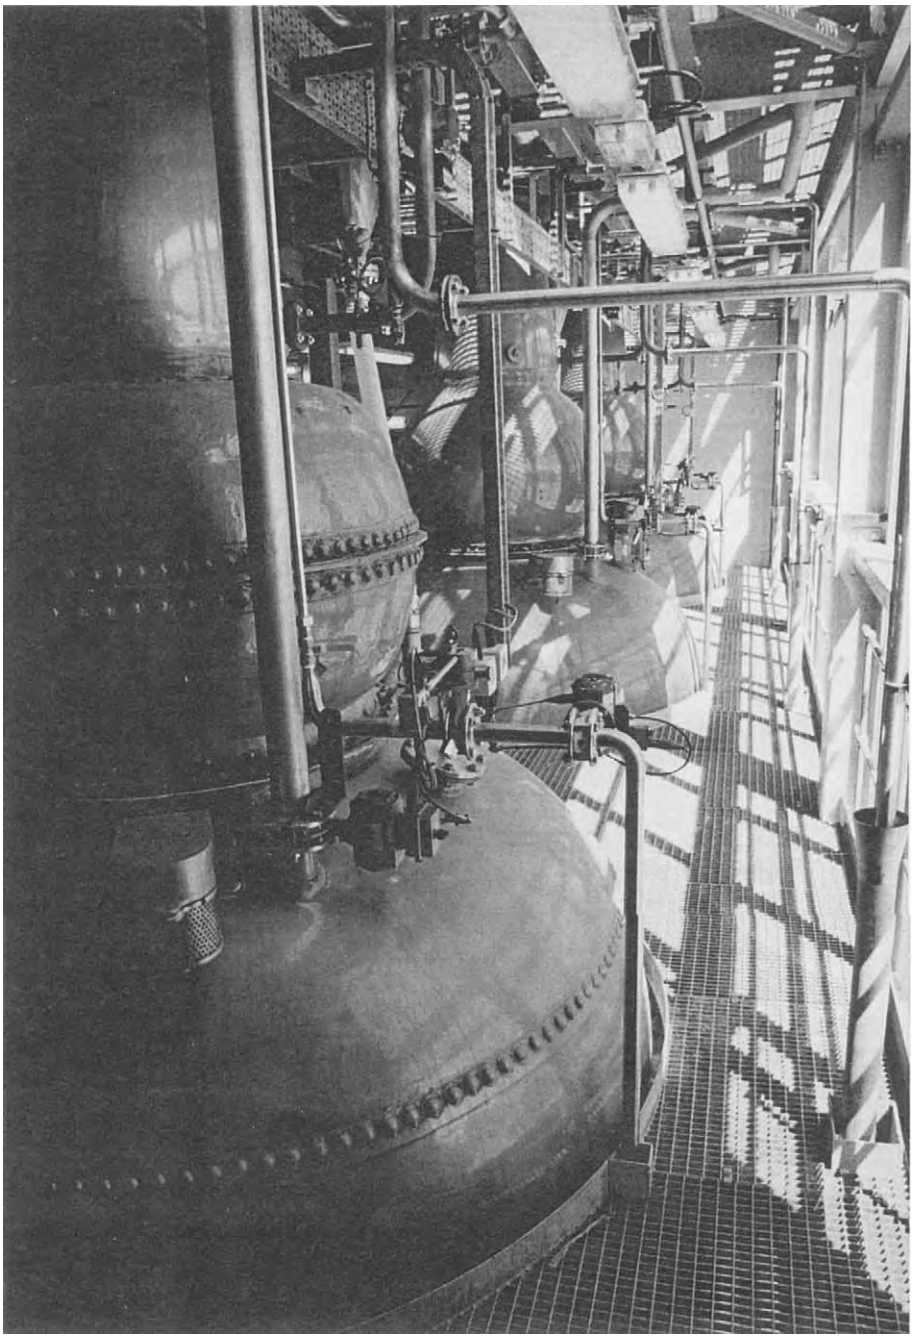

Figure 3 Modern Tanqueray Gordon distillery equipped with old traditional gin stills.

the process, and Figure 3 shows a photograph of the modern Tanqueray Gordon distillery equipped with old traditional gin stills.

The start of the distillation process involves charging the still with water followed by neutral alcohol in order to achieve an alcoholic strength around 60% vol. Botanical ingredients are then added into the still, either loose or in a bag suspended above the liquid. The still is closed, and heat is applied, nowadays using a steam coil. As the liquid starts to boil, the alcoholic strength of the distillate is greatest and contains the most volatile botanical congeners (mainly monoterpenes). This first fraction is known as 'heads' and is kept separate, as it is not required. The second fraction is the main product and is collected as distilled gin at around 80% vol. alcoholic strength. This fraction contains all the congeners found in gin, including monoterpenes, terpineols, and sesquiterpenes). Lastly, as the alcohol content of the distillate starts to fall, the temperature increases,

and the character of the distillate changes as the less desirable low volatile congeners begin to boil. The third 'tails' fraction is then collected separately with extra heat applied to the still to recover as much alcohol as possible. The heads and tails fractions are combined as *feints* and subject to a separate alcohol recovery process.

Throughout the process, the gin distiller will carefully control the rate of heating, monitor the alcoholic strength of the distillate and check the sensory properties of the gin. The gin distillate may then be simply diluted with water down to bottling strength (to produce a 'one shot' gin) or may be blended with other distillates and alcohol to produce the final distilled gin.

Lastly, compounded gin may be made by adding gin essences or flavoring to alcohol. This is the simplest way of making a cheaper product. The essences are normally made by a specialist flavor company according to a defined recipe. No further processing is required except reduction to bottling strength. Such products may not be called distilled gin.

Packaging and Distribution

Immediately before bottling, gin is reduced with water to the required bottling strength and passed through a fine filter. Final alcoholic strengths commonly range from a minimum of 37.5 and 40% in domestic markets up to 47.3% vol. in duty free shops. Gin is normally packaged in glass or PET (polyethylene terephthalate) plastic bottles in common with other popular distilled spirits. The most popular bottle sizes are 700 ml, 750 ml, and 1 l. Fifty-milliliter PET bottles are common in the airline trade. Gin is often distilled at one site and packaged at another. Many brands are shipped overseas at high alcoholic distillation strength in stainless steel tanks for local bottling in order to achieve import tax and transport cost savings by using locally sourced packaging. Gin is a very stable product undergoing no degradation when stored under good conditions in a properly sealed bottle.

Flavored Gins

A range of specialty products are based upon gin and are made by both commercial and cottage industries. Sloe gin is traditionally made by steeping sloe berries (*Prunus spinosa*) in gin in order to extract its natural flavors and juices from the fruit. Similarly, orange and lemon gins are made by steeping the peels of these fruits in gin. After a number of weeks, the steeps are filtered, sweetened to taste with sugar, and reduced in alcoholic strength with water ready for bottling. Ingredient variations on these processes include the use of fruit juices and flavorings.

Table 1 Major eight gin brands, their key markets, and sales in 2000

Brand	*Region*	*Sales (millions of 9 liter cases)*
Ginebra San Miguel	Philippines	27.3
Gordon's gin	International	5.05
Seagram's gin	USA	3.42
Gilbey's	International	2.25
Beefeater	International	2.20
Larios gin	Spain	2.15
Tanqueray gin	International	1.83
Bombay Sapphire gin	International	1.82

Gin Today

Gin is one of the major international generic distilled spirits with only vodka and Scotch whisky selling greater volumes. Table 1 lists the major eight gin brands in the year 2000.

In addition, there are a large number of other local brands to be found plus many own-label brands produced for sale in supermarkets. The more expensive brands tend to be distilled gins, and the cheapest brands are often made using compounding processes.

As with most distilled spirits, many rival products seek to imitate the leading brands. Analytical methods have been developed by which the authenticity of suspect samples may be checked, thus helping protect the interests of the consumer and brand owner.

Composition and Analysis

E Guerra Hernández, Universidad de Granada, Granada, Spain

Introduction

Gin is a colorless spirit obtained by distilling an aqueous mixture of alcohol together with aromatic plant materials, generally juniper berries (*Juniperus communis* L.), to which water and alcohol and at times fruit juices, extracts, and/or essential oils of fruits may be added. According to this definition there are more than 10 different types of gins on the market, produced in various parts of the world. The components of gin are water, alcohol, and compounds derived from the plant materials, essential oils and fruits used in its production.

Composition

Alcohol

The carbohydrate source for obtaining alcohol by fermentation is a grain mash consisting of corn, malt, and rye in varying proportions according to the country of production. Alcohol obtained in this way is purified by distillation to eliminate the flavor of the fermentation products until a clear, clean, and neutral alcohol in taste and odor is obtained. Following this procedure, only minor traces of aldehydes, esters, and higher alcohols are found in the majority of gins, with the exception of Dutch gin, which is made from unrefined alcohol.

Plant Ingredients

The main plant ingredients used are juniper berries together with coriander seeds and angelica root. The precise proportion in which the distilleries use these three components in combination with other plant ingredients, such as anise seed, bitter orange peel, cinnamon bark and cassia bark, is a secret of the distillery, since this is what determines the distinctive taste of each gin.

The essential oil of these ingredients gives gin its characteristic flavor and is obtained by distilling alcohol together with the particular plant ingredients (distilled gin) or, if the essential oil is already in liquid oil form, it is added to the alcohol, as in the case of compound gin.

This essential oil contains terpenes (α-pinene, myrcene, limonene, γ-terpinene, linalool, terpine-4-ol, geraniol, borneol) and their proportion varies according to the combination in which the plant materials are used.

In summary, all types of gin contain, as main components, ethyl alcohol (38–50% alcohol by volume) and water, and in smaller quantities terpenic compounds, which are precisely those which define it and distinguish it from any other alcoholic beverage. Only a few gins contain sucrose, and in others esters, aldehydes, and higher alcohols are found in appreciable concentrations.

Flavor Components

The most common gin is the London type in which the flavor components are derived from the plant ingredients used in its production. A distilled dry gin is a distilled gin with a very small proportion of plant-derived components.

The two main plant ingredients are *J. communis* L. berries and *Coriandrum sativum* L. seeds. The main components of essential oil from these plants are terpenes which constitute the major part of the flavor of the gin. The components found in these plants and in the gins made from them are given in Table 1.

As can be observed, the main terpenic components of the gin, α-pinene and linalool, coincide with those of its plant ingredients. If only the heart of the distilled fraction is used, the proportion of the main components with low molecular weight (unoxygenated monoterpenes) from *J. communis* L. is reduced.

Some gins use not only these components but also other plant ingredients which contain a high proportion of essential oil and, in addition, possess a terpene content near to or exceeding 50%. Their effect, although they are only used in small proportions to give the gin aroma, can significantly affect the final aroma. This is the case with the use of orange oil, which contains 90% *d*-limonene, and cinnamon and cassia bark, whose oils contain 70–95% and 60–70% cinnamic aldehyde respectively.

Table 1 Range of main terpene components (expressed as relative percentage) in berries of *Juniperus communis* L. and seeds of *Coriandrum sativum* L., and main terpenes found in samples of gin

J. communis		C. sativum		*Gin*
α-Pinene	30–35	Linalool	65–75	Linalool
β-Myrcene	18–30	*p*-Cymol	5–7	α-Pinene
β-Pinene	2–14	Borneol	0.2–7	Sabinene
Limonene	4–10	α-Pinene	2.5–6.5	β-Myrcene
Terpinen-4-ol	0.1–10.5	γ-Terpinene	1.4–10	Limonene
Terpinolene	0.5–3	Geraniol	2–4	γ-Murolene
γ-Murolene	1–4.3	β-Pinene	0.3–1.4	Terpinen-4-ol
Sabinene	0.2–3	Limonene	0.1–1.7	Geraniol
γ-Cadinene	0.4–1.6	Camphene	0.4–0.8	γ-Terpinene
p-Cymene	0.1–1.5	Sabinene	0.1–0.2	α-Terpinene

The odor threshold for linalool (a major component of coriander oil) in 20% ethanol is 9 p.p.m., while for γ-terpinene it is 1.5 p.p.m.; as both have an 'orangey' aroma, the latter compound can be more dominant than linalool in the aroma.

The main component of juniper (α-pinene, threshold value 5 p.p.m.) seems to play a decisive role in the aroma, which is not the case for *p*-terpineol (threshold value 13 p.p.m.).

Limonene, although having a high odor threshold (6.5 p.p.m.), contributes decisively to the flavor of 'orangey' gins which are made with oranges and lemons. However, this is not the case with cinnamaldehyde (the major component of cassia and cinnamon bark), which is normally found in gins at concentrations below its odor threshold (3 p.p.m.).

In Dutch gin, together with the terpene hydrocarbons, the components responsible for the flavor include higher alcohols, especially isomyl alcohol and, to a lesser degree, isobutanol, propanol, ethyl acetate, and 2-butanol.

Effects of Storage

Gin does not age and it does not require a period after production to reach maturity. On the contrary, since the aromatic components of the gin are essential oils which tend to oxidize and produce the so-called terpene-like character, it is best to consume the products as soon as possible. Terpenes may also be lost owing to their high volatility.

Analytical Methods (Authentication)

The following factors determine the flavour of bottled gin: quality of initial alcohol, formulation of plant ingredients, and distillation technique. Control of the distillation technique (steam pressure, water flow, etc.) is automated in the majority of distilleries.

Analysis of the alcohol is usually restricted to the determination of extract, acidity, esters, aldehydes, methanol, higher alcohols, nitrogenated bases and furfural, analyses which can be performed using traditional chemical methods. For example, the extract is determined by weighing the samples after evaporation to dryness. The total acidity is determined by neutralization with a standard alkaline solution. Esters (expressed as ethyl acetate) are quantitated by reaction with alkaline hydroxylamine to form a hydroxamic acid which, after acidification, forms a colored complex with ferric ions. Ester concentration is proportional to absorbance at 525 nm at constant alcohol concentrations. Aldehydes (expressed as acetaldehyde) are quantitated with an excess of sodium bisulfite, addition of iodine and analysis of remaining iodine with sodium thiosulfate. Methanol is determined by measuring the absorbance at 575 nm after the addition of potassium permanganate and chromotropic acid to a sample, previously diluted at constant alcohol concentration. Higher alcohols (fusel oil) are determined by means of the formation of colored derivatives with *p*-dimethylaminobenzaldehyde, which are measured at 538–543 nm, or with the sodium salt of 4-hydroxybenzaldehyde sulfonic acid, which is then measured at 445 nm. The content in nitrogenated bases is based on fixing them using phosphoric acid followed by an initial distillation. The bases are liberated with sodium hydroxide and a second distillation is performed. The second distillate is tested with hydrochloric acid. The presence of furfural is detected by the reddish color that appears when this compound reacts with aniline in acetic medium.

These methods are acceptable if there are high levels of the compounds in question, but are not as useful when the levels are very low, in which case it is recommended that the analysis be carried out by gas chromotography using polar columns (Carbowax 1500) under isothermal conditions with flame ionization detection. This allows not only detection of components at very low levels but also individual concentration of each component. With this method aceltaldehyde, ethyl acetate, methanol, and higher alcohols can be determined simultaneously.

When the quantities of the above compounds are high, the alcohol must be purified before it is used in the production of gin.

Analysis of the plant components is normally carried out for juniper berries, coriander seeds, and angelica root. Any other plant components are distilled and compared by taste with accepted standards.

A quality essential oil made from juniper must have a refractive index between 1.4840 and 1.4870; lower levels are indicative of a high content of low-boiling terpenes, which are undesirable in the production of gin. The refractive index for coriander seed oil must be between 1.463 and 1.471 and for angelica root between 1.476 and 1.488.

Measurement of the ultraviolet absorption spectra of these oils also provides quick and useful data with regards to the quality of the oils. Thus, juniper oil absorbs strongly between 220 and 240 nm, coinciding with the absorption of one of its components, terpine-4-ol, while coriander oil begins to absorb at lower wavelengths between 200 and 225 nm. Dilutions of these essential oils in alcohol are compared by taste with a sample standard and, according to the aromatic level required in the final gin, the appropriate plant components are mixed well before proceeding with the distillation stage.

Sensory Analysis

Quality control in large distilleries is carried out by taste panels of 20–30 members. These people examine similar samples in difference tests (triangular test). This panel is used both to insure uniformity of the gin which comes to the market as well as for examining the initial alcohol and the solutions of essential oil extracted from the plant ingredients.

To control the quality and authenticity of a gin that is produced, a sensorial analysis, by means of a taste panel, is used. This provides a profile of the taste and character of the gin. According to these analyses various gins can be identified, e.g., those with a taste derived from juniper berries, and gins with a faint orange taste which corresponds to those gins that contain coriander oil; if the orange taste is strong, this indicates that it contains other ingredients which provide limonene. Finally, those flavors are labeled 'tails' that correspond to samples which contain other components such as those containing cinnamaldehyde. When gins are produced with high levels of cassia or cinnamon, or the samples similar to Dutch gin, their aroma is derived not only from the plant components but also from the initial alcohol, which gives it an aroma similar to that of whisky.

Chemical Analysis

The main ingredient together with water is ethyl alcohol, which can be determined, after distillation, by density measurement with a hydrometer.

The content of extract, total acidity, aldehydes, esters, nitrogenated bases, and furfural can be analyzed by the traditional methods mentioned early. The methanol and higher alcohols (2-butanol, 1-propanol, 2-methyl-1-propanol, 1-butanol, 2-methyl-1-butanol and 3-methyl-1-butanol) are quantified by means of chromatography in Carbowax 1500 column and with 4-methyl-2-pentanol as internal standard. (*See* **Chromatography**: Gas Chomatography.)

Analysis of reducing sugar is done by the reducing properties of the sample, previously clarified, in a cuproalkaline solution. The technique is also applicable to sucrose analysis. The sample content is established by the difference in the reducing capacity before and after inversion with hydrochloric acid. (*See* **Carbohydrates**: Classification and Properties.)

Heavy metals As, Pb, Zn, and Cu, are determined by atomic absorption spectrophotometry. (*See* **Spectroscopy**: Atomic Emission and Absorption.)

Analysis of compounds from the plant ingredients which give the gin its character is mainly by ultraviolet spectroscopy and gas chromotography. Ultraviolet spectroscopy is used to characterize gin in the same way as for the analysis of the plant ingredients; analysis between 220 and 240 nm gives information about the level of juniper oil in the gin when compared with diluted essential oil in alcohol of the same proof. Measurements between 200 and 225 nm give the level found in coriander oil. The results obtained provide a partial indication of 'total flavor level' as 'juniper' or 'coriander' because the oils used for standardization are steam-distilled products, whereas gin is distilled in ethanol and part of the terpene components of plants is rejected as 'feints' (combined heads and tails).

Moreover, this type of analysis has other disadvantages. The first is that it gives only a general idea of the flavor but no information as to the identity of the components. It does not allow a distinction to be made between gins which contain orange and coriander oil from those that only contain the latter, since both absorb at the same wavelength. Finally, this method is only applicable to gins whose initial alcohol has been purified, or else the aldehydes, esters, and higher alcohols that may be present will interfere with the spectrophotometric measurements.

The chromatographic method offers the advantage of identifying individual volatile components of the gin but the disadvantage is that the sample must be concentrated, owing to the low levels of the components, with the risk of obtaining results which may not be accurate since the proportion of the components obtained in the concentrate may not be the same as in the initial sample. There is also a risk of introducing artifacts. Furthermore, the increased time required for the analysis and material waste must be considered.

The two most important techniques for concentration of the volatile components in alcoholic beverages are liquid–liquid extraction and methods based on absorption–desorption. Both procedures have been used on gin. It has also been found that the best solvents are dichloromethane, trichlorotrifluorethane, and a 1:1 mixture of these. The results were reproducible after an extraction time of 5 h and 50 ml of solvent was used to extract 100 ml of the sample; the concentration factor obtained was 20 and the yields were 80% for monoterpenes and 100% for oxygenated monoterpenes. In order to obtain higher concentration factors, continuous extraction methods may be used. For studying concentration through absorption–desorption, charcoal columns have been used.

These two methods have been applied to the analysis of samples of commercial gin using dichloromethane as a solvent for the concentration with an orbital shaker and trichlorofluoromethane for concentration using continuous extraction. The extracts were analyzed by gas chromatography, using a packed polar column (Carbowax 20M). The number

of compounds clearly identified was six with the first procedure and more than 20 with the second, with the latter having the advantage that the extract, once constituted, was identical to the initial sample, from a sensory point of view.

Discontinuous liquid–liquid extraction for the quantitative analysis of volatile components has also been used. The solvent was diethyl ether (200 ml) and was concentrated to a final volume of the extract of 6 ml. The volume of the initial sample was 60 ml and the column utilized was polar (Carbowax 20M), but in this case using a capillary column of 50 m length.

Quantification was carried out by dissolving the terpenes in 40% alcohol by volume at different concentrations and using the same method as with the gin, thereby obtaining standard curves for each component.

In this study 21 different terpene components were quantified (α-pinene, β-pinene, sabinene, δ-3-carene, β-myrcene, limonene, 1,8-cineole, γ-terpiene, *p*-cymene, α-terpinolene, camphor, linalool, linalyl acetate, bornyl acetate, isobornyl acetate, caryophyllene, terpinen-4-ol, myrtenyl acetate, α-terpineol, geranyl acetate, geraniol). **Figure 1** shows a chromatogram obtained by this method.

The main components identified were similar to those obtained in other studies, and were (**Table 1**) linalool, α-pinene, β-myrcene, limonene, terpinen-4-ol and geraniol, with the exception of γ-murolene, a component not found in gins analyzed, but which was detected in the juniper berries in an appreciable quantity and which could have been an indicator of the quality of the gin.

In summary, the only components identified in gin, together with alcohol and water, are the terpenes and these, when found at low levels, require concentration prior to analysis. For the determination of individual compounds a gas chromotographic analysis with high-resolution columns is necessary due to the structural similarity of the terpenes.

Together with these components, the Dutch gins contain higher alcohols (propanol, isobutanol, and isoamy alcohol) in such concentrations (70–90 mg l^{-1}, 70–115 mg l^{-1}, and 315–320 mg l^{-1} respectively) that it is possible to determine them directly in the sample by gas chromotography.

The use of terpenic compounds permits differentiation between gin brands by applying several multivariate statistical methods (principal component; linear, quadratic and nearest neighbor discriminant; cluster analysis and outlier detection). The distilleries reproduce the process of elaboration of gin to obtain uniform terpenic coumpounds and flavor gin.

The chemical components of the gin for which limits have been established, because they reduce the quality of the gin or because they may be toxic are acidity, which must not exceed 10 mg l^{-1}, expressed as acetic acid; methanol, which must not exceed

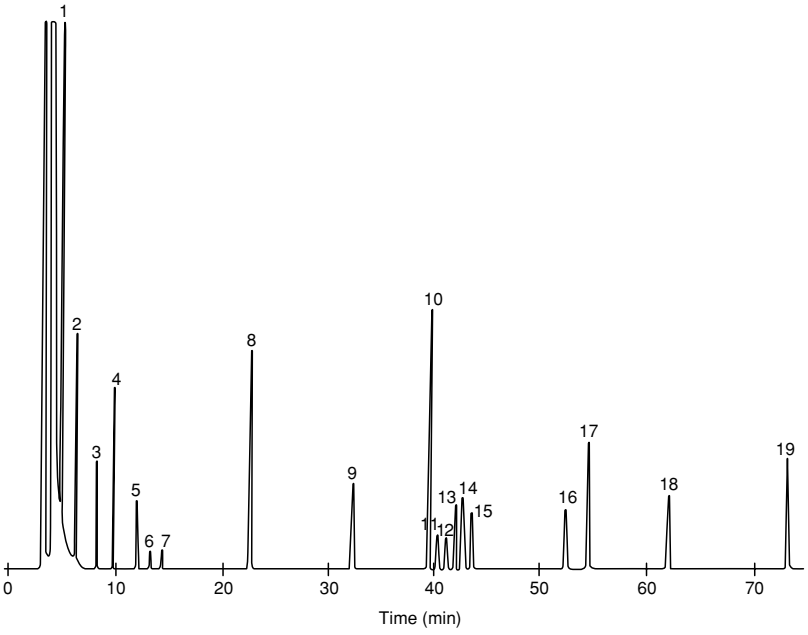

Figure 1 Chromatogram of terpene components found in a sample of commercial gin: (1) α-pinene; (2) β-pinene; (3) β-myrcene; (4) limonene; (5) γ-terpinene; (6) *p*-cymene; (7) α-terpinolene; (8) methyl caprylate (internal standard); (9) camphor; (10) linalool; (11) linalyl acetate; (12) bornyl acetate; (13) isobornyl acetate; (14) caryophyllene; (15) terpinen-4-ol; (16) myrtenyl acetate; (17) α-terpineol; (18) geranyl acetate; (19) geraniol.

$1\,g\,l^{-1}$ (determined chromatographically); and heavy metals As, Pb, Zn, and Cu, which must not exceed concentrations of 0.5 p.p.m. for the first two and 10 p.p.m. for the last two.

The concentration of reducing material must not exceed $35\,g\,l^{-1}$. Finally, commercial gins must not contain apreciable amounts of nitrogenated compounds or furfural.

GLUCOSE

Contents

Properties and Analysis

C V K Sreeranjit and J J Lal, Centre for Development of Science & Technology, Thrissur, Kerala, India

Background

Glucose is a word derived from the Greek word 'gleukos' meaning sweet wine. The term glucose was introduced by André Dumas in 1838 to refer to the sweet compound obtained from honey and grapes. Later, Frederich August Kekulé von Stradonitz called it dextrose because the naturally occurring glucose is dextrorotatory in nature. When Fisher studied this sugar, he called it glucose, and chemists have used the same word ever since.

Glucose is a widely distributed, sweet, simple sugar (monosaccharide) synthesized in plants by photosynthesis and usually stored as polysaccharides. In animals dietary carbohydrates, after digestion, diffuse into the blood in the form of glucose and are assimilated by the liver. In the liver, glucose is used for the synthesis of other carbohydrates, used as a major fuel (for energy production) for the tissues of organisms, or converted to other carbohydrates with highly specific functions such as glycogen for storage, ribose in nucleic acid, galactose in lactose of milk, in certain complex lipids (glycolipids), and in combination with proteins in glycoproteins and proteoglycans. The storage form of glucose is glycogen (liver or muscle glycogen) in animals, and starch or cellulose in plants.

Chemical Structure

The structure of glucose can be represented in different ways as a straight chain, simple ring, or chair form. The straight-chain form (aldo sugars are written with the aldehyde group at the top and the primary alcohol at the bottom) can account for some of

the properties of glucose, but a cyclic structure is favored on thermodynamic grounds. X-ray diffraction analysis has revealed that it has chair form (Figures 1–3).

Isomerism

Compounds that have the same structural formula but differ in their spatial configuration are known as stereoisomers. This phenomenon is mainly due to the presence of an asymmetric carbon atom in the compound. In the glucose molecule, there are four such asymmetric carbon atoms, and so there are 16 isomers in nature.

D and L forms The orientation of the —H and —OH groups around the carbon atom adjacent to the terminal primary alcohol carbon determines whether it belongs to the D or L series. In this spatial relationship, if the —OH group on the fifth carbon is on the right, it is D (dextrorotatory)-glucose, and if it is on the left, it is L (levorotatory)-glucose (Figure 4), i.e., the presence of asymmetric carbon atoms confers the optical activity of glucose. When a beam of plane-polarized light passes through glucose solution, it is rotated either to the right (dextrorotatory) (+) or to the left (levorotatory) (−), but if the mixture contains an equal quantity of dextro- and levorotatory forms (a DL mixture), it does not exhibit any optical activity, since the activities of each isomer cancel each other out. This mixture of isomers is also called a racemic mixture.

Pyranose and furanose forms In some cases, glucose is found in a stable ring form similar to pyran (α-D-glucopyranose) or furan (α-D-glucofuranose) as in Figures 5 and 6. In solution, about 99% of glucose is in the pyranose form, and the remainder is in the furanose form.

α and β anomers A ring structure, called a hemiacetal, is formed by the combination of an aldehyde

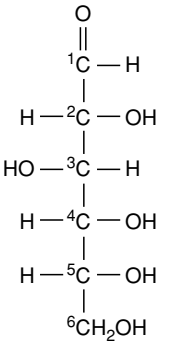

Figure 1 Straight chain.

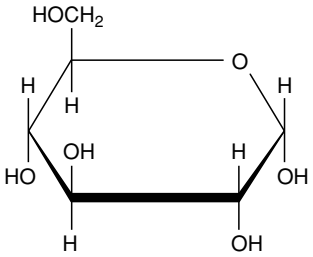

Figure 2 Ring form.

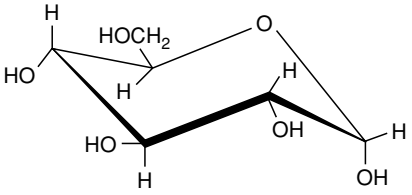

Figure 3 Chair form.

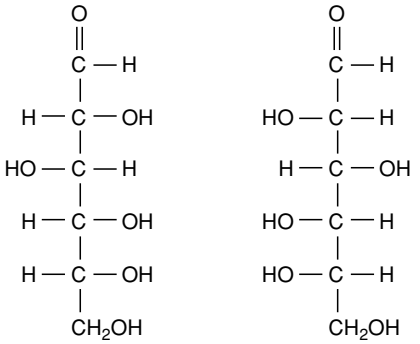

Figure 4 D-Glucose and L-glucose.

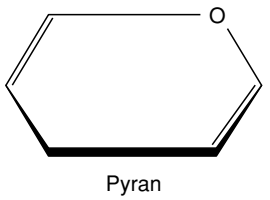
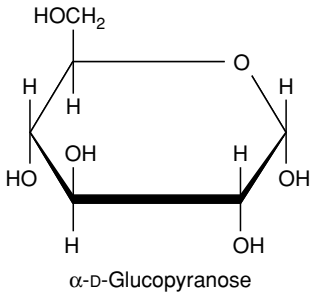


Pyran



α-D-Glucopyranose

Figure 5 Pyranose form of glucose.

and an alcohol group in glucose. While dissolving in water, the optical rotatory power of the solution of monosaccharides gradually changes until it reaches an equilibrium. The freshly prepared solution of glucose has a specific rotation of $+112°$, and when this solution is allowed to stand, the rotation falls to $+52.7°$ and remains constant. This change in specific rotation is called mutarotation (Figure 7). In solution, the ring structure (α-D-glucopyranose) undergoes isomerism at position 1 or the anomeric carbon atom to form β-D-glucopyranose.

Epimers Epimers are isomers of glucose with different configurations of —OH and —H on the 2, 3 and 4 carbon atoms. The biologically important epimers of glucose are mannose and galactose formed by epimerization at the second and fourth carbon atoms (Figure 8).

Aldoses and ketoses Glucose and fructose have the same molecular formula but differ in their structural formula. In glucose, the first carbon atom has an aldehyde group, while in fructose, there is a keto group in the second carbon.

Configuration of C1 in glucose

The configuration of C1 in glucose may be α (with the —H atom to the left and the —OH group to the right) or β (with the —H atom to the right and the —OH group to the left). The empirical rule states that the α anomer has a higher dextrarotation. Hence, the α-D(+) glucose has a specific rotation of $+111°$, and β-D(+) glucose has a specific rotation of $+18.7°$. In negative rotation, the β anomer has a more negative rotation than the α-anomer.

Properties

Oxidation

Sugars contain numerous oxidizable groups. Mild oxidation converts only the aldehyde into a carboxylic acid (aldonic acid), but more vigorous oxidation results in the oxidation of both aldehyde and primary alcohols to carboxylic acids (alaric acid). Even more vigorous oxidation ruptures the six-carbon framework due to the oxidation of the secondary hydroxyl groups. Mild oxidation of glucose using the enzyme glucose oxidase produces gluconic acid, vigorous oxidation of glucose with strong oxidizing agents produces glucaric acid, and even more vigorous oxidation results in the formation of glucosaccharic acid. Periodic acid treatment results in the complete breakdown of the carbon chain.

Reduction

Similar to the process of oxidation, the product of reduction depends on the nature of the reagent. Sodium amalgam, sodium borohydride, high-pressure catalytic hydrogenation, or electrolyte reduction in an acid solution converts aldoses into the corresponding alcohols, and similarly, glucose is converted to sorbitol. Reduction of glucose with concentrated hydrochloric acid and red phosphorus at 100 °C produces 2-iodohexane, and prolonged heating finally gives n-hexane.

Fermentation

Glucose is fermented by yeast to produce ethanol and forms glucosates with various metallic hydroxides. Treatment with calcium hydroxide produces calcium glucosate ($C_6H_{12}O_6CaO$).

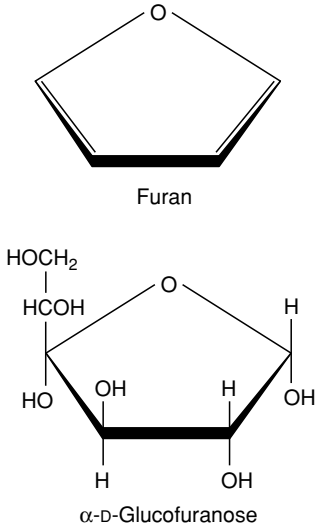


Figure 6 Furanose form of glucose.

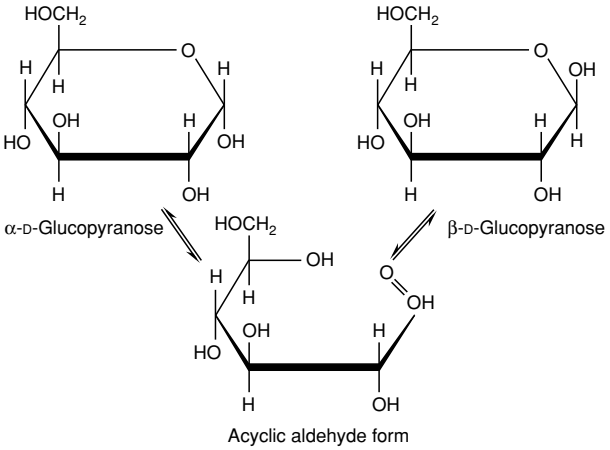

Figure 7 Mutarotation of glucose.

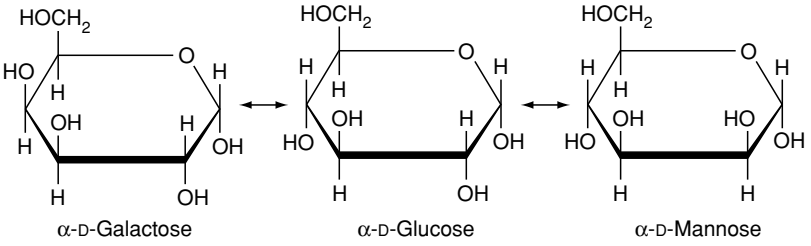

Figure 8 Epimerization of glucose.

Glycosides

Generally, hemiacetals react with another molecule of an alcohol to form acetals. Similarly, sugars (in their ring form) react with a molecule of an alcohol to form an acetal derivative generally called a glycoside. The glycosides of glucose are called glucosides.

Analysis

Monosaccharides contain free aldehyde (—CHO) or ketone (═CO) groups, and so their chemical properties vary, depending on the number of hydroxyl groups and the presence or absence of —CHO/=CO groups. These variations are the basis of color reactions for identifying various monosaccharides. The common methods for conformational (structural), qualitative, and quantitative analyses of glucose are as follows.

Conformational Analysis

Various methods are used to study the conformation of monosaccharides. The common method is to estimate the instability rating of various conformations by using various instability factors such as chair or boat forms, number of axial hydroxyl groups (by considering each axial —OH group result in one instability unit), 1,3 interactions involving the axial —OH group (0.5 instability unit) an axial CH_2OH group (result in two instability units) and if the —OH group on C2 is axial, and the oxygen atom on C1 is equatorial (resulting in 2.5 instability units).

In addition to this instability rating for conformational analysis, various physical methods are used for conformational analysis and to identify and elucidate the structures of various monosaccharides.

X-ray analysis This method is limited to studies on crystals (solid components), and the results may not apply to conformations when the compound in solution. The X-ray analysis of D-glucose has shown that it is in pyranose form.

Infrared spectroscopy This method is used to identify, and determine the structure, configuration, and conformation of, monosaccharides.

Nuclear magnetic resonance spectroscopy This technique is used for the purposes of identification and assignment of configuration and conformation. Deuterium oxide is used as the solvent to examine all C—H protons, and dimethylsulfoxide is used as the solvent to examine —OH protons.

Mass spectrometry This is the most advanced technique used to determine the size of a ring of a monosaccharide (pyranose or furanose), the number and position of methyl, ether, and acetyl groups in methylated sugar, the position of linkage in a disaccharide, etc.

Chromatography This is used to separate, estimate, and identify monosaccharides, using various techniques such as paper, column, gas–liquid (GLC), and thin-layer chromatography (TLC). Column chromatography is used almost exclusively for preparative purposes, and GLC and TLC are particularly useful in analytical work. Definite identification is carried out by isolating the sugar then determining the physical characteristic and precipitating the crystalline derivative. The presence of a reducing sugar on a paper chromatogram is detected using various reagents, e.g., spraying with ammoniacal silver nitrate (black spot formation) or a solution of salt of an aromatic amine, e.g., *N,N*- dimethylaniline hydrochloride, to examine the appearance of colors characteristic of the type of reducing sugar.

Qualitative Analysis

The occurrence of glucose in a carbohydrate solution can be detected by various methods. The commonest tests are as follows.

Molisch's test The principle of this test is that monosaccharides, derived from carbohydrates by hydrolyzing the glycosidic bonds (using concentrated sulfuric acid), become dehydrated to furfural and its derivatives. These products then combine with sulfonated α-naphthol to give a purple complex.

Two drops of α-naphthol solution are added to 2 ml of the test solution in a test tube, and then

about 1 ml of concentrated sulfuric acid is added down the side of the tube so as to form two layers. A color change observed at the interface of the two liquids confirms the presence of carbohydrates in the test solution.

Anthrone reaction The principle of this test is that the aforementioned furfural and derivatives react with anthrone (10-keto, 9,10-dihydroanthracene) to give a blue–green complex.

Five drops of the test solution are added to about 2 ml of anthrone reagent (a mixture of 2 g of anthrone per liter of sulfuric acid) and the solution mixed thoroughly. The appearance of a blue–green color confirms the presence of carbohydrates in the test solution.

Fehling's test This test uses two reagents: Fehling's reagent A (34.65 g of copper sulfate dissolved in distilled water and made up to 500 ml) and Fehling's reagent B (125 g of potassium hydroxide and 173 g of potassium sodium tartrate dissolved in distilled water and made up to 500 ml). The blue alkaline cupric hydroxide present in the solution when heated in the presence of reducing sugar is then reduced to yellow or red cuprous oxide and precipitated.

To 1 ml of the Fehling's solution A and 1 ml solution B few drops of test solution are added and the mixture boiled for a few minutes. The appearance of a yellow or brownish precipitate confirms the presence of glucose in the solution.

Benedict's test Benedict's reagent is made by dissolving 173 g of sodium citrate and 100 g of sodium carbonate in 800 ml of warm water, and the solution filtered and made up to 850 ml with water. Then, 17.3 g of copper sulfate is dissolved in 100 ml of water, the solution made up to 150 ml, and the copper sulfate solution slowly added to the first solution while stirring. The alkaline cupric hydroxide present in the solution, when heated in the presence of reducing sugar, is reduced to yellow or red cuprous oxide and is precipitated.

Five drops of the test solution are added to 2 ml of Benedict's reagent the mixture placed in a boiling water bath for 5 min and the color (green–yellow–orange–red) development against a standard glucose solution. The color of the final solution depends on the concentration of glucose present.

Barfoed's test Barfoed's reagent is a weakly acidic solution and is reduced by monosaccharides. The precipitate of cuprous oxide is less dense than with the previous two tests, and it is best to leave the tube to stand to allow the precipitate to settle. The color of the cuprous oxide is also different, giving a brick-red color in the presence of carbohydrates.

One milliliter of the test solution is added to 2 ml of Barfoed's reagent (made by dissolving 13.3 g of copper acetate in about 200 ml of water and adding 1.8 ml of glacial acetic acid), and the mixture is then boiled for 1 min and allowed to stand and cool. The development of a brick-red color confirms the presence of carbohydrate in the test solution.

Preparation of osazones Compounds containing the —CO—CHOH— group form crystalline osazones with phenyl hydrazine with characteristic shapes and melting points. This can be used as a better method by which to identify a reducing sugar. Phenyl hydrazine reacts with the carbonyl group of the sugar, resulting in the formation of phenylhydrazone and the osazone (Figure 9).

Five milliliters of the sugar solution are acidified with 10 drops of glacial acetic acid, a pinch of phenylhydrazine powder, and 0.1 g of solid sodium acetate. The mixture is then warmed in a boiling water bath for 10 min with occasional shaking and filtered. The filtrate is warmed in the water bath for a further 20 min and cooled very slowly. The osozone crystals can then be examined under a microscope and the shapes compared. Glucose produces needle-shaped yellow osazone crystals.

Quantitative Analysis

Anthrone method This is a very rapid and convenient method for determining hexoses either in free form or in polysaccharides. The resulting blue–green coloration shows a maximum absorption at 620 nm.

Four milliliters of anthrone reagent are added to 1 ml of a protein-free (the presence of protein results in the development of false colors) carbohydrate solution, mixed rapidly, and the tubes with lids (to prevent loss of water by evaporation) placed in a boiling water bath for 10 min. After cooling, the

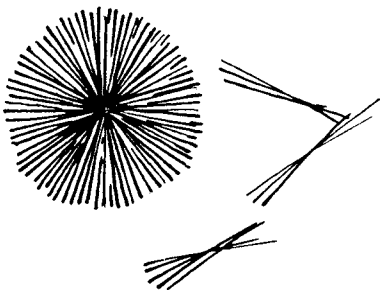

Figure 9 Crystalline appearance of glucosazone (needles or feathery).

optical density is measured at 620 nm against a reagent blank. A standard curve should be prepared using known glucose and glycogen solutions.

Nelson–Somogyi method In this method, the sugar is heated with an alkaline solution of copper tartrate, and cuprous oxide is produced, which reacts with arsenomolybdate to give molybdenum blue; the intense blue color is then measured in a colorimeter. Sodium sulfate is included in the reaction mixture to minimize the entry of atmospheric oxygen into the solution, which would reoxidate the cuprous oxide.

One milliliter of the test solution (containing approximately 50–150 μg of sugar) is mixed with 1.5 ml of water in a test tube and mixed thoroughly. Next, 0.2 ml of barium hydroxide solution ($0.3\,mol\,l^{-1}$) is added to the mixture followed by 0.2 ml of aqueous zinc sulfate solution ($50\,g\,l^{-1}$), then shaken thoroughly and centrifuged. The supernatant is used for analysis.

One milliliter of alkaline copper reagent (made by dissolving 4 g of $CuSO_4 \cdot 5H_2O$, 24 g of Na_2CO_3, 16 g of Na–K tartrate, and 180 g of anhydrous Na_2SO_4 in water and diluting to 1 l) is added and the solution mixed well. The solution is then heated on a boiling water bath for 15 min (in a test tube with a lid), the tubes cooled in cold water, 1 ml of the arsenomolybdate reagent (commercially available) added, and the solution left to stand for a minute until the effervescence ceases. The blue color is diluted with water to a final volume of 10 ml, and the extinction is read at 510 or 660 nm. A standard should be prepared, and the reading should be taken against a reagent blank.

Dinitrosalicylic acid method In this method, the sugar is heated with dinitrosalicylic acid reagent followed by a 40% solution of potassium sodium tartrate, and the dark red color developed is measured in a colorimeter at 510 nm.

The sample is mixed with dinitrosalicylic acid reagent (prepared by dissolving 1 g of dinitrosalicylic acid, 200 mg of crystalline phenol, and 50 mg of sodium sulfate in 100 ml of 1% NaOH and storing the solution at 4 °C) and heated for 5 min in a boiling water bath. Then, 1 ml of 40% potassium sodium tartrate is added and the solution allowed to cool. The intensity of the dark red color developed is read at 510 nm, and the concentration of glucose in the sample is calculated by plotting the optical density against a standard curve prepared using various concentrations of known glucose solutions.

Glucose oxidase method As glucose is a simple sugar, one of the most specific methods for the quantitative estimation of glucose is the use of glucose oxidase (EC 1.1.3.4), which catalyzes the oxidation of α-D-glucose to D-glucono-1,5 lactone (gluconic acid) with the formation of hydrogen peroxide. The oxygen liberated from hydrogen peroxide by peroxidase reacts with the *O*-dianisidine and oxidases it to a red chromophore product.

One milliliter of glucose oxidase peroxidase reagent (made by dissolving 25 mg of *O*-dianisidine in 1 ml of methanol, adding 49 ml of 0.1 M phosphate buffer (pH 6.5), then adding 5 mg of peroxidase and 5 mg of glucose oxidase to the mixture) is added to the sample. The tubes are then incubated at 35 °C for 40 min and the reaction terminated by the addition of 2 ml of 6 N HCl. The intensity of the color developed at 540 nm is read against a reagent blank, and the concentration of the sample is then calculated by plotting a standard curve using different concentrations of known glucose solutions.

Phenol sulfuric acid method In a hot acidic medium, glucose is dehydrated to hydroxymethyl furfural. This forms a green product with phenol and has an absorbed maximum at 490 nm.

To 0.2 ml of the sample solution, 1 ml of 5% phenol solution and 5 ml of 95% sulfuric acid are added and the solution mixed well. After 10 min, the test tubes are shaken and placed in a water bath at 25–30 °C for 20 min. The green color is then read at 490 nm against a reagent blank, and the amount of glucose in the sample is calculated by plotting a standard curve.

Function and Metabolism

D A Bender, University College London, London, UK

Background

Glucose, arising from dietary carbohydrates, is the major metabolic fuel, providing 50–75% of energy in most diets. In the fed state, glucose in excess of immediate requirements is used for the synthesis of the reserve carbohydrate glycogen in liver and muscle. Between meals these glycogen reserves are used to maintain a supply of glucose for the red blood cells and central nervous system – other tissues use mainly fatty acids in the fasting state, to spare glucose. In the fed state, when glucose is plentifully available, it becomes the major fuel of all tissues, and the respiratory quotient (RQ) rises from about 0.8 to near 1, indicating that glucose is the substrate for most energy-yielding metabolism.

Most glucose is metabolized by glycolysis, leading to the formation of 2 mol of pyruvate per mol of glucose, which then undergoes oxidative decarboxylation to acetyl coenzyme A (CoA), and oxidation in the citric acid cycle. In red blood cells and tissues that are active in fatty acid synthesis (liver, adipose tissue, and lactating mammary gland) the pentose phosphate pathway provides an alternative to part of the pathway of glycolysis.

Glycolysis: The (Anaerobic) Metabolism of Glucose

Overall, the pathway of glycolysis is cleavage of the 6-carbon glucose molecule into two 3-carbon units. The key features of the pathway are:

- Two phosphorylation reactions to form successively glucose-6-phosphate and fructose bisphosphate.
- Cleavage of fructose bisphosphate to yield two molecules of triose (3-carbon sugar) phosphate.
- Two steps in which phosphate is transferred from a 3-carbon substrate on to adenosine diphosphate (ADP), forming adenosine triphosphate (ATP).
- One step in which NAD^+ is reduced to NADH.

The substrate for glycolysis is glucose-6-phosphate; this may arise from two sources:

- Phosphorylation of glucose, catalyzed by hexokinase;
- Phosphorolysis of glycogen in liver and muscle to yield glucose-1-phosphate, catalyzed by glycogen phosphorylase. Glucose-1-phosphate is readily isomerized to glucose-6-phosphate.

The pathway of glycolysis is shown in Figure 1. Although the aim of glucose metabolism is ultimately to phosphorylate ADP → ATP, there is a moderate initial ATP cost; there are two steps in which ATP is used, one to form glucose-6-phosphate when glucose is the substrate, and the other to form fructose bisphosphate.

The formation of fructose bisphosphate, catalyzed by phosphofructokinase, is an important step for the regulation of glucose metabolism. Phosphofructokinase is inhibited by normal intracellular concentrations of ATP. As the ratio of ATP to ADP falls, 5′AMP is formed; it relieves the inhibition of phosphofructokinase by ATP, leading to an increased rate of glycolysis and increased formation of ATP.

Fructose bisphosphate is cleaved to dihydroxyacetone phosphate and glyceraldehyde-3-phosphate, which are interconvertible. The onward metabolism of these 3-carbon sugars is linked to both the reduction of NAD^+ to NADH, and direct (substrate-level) phosphorylation of ADP → ATP.

There is a net yield of 8 × ADP + phosphate → ATP from the oxidation of 1 mol of glucose to 2 mol of pyruvate. Initially, 2 mol of ATP are required to form fructose bisphosphate, but the pathway yields 4 × ATP by direct phosphorylation of ADP, and 2 × NADH (formed from NAD^+), which is equivalent to a further 6 × ATP when oxidized in the electron transport chain.

The glycolytic pathway also provides a route for the metabolism of fructose, galactose (which undergoes phosphorylation to galactose-1-phosphate and isomerization to glucose-1-phosphate), and glycerol. Some fructose is phosphorylated directly to fructose-6-phosphate by hexokinase, but most is phosphorylated to fructose-1-phosphate by a specific fructokinase. Fructose-1-phosphate is then cleaved to yield dihydroxyacetone phosphate and glyceraldehyde; the glyceraldehyde can be phosphorylated to glyceraldehyde-3-phosphate by triose kinase.

Glycerol, arising from the hydrolysis of triacylglycerols, can be phosphorylated and oxidized to dihydroxyacetone phosphate. In triacylglycerol synthesis most glycerol phosphate is formed from dihydroxyacetone phosphate.

The Reduction of Pyruvate to Lactate: Anaerobic Glycolysis

In red blood cells, which lack mitochondria, reoxidation of NADH formed in glycolysis cannot be by way of the electron transport chain, as occurs in other tissues. Similarly, under conditions of maximum exertion, for example, in sprinting, the rate at which oxygen can be taken up into the muscle is inadequate

to permit reoxidation of all the NADH which is formed in glycolysis. In order to maintain the oxidation of glucose, and the net yield of 2 × ATP per mol of glucose oxidized (or 3 mol of ATP if the source is muscle glycogen), NADH is oxidized to NAD^+ by the reduction of pyruvate to lactate, catalyzed by lactate dehydrogenase (Figure 2).

Lactate is exported from muscle and red blood cells, and taken up by the liver, where it is used for the resynthesis of glucose – the Cori cycle, shown in Figure 2. Synthesis of glucose from lactate is an ATP (and guanosine triphosphate (GTP))-requiring process. The oxygen debt after strenuous physical activity is due to an increased rate of energy-yielding metabolism to provide the ATP and GTP that are required for gluconeogenesis from lactate. While most of the lactate will be used for gluconeogenesis, a proportion will undergo oxidation to CO_2 in order to provide the ATP and GTP required for gluconeogenesis.

The conversion of glucose to lactate is known as anaerobic glycolysis, since it does not require oxygen. However, it is not true to say that human metabolism (apart from red blood cells) is ever wholly anaerobic. The formation of lactate is the fate of *much* of the pyruvate formed from glucose under conditions of maximum muscle exertion when oxygen is limiting, but as much as possible will continue to undergo complete oxidation.

Many tumors have a low capacity for oxidative metabolism, so that much of the energy-yielding metabolism in the tumor is anaerobic. Lactate produced by anaerobic glycolysis in tumors is exported to the liver for gluconeogenesis; this increased cycling of glucose between anaerobic glycolysis in the tumor and gluconeogenesis in the liver may account for much of the hypermetabolism and consequent weight loss seen in patients with cancer cachexia.

Truly anaerobic glycolysis does occur in microorganisms which are capable of living in the absence of oxygen. Here there are two possible fates for the pyruvate formed from glucose, both of which involve the oxidation of NADH to NAD^+:

- Reduction to lactate, as occurs in human muscle. This is the pathway in lactic acid bacteria, which are responsible for the fermentation of lactose in milk to form yogurt and cheese;
- Decarboxylation and reduction to ethanol. This is the pathway of fermentation in yeast, which is exploited to produce alcoholic beverages.

The Pentose Phosphate Pathway – An Alternative to Glycolysis

There is an alternative pathway for the conversion of glucose-6-phosphate to fructose-6-phosphate, the pentose phosphate pathway (sometimes known as the hexose monophosphate shunt), shown in Figure 3.

Overall, the pentose phosphate pathway produces 2 mol of fructose-6-phosphate, 1 mol of glyceraldehyde-3-phosphate, and 3 mol of carbon dioxide from 3 mol of glucose-6-phosphate, linked to the reduction of 6 mol of $NADP^+$ to NADPH. The sequence of reactions is as follows:

- Three mol of glucose are oxidized to yield 3 mol of the 5-carbon sugar ribulose-5-phosphate + 3 mol of carbon dioxide.
- Two mol of ribulose-5-phosphate are isomerized to yield 2 mol of xylulose-5-phosphate.
- One mol of ribulose-5-phosphate is isomerized to ribose-5-phosphate.
- One mol of xylulose-5-phosphate reacts with the ribose-5-phosphate, yielding (ultimately) fructose-6-phosphate and erythrose-4-phosphate.
- The other mol of xylulose-5-phosphate reacts with the erythrose-4-phosphate, yielding fructose-6-phosphate and glyceraldehyde-3-phosphate.

This is the pathway for the synthesis of ribose for nucleotide synthesis; more importantly, it is the source of half the NADPH required for fatty acid synthesis; tissues that are active in lipogenesis have a high activity of the pentose phosphate pathway.

The pentose phosphate pathway is also important in red blood cells, where the NADPH is required to maintain an adequate pool of reduced glutathione (GSH), the reducing agent for glutathione peroxidase, which reduces $H_2O_2 \rightarrow H_2O$ and O_2. Oxidized glutathione (GSSG) is reduced back to active GSH by glutathione reductase, which uses NADPH as the reducing agent.

Partial or total lack of glucose-6-phosphate dehydrogenase (and hence impaired activity of the pentose phosphate pathway) is the cause of favism, an acute hemolytic anemia with fever and hemoglobinuria, precipitated in genetically susceptible people by the consumption of broad beans (fava beans) and a variety of drugs, all of which, like the toxins in fava beans, undergo redox cycling, producing hydrogen peroxide. Infection can also precipitate an attack, because of the increased production of oxygen radicals as part of the macrophage respiratory burst.

Because of the low activity of the pentose phosphate pathway, there is a lack of NADPH in red blood cells, and hence an impaired ability to remove hydrogen peroxide, which causes oxidative damage to the cell membrane lipids, leading to hemolysis.

The Oxidation of Pyruvate to Acetyl CoA

The first step in the complete oxidation of pyruvate is catalyzed by the pyruvate dehydrogenase multienzyme complex; an oxidative decarboxylation that results in the formation of acetyl CoA. The oxidation involves the reduction of NAD^+ to NADH. Since 2 mol of pyruvate are formed from each mol of glucose, this step represents the formation of 2 mol of NADH, equivalent to $6 \times$ ATP for each mol of glucose metabolized. The acetate is released from the enzyme esterified to coenzyme A as acetyl CoA (Figure 4), which undergoes oxidation in the citric acid cycle.

The decarboxylation and oxidation of pyruvate to form acetyl CoA requires the coenzyme thiamin diphosphate, which is formed from vitamin B_1. In thiamin deficiency this reaction is impaired, and deficient subjects are unable to metabolize glucose normally. Especially after a test dose of glucose or moderate exercise they develop high blood concentration of pyruvate and lactate. In some cases this may be severe enough to result in life-threatening acidosis.

Glycogen Synthesis and Utilization

In the fed state, glycogen is synthesized from glucose in both liver and muscle. The reaction is a stepwise addition of glucose units on to the glycogen that is already present. In muscle insulin stimulates both the uptake of glucose from the blood stream by active transport and also the activity of glycogen synthetase. In the liver, glycogen synthetase is also stimulated in response to insulin, but glucose uptake is insulin-independent and occurs by a carrier-mediated passive process followed by metabolic trapping as glucose-6-phosphate. There are two isoenzymes of hexokinase in the liver:

- An isoenzyme with a low Michaelis constant (K_m) which is saturated, and therefore acting at its maximum rate, at concentrations of glucose very much lower than occur in tissues. This isoenzyme therefore acts at a more or less constant rate regardless of the concentration of glucose available, and

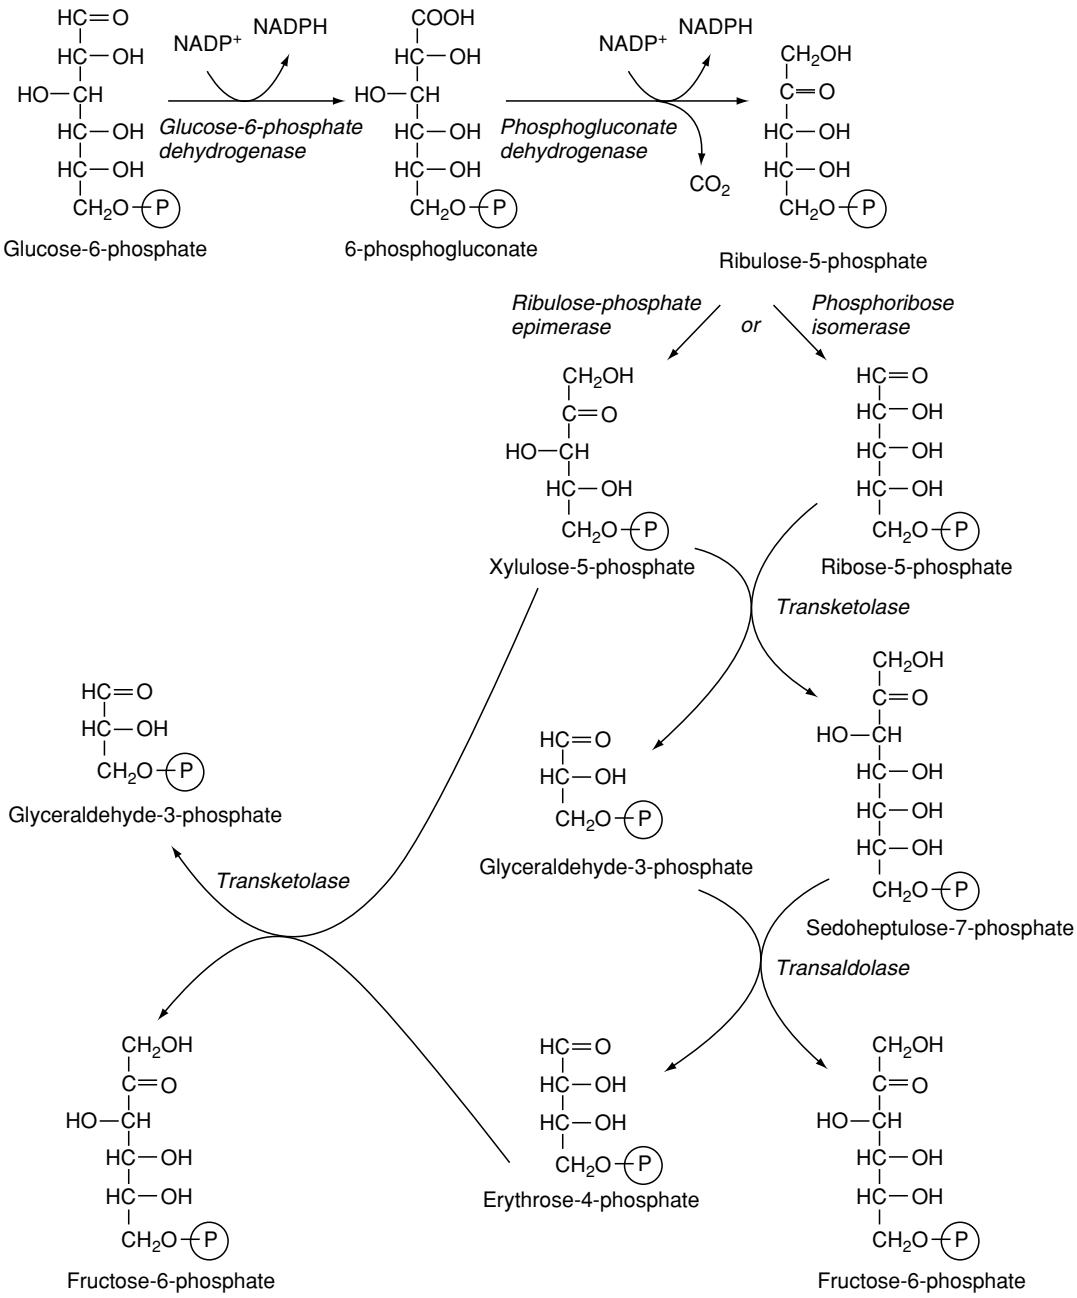

Figure 3 The pentose phosphate pathway. Glucose-6-phosphate dehydrogenase EC 1.1.1.49, phosphogluconate dehydrogenase EC 1.1.1.44, ribulose phosphate epimerase EC 5.1.3.1, phosphoribose isomerase EC 5.3.1.6, transketolase EC 2.2.1.1, transaldolase EC 2.2.1.2.

provides glucose-6-phosphate to meet the liver's requirements for glycolysis.

- An isoenzyme with a high K_m (also known as glucokinase) which only has significant activity as the concentration of glucose coming from the small intestine in the hepatic portal vein rises to above 10–15 mmol l^{-1}. In the fed state this isoenzyme produces glucose-6-phosphate considerably in excess of the liver's requirement for glycolysis; it is used for glycogen synthesis.

As shown in Figure 5, glycogen synthesis involves the intermediate formation of uridine diphosphate (UDP) glucose by reaction between glucose-1-phosphate and uridine triphosphate (UTP). As each glucose unit is added to the growing glycogen chain, so UDP is released, and must be rephosphorylated to UTP by reaction with ATP. There is thus a significant cost of ATP for the synthesis of glycogen: 2 mol of ATP are converted to ADP + phosphate for each glucose unit added, and overall the energy cost

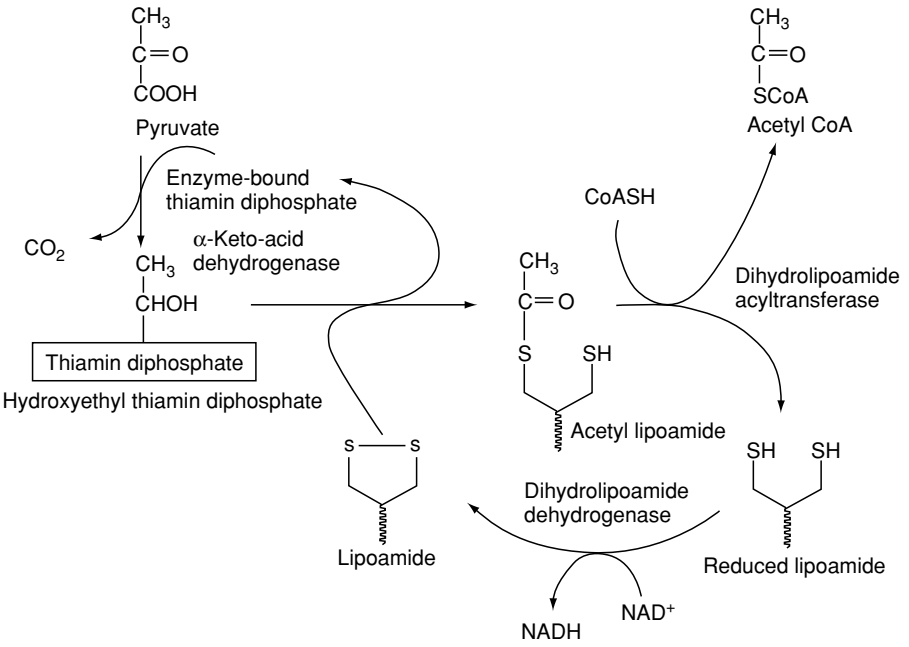

Figure 4 The reaction sequence of the pyruvate dehydrogenase multienzyme complex (EC 1.2.4.1).

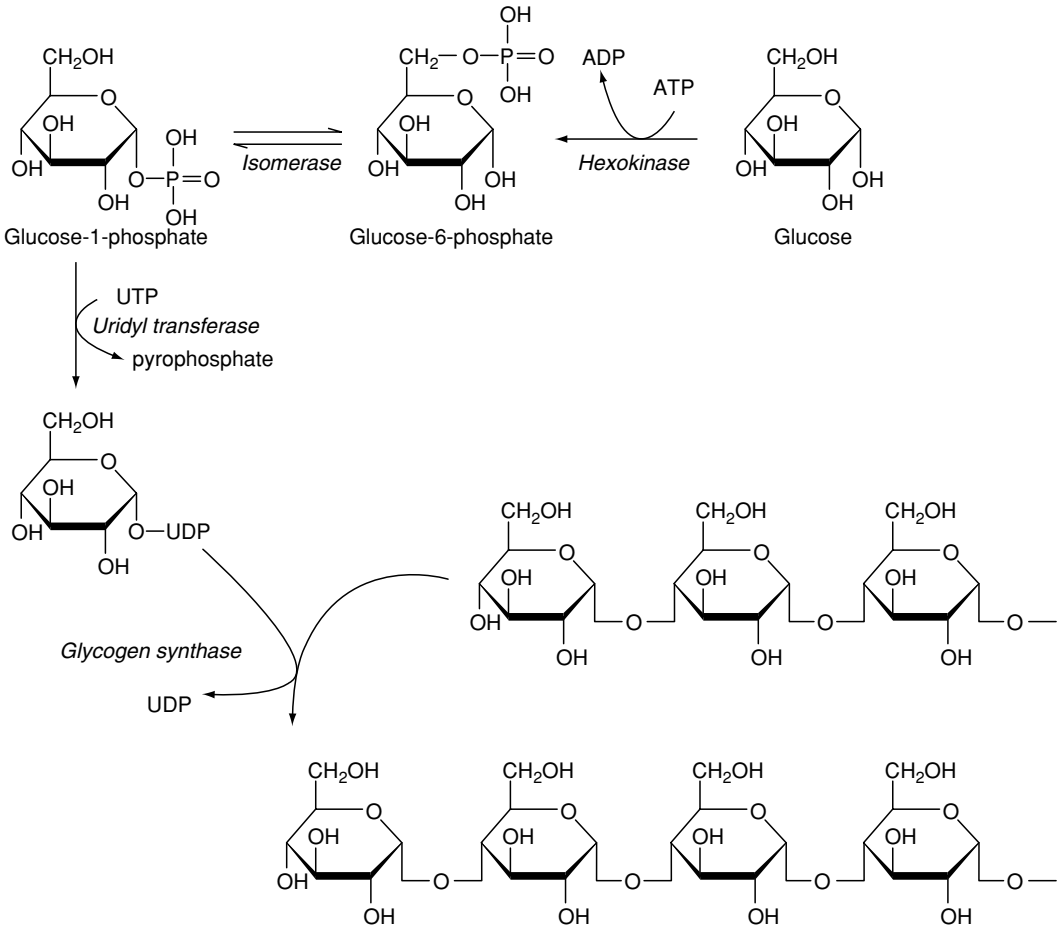

Figure 5 The synthesis of glycogen. Hexokinase EC 2.7.1.1, uridyl transferase EC 2.7.7.9. glycogen synthase EC 2.4.1.11. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

of glycogen synthesis may account for 5% of the energy yield of the carbohydrate stored.

Glycogen synthetase forms only the $\alpha 1 \rightarrow 4$ links that form the straight chains of glycogen. The branch points are introduced by the transfer of 6–10 glucose units in a chain from carbon-4 to carbon-6 of the glucose unit at the branch point.

In the fasting state, glycogen is broken down by the removal of glucose units one at a time from the many ends of the molecule, in response to stimulation by the hormone glucagon. The reaction is a phosphorolysis – cleavage of the glycoside link between two glucose molecules by the introduction of phosphate. The product is glucose-1-phosphate, which is then isomerized to glucose-6-phosphate. In the liver, glucose-6-phosphatase catalyzes the hydrolysis of glucose-6-phosphate to free glucose, which is exported for use by the brain and red blood cells.

Muscle cannot release free glucose from the breakdown of glycogen, since it lacks glucose-6-phosphatase. However, muscle glycogen can be an indirect source of blood glucose in the fasting state. Glucose-6-phosphate from muscle glycogen undergoes glycolysis to pyruvate (Figure 1), which is then transaminated to alanine. Alanine is exported from muscle, and taken up by the liver for use as a substrate for gluconeogenesis.

Glycogen phosphorylase stops cleaving $\alpha 1 \rightarrow 4$ links four glucose residues from a branch point, and a debranching enzyme catalyzes the transfer of a three-glucosyl unit from one chain to the free end of another chain. The $\alpha 1 \rightarrow 6$ link is hydrolyzed by a glucosidase, releasing glucose.

The branched structure of glycogen means that there are many points at which glycogen phosphorylase can act; in response to stimulation by epinephrine (adrenaline) there can be a rapid release of glucose-1-phosphate from glycogen.

Endurance athletes require a slow release of glucose-1-phosphate from glycogen over a period of hours, rather than a rapid release. There is some evidence that this is achieved better from glycogen that is less branched, and therefore has fewer points at which glycogen phosphorylase can act. The formation of branch points in glycogen synthesis is slower than the formation of $\alpha 1 \rightarrow 4$ links, and this has been exploited in the process of 'carbohydrate loading' in preparation for endurance athletic events. The athlete exercises to exhaustion, when muscle glycogen is more or less completely depleted, then consumes a high-carbohydrate meal, which stimulates rapid synthesis of glycogen, with fewer branch points than normal. There is little evidence to show whether this improves endurance performance or not; the improvement that has been reported may be the result of knowing that one has made an effort to improve performance rather than any real metabolic effect.

Gluconeogenesis – The Synthesis of Glucose from Noncarbohydrate Precursors

Because the brain is largely dependent on glucose as its metabolic fuel (and red blood cells are entirely so) there is a need to maintain the blood concentration of glucose between about 3 and 5 mmol l^{-1} in the fasting state. If the plasma concentration of glucose falls below about 2 mmol l^{-1} there is a loss of consciousness – hypoglycemic coma.

In short-term fasting the plasma concentration of glucose is maintained by the use of glycogen, and by releasing free fatty acids from adipose tissues, which are preferentially used by muscle, sparing such glucose as is available for use by the brain and red blood cells.

However, the total body content of glycogen would be exhausted within 12–18 h of fasting if there were no other source of glucose. Gluconeogenesis is the synthesis of glucose from noncarbohydrate precursors: amino acids from the breakdown of protein, and the glycerol of triacylglycerols. It is important to note that, although acetyl CoA, and hence fatty acids, can be synthesized from pyruvate (and therefore from carbohydrates), the decarboxylation of pyruvate to acetyl CoA (Figure 2) cannot be reversed, and pyruvate cannot be formed from acetyl CoA. Since two molecules of carbon dioxide are formed for each 2-carbon acetate unit metabolized in the citric acid cycle, there can be no net formation of oxaloacetate from acetate. It is not possible to synthesize glucose from acetyl CoA, and fatty acids and ketone bodies cannot serve as substrates for gluconeogenesis under any circumstances.

The pathway of gluconeogenesis is essentially the reverse of the pathway of glycolysis, shown in Figure 1. However, at three steps there are separate enzymes involved in the breakdown of glucose (glycolysis) and gluconeogenesis. The reactions of pyruvate kinase, phosphofructokinase, and hexokinase cannot readily be reversed (i.e., they have equilibria which are strongly in the direction of glycolysis and the formation of pyruvate, fructose bisphosphate, and glucose-6-phosphate, respectively).

There are separate enzymes, under distinct metabolic control, for the reverse of each of these reactions in gluconeogenesis:

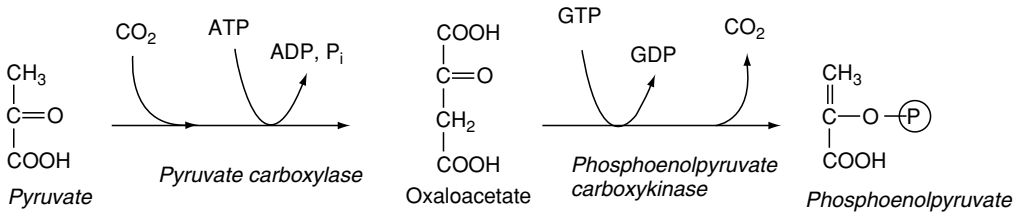

Figure 6 Reactions in the reversal of the pyruvate kinase reaction in gluconeogenesis. Pyruvate carboxylase EC 6.4.1.1, phosphoenolpyruvate carboxykinase EC 4.1.1.32. ATP, adenosine triphosphate; ADP, adenosine diphosphate; P_i, inorganic phosphate; GTP, guanosine triphosphate; GDP, guanosine diphosphate.

- Pyruvate is converted to phosphoenolpyruvate for glucose synthesis by a two-step reaction, with the intermediate formation of oxaloacetate, as shown in Figure 6. Pyruvate is carboxylated to oxaloacetate in an ATP-dependent reaction in which the vitamin biotin is the coenzyme. Oxaloacetate then undergoes a phosphorylation reaction, in which it also loses carbon dioxide, to form phosphoenolpyruvate.
- Fructose bisphosphate is hydrolyzed to fructose-6-phosphate by a hydrolysis reaction catalyzed by the enzyme fructose bisphosphatase;
- Glucose-6-phosphate is hydrolyzed to free glucose and phosphate by the action of glucose-6-phosphatase.

The other reactions of glycolysis are readily reversible, and the overall direction of metabolism, either glycolysis or gluconeogenesis, depends mainly on the relative activities of phosphofructokinase and fructose bisphosphatase.

Many of the products of amino acid metabolism can also be used for gluconeogenesis, since they are sources of either pyruvate or one of the intermediates in the citric acid cycle, and hence give rise to oxaloacetate. The requirement for gluconeogenesis from amino acids in order to maintain a supply of glucose explains why there is often a considerable loss of muscle in prolonged fasting or starvation, even if there are apparently adequate reserves of adipose tissue to meet energy needs.

Maintenance of Blood Glucose Level

V Marks, Haslemere, UK

Glucose

Glucose is almost the only simple sugar found in most body fluids in anything more than trace amounts and for all practical purposes is confined to extracellular water. Lactose and fructose are the major sugars in milk and semen, respectively. This article reviews the major factors determining the concentrations of glucose in blood under everyday physiological and pathological conditions.

Body Glucose Pool

The body of an adult subject seldom contains less than 8 g, or more than 28 g, of glucose at any one time (corresponding to blood glucose concentrations of 3.5–10 mmol l^{-1}) despite enormous fluctuations in demand and supply. This quantity of glucose can be looked upon as constituting a hypothetical body pool (**Figure 1**) confined within a glucose space equal in volume to the combined water in blood and the interstitial fluid, i.e., some 35% of total body water.

Glucose enters the cells by facilitated transport utilizing one or more of the genetically determined glucose transporter proteins that have been identified, depending on the tissue. Upon entering a cell, it is immediately phosphorylated and consequently removed from the glucose pool.

Although its subsequent conversion into carbon dioxide and water or other metabolites (most notably glycerol, fatty acids and the glycomoieties of mucopolysaccharides and glycoproteins) is the only way that glucose can ordinarily leave the glucose pool, its loss in the urine may become a major factor in diabetes mellitus.

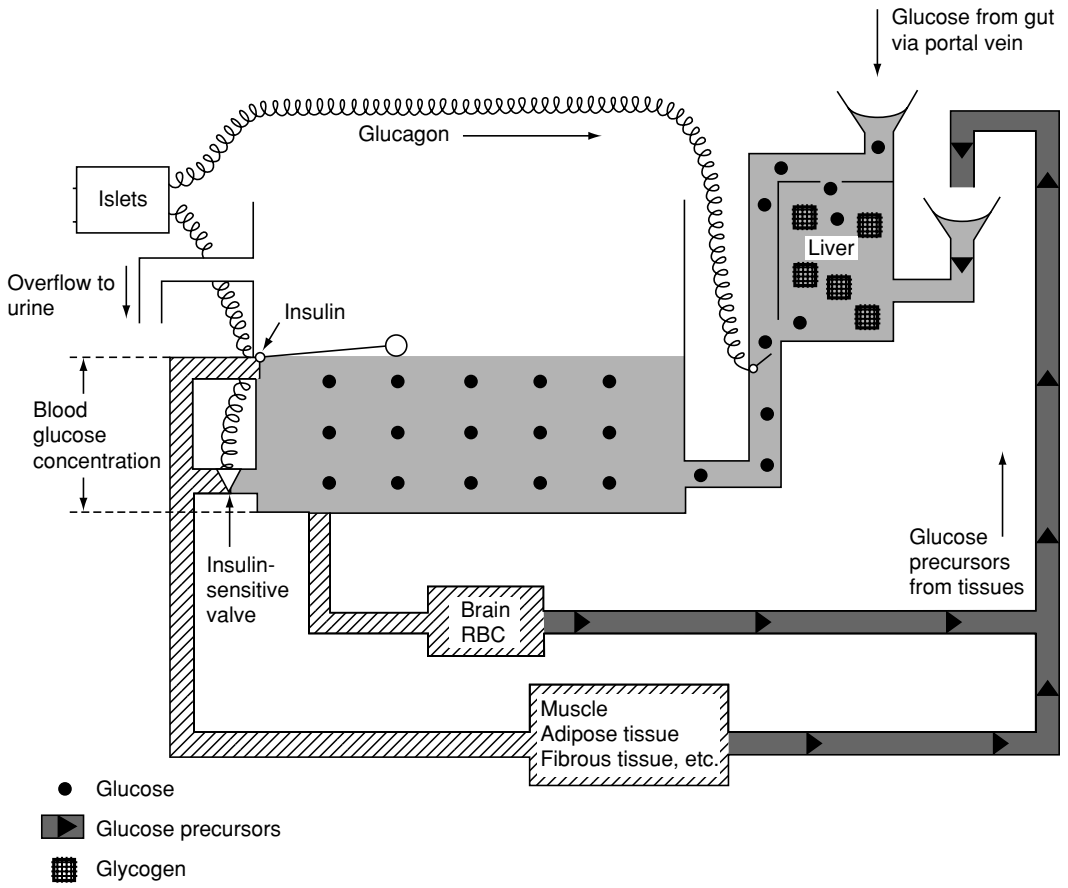

Figure 1 Schematic representation of blood glucose concentration and its relationship to the body glucose pool. The central system represents the hypothetical glucose pool, the actual size of which is represented by the horizontal axis, i.e., volume of distribution multiplied by blood (and extracellular fluid) glucose concentration. The postulated homeostatic switch is the cells of the endocrine pancreas that respond to blood glucose concentration modulated by hormonal and neural factors, themselves controlled by messages received from the gut (enteroinsular axis) and the autonomic nervous system. RBC, red blood cells.

Glucose enters the glucose pool from food via the hepatic vein or, in the postabsorptive subject, by release of glucose from preformed glycogen or molecules newly synthesized by liver cells – also into the hepatic vein.

Glucose Space

The glucose space is constant in any individual, and consequently, the amount of glucose in the pool is directly proportional to its concentration in the blood (see below). It is this concentration that is homeostatically controlled through a series of rather complicated control mechanisms, the most important of which involve individual pancreatic islets of Langerhans that function semiautonomously.

When pool size increases above a threshold, corresponding to a concentration in blood of about $10\,\text{mmol}\,\text{l}^{-1}$, glucose filtered at the glomeruli exceeds the tubular capacity to reabsorb it, and consequently, glucose spills over into the urine. Although temporary increases in glucose pool size (hyperglycemia) are not immediately harmful, decreases in glucose pool size (hypoglycemia) are. Indeed, they are potentially so dangerous that many defense mechanisms have evolved to prevent or overcome it (see below).

Blood Glucose

The brain is the only important drain on the glucose pool in the fasting subject when plasma insulin levels are minimal. It consumes glucose at the rate of about 78 mg per gram of tissue per day. This amounts, in an adult man, to about 110 g per day or 75 g per day in a 1-year-old child. A much smaller loss is into the erythron, which consists mainly of the bone marrow and red blood cells. Estimates of glucose turnover suggest that about 9 g of glucose enter and leave the glucose pool every hour in the average overnight fasting healthy subject.

The concentrations of glucose in venous and arterial blood are similar in the fasting subject because peripheral tissues such as muscle, skin, and connective tissue

do not extract significant amounts of glucose from the blood under these circumstances. In the recently fed subject, however, glucose uptake by peripheral tissues increases markedly under the influence of insulin released in response to the ingestion of a meal. This can produce a difference in arterial and venous blood glucose concentrations of 2 mmol l^{-1} or more.

This fact, known for more than 80 years, is still often forgotten or ignored by both experimentalists and clinicians. It not only has implications as regards our understanding of the physiology of glucose homeostasis, but sometimes has unfortunate consequences for patients who may, if only venous blood is sampled, be misdiagnosed as suffering from hypoglycemia (i.e., blood glucose < 3.0 mmol l^{-1}) when it is not really present. It is, after all, arterial, and not venous blood glucose, that is homeostatically controlled and relevant to brain physiology.

Venous blood is much easier to obtain than arterial blood and explains why, despite its theoretical and practical disadvantages, it is so often used in studies of glucose homeostasis and clinical practice. Fingerprick or earlobe-capillary blood accurately reflects arterial blood glucose levels under most circumstances but is more difficult to obtain in more than small amounts. So-called arterialized venous blood collected from heat-distended veins on the back of the hands can often be used in studies of glucose homeostasis when collection of arterial blood would not be ethical.

Blood glucose concentrations generally lie within the range 3.5–6.0 mmol l^{-1} in healthy fasting adult subjects and seldom rise above 11 mmol l^{-1} in arterial, or 10 mmol l^{-1} in venous blood, even after a large carbohydrate-rich meal. Glucose and other simple sugars given in solution produce greater rises in blood glucose than equal or larger amounts of glucose-yielding carbohydrate taken as part of a solid mixed meal. Conversely, prolonged starvation for as long as several weeks rarely causes the blood glucose concentration to fall below 3 mmol l^{-1}, except in children and adults with impaired gluconeogenesis.

The remarkable ability of the body to regulate the size of the glucose pool under such widely diverse conditions depends mainly upon two organs – the liver and the pancreas – although during prolonged starvation, the kidneys become important generators of new glucose molecules.

Effects of Feeding on Blood Glucose

Glucose

Glucose and the two lesser dietary monosaccharides – fructose and galactose – enter the circulation through the intestinal mucosa. The speed with which they can be absorbed is limited by the rate of transfer from the intestine but rarely exceeds 50 g (0.28 mol) of carbohydrate, as glucose, per hour. This comparatively massive influx of glucose into a pool of ~20 g ordinarily produces a remarkably small perturbation in blood glucose, as the rate of removal from the glucose pool rises to match glucose input.

In healthy people, arterial blood glucose concentrations generally return to fasting levels within 2 h of eating a carbohydrate-rich meal. This remarkable feat of homeostasis is achieved through the prompt, but appropriate, release of insulin into the circulation. This is a consequence of stimulation of pancreatic B cells (the source of insulin) by a rising arterial blood glucose concentration augmented by nervous impulses originating in the brain (cephalic phase), mouth, gut wall, and portal vein, as well as the insulinotropic hormones, GIP and GLP-1, released by endocrine cells in the intestinal mucosa.

Under the influence of the insulinemia so produced, hyperglycemia resulting from glucose inflow from the gut and a reduction in glucagon secretion, the liver reduces its rate of glucose input into the pool and starts extracting it. Peripheral insulin-sensitive tissues, such as connective tissue, skin, fat, and especially striatal muscle start removing glucose. As a result, the arterial blood glucose concentration falls, and the stimulus to insulin secretion declines.

Ordinarily, the rates of change of glucose inflow from the gut into the glucose pool and the outflow of glucose into the tissues are so well aligned that arterial blood glucose levels rarely fall below fasting levels after a meal, and then only temporarily. Under the somewhat unnatural conditions resulting from ingestion of large amounts of sugar in solution on an empty stomach a 'reactive hypoglycemia' may result from persistence of insulin action after plasma insulin has fallen to basal levels and all of the glucose has been absorbed from the gut. It may be, but usually is not, sufficiently severe to produce (neuroglycopenic) symptoms, even in perfectly healthy individuals.

Disposal of an Oral Glucose Load

The exact disposition of glucose absorbed from the gut after a carbohydrate-rich meal by healthy subjects varies widely from individual to individual, and depends on the size, composition, and physical nature of the meal.

All in all, some 70% of a 70-g oral glucose load is taken up by the peripheral tissues, where most of it is used, within 4 h of ingestion, to generate energy by oxidation to carbon dioxide and water. The remaining 30% is removed by the liver during its passage from the gut to the periphery and converted into glycogen, triglycerides, or other metabolites.

Volunteers given a meal consisting of glucose (1 gram per kilogram of bodyweight) as a 45% solution on an empty stomach reduced their normal basal release of glucose from preformed glycogen in the liver from $9\,g\,h^{-1}$ to about $2.2\,g\,h^{-1}$, i.e., by about 75%. This persisted for a period ($\sim 3\,h$), during which glucose was being absorbed from the gut. In other words, although there is a small net uptake of glucose by the liver following a carbohydrate-rich meal, the liberation of glucose from preformed glycogen does not cease completely. Put differently, glycogenolysis and gluconeogenesis take place simultaneously though at different rates, depending on whether glucose is or is not being absorbed, as well as on the amount and nature of the hormones released by the pancreas and intestine in response to the presence of food.

Fructose and Galactose

Galactose and fructose are absorbed from the gut by different mechanisms from one another: galactose shares a transporter mechanism with glucose, whereas fructose has a less efficient one of its own. Once in the portal circulation, both sugars are rapidly taken up by the liver and largely converted into glycogen. This, together with glycogen formed from glucose, provides a small store of carbohydrate that is released as glucose into the body pool during the period when absorption from the gut is no longer occurring, and gluconeogenesis has not yet become fully reestablished.

Starches and their hydrolytic products are converted enzymatically into glucose in the gut lumen and brush border of the mucosa at a rate dependent upon their exact composition. Some starches are absorbed as rapidly as performed glucose, whereas others are absorbed much more slowly. Sucrose is cleaved into glucose and fructose, and lactose into glucose and galactose, before absorption into the body. Intraluminal hydrolysis is rarely a factor in limiting the rate of absorption of simple sugars. Each moiety is dealt with separately.

Postabsorptive Stage

The exact duration of the absorptive phase that follows ingestion of a meal depends on many factors. These include the rate of gastric emptying as well as the size, composition and physical nature of the food. It is unlikely, however, that an average adult eating three meals a day is truly postabsorptive, i.e., absorbing no glucose at all through the intestinal mucosa, for more than a few hours in any 24-h period, and this is mainly between 02.00 and 08.00. During this brief fasting period, glucose lost from the glucose pool by a constant drain into the brain and erythron is replaced by glucose from the liver. This is derived either from reserves of glycogen built up during the absorptive phase of a meal or from new glucose molecules formed from glucose precursors such as lactate, pyruvate, glycerol, and alanine, brought to it in the blood from peripheral tissues. Gluconeogenesis increases under the influence of rising levels of glucagon and fatty acids, both of which are a consequence of falling plasma insulin levels.

The amount of glycogen in the liver varies with the nature of the diet, the size and composition of the last meal, and its timing. The average amount of glycogen in the liver after an overnight fast is about 44 g (range 15–80 g) and does not increase very much after a meal; in other words, gluconeogenesis is already well under way within 12 h of eating the last meal. Nevertheless, after 36 h without food, liver glycogen stores may fall to as low as 4–8 g. Paradoxically, more prolonged fasting has little additional effect: indeed, hepatic glycogen stores may actually be replenished as the brain shifts from using glucose to β-hydroxybutyrate as its main source of energy.

Glycogen probably never disappears from the liver completely except *in extremis*, and there is evidence that it may be an intermediary in the production of glucose by the gluconeogenic pathway. Striatal muscles lack glucose-6 phosphatase, and consequently, although they contain substantial amounts of glycogen, they cannot convert and release it into the blood as glucose. They can, however, release its main breakdown product, lactate, into the blood for reconversion into glucose in the liver.

Gluconeogenesis

The mechanism whereby the liver and, to a smaller but significant extent, the kidneys make new glucose molecules from chemically simpler compounds is referred to as 'gluconeogenesis.' Much attention has been paid to the role of specific hormones, such as glucagon and cortisol, and the enzymes they affect, in determining the rate of gluconeogenesis. The supply of glucose precursors is also important. In humans, lactate is probably the most important precursor, especially during exercise. Others, in descending order of importance, are alanine, pyruvate, glycerol, and, finally, some glucogenic amino acids, including glutamate. The last named is especially important in gluconeogenesis in the kidney. Fatty acids, apart from propionate, do not serve as glucose precursors to any significant degree.

The contribution made by alanine to gluconeogenesis may have been exaggerated in the past, though it does have a role in transporting three-carbon skeletons derived from muscle glycogen to the liver

during fasting for conversion into glucose. It is also formed from amino acids released by proteolysis of nonstructural muscle proteins during periods of prolonged fasting and starvation.

Gluconegenesis is inhibited by eating, mainly through an increase in insulin, and a decrease in glucagon, action. It is enhanced by fasting, probably by the reverse procedure. Alcohol specifically inhibits gluconeogenesis, from lactate but not alanine, by adversely changing the redox potential within the hepatocytes and reducing the availability of nicotinamide adenine dinucleotide (NAD), which is an essential component in the formation of glucose from lactate but not, for example, from other sugars. The inhibition of gluconeogenesis by modest amounts of alcohol can be so profound that severe hypoglycemia may develop in fasting subjects, especially children, who are totally dependent upon gluconeogenesis for glucose needed by their brain and erythron.

Hormones and Glucose Homeostasis

Insulin is the only major hormone capable of lowering blood glucose levels. It does so by inhibiting glycogen breakdown in the liver and inhibiting gluconeogenesis and by encouraging glucose to leave the glucose pool by entering peripheral tissues. It achieves this mainly by activating the glucose transporter protein GLUT 4: an action that is enhanced by exercise and hyperglycemia. Consequently, insulin lowers blood glucose by two independent mechanisms. Which of the two actions predominates depends upon the circumstances: one of the most important is the concentration of insulin in the blood; another is whether it is of exogenous or endogenous (pancreatic) origin. Exogenous insulin reaches peripheral tissues at a concentration in blood greater than in blood perfusing the liver and is unaccompanied by C-peptide. Endogenous insulin, however, reaches the liver at a higher concentration than peripheral tissues and is accompanied by C-peptide, for which there is increasing evidence of synergism with insulin action.

Insulin released into the portal circulation is partially or completely removed by the liver. Insulin injected into skin, muscle, or a vein reaches insulin-sensitive tissues in the periphery at a concentration equal to, or greater than, the liver. Not all tissues on which insulin acts are equally sensitive to its actions: fat cells, for example, are more sensitive to its antilipolytic actions than muscle cells are to its glucose uptake-stimulating properties.

At the concentration at which insulin normally circulates in the peripheral blood of fasting subjects ($\sim 30\,\text{pmol}\,\text{l}^{-1}$), it depresses, but does not completely suppress, the unbridled release of fatty acids from lipocytes. At this concentration, insulin does not encourage glucose uptake by striatal muscle – which falls almost to zero. At insulin concentrations seen in peripheral blood in the absorptive phase of a meal (~ 150–$600\,\text{pmol}\,\text{l}^{-1}$), its effect on peripheral glucose uptake is pronounced and responsible for the marked arteriovenous glucose difference observed at this time. Similar plasma insulin levels are achieved during insulin therapy for diabetes.

The release of insulin from the B cells of the pancreatic islets is highly dependent upon the concentration of glucose in the blood perfusing them. At blood glucose levels below about 3.5–$4.0\,\text{mmol}\,\text{l}^{-1}$, insulin secretion is minimal. This means that as the arterial blood glucose falls towards its basal level in the post-absorptive state, plasma insulin levels also fall. They never fall low enough, however, in the nondiabetic subject to permit uncontrolled liberation of glucose by the liver or fatty acids by adipocytes. This does of course happen when the B cells are destroyed and results in gross hyperglycemia and ketosis, which are the hallmark of insulin-dependent diabetes.

During prolonged starvation (20 days or more without food), small amounts of insulin reach the liver. The amounts reaching the adipocytes are, however, insufficient to prevent seemingly uncontrolled lipolysis leading to hyperketonemia comparable with that seen in diabetic keto-acidosis (~ 10–$20\,\text{mmol}\,\text{l}^{-1}$). The situation differs, however, from that obtained in diabetes, in that the restraining effect of insulin on hepatic gluconeogenesis and glycogenolysis remains. Consequently, blood glucose levels are normal rather than grossly elevated as in insulin deficiency resulting from B cell malfunction.

A consequence of the reduction of insulin release as blood glucose levels fall after absorption of a meal is liberation of the A cells, which are 'downstream' of B cells in the islet, from the suppressive effect of (endogenous) insulin on their own release of glucagon. On reaching its target organ, glucagon promotes glycogenolysis and gluconeogenesis in the liver, in effect reversing the effect of insulin during the absorptive phase. In other words, each islet functions as a miniature homeostat.

Counterregulatory Hormones

Whilst it is possible to explain the control of blood glucose largely by means of the servoregulatory control of insulin and glucagon secretion described above, the body also has many neural and hormonal mechanisms at its disposal to correct or overcome any fall in blood glucose to below the critical level necessary for the maintenance of normal brain function. The sensors for this regulatory function are located in at least two anatomically distinct sites within the brain and in the portal vein itself.

The most important mechanisms involved are:

- stimulation of the sympathetic and parasympathetic nervous systems, which in turn lead, respectively, to release of adrenaline from the adrenal medula and noradrenaline from nerve terminals in the liver, and glucagon from the pancreas;
- secretion of vasopressin by the posterior pituitary gland; adrenocorticotrophic hormone (ACTH), growth hormone, and prolactin by the anterior pituitary gland; and cortisol by the adrenal cortex.

None of these hormones, apart from cortisol, appears to be absolutely essential individually for the maintenance of normal glucose homeostasis, but all are brought into play under adverse conditions. They produce their hyperglycemic effects in a variety of ways that can be summarized as follows:

1. Increasing the liberation of glucose by the breakdown of preformed glycogen in the liver, e.g., glucagon, adrenaline, noradrenaline, vasopressin.
2. Increasing gluconeogenesis in the liver, e.g., glucagon, cortisol.
3. Decreasing peripheral glucose utilization by peripheral tissues, e.g., growth hormone, cortisol, and prolactin.

Glycosuria

Upwards of 100 g of glucose are normally filtered from the blood at the glomeruli of the kidneys each day, more than 99% of which is reabsorbed by the kidney tubules. As a result, healthy people lose less than 150 mg of glucose in their urine each day, an amount too small to be detected by most simple screening procedures for glycosuria. When, for any reason, the amount of glucose filtered at a glomerulus is more than can be reabsorbed by the tubules, glucose appears in the urine at a concentration many times greater than it occurs in blood.

The commonest cause of significant glucosuria, i.e., the presence of glucose in the urine at a concentration greater than $0.15\,g\,l^{-1}$ ($0.8\,mmol\,l^{-1}$) is a blood glucose concentration of $10\,mmol\,l^{-1}$ or more. At or above this concentration, the amount of glucose filtered at the glomerulus is more than its associated kidney tubule can transport back into the circulation. Once this reabsorptive threshold has been exceeded, any increase in filtered glucose load is reflected by a large increase in the amount of glucose eliminated in the urine. The osmotic diuresis so produced is associated with an increased excretion of water, sodium, chloride, and potassium and is often the first clue to the existence of hyperglycemia, the characteristic hallmark of diabetes.

Glycosuria can occur at normal blood glucose levels when, for example, blood flow through the glomerulus is increased, such as during pregnancy or when, owing to either an inherited or acquired defect of renal tubular glucose transport, even the normal amount of glucose filtered at the glomerulus cannot be reabsorbed. Conversely, in people in whom blood flow through the glomeruli is reduced or in whom glomerular filtration is impaired, but in whom normal tubular glucose reabsorption is retained, even gross hyperglycemia may not be accompanied by glycosuria.

Fructose and galactose do not normally appear in urine since their concentration in blood is never sufficiently high – except in disease – for them to do so.

Glucose Tolerance and the Glycemic (Glycaemic) Index

G Frost, Nutrition and Dietetic Research Group, London, UK

Introduction

This article examines the influence of dietary carbohydrates on postprandial intermediary metabolism and insulin resistance. The link between high-glycemic-index diets with insulin resistance, type II diabetes, and cardiovascular disease (CVD) is discussed. We highlight the potential benefits of

low-glycemic diets and discuss the inadequacy of today's classification of carbohydrates to identify low-glycemic foods. We conclude by advocating that nutritional guidelines for diabetes should place greater emphasis on the glycemic index.

Glycemic Index – Definition

The glycemic index of several foods is published in international nutritional tables. Methodology on their derivation is available from previous reviews. In summary, the glycemic index is a measure of a carbohydrate's postprandial glucose response (Figure 1). The glycemic index provides a standardized comparison of a carbohydrate's 2-h postprandial glucose response with that of white bread or glucose (Table 1).

$$\frac{\text{Incremental area under blood glucose response curve for the test containing 50 g carbohydrate}}{\text{Corresponding area after equi-carbohydrate portion of white bread}} \times 100$$

Low-glycemic-index carbohydrates have lower 2-h areas under the glucose curve than white bread, while high-glycemic-index foods have higher areas. Although the insulin response is not part of the glycemic index calculation, the lower the glycemic index of a food, the more attenuated is the insulin response.

Type of Dietary Carbohydrate and the Glycemic Index

The present classification of carbohydrates is based on structure rather than physiology. The glycemic index of a carbohydrate, however, is determined more by physiology being highly dependent on a carbohydrate's absorption rate. The glycemic index is influenced by a carbohydrate's composition, tertiary structure, and enzymic digestion (Table 2).

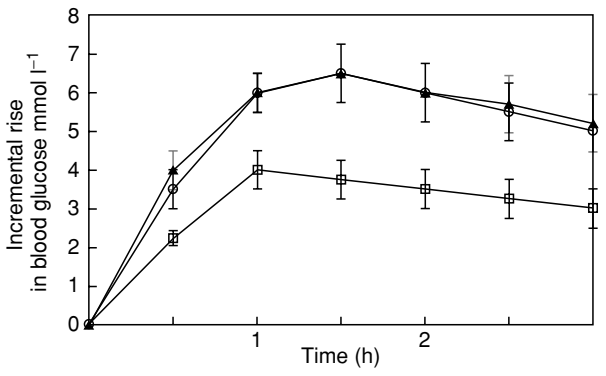

Figure 1 Mean blood glucose increment after equi-carbohydrate meals. Squares, pasta; circles, wholemeal bread; triangles, white bread.

Chain Length and Composition

Complex carbohydrates are polymeric chains of repeating monosaccharide units. Starches are comprised of repeating glucose units. The glycemic indexes of different starches are determined by their susceptibility to enzymic digestion, not chain length. White bread and pasta have similar chain lengths but bread has a higher glycemic index, due to a tertiary structure and solubility that ensure greater exposure to salivary and pancreatic amylases.

Short-chain carbohydrates are rapidly absorbed; however, when they contain nonglucose sugars the glycemic index is lowered proportionally. The

Table 1 An example of glycemic index of carbohydrate-containing foods

Food	*Glycemic index*
Breads

Sucrose	✓			✓			83

disaccharides sucrose and lactose consist of 50% glucose and 50% fructose or galactose, respectively, both have a lower glycemic index than maltose, the disaccharide formed from two glucose molecules.

Amylose and Amylopectin

The starches in cereal grains, rice, potatoes, and all green plants are composed of repeating glucose units arranged in straight, amylose, and branched-chain, amylopectin polysaccharides. The absorption rate, and hence the glycemic index, of these starches is influenced by the ratio of amylose to amylopectin. The more compact structure of amylose than amylopectin results in a smaller surface area being available for amylase digestion. Amylose-enriched starches have lower glycemic indexes than those enriched in amylopectin.

Relationship of Insoluble and Soluble Nonstarch Polysaccharides (Fiber) to Glycemic Index

Nondigestible complex carbohydrates are commonly known as dietary fiber. The more correct terminology is nonstarch polysaccharides (NSP). Dietary fiber/NSP is either soluble or insoluble. Clinical studies have shown that diets rich in soluble fiber/NSP, such as guar gum, pectin, and sugar beet fibers lower postprandial blood glucose and insulin levels. Guar gum, a beta-glactomannan from the Indian locust bean, also reduces postprandial lipemia. Nonsoluble NSP has no effect on dietary glycemic index.

Soluble NSP such as pulses, vegetables, whole fruits, oats, and barley form gelatinous gels within the stomach which delay gastric emptying and enzymic digestion, the latter by forming a physical barrier around the carbohydrate. Insoluble NSPs have little effect on gastric emptying and no effect on glucose absorption. High-fiber/high-NSP diets are therefore not necessarily synonymous with low-glycemic foods. Cellulose is the most widely used NSP in household cereals, wholemeal bread, and brown rice, and as cellulose is insoluble, these foods have the same glycemic index whether replete or deplete of their dietary fiber/NSP. For unknown reasons, All Bran is an exception and, despite its high insoluble fiber content, has a low glycemic index.

The solubility of dietary fiber/NSP needs to be specified if benefits on postprandial glycemia and hyperinsulinemia are to be expected. Nonmetabolic benefits are derived from increasing nonsoluble fiber/NSP, and are notable on bowel function and bowel pathology. However, protection against colon cancer has recently been questioned.

Cell Structure, Food Preparation, and Processing

Cooking and food preparation can modify the glycemic index. Highly processed convenience foods tend to have high glycemic indexes. When cooking and processing disrupt the cell wall of starch granules, the glycemic index is increased. Cooked pulse vegetables have low glycemic indexes as their cell walls are resistant to cooking. The intact cereal grains of pumpernickel rye bread, granary bread, and burgule wheat all have low glycemic indexes. However, when granary bread is processed to wholemeal bread these grains are disrupted and the glycemic index rises. Cooling can paradoxically lower the glycemic index of certain starches, such as potatoes, due to the formation of retrograde starches which are resistant to amylase digestion. Food particle size as well as the constituency of the food bolus on swallowing also influence absorption rates, as seen with boiled and mashed potatoes.

Concerns Relating to the Glycemic Index

Despite the 1998 World Health Organization/Food and Agriculture Organization nutritional report advocating greater use of the glycemic index, no American or British dietetic guidelines promote its use. In fact, the only guidelines that do support the use of the glycemic index are the 1998 European guidelines.

Carbohydrates are still broadly grouped on their biochemical basis into refined and complex carbohydrates; starch and NSPs and soluble and insoluble fiber. Part of the failure of the glycemic index not being more widely used is due to concerns relating to its reproducibility, accuracy when part of a mixed meal, and its overall validity. In terms of reproducibility, the glycemic index, like all *in vivo* measurements, such as the oral glucose tolerance test, is dependent on physiological variables and, if these are not controlled for, some variability in its measurement is inevitable. Concerns relating to the glycemic index when part of a mixed meal are theoretical rather than actual, such as the glycemic response of a mixed meal, can be reliably calculated knowing the glycemic index of each constituent carbohydrates and their proportional contribution to that meal. The concerns on validity are centered on the way the glycemic index is calculated, emphasizing the 2-h integrated area rather than the pattern of response. The way the glycemic index is calculated can result in two obviously metabolically different carbohydrates, which would evoke different patterns of glucose and insulin release having similar glycemic indexes (Table 2), for example, a rapidly absorbed and metabolized carbohydrate, such as sucrose, and a complex carbohydrate with poor intestinal absorption and subsequent colonic fermentation. However, in practice the glycemic index of most carbohydrates provides a good indicator of the 2-h plasma glucose and insulin exposure.

Clinical Significance of Postprandial Versus Fasting Hyperglycemia in Diabetic and Nondiabetic Populations

Postprandial hyperglycemia in nondiabetic populations is a stronger predictor of insulin resistance and CVD than fasting glucose. The combined 20-year mortality data on men from the Whitehall, Paris Prospective, and Helsinki Policemen studies showed that the upper quintile compared with the lower for the 2-h postplasma load glucose was associated with a 2.7 times increased risk of CVD mortality. The fasting glucose values were less discriminatory for CVD, with only the upper 2.5% values conferring a 1.8-fold increased mortality risk. Over a 7-year period, elderly women in a study with isolated postprandial hyperglycemia, 2-h value > 11.1 mmol l^{-1} and fasting value < 7.0 mmol l^{-1} on a 75-g oral glucose tolerance test had an approximately threefold increased risk of heart disease when compared with women whose 2-h values were below 11.1 mmol l^{-1}.

In established diabetes postprandial glycemia appears to have a stronger relationship with microvascular and macrovascular disease than fasting blood glucose. Similarly, in gestational diabetes adverse pregnancy outcome is more closely related to postprandial glycemia than fasting and premeal glycemic values.

The Benefits of Low-Glycemic-Index Carbohydrates on Diabetic Control

Three-month clinical studies have shown that low-glycemic-index carbohydrates improve glycemic control in both type 1 and type 2 diabetes and reduce postprandial glucose and insulin values. Good glycemic control and favorable lipid and fibrinolytic profiles have also been reported in individuals with type 1 and 2 diabetes who habitually consume low-glycemic-index dietary carbohydrates. It remains to be seen whether these diets bestow long-term benefits on micro- or macrovascular complications.

The Benefits of Low-Glycemic-Index Carbohydrates on CVD Risk Factors

High-glycemic-index foods induce postprandial hyperinsulinemia, which is a powerful predictor for metabolic risk factors and CVD in epidemiological studies. Both cross-sectional and prospective population studies have shown favorable lipid profiles in association with high-carbohydrate diets. Initially, these benefits were attributed to a high fiber content. However, when the glycemic index is controlled for, it is the low-glycemic-index diets rather than high fiber content that have the greatest influence on high-density lipoprotein (HDL)-cholesterol, insulin sensitivity, and fibrinolytic parameters. In one large cross-sectional study on middle-aged ambulatory subjects, glycemic index was a stronger determinant of HDL cholesterol than any other dietary carbohydrate or fat. Low-glycemic-index diets also lower serum cholesterol and triglyceride levels in hyperlipidemic subjects.

Potentially Detrimental Effects of a High-Carbohydrate Diet

High-carbohydrate diets (> 60% of total dietary energy) that consist predominantly of high glycemic carbohydrates have detrimental metabolic effects. These diets increase serum triglyceride and insulin resistance, having the greatest adverse effect in insulin-resistant states, such as type 2 diabetes or pregnancy. As a consequence of this, the American Diabetic Association recommends limiting dietary carbohydrates to 45% in diabetic pregnancies and to 80% of total energy derived from carbohydrate

and fat outside pregnancy. By contrast, the British Diabetic Association's guidelines advocate that 55% of total dietary energy should come from dietary carbohydrates. The European guidelines are the only ones that specify the use of low-glycemic carbohydrates and the current American Dietetic Association recommendations for the USA give glycemic index an evidence-based rating of B, suggesting more long-term studies are needed.

Several short-term clinical studies have shown that high-carbohydrate/low-glycemic-index diets reduce insulin sensitivity and adversely influence lipid profiles in both normoglycemic and type 2 diabetic subjects. Similar results have been seen in healthy pregnancy and in individuals at risk of cardiovascular disease. In all these studies, substitution of the dietary carbohydrate with a low glycemic index reverses these trends. Interestingly, the very-low-density-lipoprotein (VLDL)-rich triglyceride particles generated from high-carbohydrate diets are thought to be less atherogenic than those associated with the insulin resistance syndrome.

High-carbohydrate diets have been associated with both the development of and the prevention of type 2 diabetes and CVD. These conflicting studies are likely to be explained by differences in dietary glycemic index. Previously many clinical and epidemiological dietary studies have not specified the glycemic index. High-carbohydrate diets in non-industrialized rural populations, such as Africa, are typified by low-glycemic starches and soluble NSP, carbohydrates associated with reduced insulin resistance, and metabolic CVD risk factors. By contrast, high-carbohydrate diets in westernized industrial societies such as North America, with high background incidences of obesity, insulin resistance, and type 2 diabetes, contain high-glycemic carbohydrates due to food processing and soft drinks, and it is these diets which are metabolically disadvantageous.

Obesity and Glycemic Index

Obesity contributes to the pathogenesis and morbidity of type 2 diabetes. Obesity is associated with changes in carbohydrate and fat metabolism that are central to the development of insulin resistance. While low-glycemic-index diets reduce insulin sensitivity and improve metabolic cardiovascular risk factors, they will not reduce weight unless part of an energy-deficient diet. However, in obese subjects, when low-glycemic carbohydrates are incorporated into a hypocaloric diet, there is a greater fall in insulin resistance than can be accounted for by weight loss alone.

Glycemic Index and the Prevention of Type 2 Diabetes

Changes in diet and physical activity levels, both alone and in combination, reduce the progression of impaired glucose tolerance to diabetes. Two large American prospective population studies have demonstrated protection against type 2 diabetes for both men and women when the habitual diet is characterized by having a low glycemic index and low fat content. A similar protective effect against diabetes has been reported in populations consuming high-fiber foods and high quantities of fruit and vegetables. Although it was not calculated, one would predict that these diets would also have a low glycemic index.

Pregnancy and Glycemic Index

Throughout pregnancy in well-nourished urbanized women consuming typical westernized diets, there is a deterioration in glucose tolerance. African women during pregnancy, living in traditional rural populations and consuming high-carbohydrate/low-glycemic-index diets, do not invariably experience deterioration in their glucose tolerance. Clinical studies in the west show that women consuming similar high-carbohydrate/low-glycemic-index diets throughout pregnancy also have no deterioration of glucose tolerance despite the physiological increase in insulin resistance that occurs secondary to maternal and placental hormones. When the proportion of dietary carbohydrate increases above 50% in women with gestational diabetes, if no emphasis no low-glycemic-index carbohydrates is given, glucose tolerance will deteriorate.

Proposed Mechanism by which Dietary Carbohydrates Influence Insulin Resistance

Adipocyte metabolism is central to the pathogenesis of insulin resistance and dietary carbohydrates influence adipocyte function. The previous simplistic view, that insulin resistance resulted from the downregulation of the insulin receptors in response to hyperinsulinemia, is being replaced by the hypothesis that high circulating nonesterified fatty acid (NEFA) levels both impair insulin action and reduce pancreatic β-cell secretion. A plausible explanation of how low-glycemic-index carbohydrates can reduce insulin sensitivity is by their ability to reduce adipocyte NEFA release.

Adipocyte release of NEFA is increased in insulin resistance as a consequence of suppressed hormone-sensitive lipase activity. An inverse relationship between adipocyte NEFA release and insulin sensitivity

has been demonstrated in patients with coronary heart disease. High circulating NEFA levels reduce muscle uptake of glucose and downregulate the insulin receptor. High circulating NEFA levels reduce hepatic insulin clearance; this exaggerates the pre-existing hyperinsulinemia and insulin resistance. Reduced lipoprotein lipase activity increases NEFA levels and hepatic VLDL production; however, VLDL clearance is reduced, and this results in a lower high-density lipoprotein concentration and increased TG-enriched VLDL particles. The latter are catabolized into smaller atherogenic forms of LDL. The metabolic consequences of increased adipocyte NEFA release therefore fuel lipoprotein changes associated with coronary heart disease.

High circulating NEFA levels also adversely affect insulin secretion. High NEFA levels have been postulated to have a lipotoxic effect on the β-cells due to their ability to increase nitric oxide production which is cytotoxic to islets. In addition, when triglyceride accumulates within the β-cell, glucose-stimulated insulin secretion is blunted.

Many of the metabolic benefits associated with low-glycemic-index carbohydrates can be attributed to their ability to reduce adipocyte NEFA release. Low-glycemic-index foods have been consistently shown to improve insulin sensitivity and animal studies have shown that improvements in fat and muscle insulin sensitivity are accompanied by decreases in fatty acid synthatase activity, adipocyte size, and lipid storage. Although human studies have shown that low-glycemic-index diets consumed over 3 weeks increase adipocyte insulin sensitivity, no direct effect on adipocyte metabolism has been identified so far.

Low-glycemic-index diets, by attenuating the insulin response, ensure a more prolonged suppression of postprandial NEFA levels than those following high-glycemic foods. Low-glycemic meals taken in the evening can effectively suppress circulating NEFA concentrations and hepatic glucose output throughout the night. These metabolic effects would be predicted to promote insulin sensitivity.

Our own work has shown that insulin-resistant adults with a history of, or who are at risk of CHD improve their adipocyte insulin sensitivity when consuming a low-glycemic-index diet and in addition their circulating NEFA levels decline. These human studies complement the animal work that show low-glycemic-index diets improve insulin sensitivity by modulating adipocyte metabolism.

Conclusion

The glycemic index of a diet provides a measure of postprandial metabolism. Dietary carbohydrates are absorbed and metabolized differently and therefore influence postprandial glucose, insulin, and NEFA concentrations differently. In western society the proportion of the day that we spend in the postprandial state is increasing as the tendency to snack throughout the day replaces sit-down main meals. The known detrimental consequences of high-glycemic foods on postprandial metabolism should encourage us to advocate low-glycemic diets to counteract the present epidemic of insulin resistance-related diseases, notably CVD and diabetes. The relevance of the glycemic index to these two major preventable diseases of the western world argues strongly for its greater acceptance into our current nutritional guidelines.

GLUCOSINOLATES

B Holst, Nestlé Research Center, Lausanne, Switzerland
G R Fenwick, Institute of Food Research, Norwich, UK

Introduction

Glucosinolates are secondary plant metabolites that are characteristic of the Cruciferae and related families within the order Capparales. Glucosinolate-containing plants have always made major contributions to the diets of humans and farm animals, and include condiments and relishes (mustard and wasabi), traditional leaf vegetables (cabbage, swede), and crops used as animal feedstuffs (rapeseed, kale, turnip).

Glucosinolates are thioglycosides that differ in the structure of the aglycone side chain; they are relatively biologically inactive *per se*, but following tissue disruption they undergo hydrolysis to form a broad range of structurally diverse hydrolysis products possessing varying biological activities. These products are the basis of the sensory characteristics typical of brassicas but also, through their biological effects, affect their nutritional value. Some of the hydrolysis products (goitrin, thiocyanate ion, several isothiocyanates, and nitriles) may have antinutritional or toxic effects; others, especially isothiocyanates (e.g., sulforaphane), are considered to be responsible for the protective, anticarcinogenic effects of a cruciferous-rich diet. These adverse and beneficial effects are highly dose-dependent and the physiological range is relatively narrow. Glucosinolate hydrolysis products also exert antifungal, antimicrobial, and insecticidal properties, and so contribute to the plant's overall defense mechanism.

The large number of glucosinolates, the plethora of hydrolysis products possessing differing biological activities, and the dose dependence of the effects observed make research in this area both challenging and complex. Thus, plant-breeding strategies that concentrated solely on reducing the glucosinolate content of rapeseed for nutritional benefits succeeded in producing very low ('zero') glucosinolate varieties that were more nutritious but these required a significantly increased expenditure for crop protection. On the other hand, pest-resistant crop cultivars that contain high amounts of individual glucosinolates may have unacceptable sensory characteristics and may, possibly, also exhibit antinutritional properties.

Chemical Structure, Properties, and Nomenclature

Naturally occurring glucosinolates are (Z)-*cis*-*N*-hydroximinosulfate esters, possessing a sulfur-linked β-D-glucopyranose moiety and an amino acid-derived side chain ($\mathbf{R_1}$: **Figure 1**). The side chain and sulfate group have an antistereochemical configuration, the structure of the former being highly variable; the glucosinolates may posses aliphatic (alkyl, alkenyl, hydroxyalkenyl, ω-methylthioalkyl), aromatic (benzyl, substituted benzyl), or heterocyclic (indolyl) side chains. Aliphatic- and aromatic glucosinolates share the same degradation pathways but glucosinolates with side chains possessing a terminal double bond or a β-OH group form different products. The major glucosinolates may be subdivided into

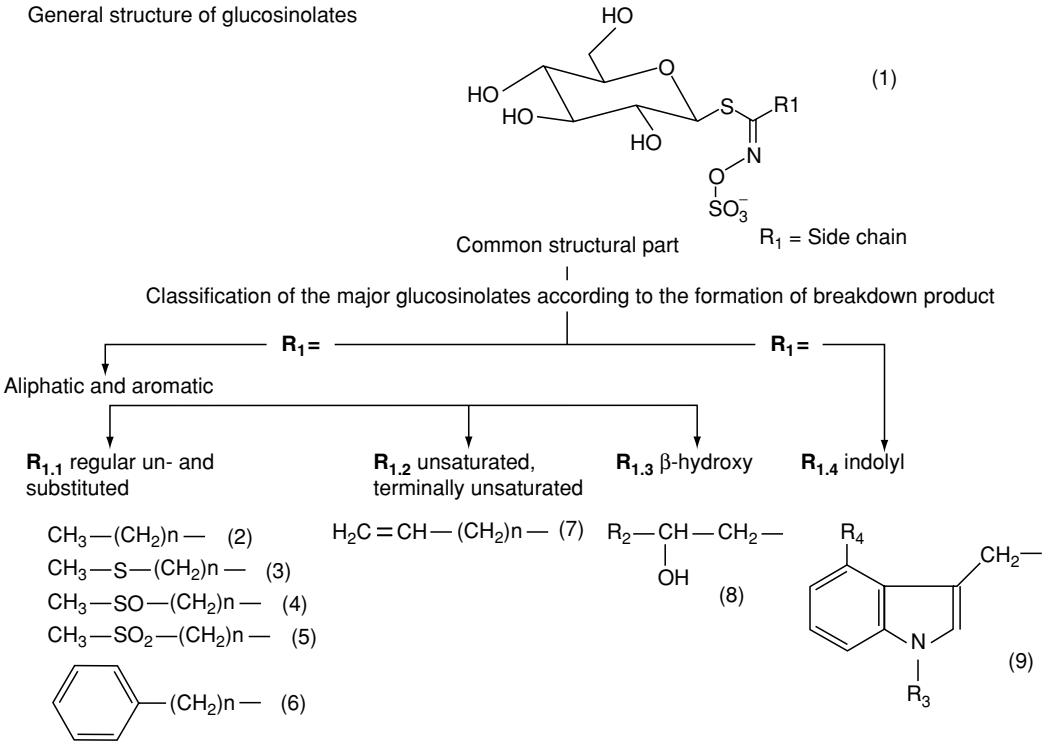

Figure 1 General and individual glucosinolate structures.

aliphatic and aromatic ($\mathbf{R_{1.1}}$), terminally unsaturated ($\mathbf{R_{1.2}}$), β-hydroxy-($\mathbf{R_{1.3}}$), and indolyl ($\mathbf{R_{1.4}}$) groups according to their breakdown. The first group includes a wide range of homologs ($n = 3$ to $n = 11$) and structural classes. The most common side chains include ω-methylthio (**3**), ω-sulfinyl (**4**), ω-sulfonylalkyl (**5**), and aromatic (**6**) groups.

The presence of the sulfate group confers strongly acidic properties on glucosinolates, irrespective of the chemical structure of the side chain, and they occur as salts with the glucosinolate anion usually counterbalanced by potassium, less frequently by sinapinium cation. The sulfate group and thioglucose moiety make glucosinolates nonvolatile and hydrophilic, and the naturally occurring forms exhibit levrotation in solution. Trivial nomenclature was used for many years, but latterly a more precise system has been developed that uses prefixes characteristic of the side chain followed by the word 'glucosinolate.' Although this nomenclature is more informative and prevents confusion, the trivial names are still widely used.

Occurrence

Glucosinolates are limited to a restricted number of dicotyledonous angiosperms and are prevalent throughout 15 botanical families of the order Capparales, e.g., the Brassicaceae, Capparaceae, Resedaceae. As more than 80% of glucosinolates so far identified occur in the Brassicaceae, their presence has been used as a chemotaxonomic criterion for classification within this family. Species of the Brassicaceae are of great economic importance as vegetables (e.g., cabbage, broccoli, cauliflower, Brussels sprouts; root vegetables, e.g., radish, turnip, swede, and leaf vegetables, e.g., rocket salad), relishes (e.g., wasabi, mustard), oilseeds (canola, rapeseed), and forage crops (kale, forage rape).

Glucosinolates have been found in all parts of these plants and, whilst as many as 15 different glucosinolates have been found in the same plant, three to four usually predominate. Occurrence and concentrations vary according to species and cultivar, tissue type, physiological age, plant health, agronomic practice, and nutrition. Levels in reproductive tissues (flowers and seeds) are much higher (up to 10% dry weight) than in vegetative tissues (1–5000 ppm). Glucosinolates are synthesized in the silique walls from relatively few protein amino acids and chain-elongated homologs and translocated to the seeds, where they accumulate inside the vacuole.

The common glucosinolate biosynthetic pathway involves aglycone synthesis via initial *N*-hydroxylation, oxidative decarboxylation to form an aldoxime, incorporation of sulfur to yield a thiohydroximic acid

that undergoes *S*-glucosylation to the desulfoglucosinolate and, finally, sulfation. Modifications of the side chain, including oxidation, hydroxylation, and reduction, are responsible for the observed structural diversity of glucosinolates.

Although several individual steps of the overall biosynthetic pathway remain to be elucidated and several enzymes require purification and characterization, existing knowledge may be exploited for breeding or biotechnological production of new plant varieties with enhanced flavor and functionality, including putative health-promoting activity. Thus breeding has produced rapeseed varieties with very low glucosinolate concentrations, e.g., the 'double zero' rapeseed with a very low content of 2-hydroxy-3-butenylglucosinolate, the precursor of 5-vinyloxazolidine-2-thione (goitrin). Recently there have been attempts to increase levels of certain glucosinolates in crops used as human foods, e.g. enhancing 4-methylsulfinylbutylglucosinolate, the precursor of the anticarcinogenic isothiocyanate, sulforaphene.

The role of the complex myrosinase (β-thioglucosidase, EC 3.2.3.1.)-glucosinolate system in plants is considered to be diverse; glucosinolates may represent a sink for nutrients like nitrogen, sulfur, or growth factors (e.g., indole-3-acetic acid, IAA) and, hence, may be involved in growth regulation, while their hydrolysis products contribute to nonspecific plant defense mechanism against insect, fungi, and microorganism infections (Table 1).

Whilst disruption of cellular tissue leads to hydrolyses of glucosinolates, under some conditions (after plant–fungi, plant–insect, and plant–microorganism interactions, or mechanical wounding) *de novo* synthesis may be induced. Thus, under conditions of low stress and minor cell damage, *de novo* synthesis of glucosinolates may balance – or indeed exceed – losses due to their breakdown. More work is required to establish the underlying biochemical mechanisms controlling these processes.

Table 1 Factors affecting glucosinolate profiles and concentration

Biotic factors	*Abiotic factors*
Fungi	Temperature
Insects	Light (ultraviolet irradiation)
Microorganisms	Water supply
Animals	Fertilizer
Weeds and other competing plants	Harvest conditions
Plant density	Postharvest and storage conditions
Developmental stage	Processing conditions
Part of the plant (organ)	

Hydrolysis

As emphasized above, hydrolysis products – rather than intact glucosinolates – are responsible for the biological activities and flavor characteristic of cruciferous vegetables. Depending on reaction conditions, glucosinolate breakdown may be enzymatic and/or nonenzymatic; since myrosinase co-occurs with glucosinolates in plant tissue, the former predominates, with chemical hydrolysis only taking place where myrosinase is inactivated, e.g., after cooking, or under highly acidic/basic conditions. Myrosinase isoenzymes and glucosinolates are localized in all cells but are compartmentalized; glucosinolates are stored in the vacuole and myrosinases are localized in cytoplasm.

Following tissue damage, enzyme and substrate come into contact, causing hydrolysis of the *S*-glucose bond and, thereby, yielding glucose and an unstable aglycone (**10**, Figure 2) that undergoes spontaneous rearrangement to an isothiocyanate, or nitrile and elemental sulfur. Only allyl-, benzyl-, and 4-methylthiobutyl glucosinolates appear to undergo enzymatic degradation to thiocyanates, although the mechanism remains obscure. Other products, such as epithionitriles and oxazolidine-2-thiones, can also be formed; the nature of the resulting product depending on side-chain structure and reaction conditions (pH, temperature, presence of protein cofactors modifying the action of the enzyme).

Structure of the Side Chain

At a pH of 6–7, most glucosinolates yield stable isothiocyanates (**11, 12**). However, those possessing a β-hydroxylated side chain form unstable hydroxyisothiocyanates that spontaneously cyclize to oxazolidine-2-thiones (**13**), the best-known example being 5-vinyloxazolidine-2-thione (goitrin). Indole glucosinolates also form unstable isothiocyanates; these undergo lysis, initially forming the corresponding alcohol, e.g., indole-3-carbinol (**14**) and subsequently condensing to the dimer (**15**), trimer, or tetramer. In the presence of ascorbic acid, ascorbigen (**16**) is the major product (Figure 3).

Depending on the plant species, autolysis of fresh material (pH $\sim$ 6) can yield nitriles (**17–21**). Several authors have discussed a 'nitrile-forming factor' but this has neither been isolated nor characterized. Under acidic conditions, nitriles are the major degradation products (**17, 18, 20, 21**: Figure 4). In the presence of active epithiospecifier protein (ESP) and Fe^{2+} ions, glucosinolates with terminally unsaturated side chains transfer sulfur from the *S*-glucose moiety to the alkenyl moiety to form an epithionitrile (**19**). ESP is a small protein, which co-occurs and interacts

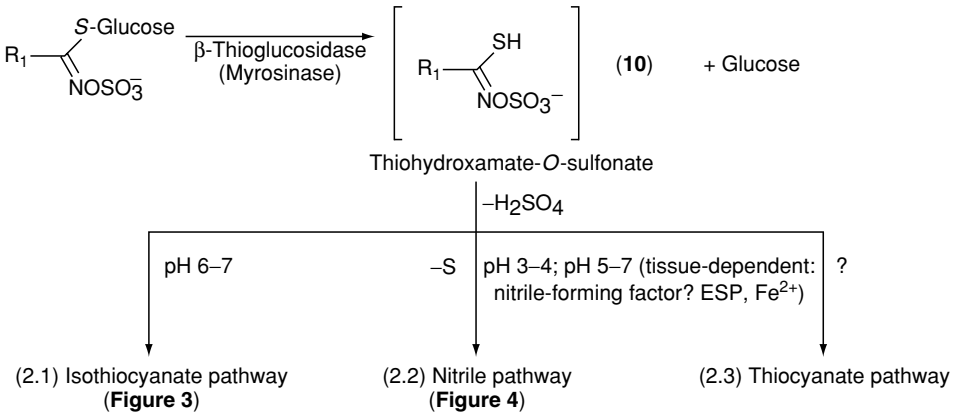

Figure 2 General and initial step of enzymatic glucosinolate hydrolysis.

with myrosinase but is not present in all glucosinolate-containing species. In the absence of ESP the addition of ferrous ions to reaction mixtures promotes nitrile formation (18).

Reaction Conditions

Most factors modifying glucosinolate hydrolysis affect either myrosinase activity and specificity, or the activity of ESP, which is a very labile protein, in marked contrast to myrosinase. Low concentrations of ascorbic acid increase myrosinase activity in some species, whilst high concentrations are inhibitory. The broad range of possible degradation pathways and their resulting complexity, as well as the diversity of hydrolysis products, are most likely due to their function in plant defense mechanisms. Hydrolysis products, particularly thiocyanate ion and isothiocyanates, are toxic to animals, fungi, and microbes as well as to other plants. Catabolic detoxification is achieved by transformation to a variety of simple compounds that are either recycled or excreted as volatiles such as methylisothiocyanate, methylthiocyanate, methylthiol, dimethyldisulfide, and disulfide. Plant cell damage, accompanied by competing processes of hydrolysis and *de novo* biosynthesis of specific glucosinolates, especially indole glucosinolates, occurs during storage and processing of cruciferous vegetables. Chopping, cooking, freezing, and fermenting lead to enzymatic and/or nonenzymatic glucosinolate hydrolysis and *de novo* glucosinolate biosynthesis as a wound response. Leaching into cooking liquor is a major cause of glucosinolate loss during processing. There are thus prominent changes in glucosinolate profiles and in the quality and quantity of hydrolysis products formed (and hence flavor characteristics) during processing.

Predicting the degree of glucosinolate loss, and the nature of hydrolysis products formed, is difficult because of the high number of parameters which affect the process; these include the final size of the plant material after chopping, the amount of cooking water, the use of cold or boiling water at the start of the cooking process, the nature of the processing/cooking, cooking time, and precooking/storage conditions (frozen material will be more heat-sensitive than fresh). There are attempts to investigate systematically the effects of single and combined processing parameters on glucosinolate hydrolysis; by modulating these it may eventually be possible to predict the outcome of a given process and identify the major parameters affecting changes in glucosinolates.

Analysis

The type of glucosinolate analysis depends on the particular data required, i.e., overall (total) concentration, amount of individual glucosinolates, quantity and type of degradation products and/or metabolites. For screening purposes in plant breeding and/or the study of environmental influences, the easiest, fastest, and cheapest method to determine total glucosinolate concentrations is by glucose release. Myrosinase-mediated hydrolysis of glucosinolates releases glucose and sulfate in equimolar amounts. Both can be used for total glucosinolate determination but glucose, which can be measured instrumentally with a high sample throughput and low cost, is the analyte of choice if large numbers of samples need to be screened.

The chemical and biological properties of individual glucosinolates and their products can be very different, which is why determination of the levels of individual glucosinolates is often the goal. Intact glucosinolates can be separated by high-performance liquid chromatography (HPLC) on reverse-phase matrices using ion pair reagents to neutralize the strongly ionic sulfate group. Desulfation has been used to circumvent the need for ion pair reagents and also represents a useful – indeed, frequently necessary – clean-up step. Such a method has been declared as a European Union (EU) reference method. Whilst lack of standards makes identification by ultraviolet detection at 227 nm or using diode array detectors difficult, novel coupling techniques such as HPLC – mass spectrometry (MS) or HPLC–MS nuclear magnetic resonance (NMR) have facilitated glucosinolate separation and identification without derivatization.

HPLC–MS is also the method of choice for analyzing glucosinolate hydrolysis products and metabolites; these, together with the parent glucosinolates, can be separated on reverse-phase columns. Since high-performance MS instruments and techniques allow the identification and quantification of compounds incompletely separated, it is now possible to analyze complex mixtures.

Extracts of plant material, biological fluids, and cell culture media or biological tissues are all very complex; depending on the subsequent type of analysis, time- and labor-intensive extraction and purification procedures may be necessary. The most common extraction procedure for glucosinolates uses hot methanol followed by separation on strong ion exchange materials. Novel, liquid chromatography (LC) integrated preparation methods save time and can improve results through on-column analyte enrichment; quantitative and matrix-independent recovery; increased analytical capacity; and low throughput cost per sample.

Bioactivity

While glucosinolates *per se* are biologically inert, their hydrolysis products possess chemical properties rendering them powerful allelochemical agents against microbes, fungi, and plants. They also contribute significantly to the typical flavor of cruciferous vegetables; however, considerable current interest centers on their biological effects on humans and animals, which are highly dose- and structure-dependent, and may elicit positive, protective effects as well as antinutritional and potentially toxic responses.

Cancer-Preventive Potential

The inverse correlation between *Brassica* consumption and cancer risk is well established through many epidemiological studies. However, only limited human intervention studies have been conducted (e.g., with Brussels sprouts) to confirm these results. Mechanistic investigations, largely based on cell culture studies, have demonstrated glucosinolate hydrolysis products to be a source of the anticarcinogenic effects. Thus, indole-3-carbinol derived from 3-indolylmethylglucosinolate modulates the estrogen hydroxylation pathway to produce a less potent form of estradiol and, thereby, might confer protection against estrogen-related cancer.

Individual glucosinolate-derived isothiocyanates, e.g., phenethyl- and 4-methylsulfinylbutyl isothiocyanate (this latter commonly termed sulforaphane), have been shown to prevent formation of chemically induced tumors of the esophagus, stomach, liver, lung, and mammary gland in animals, most likely through mechanisms involving inhibition of cytochrome P-450 carcinogen activation and induction of phase II enzymes such as glutathione-*S*-transferase and NAD(P)H:quinone reductase. Glucosinolate-derived isothiocyanates may alter the balance of phase I/II enzyme metabolism such that phase I oxidative activation of carcinogens is decreased as compared with the increased rate of phase II detoxification.

Several isothiocyanates may also induce cell cycle arrest and apoptosis in colon cancer cells, which represents an alternative mechanism of anticarcinogenic activity. Thus, individual isothiocyanates belong to a small, but important group of compounds exhibiting dual inhibitory action against carcinogenesis. It is not surprising, therefore, that glucosinolate-derived compounds have been identified as targets for functional food or nutraceutical product

development. However, concentration-dependent adverse effects of many glucosinolate hydrolysis products must be considered: dose–effect relationships are not clinically proven and tissue bio-availability remains unknown. It is also unclear if, to what extent, and in which chemical form, they are absorbed, distributed, and metabolized, and also whether active metabolites reach possible target organs. Given these factors, and the absence of information derived from preclinical studies or studies involving animal pharmacology and toxicology, much work is needed before any overall recommendations can be offered regarding their likely beneficial effects on human health.

Antinutritional Effects

In contrast to the above putative beneficial properties, many glucosinolate-derived hydrolysis products are considered as natural toxicants, thereby being the focus of breeding and processing strategies to reduce/remove them from animal feeding stuffs. These compounds elicit a variety of adverse effects on the morphology and function of different cells and organs (*See* **Goitrogens and Antithyroid Compounds**) and antioxidant status. Liver, kidney, thyroid gland, and pancreas are the main target organs; in rats, toxic effects were observed with daily doses of 10–50 mg kg^{-1} body weight. In high concentration, certain isothiocyanates and nitriles may initiate mutagenic, cytotoxic, and carcinogenic processes; thus untreated juice of certain cruciferous vegetables can induce genetic mutations in both bacterial and mammalian systems and subsequent analysis implicated glucosinolate breakdown products as the primary source of mutagenesis. Differences in genotoxicity amongst varieties of cruciferous vegetables have been interpreted on the basis of the nature and amount of individual glucosinolates. Cytotoxicity and genotoxicity studies using, for example, human colon adenocarcinoma HT29 cells, have demonstrated the dose-dependent cytotoxicity of individual glucosinolate hydrolysis products (diindolylmethane (DIM) and sulforaphane) at $< 1.0\,\mu g\,ml^{-1}$; these products were, moreover, able to inhibit quiescent cells from reentering the cell cycle. Although very effective on undifferentiated HT29 cells, DIM and sulforaphane do not appear to affect the viability of differentiated intestinal cells – a significant finding given that cancer cells are undifferentiated.

Bioavailability

The biological effects of glucosinolate hydrolysis products depend greatly on their bioavailability, defined not only by oral dose, but also by their absorption, distribution, metabolism, and excretion (ADME) that, together, offer a measure of tissue bioavailability. Thus, phenylhexylisothiocyanate (a synthetic product) enhances esophageal cancer because of its extreme bioavailability (the highly lipophilic phenylhexenyl group increasing membrane permeability and, hence, absorption) whereas lower homologs decrease esophageal cancer (phenylpropylisothiocyanate > *phenylethylisothiocyanate > phenylbutylisothiocyanate > *benzylisothiocyanate: the asterisk denotes that it is naturally occurring) since reduced bioavailability leads to optimal tissue levels. The broad opinion that even low concentrations of nitriles, arising from glucosinolate breakdown, may exert toxic effects needs to be reconsidered, since their individual chemical structures, and subsequent bioavailabilities, will be key parameters in determining their mode of action. Thus, 1-cyano-2-hydroxy-3-butene may be the most active anticarcinogen in Brussels sprouts, acting via induction of phase II enzymes.

Although chewing will liberate intact glucosinolates, it also causes enzymatic hydrolysis; the extent of these processes has not been investigated. The same is true for the effect of gastric digestion, including the binding of intact glucosinolates/hydrolysis products to peptides, smaller glycoproteins, and other food components. A substantial proportion of the intact glucosinolates in the food may, therefore, not be absorbed in the small intestine and will reach the colon, to be hydrolyzed by endogenous microflora; they might, therefore, have potential for delivering bioactive hydrolysis products directly to the colon and so be effective against colon tumor development. In this context, the precise role of microbial thioglycosidases is controversial and needs further investigation.

Even if absorption is high, bioavailability may be limited by rapid and extensive metabolism. The major form of first-pass metabolism of isothiocyanates is conjugation with glutathione (catalyzed by glutathione-*S*-transferases), but the site of this conjugation is unclear. Little is known about the metabolism of nitriles but structural features appear to influence the formation of cyanide and thiocyanate ions.

Lack of fecal recovery of intact glucosinolates indicates that extensive metabolism is likely and numerous animal studies have shown that, following first-pass metabolism, extensive transformation of glucosinolates and hydrolysis products occurs. The site of metabolism and the nature of intermediates remain unclear. Most studies have been unable to study metabolism quantitatively and 25–65% of metabolites are unidentified. Depending on the animal species, the major urinary metabolites are *N*-acetyl cysteine conjugates (mercapturic acids), thiocyanate

ion, and hippuric acid conjugates. Attempts to identify primary compounds or metabolites in blood failed but the feeding of radiolabeled compounds demonstrated a rapidly occurring peak of radioactivity in the blood that was both species-specific and of short half-life.

There is only very limited knowledge on the metabolism of nitriles; some, e.g., benzyl cyanide, release hydrogen cyanide (HCN) following the action of a microsomal mixed-function oxidase, probably as a result of α-methylene hydroxylation to form an unstable cyanohydrin. The liberated HCN can be converted to less toxic SCN^- by sulfur transferase. The individual structure of the organonitrile affects SCN^- excretion.

The short-term biological activity of phytochemicals (including glucosinolate hydrolysis products) is relatively weak; they have multiple targets and may elicit both beneficial and adverse effects. This poses particular problems in determining the net effect because plant foods contain a complex mixture of phytochemicals with a wide range of physiological effects. One key question to address is: how much does a particular food component contribute to a specific health outcome compared with other dietary constituents? Another is: to what extent does this affect the disease outcome? The availability of a robust and reliable surrogate biomarker should provide answers by facilitating measurement of exposure and by indicating a positive/negative physiological effect prior to the final outcome.

Future Research

The need for future research has been identified in the individual sections above. After a century of glucosinolate study, research into their biological activity and physiological significance remain in their infancy. Determination of their ADME and human studies, following on from animal and cell culture experiments, should be a prime focus of future research. As yet, there are no validated biomarkers of exposure, effect, and susceptibility to dietary glucosinolates that would enable correlation of dose and effect in human intervention studies. Since presystemic metabolism affects tissue bioavailability, knowledge of how individual enzyme status and polymorphism in human glucosinolate-metabolizing enzymes affect ADME is vital. Current data are both insufficient and controversial. Insufficient attention has been paid to the effect of the food matrix, since food contains a range of bioactive compounds, nutrients and non-nutrients, and detailed investigation of their interactions, competition, and synergism with one another and with proteins and carbohydrates will be necessary if an understanding of overall sensory and physiological characteristics is to be achieved.

A second focus for research is elucidation of the complex parameter affecting levels of glucosinolates and hydrolysis products in food. If the biological effects of glucosinolates are to be exploited for social and economic benefit through the breeding or genetic engineering of nutritionally enhanced crops, further information on their biosynthesis, on the genes involved, and on their function and possible linkages is needed. Details of the myrosinase-glucosinolate system is required and factors responsible for directing hydrolysis toward specific products understood; recommendations for processing cruciferous vegetables to optimize glucosinolate hydrolysis products may then follow.

Finally, understanding of the antimicrobial, insecticidal, and fungicidal properties of glucosinolate hydrolysis products will assist targeting of future breeding programs, facilitate integrated crop protection, and provide natural options for plant husbandry in response to consumer concerns.

GLYCOGEN

M H M Rocha Leão, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Introduction

Glycogen is a glucose polysaccharide occurring in most mammalian and nonmammalian cells, in microorganisms, and even in some plants. It is an important and quickly mobilized source of stored glucose. In vertebrates it is stored mainly in the liver as a reserve of glucose for other tissues. In hepatocyte cells it is accumulated and mobilized according to blood glucose availability and to extrahepatic cells. Glycogen is also stored in muscles and fat cells. In the muscle it seems to be mainly used for energy purposes as metabolic fuel for glucolysis producing glucose 6-phosphate. Thus, glycogen plays a crucial role as a systemic and cellular energy source and also as an energy store. A great number of enzymes and hormones control the synthesis and degradation of glycogen. Consequently, stores of human body glycogen may vary dramatically due to diet, exercise, and stress.

Structure, Isolation, and Location

The glycogen molecule is formed by (1→4) linked chains of alpha-D-glucose residues and branched at intervals of 8–12 glucose residue units, with (1→6)-alpha-D-linkages which produce a bush-like structure, called beta-particles. Dimers and trimers of beta-particles are linked upon a single protein backbone known as glycogenin. The backbones of several fundamental units are joined to form a macromolecule named an alpha-particle, of 100–150 nm diameter. Due to its polymeric nature, glycogen is osmoticaly inactive and can be stored in large quantities within the cells. The branched glycogen has two advantages: it increases its solubility and facilitates the rapid turnover of sugar residues. The latter is due to exhibition of a greater number of nonreducing ends for simultaneous enzymatic reactions.

Studies on the cellular location of glycogen in several cell types have led to some different interpretations which are due to different procedures employed for glycogen extraction (hot potassium hydroxide (KOH), cold or hot tricarboxylic acid (TCA), hot sulfuric acid (H_2SO_4), and cold or boiling water) used in different laboratories. In yeast, it is accepted that there are two pools of glycogen location. One is water-insoluble or acid-extractable, occurring outside the cellular membrane. This pool corresponds to the major fraction of the yeast glycogen. The second is water-soluble or alkali-extractable, occurring inside the cellular membrane. In the past some authors showed the relationship between the location and their metabolic compartmentalization. However if the two pools have distinct roles in yeast metabolism this remains to be proven.

Recently, an original glycogen structure surrounding the finger-like plasma membrane invaginations in a ring was discovered and visualized by electron microscopy. In tissues, the glycogen is associated with 2–4 times its weight with proteins by adsorption

mechanism. These proteins appear to be mainly the enzymes of its own metabolism. Because glycogen is intimately associated with protein in the cell and the protein–glycogen complex forms an independent functional unit, it is considered as a dynamic organelle called glycosome without a membranous envelope and morphologically similar to ribosome.

Both types of supramolecular structure have protein particles and both are attached to endoplasmic reticulum membranes and cyto-skeleton components. Glycosomes may occur free in cytosol (lyoglicosomes) and are acid-labile, whereas the glycosomes associated with cellular structures (desmoglycosomes) are acid-resistant. Although glycogen structure has been studied after isolation using different mild extraction (cold water, cold TCA, or enzymes to lysis cell walls), or by direct observations by means of electron microscopy, the results from the literature are sometimes controversial and this matter is still debated. The different methodologies used by different groups of researchers have led to different results inducing sometimes different interpretations. Nowadays it is hypothesized that there are two forms of physiological glycogen which differ in the proportion of protein relative to carbohydrate and location in the cells. One form corresponds to protein-rich, and it is acid-insoluble, while another is protein-poor and is acid-soluble. The former is called desmoglycosomes and the latter is called lyoglycosomes. Progress for establishing the relationship between glycosomes (lyo- and desmo-) and glycogen metabolism is expected.

Function

Glycogen metabolism is strongly related to glucose metabolism despite the cell type or the organism where it is found. On the other hand, fats are the major source of energy in the human body but they are only mobilized during prolonged periods of starvation from adipose tissue by lipolysis. The fatty acids produced are degraded to acetyl Coenzyme A (CoA) in the liver via the beta-oxidation pathway. Under these conditions the amounts of acetyl CoA are very high and exceed the degradative capacity of the citric acid cycle. Thus, acetyl CoA is used as a substrate to form ketone bodies which are utilized by all body organs as an energy source under starvation. So, in the human liver, fatty acids are not transformed into blood glucose. If starvation is very prolonged, proteins are also used as an energy source.

Glycogen as an energy reserve stored in the liver is low when compared to fat. The body has more fat tissue and fats yield more energy than carbohydrates. When the energy supply is low the liver responds, mobilizing stored, glycogen and after 6–12 h it is exhausted. When glycogen is depleted there is an increase in the glyconeogenesis rate for glucose synthesis. Humans can store up to 150 g (a third of all glycogen in the body) glycogen in the liver which will serve to maintain the blood glucose level in the postresorptive phase. Therefore, in this organ it falls drastically and can decrease to almost zero during starvation lasting more one day. The buffering effect of liver glycogen to maintain blood glucose level is caused by glucose 6-phosphatase catalysis. Since this enzyme only exists in liver, glycogenolysis in muscles channel glucose 6-phosphate into glycolysis without any adenosine triphosphate (ATP) waste.

Muscle glycogen serves as an energy source during mechanical work. During light exercise glucose, fatty acids, and ketone bodies are completely degraded to CO_2 and H_2O. ATP and creatine phosphate present in resting muscles sustain the necessary energy to muscle contraction for a few seconds.

Glycogen is the most important energetic reserve in muscle tissue. It can form 2% of muscle mass. Glucose 1-phosphate, the first metabolite produced when glycogen is degraded, is processed to glucose 6-phosphate via isomerization. This metabolite yields ATP either via oxidative phosphorylation, when O_2 is present, or through conversion to lactate via anaerobic glucose. There are two types of muscle in animals: the white muscle of rapid contraction and the red muscle of slow contraction. The former works for short periods of time during heavy exercise with high ATP requirements via anaerobic glycolysis. The latter works for long periods of time during prolonged exercise and in continuous contraction, as in cardiac muscle. Red muscle requires low ATP per minute because it is rich in mitochondrial organelles and therefore converts glucose 6-phosphate more slowly to CO_2 and H_2O when compared with white muscle.

Knowledge of microbial nutrition has become more relevant in recent years with the increased use of microorganisms and their products as food additives and supplements. *Saccharomyces cerevisiae* (baker's yeast) is an important microorganism used in food technology which mobilizes glycogen after glucose is exhausted from the medium and in the budding process as carbon and energy sources. Recently, it was found that glycogen plays another important role when *S. cerevisiae* is submitted to stress conditions in the medium of glucose. The effect of stress is to stimulate the recycling of glycogen instead of promoting either its accumulation or its degradation. It is important to note that, under stress, cell growth is arrested, thus there are ATP imbalances in the upper and lower part of the glycolytic pathway. Like a

'turbo' design model, glucose oxidation by glycolysis leads to overproduction of ATP, glucose 6-phsphate, phosphate depletion, and cell death. The solution to this cellular problem is possible because stress induces transcriptional activation and the relative enzymes for glycogen metabolism are under this control. Moreover, as a result, both synthesis and degradation enzymes are expressed to the same extent. Thus, it has been suggested that glycogen turnover may function as a glycolytic safety valve to avoid substrate-accelerated death and also that glycogen in these cells confers survival advantages for cell proliferation and stress resistance. In this manner, the glycogen level or glycogen used as a futile cycle contributes to the fitness of the yeast in different environments and under industrial processes. In brewery fermentation yeast is added at the beginning of each batch for eight or more cycles. Before each cycle it is replaced in proliferation conditions and must break down its glycogen for sterol and fatty acids biosynthesis. Glycogen is the sole carbon source used in membrane component biosynthesis. Naturally, the glycogen content at the beginning of the brewery fermentation has a direct impact on yeast vitality (metabolic activity) and a significant improvement in brewer quality.

Biosynthesis and Degradation

Glycogen phosphorylase is a dimmer catalyzing the first and controlled step in glycogen degradation generating glucose 1-phosphate. The cyclic adenosine monophosphate (cAMP) cascade action yields the active form of glycogen phosphorylase a, which has a phosphoryl group linked to Ser14 in each subunit. The less active form, which is phosphorylase b, is dephosphorylated. Both forms are finely regulated. They contain the vitamin B_6 derivative pyridoxal-5-phosphate, covalently linked, which is required for their activities. The glucose 1-phosphate is converted by phosphoglucomutase to a glucose 1,6-bisphosphate intermediary which is an important enzyme regulator occurring *in vivo* at low concentration to maintain phosphoglucomutase fully active. To debranch the glycogen, two catalytic sites in debranching enzyme for both transferase and alpha (1→6)-glucosidase are required, increasing enzyme efficiency. Although the reaction catalyzed by glycogen phosphorylase is reversible, under physiological conditions glycogen breakdown is a thermodynamically favorable process. Consequently, glycogen biosynthesis and degradation must occur by two separate pathways. This strategy has two advantages: biosynthesis and degradation may occur at the same time and each pathway may be independently regulated. Since under physiological conditions the glycogen biosynthesis from glucose 1-phosphate to glycogen is an unfavorable process, the glycogen biosynthesis needs an exergonic step. So, glucose 1-phosphate reacts with uridine triphosphate (UTP) to form uridine diphosphate glucose (UDPG) via UDPG pyrophosphorylase catalysis. This reaction produces pyrophosphate (PPi) which is hydrolyzed in a thermodynamically highly favorable reaction catalyzed by pyrophosphatase. Both free energy of PPi and free energy of UTP are utilized to drive the glycogen biosynthesis pathway entropically. Glycogen synthase can only act on preexisting alpha (1→4)-linked glucose residues chain. So, the first step in glycogen biosynthesis is the attachment of glucose residue from UDPG to the Tyr group of an autocatalytic enzyme named glycogenin. Sequentially, the autocatalytical glycogenin extends the glucan chain by six or seven alpha-1,4-linked glucose residues, again derived from UDPG. Note that glycogenin is a glucosyl transferase enzyme and serves as an initiator for glycogen biosynthesis. The latter shows that glycogenin has a structural role in glycogen molecule and its biogenesis. Glycogen synthase associates with branching enzyme, elongating the glucan chain and building the glycogen molecule on to the protein backbone. The branching enzyme amylo-(1,4→1,6) transglycosilase breaks segments of at least 11 glucose residues of the linear chain (alpha-amylose), transferring to the C_6-OH groups to the same or another chain.

Allosteric Regulation

Glycogen phosohorylase and glycogen synthase are under finely tuned and reciprocal regulation. The activity of glycogen phosphorylase is allosterically controlled by metabolic effects produced in cellular metabolism. In muscle this enzyme is activated by adenosine monophosphate (AMP) and inhibited by ATP and glucose 6-phosphate. The liver isoform, unlike the muscle isoform, is more tightly controlled by phosphorylation than by allosteric regulation. In addition, in the liver, free glucose readly inhibits glycogen phosphorylase a. So, when cellular energy is high the enzyme is inhibited, and when cellular energy is low it is activated. Naturally, when ATP and glucose 6-phosphate concentrations are high, glycogen biosynthesis is favored. In terms of the symmetry model of allosterism, glycogen phosphorylase may assume the enzymatically inactive T (tense) conformation or the catalitically active R (relaxed) conformation which are differently responsive to allosteric effects. When in R-state, the enzyme has a high-affinity substrate phosphate-binding site, whereas in the T-state this catalytic enzyme site is

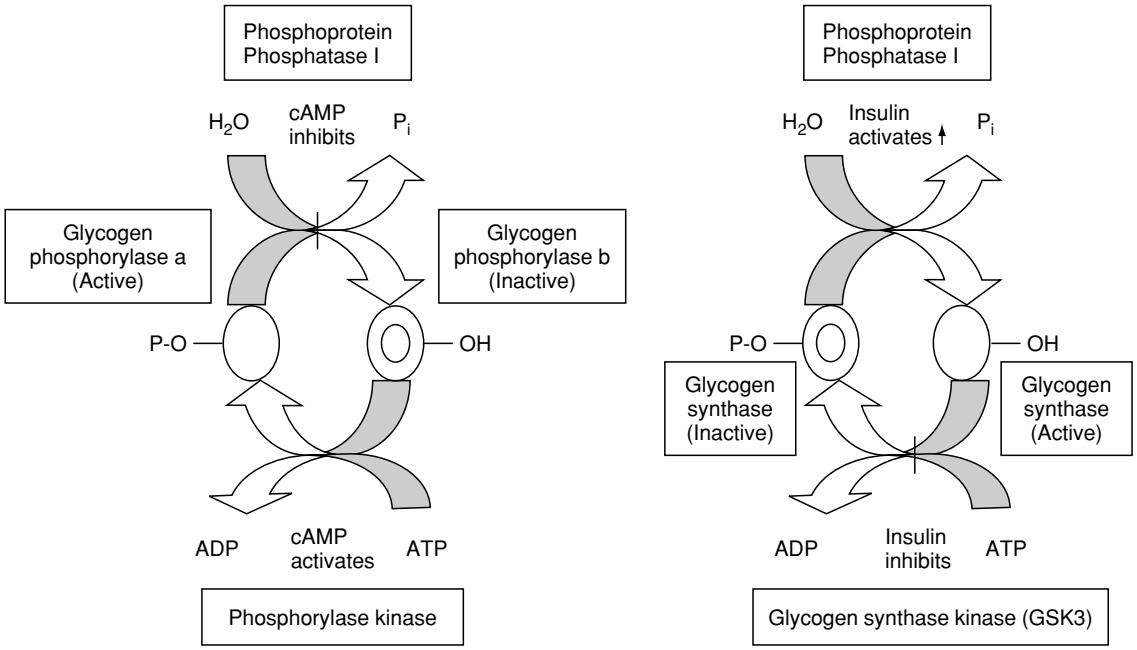

Figure 1 Controls of glycogen phosphorylase and glycogen synthase via enzyme phosphorylase.

inaccessible. Moreover, the R-state is favored by dephosphorylation and allosteric activators, while the T-state is favored by dephosphorylation and by inhibitors. Besides allosteric controls there are enzymatic interconversions through a bicyclic cascade involving three enzymes: phosphorylase kinase, cAMP protein kinase, and phosphoprotein phosphatase, which are themselves under allosteric control (Figure 1). The cascade functions in order to amplify the sensitivity of the system to an allosteric effect. So, a small alteration in cAMP concentration produces large modifications in the cascade action.

Glycogen synthase, a homotetrameric enzyme, contains 1–9 Ser residues to be phosphorylated. Thus, it can exist in several intermediate phosphorylated forms that have depressed ratios but have enhanced sensitivities to glucose 6-phosphate concentration. In muscles a less active form of glycogen synthase b is strongly inhibited by physiological concentrations of ATP, adenosine diphosphate (ADP), and Pi, its allosteric inhibitors, and due to low physiological concentration of glucose 6-phosphate, its allosteric activator, the enzyme b-form is almost totally inactive. In contrast, the more active enzyme a-form is independent of these effects. In this way, the glycogen synthase activity *in vivo* varies with the fraction of the enzyme in dephosphorylated form and the degree of the enzyme phosphorylation. The fraction of a-form is controlled by the same bicyclic cascade involved in glycogen phosphorylase through phosphorylase kinase and phosphoprotein phosphatase 1 enzymes. Moreover, the involvement of multiple protein kinases and protein phosphatases in glycogen synthase activity has been suggested. cAMP protein kinase, protein kinase C, calmodulin-dependent protein kinase, and glycogen synthase kinase-3 are present in this process. The phosphoprotein phosphatase 1 in muscle is only active when it is bound to glycogen via its G subunit. It is regulated by phosphorylation by insulin-stimulated protein kinase and by cAMP-protein kinase. Phosphatase 1 is also inhibited by its binding to the phosphoprotein phosphatase inhibitor 1, which also is modified by phosphorylation/dephosphorylation. Due to this fine control glycogen synthase has been considered to control the glycogen synthesis rate. In muscle it was demonstrated through theoretical quantitative model that glucose transport/hexokinase controls the glycogen synthesis rate and that the role of covalent phosphorylation of glycogen synthase is to adapt the activity of the enzyme to the flux and to control the metabolite level, not the flux. Phosphoprotein phosphatase 1 in the liver can be bound to R and T states of glycogen phosphorylase but only in the T-state enzyme is it accessible for hydrolysis by phosphoprotein phosphatase 1, which converts glycogen phosphorylase a to glycogen phosphorylase b. Thus, phosphoprotein phosphatase 1 results in glycogen phosphorylase inactivation and glycogen synthase activation.

In yeast, two distinct genes *GSY1* and *GSY2* encode two distinct glycogen synthases. The former

is expressed constitutively and the latter is expressed under catabolite depression, heat shock, and nitrogen starvation. The gene product (Gsy2) seems to be the predominant glycogen synthase. Gsy1 and Gsy2 isoforms occur in phosphorylated (less active) and in dephosphorylated (active) forms and have activities also subjected to allosteric control. Glucose 6-phosphate is a direct activator and also controls the phosphorylation state of this enzyme by inhibiting a glycogen synthase kinase. The cAMP-protein kinase and a (Ser/Thr) protein kinase named Snf1 also appear to play a central role in the control of glycogen metabolism in yeast. Using depressed mutant or less repressed sugars it was demonstrated that glycogen accumulation occurs associated to cell growth under both oxidative metabolism and low specific growth rate. Lipase–glycogen interactions have been observed in *Yarrowia lipolytica* lipase *in vitro* as well as during lipase production process. *Y. lipolytica* under stress condition shows a relationship between the lipase liberation rate and glycogen recycling followed decline.

Hormonal Control

In the past, research on glycogen metabolism led to general important discoveries such as the concept of second messenger. The great number of these molecules synthesized after hormone–receptor complex binding in cellular membranes amplifies the hormone signal in target cells. Glycogen metabolism regulation in the body is adjusted with meals at periodic intervals which can vary from short to longer periods. After a meal, blood glucose may increase from 90 to 140 mg dl^{-1} in an hour but reverts to normal in a nondiabetic person in 2 h due to the buffering effect of the liver. Although the general mechanism of glycogen biosynthesis and breakdown is the same in all tissues, the rates of these important pathway are differently regulated by chemical signaling to hormone release into the blood by gland cells. Then, from the blood to target tissues, insulin, epinephrine (adrenaline), and glucagon start the signal transduction in response to available blood glucose and other stimulus such as fight or flight. Under epinephrine and glucagon (Figure 2) a fine cellular control of the signal amplification is mediated by G-protein followed by adenylate cyclase activation, which catalyzes the synthesis of cAMP from ATP. Then, the signal is transduced via phosphorylation/dephosphorylation cascades adjusting glycogen biosynthesis and degradation to several physiological states. The rapid changes in the cAMP concentration are also under phosphodiesterase control, promoting its hydrolysis to AMP. On the other hand, insulin collects a protein family called Ser/Thr kinases in its target cells to advance its anabolic and anticatabolic programs. In the presence of insulin glycogen synthase kinase 3 is inactivated via protein kinase B, thus preventing the latter inhibiting glycogen synthase. Simultaneously, insulin activates protein phosphatase 1, thus activating glycogen synthase. Liver uptake of glucose across hepatocyte plasma membrane by transporter systems is outside the control of insulin. An increase in glycogen synthesis caused by insulin induction of the glycogen synthase in response to blood glucose level also activates the hexose monophosphate shunt, producing NADPH in fatty acid synthesis. The insulin/glucagon rate increase accelerates glycolysis by induction and activation of the glycolytic key enzymes. Besides blood glucose level, the protein and lipids supplied in food producing amino acids and fatty acids in the digestive system place the liver under anabolic states during the absorptive state. In contrast, in the postresorptive state the insulin/glucagon rate decreases causing a direct effect on gluconeogenesis activation as well as on glycogen degradation and on glycolysis deceleration, conducing the liver to enter in to a catabolic state. Glucagon induces the gluconeogenesis enzymes glucose 6-phosphatase, fructose 6-phosphase, fructose 1,6 bisphosphatase, and pyruvate carboxylase and represses the glycolytic enzyme pyruvate kinase, whereas insulin induces the glycolytic enzymes, phosphofructokinase 1, pyruvate kinase, and hexokinase. Glucagon also acts on the glycogen phosphorylation/dephosphorylation enzyme cascades via cAMP control. A similar glucagon effect is found in pyruvate kinase deactivation. Glucose 6-phosphate, ATP, AMP, acetyl CoA and fructose 2,6-bisphosphatase regulate both glycogen biosynthesis and glycogen degradation. The latter is synthesized from fructose 6-phosphate by nonphosphorylated phosphofructokinase 2 under cAMP protein kinase control. In its phosphorylated form it removes phosphate from fructose 2,6 bisphosphate, producing fructose 6-phosphate. Fructose 2,6-bisphosphate is the major glycolysis and gluconeogenesis regulator. It occurs at low cellular concentrations, activating phosphofructokinase 1 and inhibiting fructose 2,6-bisphosphatase. In this way it regulates biosynthesis and the degradation glycogen pathway. In muscle and fat tissues glucose uptake is regulated by insulin and similarly in the liver this hormone activates both glycogen biosynthesis and glycolysis by activation/inhibition, as well as induction/repression of the key enzymes of carbohydrate metabolism. On the other hand, in muscle epinephrine but not glucagon released in fight-or-flight situations activates glycogen degradation and inhibits glycogen biosynthesis at the same time. The

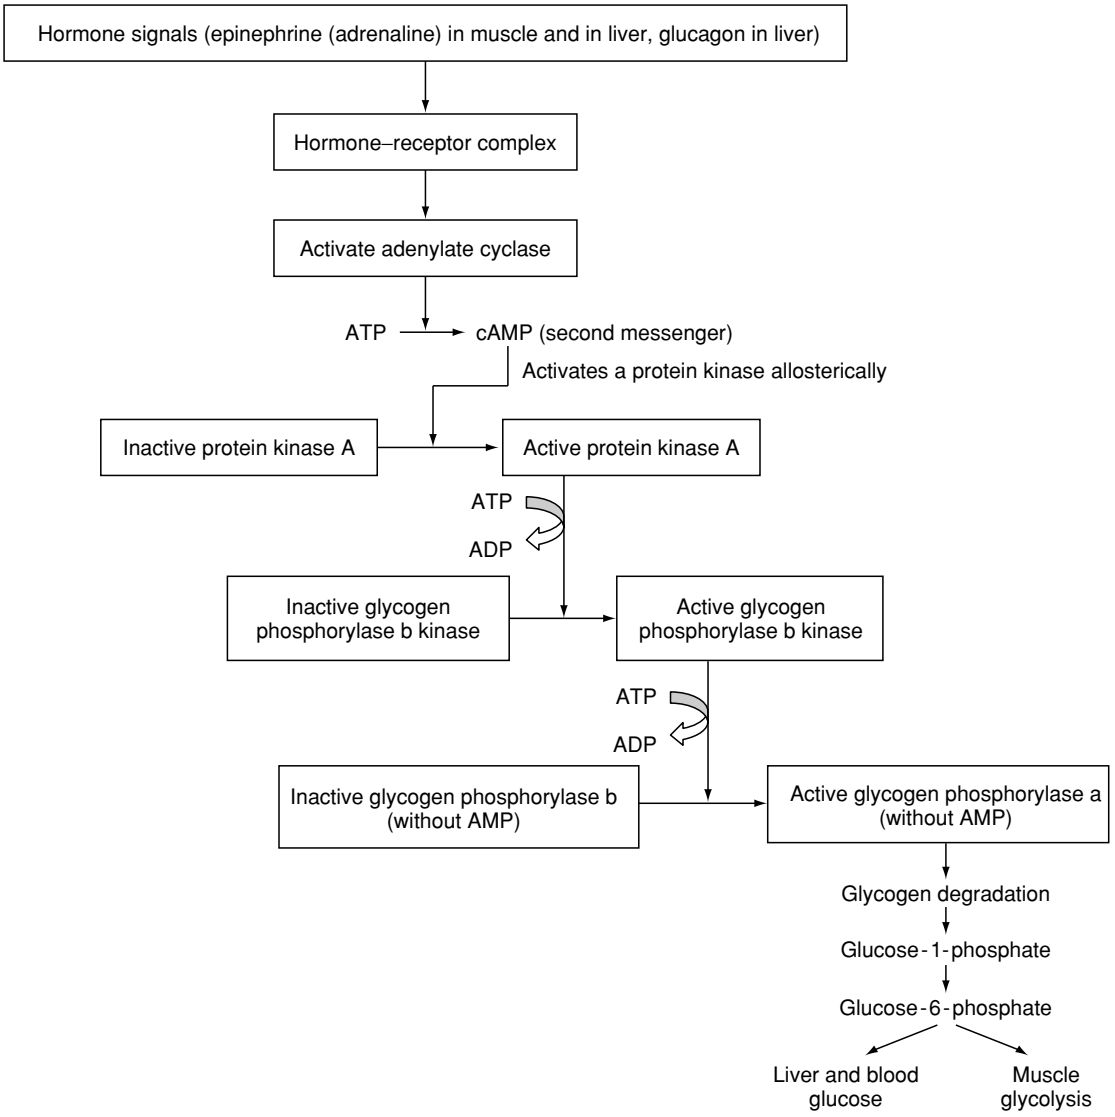

Figure 2 Glycogen degradation via hormone signaling.

activation of glycogen phosphorylase by epinephrine is preceded by cyclic cascade via cAMP protein kinase action, after signaling epinephrine–receptor complex. Ca^{2+} ions are released from the sarcoplasmic reticulum to cytoplasm, after nervous signal, during muscle contraction. Under emergency degradation of glycogen (fight-or-flight), Ca^{2+} ions sustain glycogen phosphorylase in full activity via subunit-calmodulin activation. This process is cAMP-independent. But, under normal muscle contraction, Ca^{2+} ions partly activate phosphorylase kinase which gives partial activation of glycogen phosphorylase.

Glycogenolysis and Physical Activity

The glycogen content stored in the human muscle before exercising is related to the state of preservation. On a high-carbohydrate diet, muscle glycogen may rise to $25\,g\,kg^{-1}$ of muscle. If carbohydrate intake occurs after glycogen is depleted by drastic exercise it may rise to $30\,g\,kg^{-1}$ and in dietary and exercise programs it may reach $40\,g\,kg^{-1}$. This phenomenon is called supercompensation and it is used in baker's yeast production in order to increase the glycogen content of the commercial product. So, baker's yeast is submitted to periods of high-carbohydrate consumption followed by fasting periods.

In athletes either short- or long-duration exercise determines if the glycogen-lactic acid system can provide energy or if an aerobic system is necessary to generate energy. This mechanism may be due both to the lactic acid disappearing rate in the liver for glucose conversion via gluconeogenesis, and the oxygen-replenishing rate in the muscle. Obviously,

in long-duration exercise aerobic glycogen degradation and oxidative phosphorylation are the most important pathways, although fatty acids may also sustain the working muscle. When glycogen is low during exercise an expressive amount of energy comes from fat degradation. Moreover, the muscle macroglycogen (MG) pool, which is a protein-poor glycogen (acid-soluble), as well as the proglycogen (PG) pool, which is a protein-rich glycogen (acid-insoluble) are differently affected by metabolic changes, by diet manipulation, and by glycogen-depleting exercises, respectively. The PG pool accumulates more easily after drastic exercise and the supercompensation phenomenon appears to be related to an increase in MG. The PG pool is less resistant to mobilization and its catabolism is inhibited less rapidly than the MG pool during intensive exercise. Glycogen content and glycogenolysis are positively related, thus glycogen amounts in the muscle before exercise is a regulator of glycogenolysis rate. All these facts suggest that the metabolic regulation of the two pools must be different and that the MG pool is a more stable form than the PG pool. On the other hand, the greater fraction of human muscle MG than PG is utilized in a marathon and accumulation of MG is delayed after this strenuous physical exercise, particularly in type 1 fibers, indicating local control for the glycogen biosynthesis pattern.

Glycogen Storage Disease

Due to the high number of enzymes and isoenzymes involved in glycogen metabolism and because gene expression, enzyme activities, and enzyme-regulatory mechanisms vary between tissues, a large number of diseases are linked to storage and/or structure of the glycogen appearing in a specific tissue but not in another. All of these abnormalities are named glycogenoses or glycogen storage diseases. They are divided into liver and muscle diseases respectively and are classified numerically from I to VIII, including subclassifications. Liver defects manifest hepatomegaly, hypoglycemia and other metabolic disorders, whereas muscle defects manifest cramps, pain, inability to increase the blood lactate level, and exercise intolerance. We must keep in mind that liver glycogen metabolism but not muscle glycogen metabolism is dramatically linked to glucose homeostasis of the human body. Hence, glycogen-liver diseases play a crucial role in human health and survival. Besides glycogen storage diseases, mutations in genes involved in insulin biosynthesis and action affect glycogen-liver metabolism. Diabetes is a chronic metabolic disorder afflicting millions of persons. Type 2 diabetes or noninsulin-dependent diabetes is a less severe form and is a polygenic disease characterized by multiple defects in insulin actions. Patients with type 2 diabetes have excessive hepatic glucose production which contributes to diabetic hyperglycemia in postabsortive state and in postprandial states. Compounds with action antiglycogenolytic that decrease blood glucose *in vivo* such as CP-91149, an allosteric inhibitor of the glycogen phosphorylase which is 200-fold more potent in direct comparison with caffeine, have shown that liver phosphorylase is a pharmacological candidate target for controlling hyperglycemia in diabetes.

Meat

N H Casey, W A Niekerk and E C Webb, University of Pretoria, Pretoria, South Africa

Introduction

Goats' meat is an important nutrient source, particularly for people of developing regions, which are situated mainly in the tropics. These regions account for more than 90% of the world goat population of approximately 650 million. Asian, African, and Caribbean peoples in particular consume goat meat. An estimate of the gross distribution of the world goat population is 56% in Asia, 33% in Africa, and 7% in Central America and the Caribbean. Production in these regions is associated primarily with subsistence agriculture. Commercial farming for metropolitan markets is practiced to some degree in Asia, Africa, and in Central and South America.

Domesticated goats, descendants of the wild goat *Capra hircus*, are among the earliest species of livestock to have evolved with pastoralist humans. Although the distinction between wild and domestic forms is vague at best, it is accepted that the bezoar or wild goat originated in the hills of western Asia. Early farmers began herding these wild goats that were drawn to their fields of cultivated grains. The oldest reliable evidence of domestic goats is from a site more than 9000 years old in Iran. Herding of wild goats altered the environmental stresses, allowing animals to acquire the characteristics of domesticated stock. The many goat breeds throughout the world are the result of translocations of humans over the globe, the influences of physiographic and climatic conditions, and of husbandry men breeding and selecting livestock for specific characteristics.

Consumer Preference

Cultural and traditional backgrounds and the socioeconomic status of the community dictate consumer preference for goats' meat. Virtually no cultural or religious taboos restrict the eating of goat meat, with the result that goat meat is readily available to societies in which eating beef, pork, or other meat types is prohibited.

In parts of the world, notably the tropics, subtropics, and arid regions of mainly developing countries, the demand for goats' meat exceeds supplies. Consequently, goat is sold at premium prices, but is increasingly substituted by cheaper mutton.

Goats' meat is not favored in the west. The results of taste panels in which westerners have assessed the acceptability of goats' meat against beef or lamb should be viewed in this perspective. Of prime importance are consumers' own concepts of value, relative to other foods or consumer items. In an attempt to overcome prejudice, Angora goat meat was marketed in the USA under the brand name Chevon. Chevon has now become a recognized commercial term for goats' meat. Goat kid is a favourite delicacy and features as cabrito in the Spanish-speaking world,

simply as goat kid in English, as chevreau in French, and as boklam in South African Afrikaans.

Production

The value of the goat lies in its flesh, milk, hair, and skin. However, meat production has remained the primary reason for goat-keeping. Meat goats therefore constitute the major proportion of the world's goat population and comprise many different breeds. Of these, the Boer goat breed is regarded as exhibiting the most desirable meat production characteristics. A recent study in Botswana concluded that a small ruminant enterprise is profitable and economically viable. Small-scale ruminant enterprises could provide a return of 34% on capital invested. In Zimbabwe, goats are often the only dependable and perennial agricultural output. Many rural farmers now regard goats as an easy income-generating venture since very little investment is required.

Goats' meat is derived from different categories of goat. Of the meat goats, kids, does, and male castrates are the preferred commercial commodities. The main sources of meat from the milch breeds are male kids and older culls. In New Zealand and Australia, dairy-type feral goats are cropped for export. Mohair-producing Angora goats are slaughtered as culls, or marketed when the price of mohair is down. Other goat products, notably milk and cheese (e.g., feta, chèvre, and Gorgonzola), hair, mohair, and cashmere, have important influences on goat populations of specific regions and the related economic value of goats. Goat hides also yield fine leather, which is used for wineskins, water containers, rugs, and clothing of high quality.

Goats generally feed on the leaves and shoots of shrubs, which enables them to thrive in semiarid scrublands and mountains. Traditionally, goats in the developing regions are free-range or are herded communally with little management care, including veterinary care, nutrition, and breeding. Household/personal herds may contain as few as three breeding does, with an average of between five and eight in tropical and subtropical Africa. Commercial herds in Namibia and other regions of southern Africa may number several hundred breeding does in a ratio of one buck to 25 does.

Meat Production Characteristics

General characteristics of goats favoring meat production are:

1. Females are early-maturing, highly prolific, and have good fecundity and mothering ability.
2. An extended breeding season is usual among goats in the tropics, and this is particularly advantageous to meat production.
3. Foraging preferences of goats cause them to graze a wider spectrum of plants than other small stock, which accounts for their ability to thrive in adverse conditions.
4. Foraging may account for relatively low parasite infestation.
5. Goats exploit available feed resources selectively, consuming material with sufficient digestible organic matter at or exceeding their maintenance needs, and their small size enables goats to utilize tropical shrub and shrub pastures more efficiently than cattle.
6. Goats are generally well adapted to hot environments, tolerating the extremes of desert conditions and high-temperature/humidity conditions of the tropics, because of their small size, large surface area to body weight ratio, an ability to conserve water, limited subcutaneous fat cover, and the particular nature of their coats.

Breeding and Performance Testing

Goats can be bred for carcass and meat characteristics by exploiting quantitative and qualitative gene effects. Performance testing as a means of improving productivity of meat goats was introduced in South Africa in 1970. The scheme provides for the performance testing and selection of goats specifically for meat production, according to five phases:

1. characteristics of the dam, her milk production and preweaning growth rate of her progeny
2. postweaning growth rate of progeny at various ages
3. feed conversion efficiency and body weight of male progeny under standardized conditions at a central testing station
4. postweaning growth rate of male progeny under standardized conditions:
   a. on a farm under direction of the Department of Agriculture and
   b. at a central location of a cooperative institution, also under the auspices of the department
5. qualitative and quantitative evaluation of the progeny of a buck

Nutrition and Growth

Well-nourished livestock have a high tolerance to parasites and disease, exhibit good fecundity with low mortalities, grow well, and generally thrive. Nutrient requirements of goats are determined by their physiological state. Specific information can be

obtained from the recommendations of the US National Research Council on the nutrient requirements of goats. Growth rate is an important criterion for efficiency in commercial meat production and is determined by the animal's genetic growth potential, nutrition, and health. Generally, goats do not have a high growth rate, compared with lambs. West African dwarf goats have growth rates of 10–30 g day^{-1} on variable-quality tropical grasses. Poor-quality tropical grasses (e.g., *Gliricidia sepium*) supplemented with a legume (*Leucaena leucocephala*) would improve the growth rate up to 46 g day^{-1}; a concentrate supplement could improve growth further to 70 g day^{-1}. Goat kids, adequately supplemented with small quantities of essential nutrients, will perform equally well on feeds with a low digestibility compared to other animals on forages with higher digestibility. Under favorable conditions, Boer goats may gain weight at more than 200 g day^{-1}. When protein intake is increased above that required for maintenance and growth, puberty and fertility can be achieved at an earlier age in young growing male kids.

Fertility

The good fertility, mothering ability, and extended breeding season of does in the tropics and subtropics permits mating twice per year or three times per 2 years. Thus, the number of kids per doe can be increased dramatically. Twins are more the rule than the exception. Sexual activity of bucks is greatest from sunset to midday. An apparent decline in male libido in spring and summer needs to be taken into account when twice-yearly breeding is practiced.

Angora goats and goats originating from the tropics have limited breeding seasons. In general, small ruminants in Africa are year-round breeders and, as a result, lamb or kid all year round except where a specific management system so dictates. The techniques of caprine embryo transfer, embryo freezing, embryo splitting, sex determination, *in vitro*, and caprine nuclear transfer have all been successful.

Goat Management

Animal productivity is improved by applying even the most basic management practices: herding as opposed to free-ranging, penning at night, removing unproductive animals from the herd, and controlled breeding. More sophisticated management practices, including nutrition supplementation and veterinary care, although yielding high dividends, require additional expenses that may be beyond the reach of subsistence farmers. In these instances, subsidies and state services should be considered.

Carcass and Meat Quality Characteristics

Goats have carcass characteristics slightly different from those of sheep. Goat carcasses are generally lean in appearance, less compact than sheep, and of differing carcass proportions with less total tissue distributed to the hind leg than in sheep. Goats' meat is also different, being coarser-grained, with a detectable different flavor and aroma. Studies on chemical composition and meat quality have suggested that goat meat is not inferior to lamb, but may be darker red in color than lamb. Color of goat meat is important, especially in the case of Capretto carcasses, where flesh should be pale or pink.

Grading

Communicating the expected quality of meat to consumers in a reliable and effective way is important in merchandising meat. This is achieved by grouping carcasses within a series of like quality characteristics into distinct categories, taking into account:

1. physiological age differences due to young animals having more tender meat because of the greater solubility of the collagen in the connective tissue and older animals having a stronger flavor;
2. sex differences due to the coarser grain of males and the strong flavor of the buck's meat;
3. fat differences due to the quality and palatability fat imparts to the meat and the association between fat and meat yield;
4. conformational differences due to its commercial value in some markets and its predictive value, although limited, in determining yield.

Age has an influence on palatability, with the meat from older goats regarded as being juicier. Muscle color may be darker and fat color more yellow with increasing animal age.

Carcass quality generally refers to lean/fat content, conformation, and the extent of damage (bruising, abscesses, and parasite infection). Meat quality includes appearance, composition in terms of lean, fat, and connective tissue and, in commercially displayed cuts, bone content, pH, drip, palatability, nutritive values, ease of processing, and shelf-life.

Dressing Percentage

Carcass yield is an important production criterion and is expressed as the dressing percentage ([dressed carcass weight/live weight] $\times$ 100). However, since it expresses a ratio of live weight to carcass weight and many factors influence these fractions (e.g., alimentary tract size and fill, slaughtering procedures, fleece or skin mass, distribution of body fat, and secondary sex characteristics), the dressing percentage must be

interpreted carefully and comparisons made within species, within breed types, and within slaughtering procedures. The dressing percentage of goats varies between 40% in very young animals and 56% in entire mature males. In regions where body components (head, organs, intestine, and skin) are prized and regarded as part of the carcass, the dressing percentage ranges between 66 and 82%. The dressing percentage increases with age, mass, and fatness, and is a consequence of increasing metabolizable energy per kilogram dry matter (ME kg^{-1} DM) in the ration.

Muscle

Muscle-to-bone ratio Goat carcasses have a higher muscle-to-bone ratio than is apparent from their conformation. A greater carcass and leg length results in a less compact carcass, which may be interpreted erroneously as signifying poor muscling. In addition, goats have less total muscle distributed to the leg and more to the forequarter than sheep. This is illustrated by the muscle distribution of castrated male Boer goats and South African Mutton Merino wether lambs, respectively: forelimb 17.3 and 16.2%; neck 9.3 and 8.3%; ventral trunk 25.8 and 20.9%; dorsal trunk 19.3 and 20.6% and hindlimb 28.4 and 34.1%. (*See* **Meat**: Structure.)

pH Goat muscle contains both aerobic (red) and anaerobic (white) muscle fibers and undergoes the same postmortem biochemical changes as beef and mutton. The decline of goat muscle pH follows a pattern typical of red meat carcasses to stabilize at around pH 5.4. Variations occur due to differences between muscles, sexes, and premortem stress. Exhaustive premortem stress yields dark, firm, and dry meat with a high ultimate pH (pH > 6.0). Postmortem biochemical changes are associated with the loss of water-binding capacity as the pH reaches the isoelectric point of the muscle proteins, the onset of rigor mortis, and the release and activation of proteolytic enzymes, notably cathepsins, responsible for the ripening of meat.

Collagen Goat muscle fibers are thicker and the fiber bundles larger than those of sheep, giving goats' meat a characteristic coarser grain. The attributed toughness of goat has been ascribed to the marketing of mature animals, in which the collagen in the connective tissue has a decreased ability to gelatinize under the influence of heat and moisture. Several studies have indicated that goats' meat is inherently less tender than that of sheep. Muscles of male Boer goat kids have a higher collagen content with lower collagen solubility than those of male lambs of four sheep breeds. Lambs and mutton are more tender with less fibrous tissue residue and a more intense aroma than Angora and Boer goat meat. The species' flavor is also more pronounced. Goat breeds may also differ in their meat quality: meat of Angora goats has a more acceptable flavor and is more tender with less residue than meat of Boer goats, which could be explained by the lower collagen content and slightly better collagen solubility. Evaluation of collagen alone, however, would be insufficient for conclusions on differences in tenderness. Other factors may be involved, especially muscle fiber size, the type of matrix formed by collagen, and the state of muscle contraction.

Electrical stimulation Goat carcasses, having a poor insulating subcutaneous fat cover, are susceptible to muscle toughening through the effects of cold shortening. Cold shortening can be countered by electrically stimulating the carcasses immediately after slaughter. Electrical stimulation increases the rate of postmortem glycolysis, depleting the adenosine triphosphate (ATP) energy source for muscle contraction due to the anaerobic state. The residual contractile properties of muscle are reduced, rigor mortis is advanced, and the enzymes associated with the conditioning of meat are activated. Electrical stimulation of goat carcasses, as with beef, can improve meat tenderness and facilitate accelerated processing of carcasses by hot boning, preferably after a 2-h conditioning period, with no detrimental effect on total bacterial count, tenderness, or cooking loss. Advantages of hot boning are a reduced mass loss in chillers, less carcass chiller space required, and faster throughput and packaging of the meat. (*See* **Meat**: Slaughter.)

Nutrient value Muscle contains the most important quality parameters and nutrient value of meat. Goat muscle is highly nutritious with a high biological value. The percentage moisture in raw, lean tissue ranges between 74 and 76%. Protein, fat, and ash contents are, respectively, 20.6–22.3, 0.6–2.6, and 1.0–1.1%. The essential amino acids determined in the proteins (mg g^{-1}) are arginine (74), histidine (21), isoleucine (51), leucine (84), lysine (75), methionine (27), phenylalanine (35), threonine (48), tryptophan (15), and valine (54). (*See* **Amino Acids**: Metabolism.)

The most important minerals in the muscle and organs of male cross-bred goats are shown in Table 1. Red meat is an excellent source of iron: heme iron is 5–10% as available as nonheme iron. A value of around 2.1 mg g^{-1} reported for lean goat meat from Malaysia compares favorably with values for separable lean beef (2.72 mg g^{-1}), lamb (1.74 mg g^{-1}), and veal (1.11 mg g^{-1}). Refer to individual minerals.

The contents of the vitamins thiamin, riboflavin, and niacin in lean goats' meat compare well with

those of lean beef and lamb, as shown in Table 2. (*See* **Niacin**: Physiology; **Riboflavin**: Physiology; **Thiamin**: Physiology.)

The average biological value of goats' meat, based on feeding trials with rats fed a 10% level of protein, is 60.4 and beef 68.6. The digestibility coefficient of meat protein is 97%, giving ingested meat a heat combustion of 17.87 J g^{-1}. The effect of cooking on muscle is method-, time-, and temperature-dependent and the response of muscles to heat treatment varies between muscles and according to pre- and postmortem influences. Generally, temperatures below 100 °C affect palatability, but do not reduce the nutritive value of meat severely. (*See* **Protein**: Quality.)

Fat

Goat carcasses characteristically have a low proportion of subcutaneous fat and a high proportion of intermuscular fat, giving goat carcasses a lean appearance. In terms of total body fat, goats are not necessarily leaner than sheep. At the same degree of total body fatness (21% of empty body weight), dressed Boer goat carcasses recorded 22% carcass fat with 6.7% in the subcutaneous fat depot, while Dorper and South African Mutton Merino carcasses were both 24% fat, with 12.7% and 10.4% subcutaneous fat, respectively. The comparatively poor fat covering of goat carcasses means that the criterion of subcutaneous fatness, which is a reliable predictor of yield in lamb and mutton carcasses, is not suitable for classifying and grading goat carcasses. Lipogenesis occurs in a preferential order between the adipose depots. Visceral fat (omental, mesenteric, kidney, and pericardial) is the earlier-developing depot followed by intermuscular, subcutaneous, and intramuscular fat.

Carcass fat is highly variable and easily influenced by:

1. Sex – males are leaner than females and castrated males.
2. Nutrition – the greater the metabolizable energy intake (ME kg^{-1} DM), the fatter the carcass.
3. Age – increasing fatness to maturity is a phenomenon of normal growth in all sexes.
4. Physiological condition – lactating does will catabolize body fat reserves and become leaner; disease and stressful conditions reduce appetite, causing body reserves to be drawn upon.
5. Physical activity – physical activity, such as foraging or when determining social ranking, increases energy usage, yielding leaner carcasses; penned animals fatten more easily, yielding fatter carcasses.

Fat quality Fat remains an important quality determinant of carcasses and meat. The chemical and physical properties of fat have no direct effect on the commercial value of carcasses, as does fatness, but do influence the organoleptic properties and keeping quality of meat. The degree of saturation of fat, expressed as the iodine number and determined by the number of double bonds in the component fatty acids, is one of the most important characteristics affecting these quality parameters. Saturated fats containing long-chain fatty acids with no or very few double bonds solidify easily upon cooling, thus affecting the palatability of the meat. The less

saturated fats containing a greater number of fatty acids with double bonds are easily oxidized, either by direct chemical action or through intermediary activity of lipolytic enzymes. Direct chemical oxidation is less important in meat than the action of lipases that split fatty acids from triacylglycerols. The rate of autoxidation increases with the number of double bonds, increasing the probability of affecting the flavor and odor of the meat. Chemical oxidation releases peroxides with free radicals (ROO•—, RO•—, OH•—) which may react to damage proteins, enzymes, other lipids, and vitamins. In goat meat, as with other red meat with low lipid- to heme ratios, heme compounds can stabilize peroxides of free radicals and exert an antioxidant effect.

The profile of the long-chain acids of goat meat show oleic acid ($C_{18:1}$) to be the most abundant, with palmitic ($C_{14.0}$) and stearic acids ($C_{18.0}$) being relatively high. Nutritional influences on the fatty acid profile of ruminants are less than on monogastric animals, owing to the biohydrogenation and synthesis of fatty acids in the rumen. It would appear, however, that nutrition could cause subtle changes in ruminants, including goats. The high variance of each fatty acid in kids could be ascribed to the monogastric characteristic of suckling animals, which would be sensitive to nutritional influences.

Visceral fats are more saturated than subcutaneous fats, as is illustrated in the differences between the fatty acids of the subcutaneous and kidney depots. The unsaturated-to-saturated ratio in the subcutaneous fat of goats was 1.11 and of sheep 0.67. Fat from the triceps brachii, biceps femoris, and obliquus internus abdominus muscles of Korean goats contained 55.2–59.6% $C_{18:1}$ and 24.5–25.6% $C_{16:0}$. Unsaturated fatty acids predominated, ranging from 68.5 to 72.3%. Oleic acid levels were slightly higher in the subcutaneous, intermuscular, and kidney fats of Sudanese goats than sheep. Comparing iodine numbers within and between species could be misleading owing to the range of fatty acids occurring in the fat and the exogenous and endogenous influences on the fatty acid profiles. Fatty acids, particularly C_{18} and $C_{18:3}$, influence the flavor of lamb and both 4-methyloctanoic and 4-methylnonanoic acids appear to contribute to the odor of mutton and goats' meat.

Nutrient value Lipids, although recommended to constitute a smaller proportion of the western diet, are an essential nutrient source component in all human foods. In dispute is not whether lipids, including animal fat (triacylglycerols), are a health threat, but the extent to which specific fatty acids, the amount ingested as a proportion of total energy intake or cholesterol, constitute a health threat, in general. Energy-dense triacylglycerols provide readily metabolizable energy. Excessive energy consumption beyond the body's needs for a given physiological state leads to obesity and related health risks. Linoleic ($C_{18:2}$), linolenic ($C_{18:3}$) and arachidonic acid ($C_{20:4}$) acids, constituents of cell walls, mitochondria, and other active metabolic sites, are regarded as essential in the diet since the body cannot synthesize these long-chain polyunsaturates. (*See* **Fatty Acids**: Dietary Importance.)

Fatty acids appear to be closely associated with the body's immune response system. Excessive consumption of dietary fats rich in ω-6 polyunsaturated fatty acids have been shown to possess immunosuppressive properties, influencing immune function in disease, whereas ω-3 polyunsaturated fatty acids have both an antiinflammatory effect and reduce immunosuppressive properties. Goat fats have low ω-6 and ω-9 polyunsaturated fatty acids.

Cooking Normal cooking changes the composition of animal fat and increases the concentration as an energy source. Mass reduction can be 20–35%, of which 70–80% is lipid cookout. Fatty tissue of cooked meat is typically about three times as concentrated a source of energy as is cooked lean tissue, with variances between cuts. Prolonged cooking leads to rendering in which a very high percentage of fat cookout is obtained.

Processing

Traditionally, meat processing is a means of extending shelf-life (preserving) and producing a convenient item for use later and elsewhere. Processing is aimed at reducing the enzyme activity in the meat, retarding oxidation of the fat, and preventing spoilage by microorganisms. These aims have been achieved through drying, curing with salts, or smoking meat. Sausage manufacturing, for which meat is ground to varying degrees, is another form of processing, in principle for the same purpose. Either one or a combination of these procedures in various regions of the world has preserved goats' meat. (*See* **Meat**: Preservation.)

In modern times, meat is processed not only as a means of preserving, but also for producing consumer-acceptable products compatible with modern lifestyles and philosophy of a health-related quality of life. In order to achieve this the processor has to define clearly the image and commercial appeal of the envisaged product. The decision-making process of the consumer needs to be defined in terms of real and perceived value, the convenience the product offers, and its palatability.

Goat meat, regardless of breed, can be used to manufacture processed products of acceptable sensory quality, particularly when a spicy formulation is used. The low appeal of goat meat to some consumers may be due to its lack of tenderness, particularly in meat from older animals. Tenderness should not be a problem for comminuted meat products (e.g., patties) or products that undergo slow cooking or pressure cooking/retorting (e.g., curries and stews). Although goat meat has a less desirable flavor, aroma, tenderness, and juiciness than beef or pork to western taste panelists, a panel found up to 40% substitution of beef by Angora goat meat to be quite acceptable in frankfurters. The goat frankfurters had good physical attributes, being firm, resilient, and springy under forefinger pressure with a firm 'bite' – a desirable textural attribute in quality emulsified sausages. Such frankfurters would maintain their form and shape during peeling, indexing, and packaging operations. (*See* **Meat:** Sausages and Comminuted Products.)

Vienna sausages manufactured from meat of mature does (six teeth) had detectable different palatability characteristics compared with viennas manufactured from beef. The goat viennas also recorded higher shear force values ($P < 0.0002$). Differences in both physical and textural attributes could be related back to the characteristics of the raw meat. Cured and smoked buttocks of mature does (six teeth), compared with cured and smoked beef silverside (two teeth), received higher ratings ($P < 0.01$) in terms of aroma, tenderness, juiciness, and tastiness. No difference in residue could be detected.

Overall, the goat was rated 3.54 with a standard deviation of 0.6 on a scale of 0–5, as opposed to the 2.96 ± 0.97 rating of beef. The results suggest that smoked and cured goat buttock or leg of goat has the potential of being a delicacy and could compete comfortably with other products such as smoked beef and pork gammon.

Processing hot muscle holds decided advantages. Prerigor muscle has a higher water-holding capacity, better fat-emulsifying properties, and produces sausages with less moisture loss and rendering out when cooked. Patties manufactured from hot goat meat (3–4 h postmortem), not electrically stimulated, had lower cooking yields ($P < 0.05$) than patties prepared from chilled meat (24 h postmortem). However, reducing the postmortem time lapse to processing to 1–2 h improved the yield. The organoleptic scores of patties broiled in an oven at 190 °C for 15 min to an internal temperature of 72 ± 2 °C were similar for hot and chilled meat. Reheating precooked, frozen patties reduced sensory scores significantly ($P < 0.05$). The fat content of patties has a significant influence on cooking loss and flavor, texture, and overall acceptability. According to sensory scores a 20% fat content would be the optimum. The quality of warm minced goat meat (3 h postmortem) could be improved by addition of 2.5% sodium chloride and 1% tetrasodium pyrophosphate. These salts resulted in a significant increase in pH, water-holding capacity, and water-soluble proteins, and a decrease in cooking loss and improved redness and overall appearance. The effects on the emulsifying capacity and salt-soluble protein concentration were also significant. Indications are that bacterial growth can be inhibited by treatment with ammonia added at a concentration of 0.402–0.67 mol l^{-1}. The effect was more pronounced on Gram-positive bacteria. (*See* **Sensory Evaluation:** Texture; Taste.)

Milk

M Guo, University of Vermont, Burlington, VT, USA

Introduction

More people drink goats' milk than the milk of any other species on this planet, although goats' milk production ranks third after bovine and buffalo milk. Dairy goat farming plays an important role in the diet and economy of many developing countries. Goats' milk provides one of the principal sources of animal protein, calcium, and phosphorus in many regions, such as the Middle East, southern Asia, and some tropical countries. It also serves as an appropriate substitute for cows' milk and is often recommended by medical professionals in situations where bovine milk may cause allergic responses in consumers. Nevertheless, goats' milk products are considered specialty foods but becoming more popular in the USA and other developed countries. The goats' milk industry will continue to grow during the next decade.

The major breeds of dairy goats in Europe and North America are Saanen, Toggenburg, Alpine, La Mancha, Nubian, Oberhasli, and Angora. In the Middle East, Asia, and other regions, various native goats, crossbreeds, and pure imported goats are used for milk production. In this article, chemical, physiochemical, and nutritional properties of goats' milk and goats' milk product technology will be briefly discussed.

Gross Composition

Gross composition includes total solids (TS), fat, crude protein, lactose, and ash. The gross composition of goats' milk in comparison with cows' and human milk is shown in **Table 1**. The levels of TS, fat, crude protein, and ash in goats' milk are, on average, higher than those in cows' milk. The lactose content of goat's milk is 4.5%, i.e., slightly lower than cow's milk ($\sim$ 4.7%). The gross composition of milk is affected by many factors, including breed, individual animal, diet, yield, season, stage of lactation, environment, and management. Fat content is the most variable component in goats' milk, ranging from 2 to 8%. There is an inverse relationship between milk yield and the concentrations of fat, protein, nonfat solids, and ash in the milk. Fat, protein, and ash contents are high in the early stage of lactation, fall sharply to reach the lowest levels during summer months, and then increase gradually towards late lactation. Lactose content does not show considerable changes during lactation. The ash content of both goats' and cows' milk are three to four times higher than that of human milk in general, the ash content of milk is closely related to the growth rate of the species for which it was designed. An inverse relationship between lactose and ash is essential and exists to maintain the osmotic pressure of the milk.

Lipids

The lipids in goats' milk consist mainly of triacylglycerols (98% of total lipids), phospholipids (1%), and cholesterol and its esters (1%). The cream or butter of goats' milk is white in color as there is very little

Table 1 Gross composition of goats', cows', and human milk (g 100 ml^{-1})

C_{18}	13.0	13.7	7.3
$C_{18:1}$	25.2	27.1	35.3
$C_{18:2}$	2.9	3.0	6.7

β-carotene in the milk. Like cows' milk, goats' milk lipids also exist in the form of globules. The average size of the fat globules in goats' milk (2 μm in diameter) is smaller than the globules in cows' milk (3 μm) and buffalo milk (5 μm). Goats' milk has a poor creaming ability at cooler temperatures due to its small fat globules and lack of agglutinin, a clustering agent which causes fat globules in milk to cluster upon cooling.

Goats' milk has a higher level of short-chain fatty acids (C_4–C_{12}) than cows' milk (Table 2): 15% of total fatty acid in goats' milk compared to 9% in cows' milk. Most of the short-chain fatty acids are esterified at the 3-position of glycerol while the longer chains are at 1 or 2 position. Lipases attack ester linkages of short-chain fatty acids more easily than those of longer ones. The level of free fatty acids in goats' milk is also higher than that in cows' milk. The short-chain free fatty acids, especially C_6 and C_8, are responsible for the specific 'goaty' flavor of goats' milk products. There is a strong positive correlation ($r = 0.83$) between the amount of free fatty acids and the goaty flavor score of the cheese made from goats' milk. Fatty acid composition is strongly affected by diet and stage of lactation. The fatty acid profile can be manipulated by feeding different fats. The concentration of essential fatty acids and conjugated linoleic acid (CLA) in goats' milk can be increased by feeding them with canola oil. The proportion of short-chain fatty acids (C_8–C_{14}) in goats' milk is lower, while that of $C_{18:0}$ and $C_{18:1}$ is higher due to does drawing on their body fat at the beginning of the lactation. The long-chain fatty acid profile of goats' milk is similar to that of cows' milk. The lipids of both goats' and cows' milk contain an adequate amount of essential fatty acids for human consumption. (*See* **Fats**: Classification.)

Goats' milk contains 30–40 mg phospholipids per 100 g milk or 8–10 mg g^{-1} fat. About 40% of total phospholipids in goats' milk is in the skim milk, with the remainder in the fat globule membrane. The cholesterol content of goats' milk is in the range of 10–20 mg 100 ml^{-1}. The cholesterol content in the colostrum of goats' milk is much greater (40 mg 100 ml^{-1}). Most of the cholesterol in goats' milk is in the free form, with only a small fraction in the form of esters.

Proteins

Goats' milk contains more crude protein, ranging from 3.0 to 3.8%, than cows' milk. In general, the protein profile of goats' milk is similar to that of cows' milk. However, goats' milk has a lower level of casein nitrogen and a higher level of nonprotein nitrogen than cows' milk. This is responsible for a low cheese yield and a weak yogurt structure/texture. The concentrations of amino acids in goats' milk are compared with those of cows' and human milks in Table 3. (*See* **Protein**: Food Sources.)

The five major proteins of goats' milk are α_{s2}-casein, β-casein, κ-casein, β-lactoglobulin, and α-lactalbumin. Sodium dodecyl sulfate-polyacrylamide gel electrophoretograms of goats' milk show that α_{s2}-casein is the slowest-moving of the three major casein bands, β-casein the major protein in the middle, and κ-casein migrates the fastest of the caseins (Figure 1, lanes 3 and 4). The amino acid compositions of these proteins is shown in Table 4. It was previously believed that goats' milk lacked a protein homologous to bovine α_{s1}-casein. However, recent studies have shown that this protein does exist in the milk of some goat's milk. The level of α_{s1}-casein affects the coagulation properties of the milk. β-Lactoglobulin (β-lg) and α-lactalbumin (α-la) are the

two major whey proteins of goats' milk (Figure 1, lanes 3 and 4).

β-Casein is quantitatively the major component in the casein fraction of goats' milk. It consists of 213 amino acid residues, compared to 209 amino acid residues in bovine β-casein. Goats' κ-casein is a chain of 171 amino acid residues instead of 169 for its bovine counterpart due to valine and histidine being inserted at positions 132 and 133. Like the bovine homolog, goats' κ-casein has phenylalanine at position 105 and methionine in 106. Therefore, chymosin can hydrolyze the molecule between these two residues producing, *para*-κ-casein and caseinomacropeptides. This process leads to rennet-induced coagulation during cheese-making. Goat α_{s2}-casein differs from its bovine counterpart in that it contains a chain of 217 amino acid residues instead of 207.

Goat β-lg, like its bovine homolog, consists of a polypeptide chain of 162 amino acid residues. Like bovine milk, goats' α-la is a chain of 123 amino acid residues. (*See* **Amino Acids:** Properties and Occurrence.)

Like bovine milk, the casein in goats' milk exists as micelles. The majority of goat casein micelles are less than 80 nm in diameter, which is smaller than the casein micelles (120 nm in diameter) in cows' milk. The proportions of small micelles is much greater than in cows' milk. The stability, especially alcohol stability, of casein micelles in goats' milk appears to be lower than those in cows' milk.

Carbohydrates

Lactose is the major carbohydrate in goats' milk. The content of lactose in normal goats' milk is about 130 mmol l^{-1}, or in the range of 4.2–4.8%. This is slightly lower than the level in cows' milk. Other minor carbohydrates in goats' milk include inositol (7 mg 100 ml^{-1}), and trace amounts of galactose and sialic acid. (*See* **Lactose.**)

Minerals

The mineral contents of goats' milk is compared with that in cows' and human milk in Table 5. Goats' milk contains about 133 mg calcium and 100 mg phosphorus per 100 ml. Human milk contains only about 16–25% of these concentrations. Goats' milk has a higher content of calcium, phosphorus, potassium, magnesium, and chlorine and a lower level of sodium than cows' milk. Unlike the major minerals, the concentrations of trace elements in goats' milk are affected by diet, breed, individual animals, and stage of lactation. Goat colostrum has two to four times as much iron (Fe), copper (Cu), manganese (Mn), and zinc (Zn) than mature milk. Most milks, including human milk, are deficient in Fe. Mature fresh goats' milk has about 0.07 mg Fe per 100 ml (Table 4) and the zinc content is the highest among the trace elements, at 0.56 mg per 100 ml. Goats' milk generally contains more Mg, and lower or comparable levels of iodine (I) and Cu than cows' milk. (*See* **Minerals – Dietary Importance.**)

Vitamins

Goats' milk contains a higher level of vitamin A than cows' milk due to the fact that goats convert all

Table 5 Mineral concentrations in goats', cows', and human milks (per 100 ml)

Minerals	*Goat*	*Cow*	*Human*

carotenes into vitamin A, which gives the milk a whitish color. Goats' milk supplies adequate amounts of vitamin A and niacin, and excesses of thiamin, riboflavin, and pantothenate for human infants (Table 6). Both goats' and cows' milk are equally deficient in vitamin C and D; therefore, these vitamins must be supplemented with other food sources. Goats' milk contains only 20% as much folic acid as cows' milk. The bioavailability of folic acid in goats' milk is also lower than that in cows' or human milk, so goats' milk must be fortified with folic acid for infant feeding in order to prevent infants from getting anemia. (*See* **Vitamins**: Overview.)

Physiochemical Properties

The pH of goats' milk is somewhat lower than that of cows' milk, with values ranging from 6.3 to 6.7. The average pH of goats' milk is about 6.5, compared with 6.7 for cows' milk. The titratable acidity of goats' milk is 0.15%, expressed as a lactic acid, which is slightly lower than that of cows' milk (0.16%).

The osmolality of goats' milk is about 295 mosmol kg^{-1} H_2O. The freezing point of goats' milk is -0.580, compared with -0.540 for cows' milk, indicating that the former contains a higher level of solute constituents, such as salts, than the latter.

The average electrical conductivity of goats' milk is 0.0052 $\Omega\,cm^{-1}$, which is slightly greater than that of cows' milk (0.0048 $\Omega\,cm^{-1}$). The refractive index of goats' milk lies midway between those of cows' and buffalos' milk, in a range of 1.3454–1.3492 at 40 °C.

The surface tension of goats' milk is similar to that of cows' milk, with values ranging from 40 to 55 dyn cm^{-1}, which is much less than water (72 dyn cm^{-1}). The viscosity of goats' milk is about 13 mPa, which is slightly lower than that of cows' milk (15 mPa).

Like milk from other species, goats' milk has a rather wide range of specific gravity – 1.026–1.042. The relationship between percentage of TS and specific gravity (SG) and fat (F) content for goats' milk has been reported by the author's research group as follows:

$$TS = 0.13SG + 1.41F + 4.28 (r^2 = 0.94, P < 0.01)$$

Nutritional Properties

In general, there is little difference in nutritional value between goats' and cows' milk since the chemical composition of both milks is very similar. A randomized double-blind clinical study on the growth of undernourished children using goats' milk as a substitute for cows' milk showed that goats' milk has a nutritional value similar to that of cows' milk.

Goat's, cows', and human milk provide approximately the same amount of energy: each furnishes about 3135 kJ of energy per liter. The outstanding difference is in the proportions of energy derived from lactose and protein. In goats' and cows' milk, fat, protein, and lactose account for about 50, 25, and 25% of the energy, respectively, but in human milk they furnish 55, 7, and 38%, respectively.

A human infant fed solely on goats' milk is oversupplied with protein in relation to calories. In terms of protein quality, profiles for human and cows' milk proteins are similar to those of goats' milk. The three milks differ in the proportions and kind of proteins, but the overall amino acid composition of the mixture of proteins is similar in all three. All three have a satisfactory balance of essential amino acids, meeting or exceeding the Food and Agriculture Organization – World Health Organization requirements for each amino acid.

Both goats' and cows' milk contain adequate concentrations of essential fatty acids (e.g., linoleic acid) for human infants. In either of these milks, linoleic acid provides about 1% of the total calories. The fat in goats' milk has been reported to be more easily

digested than that of cows' milk because the fat globules are smaller in goats' milk. However, there is no scientific evidence to confirm this claim. Nearly 20% of the fatty acids of goats' milk fat are in the category of short- and medium-chain length (4–12 carbons). Cows' milk fat contains only about 12% of fatty acids in this category. This difference may contribute to a greater ease in the digestion of goats' milk fat as lipase attacks ester linkages of such fatty acids more readily than those of longer chains.

One of the most important contributions of milk to human nutrition is the supply of calcium and phosphate. Goats' milk contains about 120 mg 100 ml^{-1} or 300 mg per serving of Ca, and 100 mg 100 ml^{-1} or 250 mg per serving of P. These concentrations are similar to those in cows' milk. Human milk contains much lower levels of these minerals, with only about 25% as much calcium and ~15% as much phosphorus. Therefore, goats' milk provides an excess of calcium and phosphorus in relation to energy for human infants. Most milks, including goats' milk as well as human and cows' milk, are deficient in iron. Iron is absorbed and poorly retained from most food sources. This metal is absorbed better from human milk than from cows' milk due to a higher level of lactoferrin in human milk. It should be noted that both goats' and cows' milks contain higher concentrations of potassium and chloride than human milk. These milks should be diluted before feeding to human infants in order to prevent the onset of acidosis.

Goats' Milk Products

Traditionally, goats' milk was produced on small farms for home consumption more economically than cows' milk. However, nowadays, fresh goats' milk is sold pasteurized in a variety of packaging in supermarkets and health food stores in the USA. Yogurt, icecream, cheese, and powdered milk are also considered to be specialty products in many western countries.

Pasteurized and homogenized goats' milk products are available in US markets, including 2% fat and whole milk, with or without fortification of vitamins A and D.

Yogurt and other fermented milks have been made from goats' milk for centuries. Yogurt products have been shown to be effective in the prevention and treatment of gastrointestinal disorders, such as diarrhea and infantile gastroenteritis, due to the antimicrobial activities of probiotic cultures in the gut. Yogurt and other fermented milks are also reported to have other health benefits, including blood cholesterol reduction and possible cancer prevention. Goats' milk yogurt can be made in a similar manner to cows' milk yogurt. Because of the low casein content in goats' milk, the most realistic and economical approach for the production of goats' milk yogurt with good texture and consistency is through fortification of goats' milk with milk powder and/or stabilizers. A probiotic goats' milk yogurt with improved texture by enzymatic cross-linking has been developed in the author's laboratory at the University of Vermont. Goats' milk is also suitable for the production of other functional fermented products, such as kefir and dietary supplements, e.g., *Lactobacillus acidophilus* capsules or tablets.

Goats' milk icecream is being produced by a number of small companies, in both the USA and other countries. Because goats' milk products are considerably more expensive than comparable cows' milk products, premium icecream is warranted in order to attract consumers. A premium icecream should contain a high fat-to-milk solids nonfat (MSNF) ratio. A typical premium goats' milk icecream mix usually contains 14% fat, 10% MSNF, 18% sweetener, 1.5% egg yolk solids, and 0.25% stabilizer-emulsifier.

Over 400 varieties of goats' milk cheese are listed in the *Agricultural Handbook* of the US Department of Agriculture (No. 54–4). The large number of varieties of cheese made from goats' milk have resulted in a great diversity in the nature of the products. The most important cheeses made from goats' milk include fresh cheeses (chèvre), ripened cheeses (Cheddar, Gouda, and Roquefort), and others such as whey cheese (ricotta). France offers the best goats' milk cheeses, many of which are surface-ripened. The chemical composition of some commercial goats' milk cheeses manufactured in the USA is shown in Table 7.

Other commercial goats' milk products, such as powdered milk, butter (also called ghee in India), and evaporated milk are also being produced commercially in the USA and other countries. The manufacturing

Table 7 Composition of selected commercial goats' milk cheeses in the USA

Nutrients	*Fresh soft*	*Feta*	*Cheddar*	*Shepherd's hard*

GOITROGENS AND ANTITHYROID COMPOUNDS

J Vanderpas, Faculté Médecine, FUNDP, Namur, Belgium

Biochemistry of Thyroid Function and Environmental Factors

Besides iodine deficiency, certain environmental agents, both naturally occurring and synthetic, interfere with thyroid function. They may cause goiter and thyroid dysfunction by acting directly on the thyroid gland or indirectly by altering its regulatory mechanisms and thyroid hormone homeostasis. They are thus called goitrogens or antithyroid compounds, according to their main effect on thyroid volume or on thyroid hormone metabolism.

Figure 1 shows some of the principal steps in thyroid hormone synthesis, secretion, and metabolism which can be influenced by environmental goitrogens. The unique known function of iodine in mammals is its role in the synthesis of thyroid hormones. The uptake of iodide by the thyroid gland is stimulated by the pituitary hormone thyroid-stimulating hormone or thyrotropin (TSH), and its serum concentration can be multiplied > 100 times in some extreme environmental conditions of iodine deficiency and goitrogen toxicity. Some goitrogens, such as thiocyanate and isothiocyanate, interfere with iodide uptake.

After being concentrated by the thyroid gland, iodide is oxidized and bound to some specific tyrosyl residues of thyroglobulin, forming monoiodotyrosine (MIT) and diiodotyrosine (DIT); oxidation of iodide and iodination of selected tyrosyl residues is catalyzed by a heme-containing membrane-bound enzyme, thyroperoxidase (TPO). The same enzyme couples two iodotyrosines to form thyroxine (T_4; four iodine atoms) and triiodothyronine (T_3; three iodine atoms). The ratio of T_4 to T_3 in thyroglobulin is closely dependent on serum TSH concentration and iodine supply: in euthyroidism (normal healthy function of the thyroid gland), 85% of the hormonal content of the thyroid is represented by T_4, while in the hypothyroid state, the ratio of T_4:T_3 within the thyroid is closer to unity. Most of the goitrogens (phenol derivatives, dihydrobenzoic acid, flavonoids, goitrin, disulfides, polycyclic aromatic hydrocarbons, excess iodine) interfere with TPO activity.

Intrathyroid proteolysis of thyroglobulin results in the release of T_4 and T_3 in the systemic circulation; this step is inhibited by lithium and excess iodine. Secreted

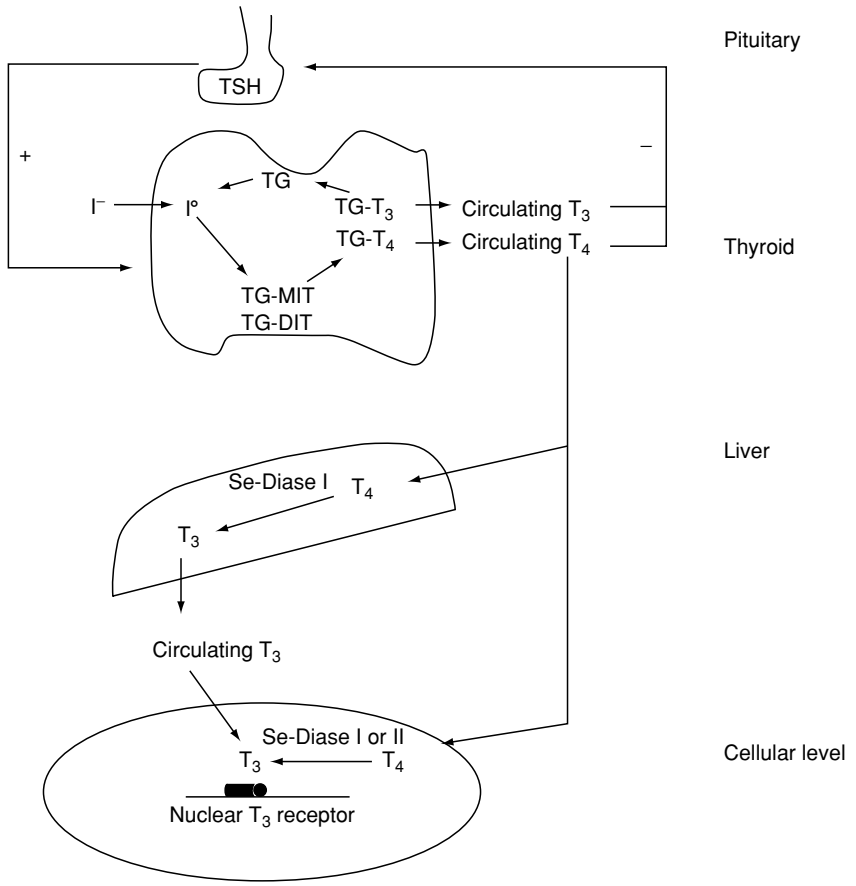

Figure 1 Some metabolic steps in iodine metabolism. Pituitary thyrotropin (TSH) stimulates thyroid iodide (I^-) uptake, and enzymatic organification of iodine (I°) by thyroperoxidase (TPO) in mono- and diiodotyrosine (MIT and DIT) which are further coupled by the same enzyme TPO in tri- and tetraiodothyronine (T_3 and T_4). Part of T_4 is further deiodinated to T_3 in the liver by a selenium-containing enzyme selenium-dependent deiodinase I (Se-Diase I). At the cellular level, the active hormone is T_3, which binds to a specific nuclear T_3 receptor. T_3 comes directly from circulating serum T_3 or from intracellular conversion of T_4 to T_3 TG, thyroglobulin.

in the systemic circulation, serum T_4 and T_3 are bound to albumin, thyroxine-binding globulin and transthyretin (also named thyroxine-binding prealbumin). The binding of thyroid hormones to serum proteins is partly inhibited by flavonoids, resulting in alterations of circulating free hormone concentrations and adaptation of feedback regulation. At the cellular level, the prohormone T_4 is deiodinated to the active hormone T_3 by the action of deiodinases; all three isoforms of deiodinases are selenium-containing enzymes. The type 1 deiodinase is abundant in peripheral tissues like liver, kidney, heart, muscle, thyroid; the type 2 deiodinase is the predominant form in the central nervous system. (*See* **Hormones**: Thyroid Hormones; **Iodine**: Physiology; Iodine-deficiency Disorders.)

Iodine Excess

Since the first descriptions of efficiency of iodine supplementation on goiter in 1820, adverse effects of iodine have been observed.

Currently, a number of drugs have a large iodine content with a very slow metabolism. For example, amiodarone is a very common antiarrhythmic drug, and the usual 200-mg tablet contains 75 mg iodine in an organic form, of which 6 mg is released every day as free iodine; as the molecule is highly liposoluble, excess iodine persists for months after therapy cessation. Other compounds rich in iodine are some X-ray contrast agents, expectorants made from potassium iodide (Quadrinal), and skin disinfectants such as povidone-iodine (Isobetadine). Maternal contamination with povidone-iodine has been documented as a cause of neonatal hypothyroidism.

Some goiter endemias result from iodine in excess in the environment, e.g., ingestion of iodine-rich seaweed in Hokkaido, Japan, or ingestion of water contaminated with iodine in Shanxi province, China (Table 1). An excess intake of iodine, defined as 2 mg or more daily, inhibits the proteolysis and release of thyroid hormones and eventually produces hypothyroidism.

Table 1 Goiter endemias attributed to goitrogens in foodstuffs or to inadequate supply of trace elements

Cause	*Country*	*Source*	*Active compound*
Goitrogens in foodstuffs	Central Africa	Cassava	Cyanogenic glucoside
	Nigeria	Cassava	Cyanogenic glucoside
	Darfur, Sudan	Millet	Flavonoids
			Cyanogenic glucoside
	Maranhao, Brazil	Babassu	?
		Mandioca	Cyanogenic glucoside
	Tasmania	Grass and weeds	Isothiocyanate (cheilorine)
	Finland	Grass and weeds	Goitrin
	Cauca valley, Colombia	Water	Coal-derived water pollutants
	Eastern Kentucky, USA	Water	Coal-derived water pollutants
Inadequate supply of trace elements	Hokkaido, Japan	Seaweeds	Iodine overload
	Zaire	Soil	Selenium deficiency
	Himalayas	Water	Fluoride excess

Iodine excess in nonendemic areas involves in the short term a blockade of iodine organification in the thyroid gland (Wolff–Chaikoff effect); in most instances, there is an escape phenomenon after a few weeks, the thyroid hormonal parameters returning to normal. In a few subjects, a persistent dysthyroid function (hypothyroidism or hyperthryroidism) develops by a yet incompletely explained mechanism. The prevalence of chronic autoimmune thyroiditis in industrialized countries is correlated with iodine intake, with the highest prevalence in countries with the highest intake of iodine, such as the USA and Japan. Iodine supplementation in areas where iodine is deficient increases the prevalence of lymphocytic infiltration of the thyroid threefold, and the prevalence of positive serum tests for thyroid antibodies in such areas rises to over 40% within 0.5–5 years. Amiodarone-induced hypothyroidism usually occurs within 18 months, and is seven times more likely to develop in patients with thyroid antibodies than in those without thyroid antibodies.

Iodine-Induced Hyperthyroidism

Universal salt iodization was the World Health Organization plan for iodine-deficient-countries in Africa, Asia and South America which were previously known as endemic in 1990–91. The marked decrease in the prevalence of goiter during the following years was a striking confirmation of the effectiveness of universal salt iodization in Africa. Nevertheless, iodine-induced hyperthyroidism was clearly documented in two countries. A balance has to be reached between the desirable daily iodine supply necessary to prevent goiter ($> 100\,\mu g\,day^{-1}$) and excessive iodine ($> 400\,\mu g\,day^{-1}$). The risk of developing iodine-induced hyperthyroidism is small (< 1% in the general population); it has been impossible to obtain a precise incidence rate up to now; this incidence rate is increased in the subgroup of women over 40 years of age with long-standing, nodular, and potentially autonomous goiter. From experimental data, it is considered that autonomy of the gland results from a mutation of TSH-receptor in thyroid tissue, which renders the hormonal function independent of its control by TSH. As long as iodine deficiency is present, the multinodular goiter is functionally inefficient. With iodine supplement, the autonomous parts of the gland become active, and the patient develops hyperthyroidism (sometimes named Jod-Basedow hyperthyroidism). Even if the number of cases is low and the clinical signs are asymptomatic or moderate most of the time (profuse sweating, weight loss, increased appetite, ocular changes (upper-eyelid retraction), tachycardia, change of mood (hyperactivity, fatigability, anxiety)), some deaths occurred in relation to the introduction of universal salt iodization in Africa. It is likely that the problem is transient in public health terms, as the *primum movens* cause – presence in the population of autonomous thyroid gland due to iodine deficiency – will decrease with time.

Sulfur-Containing Compounds

Antithyroid sulfur-containing organics identified in vegetable foodstuffs can be divided into two categories according to the way they act on iodine metabolism: (1) thiocyanate and isothiocyanate-derived compounds primarily inhibit the active concentration mechanism of iodide, and their goitrogenic activity can be overcome by iodine administration; (2) goitrin (or 1,5-vinyl-2-thiooxazolidone) is analogous to thiourea in its action, interfering with the TPO organification process, and its action cannot usually be antagonized by iodine. (*See* **Plant Antinutritional Factors**: Detoxification.)

Thiocyanate and Isothiocyanate

Thiocyanate and cyanide do not occur in the intact plant as free anions. They result from the hydrolysis of a thioglucoside by specific enzymes such as the couple linamarine–linamarase in cassava when the roots are crushed. In most populations, crushed roots are detoxified by sinking a few days in river water, or by exposing to sun. In some Central Africa rural ethnic groups (such as Mbanza and Ngbaka from Northern Democratic Republic of Congo and Central Africa Republic), cassava is poorly detoxified, resulting in an elevated content of cyanide. This last anion is rapidly detoxified by sulfur-transferases (also named rodanese) in the liver and kidney (Figure 2).

The principal vegetables containing thioglucosides are kale, cabbage, sprouts, broccoli, kohlrabi, turnips, swedes, rapeseed, and mustard. The main vegetables containing cyanogenic glucosides are cassava, lima beans, linseed, bamboo shoots, and sweet potatoes. One of the most widespread mustard oils is allylisothiocyanate (CH2═CH—CH2—N═C═S), which is the principal mustard oil in cabbage.

The inhibitory action of thiocyanate on iodine uptake is due to a competitive effect of pseudohalide with the mechanism of iodide concentration. However, under experimental conditions, rather high plasma concentrations of thiocyanate are required for inhibiting iodine uptake by the thyroid gland. In the historical use of thiocyanate as a vasodilator in hypertension, administration of 3 g of thiocyanate results in serum levels in the range of 8.0–15.0 mg dl^{-1}, far exceeding the levels attained in populations exposed to environmental thiocyanate overload (around 2.0 mg dl^{-1}). In ethnic groups with the highest prevalence of goiter, cassava is not soaked; the roots are peeled, dried in the sun for 1 or 2 days, then bruised in a mortar with corn that has been steeped for 12–24 h in water. The flour is eaten as a gruel (fuku) prepared in boiling water. In other ethnic groups of Central Africa where goiter prevalence is lower, the roots of cassava are soaked for 2–6 days and then mashed into a purée which is simmered to form a paste of firm and elastic consistency. The paste is enveloped in a palm or banana leaf (chikwangue). The cassava leaves are ground and extensively boiled before consumption (mpondu). Table 2 shows the cyanide content of foods before preparation or ready to eat. Table 3 shows that thiocyanate overload in northern Democratic Republic of Congo is present at birth, resulting from the placental transfer of maternal serum thiocyanate. Thiocyanate is not present in excess in maternal milk as compared to a group of mothers not consuming cassava. Lack of thiocyanate overload associated with a stable iodine deficiency (mammary gland does not concentrate iodine in humans) could explain the relative mitigation of endemic hypothyroidism in infants of Ubangi during the breast-feeding period, and the deterioration of thyroid function after weaning which is chronologically associated with the introduction of cassava meals in food. Figure 3 shows the relationship of iodine

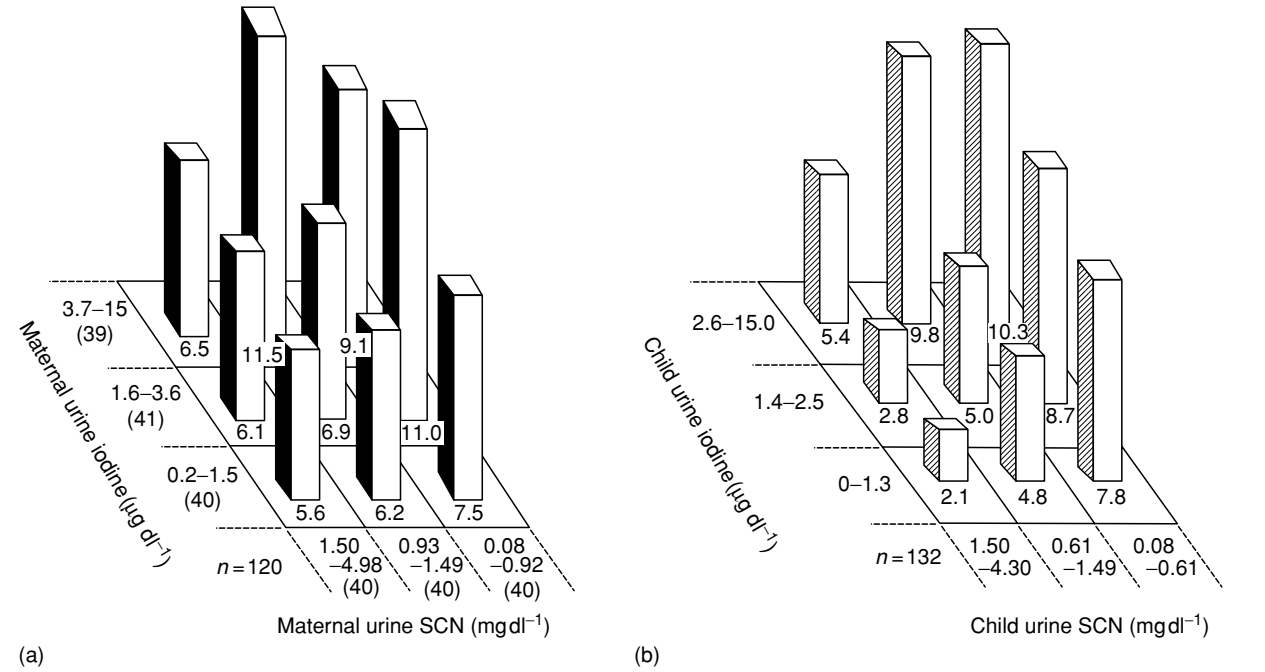

Figure 3 Level of serum thyroxine (T_4) in (a) newborn babies and (b) children aged 0–7 years according to the urine concentrations of iodine and thiocyanate (SCN). Reproduced from Goitrogens and Antithyroid Compounds, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

deficiency and of thiocyanate overload in neonates and in children of Ubangi, Democratic Republic of Congo, with mean serum T_4 concentration. At birth and during childhood, thiocyanate overload and iodine deficiency act in synergy to produce low serum T_4 concentrations. Once iodine deficiency has been corrected, the goitrogenic effect of thiocyanate is no longer present. (*See* **Cassava**: The Nature of the Tuber.)

Smoking

Tobacco smoking is another cause of thiocyanate overload. In a country with borderline iodine deficiency (Belgium), the risk of neonatal hypothyroidism seems to be higher in neonates from smoking mothers. Impaired action of thyroid hormone associated with smoking in women with hypothyroidism has also been shown: smoking was associated with greater serum TSH, total and low-density lipoprotein-cholesterol and creatine kinase concentrations, and prolonged ankle-reflex time. These effects suggest an interaction of smoking with thyroid hormone receptors, different from the effects of thiocyanate. (*See* **Smoking, Diet, and Health.**)

Goitrin and Aliphatic Disulfides

On enzyme hydrolysis, a particular thioglucoside gives rise to progoitrin, which is rapidly converted to form goitrin. Progoitrin is present in swedes and turnips. Administration of goitrin to rats for 20 days induces an enlargement of the thyroid, decreases iodine uptake by the gland, and decreases T_4 synthesis. Other sources of goitrin-like compounds have been detected in various species of herbs and shrubs of the Barbarea and Residea families.

The role of goitrin has been advocated in the development of endemic goiter in schoolchildren of Tasmania; this goiter could not be prevented by iodine supplementation. The endemia was attributed to a goitrogenic factor ingested by cattle from thousand-headed kale and transmitted by milk. However, only 0.05% of goitrin appears in the milk, and is rapidly denatured unless the milk is heated immediately. Goitrin has also been involved as an environmental goitrogen in Finland.

The major components of the volatile compounds from onion and garlic are small aliphatic disulfides which depress uptake of radioactive iodide by the thyroid of rats on a low-iodine diet. Disulfides are also present in high concentrations ($0.3–0.5\,g\,l^{-1}$) in aqueous effluents from coal-conversion processes; it is possible that these water contaminants intervene in the etiology of endemic goiter in the Cauca districts of Colombia.

Flavonoids

Flavonoids are a broadly distributed class of plant pigments, universally present in vascular plants.

They are not synthesized in animal tissues. Their number exceeds 3000 and new structures are reported at a rapid rate. All classes of flavonoids derive their carbon skeleton from cinnamic acid; chalcone is the first common intermediate. More than 1 g of various flavonoids is ingested daily in the western diet. (*See* **Colorants (Colourants)**: Properties and Determination of Natural Pigments.)

Since most flavonoids in foodstuffs are β-glucosides, they are not hydrolyzed by intestinal digestive enzymes and pass largely unaltered into the lower bowel. Microflora in the large intestine hydrolyze the flavonoid glucosides to their corresponding aglycone, and cleave the heterocyclic pyrane ring. Pharmacokinetic investigations in humans showed that 3% of an ingested dose of flavonoids (catechin) is absorbed, with peak plasma levels of 17 mg ml^{-1} after 1 h and biexponential disappearance from plasma with mean half-lives of 8.8 min and 2.4 h.

The effect of flavonoids on thyroid hormone metabolism was discovered in studies of several substances of plant origin, chemically different from ascorbic acid, which have been reported to be beneficial in the control of hemorrhage, and have been referred to as 'vitamin P.' The ability of flavonoids to induce goiter was suggested from many studies involving various plants, e.g., peanuts (arachidoside) and millet (vitexin, glucosylorientine). Millet flavonoids are potent inhibitors of iodine organification, and flavonoids and thiocyanate interact synergistically on organifying enzyme TPO. By their structural homology with thyroid hormones, the flavonoids interact with thyroid hormone transport, by displacing the hormone from their natural transporters in human serum (thyroxine-binding prealbumin and thyroxine-binding globulin).

In human populations, pearl millet (*Pennisetum americanum*) is the staple food for millions of people and livestock in Africa and Asia. Because of its perennial growth, it constitutes the main source of food energy for the very poor in the semiarid tropics. Pennisetum millet is very rich in polyphenols of the flavonoid type which inhibit TPO. Table 4 compares the dietary composition and goiter prevalence among schoolchildren in the Darfur province of western Sudan. The goiter prevalence is closely linked to the level of consumption of millet.

Table 4 Dietary composition and goiter prevalence among schoolchildren in Darfur province, western Sudan

Selenium Deficiency-Related Thyroid Dyshormonogenesis

Selenium is incorporated as selenocysteine in all three forms of deiodinases by a specific transfer ribonucleic acid (tRNA) at the cotranslational level, with a same anticodon as the tRNA binding to the amber stop codon, TGA. SECYS-tRNA in place of STOP-tRNA is incorporated in case of a stem-and-loop mRNA structure (SECYS-mRNA element) present on the transcribed mRNA. At least for deiodinase 1, the activity is reduced to 10% of the initial level when selenium is not incorporated. The presence, but not its catalytic function, is also demonstrated by molecular biology in deiodinases 2 and 3.

In iodine- (Figure 4) and selenium-deficient subjects of northern Democratic Republic of Congo, selenium supplementation in the absence of iodine supplementation involves a decrease of serum T_4 and of serum reverse T_3 concentrations; in subjects with no loss of thyroid functional capacity (iodine-deficient, otherwise normal schoolchildren), the decrease of serum T_4 was not accompanied by an aggravation of hypothyroidism, as serum T_3 and serum TSH remained stable. In contrast, in subjects with a low thyroid functional capacity (myxedematous cretins), the decrease of serum T_4 was accompanied by an increase of serum TSH and a decrease of serum T_3, clearly showing that an aggravation of hypothyroidism occurred after selenium supplementation in the absence of sufficient iodine supply (Figure 5). According to these results, in areas which are both iodine- and selenium-deficient, it is mandatory to correct iodine deficiency before selenium supplementation; selenium deficiency should be corrected thereafter too.

In Tibetan villages with an elevated prevalence of endemic osteochondrodysplasia, named Kashin–Beck disease, and related to selenium deficiency, iodine deficiency and selenium deficiency are still more severe than in northern Democratic Republic of Congo. Nevertheless, endemic myxedematous cretinism is much less frequent in Tibet than in iodine-deficient areas of Central Africa. The current hypothesis is that at least three factors interact to involve endemic myxedematous cretinism: iodine deficiency + selenium deficiency + thiocyanate overload.

Recent experimental work has shown that selenium deficiency in rats subjected to antithyroid compounds involves thyroid fibrosis: this could be the

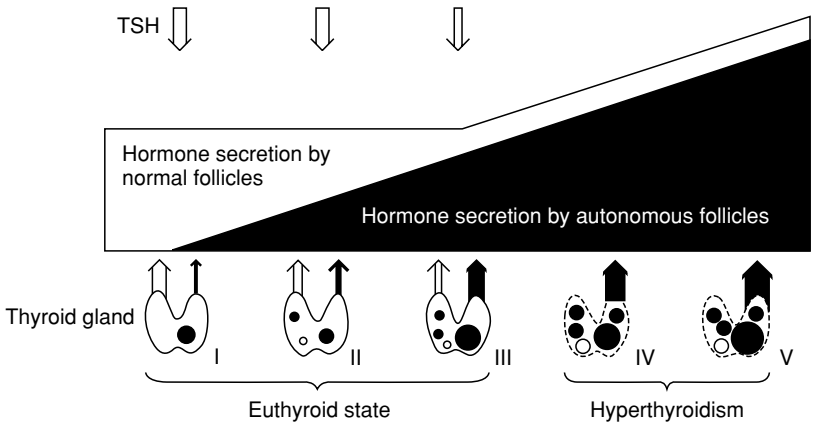

Figure 4 Proposed scheme of iodine-induced hyperthyroidism (also named Jod-Basedow hyperthyroidism). In an iodine-deficient environment, chronic thyroid-stimulating hormone (TSH) stimulation involves a multinodular goiter. This also promotes the development of some autonomous follicles. As long as the iodine substrate is not available, the hyperfunctioning gland remains silent, i.e., without concurrent clinical hyperthyroidism. Once iodine is introduced, for example, with universal iodized salt, some predisposed people (peculiarly women > 40 years) are at risk of developing hyperthyroidism. Reproduced from Braverman LE and Utiger R (eds) (1996) *Werner's and Ingbar's The Thyroid*, 7th edn. Philadelphia: JB Lippincott, with permission.

clue for the physiological mechanism of thyroid involution in endemic myxedematous cretinism.

Lithium- and Fluoride-Induced Thyroid Dysfunction

Lithium carbonate is used for manic-depressive disorders. Goiter occurs in 5–10% of treated patients, and biological hypothyroidism is reported in 5% of treated patients.

The best recognized effect of lithium on the thyroid is the inhibition of hormone release. The mechanism of action is still controversial and may involve the calcium/1,4,5-phosphatidylinositol pathway.

Lithium excess has been advocated as a cofactor of endemic goiter in Venezuela, where dietary iodine and protein intakes are low.

The consumption of ground water containing higher levels of fluoride has been reported to influence the prevalence of goiter. In 13 villages in the Himalayas, for almost the same iodine intake, the prevalence of goiter varied with different levels of fluoride and hardness of drinking water.

Phenol Derivatives

Humic substances are heterogeneous, high-molecular-weight, complex polymeric, yellow-black compounds which constitute the major organic fraction of soil and water. They are involved in the coalification process and are considered to be both precursors and decomposition products of coals. They include resorcinol, catechol, orcinol, phloroglucinol, pyrogallol, 2,6-dihydroxytoluene, 3,5-dihydroxybenzoic acids, and phtallic acids. These compounds are released into the water or soil, where decomposition occurs.

Resorcinol and hexylresorcinol are present in many topical antiseptic preparations; resorcinol has been used as an antifungal, antimicrobial, and keratolytic agent in concentrations of 2–20% in lotions, creams, and ointments. Hydroquinone and catechol are widely used in the photography industry as developers of black and white pictures or X-ray films, and in the rubber industry as antioxidants or as stabilizers of radical polymerization. Dihydroxyphenols are major components of cigarette smoke. They originate from decomposition of flavonoids.

A variety of phenolic compounds, articularly dihydroxyphenols, and related compounds with meta-substitution in a benzene ring, inhibit TPO-mediated iodide organification, *in vivo* as well as *in vitro*. (*See* **Phenolic Compounds**.)

Investigations into the causative factors in endemic goiter in iodide-sufficient areas of the Cauca valley, Colombia, and in the coal-rich Appalachian area of eastern Kentucky, USA, have demonstrated a significant correlation between watersheds rich in organic matter (coal and shale) and the high incidence of goiter.

Polycyclic Aromatic Hydrocarbons (PAHs), Including Dioxins

Polychlorinated biphenyls (PCBs) and polybrominated biphenyls (PBBs) are commonly incorporated into electrical apparatus, flame-proofing materials, hydraulic fluid, varnishes, and other types of protective coatings. These compounds are almost insoluble in water. (*See* **Polycyclic Aromatic Hydrocarbons**.)

Acute toxicity syndromes of PCB exposire in relatively large quantities have been described after an accidental industrial contamination in Japan in which over 1000 people were poisoned (Yusho disease). Alterations in thyroid function during this epidemic are not documented. In another study, 36 of 86 men who were employed in a PBB-manufacturing plant were reviewed for thyroid abnormalities; the prevalence of antimicrosomal antibodies (4 of 35) was statistically significantly higher than the 2.8% expected in a reference population. These data on the possible effect of goitrogens in thyroid autoimmunity are similar to those reported in rats submitted to other PAHs; goitrous lymphocytic thyroiditis has been observed after administration of the carcinogens, methylcholanthrene and dimethylbenzanthracene, in Buffalo inbred strains of rats, while other strains (Fisher rats) were not susceptible.

GRAPES

R S Jackson, Bic, QC, Canada

Background

Grapes are one of the most important of the fleshy edible crops. They are produced in clusters on members of the genus *Vitis*. Most of the annual production goes into producing wine, with smaller amounts used as fresh fruit or raisins. Because of unique cultural demands, particular varieties are typically grown for a single purpose. Intended use also has influenced the direction of domestication and breeding of grape cultivars.

Commercial Importance of Grapes and Wine

Global grape production averages about 60 million tonnes. By comparison, orange, banana, and apple production averages about 57, 50, and 43 million tonnes. Of this, about 70% of the crop is fermented into wine, 27% consumed as fresh fruit, and 2% dried for raisin production. Regional use varies widely, depending on the climate, but also on religious dictates of the producing or importing country (**Tables 1** and **2**).

Grape production is based primarily on cultivars of *Vitis vinifera*. Cultivation is also largely restricted to a zone between the annual 10 and 20 °C isotherms (**Figure 1**). In addition, grape culture is principally

located in regions characterized by a Mediterranean climate. Cultivation in cooler, warmer, or more moist regions is commercially feasible only when local climatic conditions or cultural practice compensate for less than ideal conditions.

Approximately 65% of the world's vineyards occur in Mediterranean Europe. Of this proportion, about 60% are located in Spain, Italy, and France. Although the coverage has declined by some 16% since the mid-1980s, grape production has actually increased by about 10%.

Grape Species and Cultivars

Grapes are produced by members of the genus *Vitis* (family Vitaceae). All members are viny and develop swollen or jointed nodes from which leaves, tendrils, or flower clusters form. Each cluster produces many, miniature, nonshowy, bi- or unisexual flowers. These develop into fleshy berries containing up to four seeds. The fruit is normally dark blue–purple owing to the production of anthocyanin pigments. Green to yellow-colored varieties do not produce these pigments.

The genus is divided into two sections or subgenera. The subgenus *Vitis* (bunch grapes) is the larger, containing all species (about 65) except *V. rotundifolia* and *V. popenoei*. These two are placed in the subgenus *Muscadinia* (muscadine grapes). Muscadine grapes are native only to coastal southeastern North America.

The origin of the genus probably involved several interspecies crosses, associated with subsequent chromosome doubling. Modern species are derived from very ancient hexaploids (plants possessing sets of chromosomes from three different species). Bunch grapes (subgenus *Vitis*) possess 38 chromosomes, whereas muscadine grapes (subgenus *Muscadinia*) have 40 chromosomes.

Domestication of *Vitis vinifera* probably started in northeastern Iran and northern Turkey some 4000 years ago. In contrast, the earliest evidence of wine production predates domestication by about two millennia. Archeologic evidence of grapevine domestication appears as changes in seed shape (length relative to width) and an increase in bisexuality (reduction in the presence of infertile pollen from female vines).

Most present-day grape varieties appear to have developed locally, possibly from the crossing of indigenous vines and introduced domesticated varieties. One view of the diffusion routes of the introduction of grape culture to Europe is given in **Figure 2**.

There are more than 5000 named grapevine cultivars. Most are of local interest only, with few having achieved world-wide distribution. Examples are 'Cabernet Sauvignon,' 'Syrah,' 'Pinot noir,' 'Tempranillo' and 'Sangiovese' (red), and 'Chardonnay,' 'Riesling,' and 'Sauvignon blanc' (white). Their productivity is usually lower, and their cultivation typically more demanding. Their reputation comes from their yielding fine, varietally distinctive wines with long-aging potential. In favorable locations, their excellent wine-making properties compensate for reduced yield and increased production costs. Modern cultivars are often crosses between North American *Vitis* species and *V. vinifera* varieties. Examples are 'Concord,' 'Chambourcin,' and 'Cayuga'. Crossing with North American and European grapes has also been crucial in the production of rootstocks that provide resistance or tolerance to many important grapevine pest, diseases, and complicating soil conditions.

Vine Cycle and Vineyard Activity

The end of one growth cycle and the beginning of another typically coincide with the onset of winter. The absence of foliage facilitates the removal of unessential shoot growth and the selection of growth from which to generate the subsequent year's crop.

The first indicator of renewed grapevine activity in the spring is the flow of sap from the ends of pruned shoots. When the average temperature rises above a critical value, buds begin to burst. Once initiated, development and enlargement of the embryonic leaves, tendrils, and flower clusters occur quickly (**Figure 3**). Disease, pest, and weed control measures begin early.

Flower development progresses from the outermost flower parts inward. Maturation of the anthers and anthesis (pollen release) coincides with separation of the fused cap of petals (calyptra) (**Figure 4**). The separation shakes pollen on to the stigma, thus initiating self-fertilization. Flower induction for the subsequent season occurs at this time in newly developing buds. Following fertilization, fruit development begins. Except for seedless varieties, one seed is required for berry development.

Once the shoots have elongated, they are typically tied to a trellis for support. Irrigation, if required, usually ceases at *véraison* (the beginning of mature fruit coloration). This restricts additional vegetative growth. Removing excessive leaf or shoot growth may be conducted to limit shading and a nutrient drain that can retard fruit ripening. Irrigation may be reinitiated after harvest to avoid stressing the vine and permit optimal shoot maturation.

As the grapes near maturity, vineyard activity shifts toward preparing for harvest. Based on chemical analysis of the fruit, environmental conditions, and the desires of the winemaker, a harvest date is set. In cool climates, frost protection measures are set in place.

Once harvest is complete, vineyard activity turns to preparing the vines for winter. In cold climates, this

may vary from mounding soil up around the shoot–rootstock union to removing the whole shoot system from its support system and burial with soil.

Grape Structure and Development

Fruit growth typically shows an S-shaped curve (Figure 5). In the initial phase, lasting 6–8 weeks, cells divide rapidly, followed by enlargement. In the second phase, lasting 1–6 weeks, berry growth slows, and the seeds develop. At the end of this period, the skin begins to lose its green color (*véraison* – Figure 4). In the final phase, the fruit enlarges to its mature size, tissues soften, acidity falls, sugars accumulate, anthocyanin pigments form (in blue-skinned varieties), and aroma compounds are synthesized.

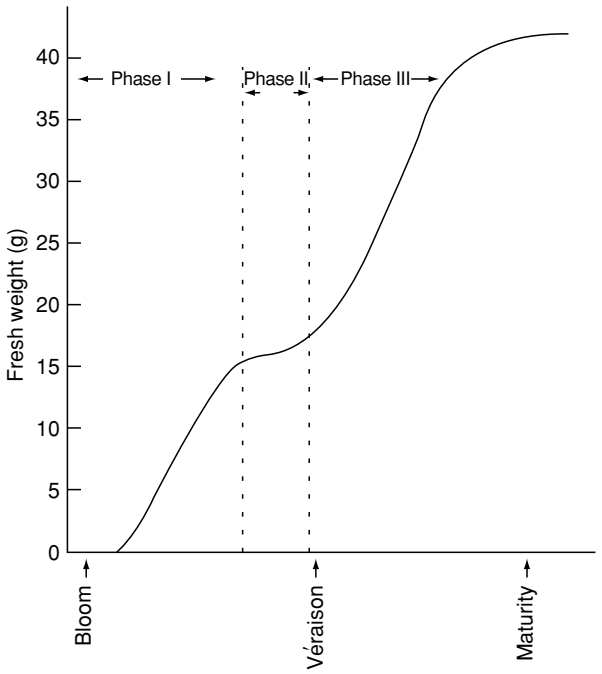

Figure 5 Diagrammatic representation of the growth phases of grapes.

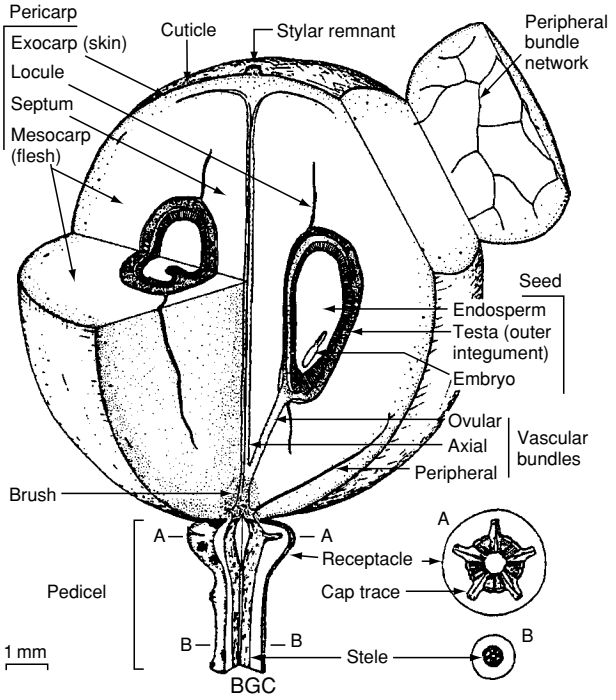

Figure 6 Diagrammatic representation of a grape berry. After Coombe BG (1987) Distribution of solutes within the developing grape berry in relation to its morphology. *American Journal of Enology and Viticulture* 38: 120–128, published by the American Society for Enology and Viticulture, with permission.

The final stage lasts 5–8 weeks. The duration of each phase is cultivar- and climate-controlled.

Mature grapes possess two morphologic regions – the skin and the flesh (Figure 6). The thin skin layer consists of an outer, single-layered epidermis and an inner hypodermis (four to 20 cells thick). The hazy coating (bloom) seen on ripe grapes comes from waxy plates and ridges of the cuticle that cover the epidermis (not yeast cells as commonly believed). Anthocyanins produced in the outer layers of the hypodermis generate the blue–purple color typical of most grapes. White grapes derive their yellowish coloration from the carotenoids and flavonoid pigments in the hypodermis. The hypodermis is also the production site for most aroma compounds.

During ripening, the cell wall of the hypodermis thickens as a result of hydration, loosening bonding between the cells. In 'slip-skin' varieties, however, a layer of cells between the flesh and hypodermis become thinner and lose much of their pectinaceous cell-wall material. This produces a zone of weakness, allowing the skin to separate readily from the flesh.

The internal fleshy tissues of the grape are subdivided into two ill-defined regions – one between the hypodermis and the peripheral vascular strands, and the innermost, being delimited by the peripheral and axial vascular strands (Figure 6).

Grape size is largely dependent on enlargement of the central vacuole of flesh cells. The vacuole is also the primary site for sugar and acid accumulation during ripening.

Chemical composition (see Table 3)

Sugars

Grape chemistry changes most significantly during the later phases of ripening, beginning with *véraison*. This is particularly marked as sugars, translocated from adjacent leaves, accumulate. A simultaneous reduction in vegetative growth, and a metabolic shift to malic acid respiration, also favor sugar deposition.

On reaching the berry, sucrose is hydrolyzed and stored as fructose and glucose. Depending on the cultivar and prevailing conditions, the sugar content may reach 12–28%. For wine-making, the desired sugar content generally ranges from about 21 to 25%. Lower sugar contents are preferred for table grapes. Small, but largely insignificant, amounts of other sugars accrue in ripe grapes – notably raffinose, stachyose, melibiose, maltose, galactose, arabinose, and xylose.

Acids

After sugar, the most marked chemical modification during ripening involves a reduction in acidity.

Table 3 Major chemical constituents in grapes (% fresh weight)[a]

Constituent	*Range*
Water	70–85
Carbohydrates	15–25
Glucose	8–13
Fructose	7–12
Pentoses	0.01–0.05
Pectins	0.01–0.1
Organic acids	0.3–1.5
Tartaric	0.2–1.0
Malic	0.1–0.8
Citric	0.01–0.05
Acetic	0.00–0.02
Phenolics	0.01–0.15
Anthocyanins	0.00–0.05
Tannins	0.01–0.1
Nitrogenous compounds	0.03–0.17
Amino acids	0.01–0.08
Ammonia	0.001–0.012
Minerals	0.3–0.5

[a]Data from Amerine MA, Berg HW, Kunkee RE *et al*. (1980) *The Technology of Wine Making*, 4th edn. Westport, CT: AVI.

Tartaric and malic acids account for about 70–90% of the berry acid content. The remainder consists of variable amounts of organic acids (citric and succinic acids), phenolic acids (e.g., quinic and shikimic acids), amino acids, and fatty acids.

The tartaric acid content of grapes generally remains stable during ripening. Its perceived acidity declines, though, as the proportion of free acid (not associated with potassium and calcium ions) decreases. In contrast, the malic acid content decreases during ripening. This trend is particularly marked in hot climates. Shoot vigor is another factor influencing fruit acidity, partially by increasing fruit shading and cooling.

Phenolics

Phenolics constitute the third most significant group of organic compounds found in grapes. Phenolics not only donate the color to red wines, but also give them their characteristic taste and aging properties. During ripening, the anthocyanin content of red grapes both increases and changes in composition. Because the final distribution can significantly influence the hue, intensity, and color stability of a wine, these changes are of great importance to wine quality. White grapes have a lower total phenolic content and do not synthesize anthocyanins. Aside from seed phenolics, both red and white grapes synthesize most of their phenolic constituents in the skin.

In addition to anthocyanins and tannins, red-skinned cultivars contain flavonols, various benzoic acid and cinnamic acid derivatives, and hydroxycinnamic acid esters of tartaric acid. They are commonly glycosidically linked to glucose, rhamnose, or glucuronic acid.

A small group of phenolic compounds, the stilbene phytoalexins, has attracted considerable attention recently. The major phytoalexin in grapes – resveratrol – is credited with many of the health benefits of moderate wine consumption.

Pectins

Pectins function as the primary glue holding grape cells together. Their retention at the end of ripening provides table grapes with their traditional texture. In contrast, pectin hydrolysis is critical to the softening of wine grapes. Softening facilitates juice and flavor release during grape crushing and minimizes the likelihood of haze production in wines.

Lipids

The lipid component of grapes consists primarily of the surface waxes (mostly oleanolic acid) and cutin fatty acids, membrane phospho- and glycolipids, and seed oils. Of these, the most significant are the long-chain fatty acids on the surface of the skin. These frequently act as important sources of unsaturated fatty acids during wine fermentation. Although they occur in minute amounts, oxidized carotenoid derivatives from grapes generate important aromatic compounds. Examples are damascenone, β-ionone, as well as several norisoprenoids.

Nitrogen-containing Compounds

The concentration of nitrogen-containing compounds in grapes is relatively low and has little direct effect on taste or flavor. Nevertheless, one of the most common amino acids in grapes (proline) may play a significant role in limiting the cytoplasmic damage caused by the rapid drop in osmotic potential associated with the storage of sugar during ripening. Also important, but to wine quality, is the most common peptide in ripe grapes, glutathione, which functions as an important antioxidant early in wine fermentation.

Aromatic Compounds

Compounds that give particular grape varieties their distinctive aroma usually occur in trace amounts, occasionally existing as a few parts per billion. Typically, they accumulate as the grapes ripen. As they collect, an increasing fraction may become bound in nonvolatile complexes, such as glycosides, polymers, or oxidized derivatives. This is particularly noticeable with flavorants such as monoterpenes, norisoprenoids, and nonflavonoid phenolics. In

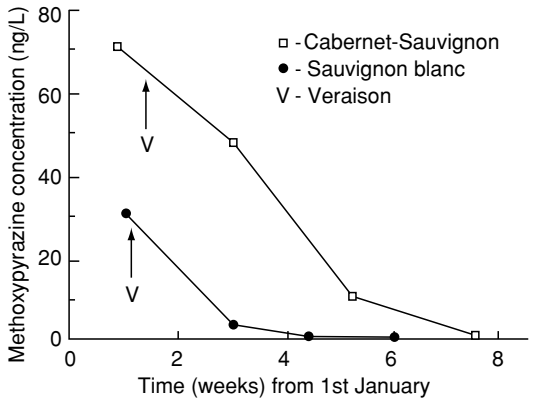

Figure 7 Decline in the concentration of grape methoxypyrazine with ripening. From Allen MS, Lacey MJ and Boyd SJ (1996) Methoxypyrazines of grapes and wines. Differences of origin and behaviour. In: Stockley CS, Sas AN, Johnson RS, Leske PA and Lee TH (eds), *Proceedings of the 8th Australian Wine Industry and Technology Conference, Adelaide, 16–19 July 1996*, pp. 167–169. Adelaide: Winetitles, with permission.

contrast, the concentration of a few impact compounds declines near maturity (Figure 7).

Most modern research confirms the belief that most flavorants collect in the skin. Nonetheless, important aroma compounds such as linalool and TDN (1,1,6-trimethyl-1,2-dihydronaphthalene) are stored in the flesh.

For several grape varieties, varietal distinctiveness depends on the synthesis of one or a few related compounds. Examples are the Cabernet group of varieties that produce methoxypyrazines and Muscat cultivars that produce monoterpenes. In other cultivars, though, varietal distinctiveness seems to come from the unique combination of many standard grape aromatics. Examples are 'Chardonnay' and 'Pinot noir.'

Cultivation

Training and Pruning

Vineyard practice aims at obtaining the maximum yield of fully ripened fruit, consistent with long-term vine health. One of the major means of achieving this goal involves training and pruning. Training usually involves a support (trellis). The specific form chosen depends on factors such as the prevailing climate, harvesting practices, and the fruiting characteristics of the cultivar. Associated with training is the positioning of fruit-bearing shoots in a microclimate optimal for grape quality, inflorescence initiation, and shoot maturation. Pruning may involve the selective removal of growing shoots, mature wood, leaves, or excess numbers of flower or fruit clusters. However, pruning typically refers to the removal of excess shoot growth of the previous season during the winter or early spring.

Central to effective grape culture is maintaining just sufficient leaf area (for photosynthesis) to adequately ripen the crop. This leaf area/fruit (LA/F) relationship is related to the more familiar concept of yield per hectare. It is more direct, though, by focusing attention on the fundamental relationship between the supply and demand for photosynthetic energy. However, because of the complex, adaptive nature of the grapevine, excess leaf area is often as detrimental to grape quality as is insufficient foliage. Excessive leaf area tends to promote extended shoot growth, causing undesirable fruit shading and directing nutrients away from the maturing grapes. Thus, it is essential to neither over- nor underprune grapevines. The appropriate level tends to be in the range of $10\,cm^2$ of leaf surface per gram of fruit. However, the value can vary considerably, depending not only on the cultivar (Figure 8), but also on the training system, soil nutrients, water supply, and climatic conditions. The target is to establish the optimal foliage canopy and placement to nourish the crop to its ideal state of ripeness.

On relatively nutrient-poor, dry soils, the vine's inherent vigor must be restrained. This can be achieved by dense vine planting (about 4000 vines ha^{-1}) and severe pruning (removal of > 90% of the

yearly shoot growth). However, on rich moist loamy soils, wide spacing of the vines (about 1500 vines ha^{-1}) with limited pruning is preferable. Under such conditions, the improved growth potential of the vine must be directed into increased yield, not undesirable vegetative growth. When an appropriate LA/F ratio is developed, both fruit yield and grape quality increase. Examples of training systems ideal for rich soils are the Scott Henry trellis, the Smart-Dyson trellis, and the Lyre. These systems not only achieve a desirable LA/F ratio, but also provide better exposure of the grapes to light and air. These features promote ideal berry coloration, flavor development, fruit health, and flower-cluster initiation.

When considering pruning, many features need to be considered, notably the prevailing climate, genetic characteristics of the rootstock and bearing cultivars, soil fertility, and training system. Of the forms available, most pruning systems can be categorized as either spur or cane pruning.

Spur pruning refers to the retention of only a short shoot segment containing about two buds. It is easier to perform, being effectively conducted by machine. In addition, spur pruning restricts fruit production to predetermined locations, making it particularly applicable to mechanical harvesting. The tendency of spur pruning to limit productivity can be either beneficial or detrimental, depending on the vigor and bearing capacity of the vine. Berry size is generally reduced with spur pruning. This has the advantage of increasing the grape surface area/volume ratio and, thus, potentially enhancing a wine's flavor and color.

Cane pruning involves retaining fewer but longer shoots. These may contain upward of 20 or more buds. Cane pruning is generally more popular in cooler, more moist climates and with cultivars bearing small fruit clusters. However, it must be conducted by skilled workers and demands more shoot support than is typical with spur pruning.

Commonly accepted norms for the number of shoots per meter of vine canopy fall in the range of about 15 shoots per meter (positioned more or less equidistantly along the vine). This assumes an average of about 12–18 buds per shoot.

Grafting

Most grapevines in commercial culture are grafted to a rootstock. In much of the world, grafting is essential to obtain resistance from a particularly devastating root-infecting pest, the phylloxera root louse. In the late 1800s, it decimated European grape culture until grafting was introduced. In other areas, rootstocks are required to achieve adequate protection against nematodes, viruses, or saline soil conditions. Certain rootstocks can also limit grapevine vigor in highly fertile, moist soils.

Irrigation and Soil Fertilization

Irrigation is outlawed in most European countries, on the mistaken belief that it is inherently detrimental to grape quality. However, when used wisely, irrigation not only permits grape growing in semiarid to arid regions, but also enhances grape quality. In a process called partial rootzone drying, selectively limited water availability limits vegetative growth and favors optimal fruit ripening. Irrigation can also be used to simultaneously apply fertilizer and pest-control chemicals to vines.

In comparison with other crops, grapevines have relatively limited nutrient demands. This, combined with the accumulation of nutrients in the woody parts of the plant, makes assessing grapevine response to fertilizer application particularly difficult. The primary method of nutrient analysis is based on sampling plant tissue. Optimal fertilizer addition is roughly equivalent to vine requirements minus the amount already available in the soil. Excessive application seldom enhances vine growth or fruit quality, and can be detrimental to both the vine and the environment.

Of inorganic nutrients, only nitrogen is often in marginally short supply. The other two major inorganic nutrients, potassium and phosphorus, are seldom limiting. Vineyard soils are rarely deficient in required micronutrients.

Organic fertilizers, such as compost or manure, have many advantages over inorganic chemical fertilizers. These include improved soil texture and a more even nutrient supply. However, the higher cost and limited availability of organic fertilizers restrict their more extensive use in commercial grape growing.

Improving Table Grape Quality

Grape quality is primarily achieved by the application of the best cultural techniques, under climatic and soil conditions ideally suited to the particular cultivar. However, table grape production requires several practices unique to their cultivation. These include training systems that permit the grapes to hang free, facilitate manual picking, and protect against sunburn, as well as the use of girdling and the application of growth regulators. Of these, the most unique to table grapes are girdling and the use of growth regulators.

Girdling typically involves the removal of a complete strip of bark from trunks or bearing canes below the clusters. This increases the supply of sugars to the fruit by stopping their translocation below the cut. With varieties that set poorly or are seedless, girdling shortly

after pollination increases the number of grapes that develop. Girdling also increases fruit size in seedless cultivars. With table grapes, girdling at *véraison* can improve fruit color and hasten maturation.

Some of the advantages achieved by girdling can be enhanced or replaced by the application of specific growth regulators. Gibberellin is of particular use in seedless cultivars, where it increases grape size. In addition, gibberellin lengthens the stalks of fruit clusters, improving spacing between the grapes. Improved pigmentation can be achieved in colored varieties by the application of ethephon.

Harvesting

Choosing the harvest date is probably the single most important viticultural decision taken yearly by the grower. It sets a limit on the qualities of the grapes. Timing usually is based on one or more chemical analyses of the fruit. In cool climates, sugar content is the primary indicator of maturity, whereas in warmer temperate climates, the sugar/acid ratio is often preferred. In either case, the accumulation of sugar often correlates well with anthocyanin and flavorant build-up in the fruit. Where the correlation is poor, direct measurement of the anthocyanin or flavorant content may be a better indicator of desirable maturity (Figure 8). A new indicator of maturity under investigation measures the glycosyl glucose content. Because most grape flavors are glycosidically bound, assessment of the glycosyl glucose content may provide a direct indicator of flavor potential.

In addition to chemical indicators of maturity, environmental factors that can reduce quality must also be considered in choosing a harvest date. The detrimental effects of early frosts and protracted rainy periods on fruit quality are well known.

Until the development of mechanical harvesters in the late 1960s, all grapes were harvested manually. Except for table grapes and premium wine grapes, labor shortages and market forces have combined to favor machine harvesting. Mechanical harvesters not only reduce harvesting costs (by up to 75%), but also permit rapid harvesting. In comparative tests, no clear sensory difference has been detected between wines produced from hand- and machine-harvested grapes. The main mechanisms used by mechanical harvesters in removing grapes are illustrated in Figure 9.

Packaging and Storage of Table Grapes

Because of the importance of appearance, table grapes are trimmed of unsightly or diseased fruit either in the field or in storage sheds before packing. Packing must be done with due care to avoid damaging the fruit. After packing, the containers are placed in cool storage.

Cooling is particularly critical when the grapes are shipped long distances. Cooling not only increases fruit shelf-life (by suppressing respiration), but also limits microbial activity. Cool temperatures also retard water loss, browning, and separation of the fruit from the cluster. If harvesting has occurred under hot conditions, the fruit is usually precooled to 10 °C, before being placed in storage at near 0 °C. Frequent fumigation of the storage area with sulfur dioxide further helps limit decay organisms, fruit browning, and fruit separation.

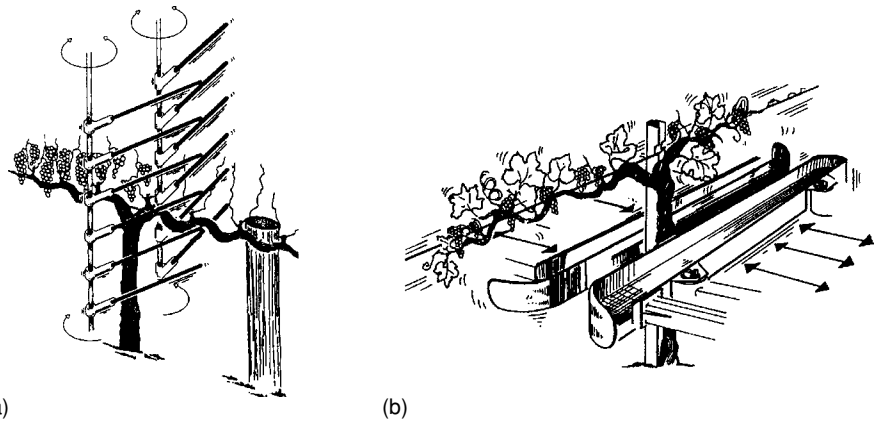

Figure 9 Two main methods of grape removal used by mechanical harvesters: (a) Pivotal strikers that strike the vine. (b) Pulsator rods that shake the vine trunk. From Hamilton RP and Coombe BG (1992) Harvesting of Winegrapes. In: Coombe BG and Dry PR (eds), *Viticulture, Vol. 2, Practices*, pp. 302–327. Adelaide: Winetitles, with permission.

Raisin Production

Table grapes, even with optimal storage, are a perishable crop. Our ancestors solved this problem by processing grapes into either wine or raisins. Raisins have a moisture content of between 10 and 15%, the remainder being almost exclusively sugar. The low moisture content and high osmolarity of the sugar content effectively stop all microbial spoilage activity.

Most grapes used for raisin production are seedless, eliminating the need to remove the seeds. The large-fruited 'Sultana' ('Thompson Seedless') is the most widely grown raisin grape. The small-fruited 'Black Corinth' ('Zante') grape is used for currant production.

Natural drying, either in the sun or under shade, produces the common dark purple–brown raisin of commerce. The browning results from the enzymatic oxidation of phenols released from cell vacuoles during drying. Sun exposure also favors the production of caramelized flavors. Submerging the grapes in a mixture of potassium carbonate and a specially formulated dipping oil disrupts the waxy fruit covering, speeding up drying and producing a golden-brown raisin. Yellow–gold raisins are primarily produced by a hot bleach dip (about 4 s in a boiling solution of dilute sodium hydroxide and sodium sulfate). This is followed by rapid dehydration. Sulfur dioxide in the bleach solution prevents the browning that typically occurs during drying.

GROUND NUT OIL

T H Sanders, United States Department of Agriculture, Raleigh, NC, USA

Introduction

Groundnut oil is expressed from the seed of *Arachis hypogaea* L., commonly known as groundnut, peanut, or earth nut, because the seed develops underground. The plant is a legume native to South America and was cultivated as early as 2000–3000 BC. Today, groundnuts are produced on a significant basis in more than 30 different countries with worldwide production figures estimated in excess of 20×10^6 t. The three largest producers of groundnut are India, China, and the USA. In recent years, these countries accounted for approximately 65% of the world production. Although cultivated for many centuries, the economic importance of groundnuts and groundnut oil has increased rapidly only in the past century. Near the middle of the nineteenth century, oil mills in France began importing groundnuts from West Africa for crushing. Because of the excellent

quality of groundnut oil, mills for crushing were soon found in other European countries and then throughout the world. In recent years, the world production of groundnut oil has accounted for about 7–10% of the world vegetable oil total. More than 50% of the groundnuts produced are crushed for oil. In India, 75–80% of the groundnuts produced are crushed for oil, whereas in the USA, groundnuts used for crushing are only approximately 12% of recent production. This low percentage is indicative of the economic importance of groundnuts as a food crop in the USA. Owing to their high content of digestible protein and unsaturated oil, and their exceptional roasted nutty flavor, groundnuts have substantial value and desirability as a food commodity. On a world-wide basis, more than one-third of the groundnuts produced are used as food. In the USA, a high percentage of the limited number of groundnuts used for oil extraction have been separated from edible stocks because of the potential for aflatoxin. The pressed cake, low in oil and high in protein, may be used for animal food if aflatoxin is found to be below acceptable levels. Unacceptable pressed cake is relegated to fertilizer usage. Depending on the extraction methods (hydraulic press, expeller, and/or solvent extractor), residue may contain 1–7% oil, and with inefficient equipment, the percentage may be much higher. Pressed cake from edible-grade groundnuts with low oil content may be ground into flour for human consumption. In many parts of the world, extraction efficiency and lack of hygienic conditions relegate residues unfit for human consumption. In these situations, the residue is utilized either for animal feed or as fertilizer. (*See* **Peanuts**; **Vegetable Oils**: Oil Production and Processing.)

Uses

Peanut oil uses include cooking and frying oil, preparation of shortenings, margarines, and mayonnaise. Some salad oil use is found, and use in pourable dressings is good because of the length of time solids are held in suspension in the oil. However, peanut oil does not meet the strict terminology for salad oil because it solidifies at 0–3 °C. As a cooking oil, especially in deep-fat frying, groundnut oil is excellent since it has a smoke point of 229.4 °C. Refined groundnut oil is odorless, whereas crude oil usually has a nut-like aroma. Groundnut oil develops few off-flavors or odors in use as a frying oil, but degradation of glycerides during frying results in the increase of free fatty acids (FFA) and a decrease in smoke point.

Oil Characteristics

Composition

The seed of the groundnut fruit commonly contain 40–50% total oil, but data indicating a range of 36–56% may be found. Oil content is considered to average about 50% and is generally independent of market type or growth habit. However, some reports suggest that the small-seeded Spanish types tend to have a higher oil content than the large-seeded Virginia types. The composition of the oil changes somewhat among varieties, but the triacylglycerol content is generally in the region of 95%. As peanuts mature, the total oil, triacylglycerol, and oleic acid/linoleic acid (O/L) ratio increase, whereas free fatty acids, polar lipids, monoacylglycerols, and diacylglycerols decrease (Table 1). The relative weight percentage of free fatty acid has been shown to decrease from 4.5 in very immature seed to 0.7 in mature peanut seed. In a study of oil characteristics of peanuts, we reported that free fatty acids decreased (0.8 to 0.05% as oleic acid), the O/L ratio increased, and the oil oven stability increased with maturity. The consistent relationship of these components to shelf-life leaves little doubt as to the relationship of maturity and shelf-life. Diacylglycerol and polar lipid fractions generally account for an additional 2% of the oil weight. Some reports suggest that the total oil percentage decreases

after full maturation, as lipids are utilized for respiration. Factors such as maturity, environment, cultural practices, variety, and soil temperature affect oil content and composition.

Fatty Acids

As previously indicated, groundnut oil is composed of mixed glycerides and contains a high proportion of unsaturated fatty acids, in particular, oleic (18:1) and linoleic (18:2). Additional fatty acids are palmitic (16:0), stearic (18:0), arachidic (20:0), 11-eicosenoic (20:1), behenic (22:0), and lignoceric (24:0). With maturation, the percentage of oleic acid increases, whereas the percentage of linoleic acid decreases slightly. The stability of groundnut oil is highly correlated with the ratio of oleic acid to linoleic acid. This ratio generally increases with seed maturity, and oil stability increases simultaneously. Fatty acid composition values have been reported to vary widely, as indicated in Table 2. The fatty acid compositions of the lipid classes of groundnut are somewhat variable. The fatty acid composition of three groundnut varieties and composition of lipid classes from those varieties are shown in Table 3. The triacylglycerol composition approximates that of whole oil since the fraction comprises about 95% of the total. Oleic acid, linoleic acid, and palmitic acid comprise about 90% of the total fatty acids. Free fatty acid fractions consistently contained higher percentages of palmitic acid than did the triacylglycerol fractions. Long-chain fatty acids (C20–C24) were generally more predominant in the *sn*-1,3-diacylglycerol than in other fractions, and only traces of long-chain fatty acids were found in the *sn*-1,2 (2,3) diacylglycerol fraction. The phospholipid fractions contained the highest concentrations of palmitic acid. (*See* **Fatty Acids**: Properties.)

Production location has a significant effect on the fatty acid composition of peanut oil, with cooler climates resulting in a greater degree of unsaturation, a lower O/L ratio, and thus, according to published correlations, a shorter shelf-life. These effects have been variously ascribed to temperature, irrigation, and maturity. The relationship between mean temperature at critical growth periods appeared to have a definite effect on oil composition. The relationships examined may provide at least partial explanation for observed problems with oxidative stability in peanuts grown in

Table 2 Reported percentages of major fatty acids in groundnut oil

Fatty acid	*Percentage*
Palmitic	7.4–12.5
Stearic	2.7–4.9
Oleic	41.3–67.4
Linoleic	13.9–35.4
Arachidic	1.2–1.9
Behenic	2.1–3.6
Lignoceric	0.9–1.7

cooler climates or with cooler temperatures during the later weeks of the growing season.

This research has demonstrated several highly significant variations in oil production from year to year for all three major peanut types, highly significant differences among the same varieties grown in different commercial production area, and highly significant interactions between location and year of production. The study has also demonstrated highly significant correlations between mean temperatures during apparently critical growth periods and the levels of major fatty acids produced.

Triacylglycerol

Studies defining over 20 and up to 36 triacylglycerol species in peanut oil have been conducted. Triacylglycerol species OOL, OOO, OLL, POL, and POO (O = oleic, L = linoleic, P = palmitic) comprised the greatest proportions of the triacylglycerol fraction. This should be expected since oleic acid, linoleic acid, and palmitic acid comprise the greatest percentages of fatty acids in peanut oil. The US Customs Service has utilized triacylglycerol species distribution as one method of identification of some international origins of peanuts. After examination of 18 Argentine and 13 Chinese samples, observations for distinguishing between the two production locations were: (1) the ratio of OOO/OOP was less than 1.0 for Chinese peanuts; it was approximately 1.5–1.7 for the Argentine peanuts; (2) PSL (S = stearic) was not measurable in Chinese peanuts and was present at about 0.2% in Argentine samples; (3) in Chinese samples, OOB (B = behenic) accounted for about 0.4% of the total triacylglycerols, whereas in the Argentine samples, it accounted for about 1.1%; (4) the percentage of OOO was about 10% in Chinese samples versus about 14% in Argentine samples. Triacylglycerol species percentage ranges for Argentine and US samples often overlapped; however, origin identification was possible through trace element analysis. (*See* **Fats:** Classification.)

Data presented in several studies have clearly demonstrated the fact that the environment affects not only the fatty acid composition of peanut oil, but also, although apparently indirectly, the spatial arrangement of those acids on the triacylglycerol molecule. Triacylglycerol composition and structure are important in the areas of nutrition, oil stability, and possible physiological effects. Table 4 provides data demonstrating the differences in triacylglycerol structure that are reasonably expected among different varieties of peanuts. The data shown in Table 4 indicate a nonrandom distribution of fatty acids among the *sn*-1, -2, and -3 positions of the triacylglycerols.

[a]Each value is the mean of three replications.

The percentages of palmitic and stearic acids were generally very low for the *sn*-2 position, higher for *sn*-3, and highest for *sn*-1. The long-chain (C20–C24) fatty acids were located almost exclusively at the *sn*-3 position. The *sn*-2 position of triacylglycerols from all the varieties was high in unsaturated fatty acids. The general patterns of fatty acids found at the *sn*-1 and *sn*-3 positions were similar for all varieties, although the mole percentages of each acid at the two positions frequently differed widely. Mole percentages of palmitic, stearic, and linoleic acids were always higher for the *sn*-1 than for the *sn*-3 position, whereas those of oleic acid were consistently higher for the *sn*-3 position. The patterns of fatty acid distribution at *sn*-2 differed not only from those at *sn*-1 and -3, but also with variety. On the *sn*-2 position, the percentage of oleic acid was higher than that of linoleic acid in Florigiant, but the percentages were about the same in Florunner. In the other four varieties, there was more linoleic acid esterified at the *sn*-2 position than oleic acid. Florigiant and Florunner triacylglycerols contained more oleic acid and less linoleic acid than the other varieties examined, and the concentration effect probably was reflected by the fatty acid placement in the molecule.

Using the data in Table 4, linear regression equations and correlation coefficients were calculated for the plots of the percentage of a fatty acid in the total triacylglycerol *vs*. the percentage of that fatty acid at one of the positions of the triacylglycerol (Table 5). Significant correlations indicate that the total fatty acid present influenced placement of that fatty acid on the triacylglycerol. It has been reported that major saturated, monoene, and diene fatty acids of corn triacylglycerols exhibited a concentration effect in all cases except for saturated acids in the *sn*-2 position. Peanut triacylglycerols exhibited this same pattern, and the low concentrations of the long-chain fatty acids in the triacylglycerol were significantly correlated with percentages found at the *sn*-3 position only. This may be due to the general restriction of the saturated acids (16:0 and 18:0) from the *sn*-2 position and the long-chain acids from the *sn*-1 and *sn*-2 positions. Any substantial deviation from the regression line has been attributed to a change in the mechanism of fatty acid distribution and suggests genetic control of the deviation. No substantial deviation of any fatty acid from the regression lines was detected in the six peanut varieties examined. Although the concentration effects were similar for the varieties, the variation in percentage of a fatty acid at any position is sufficient to indicate possible concentration differences in the various triacylglycerol species found in the total triacylglycerol fraction.

Table 5 Linear regression analyses and correlation coefficients for the relationship of fatty acids in total triacylÙglycerols and fatty acids at each position

Fatty acid	*Position*	*Slope*	*y intercept*	*r*[a]

Phospholipids

Phospholipids of peanut oil have been examined, and it has been determined that oven stability of peanut oil was related to the solvent used for extraction and that removal of phosphatides from the oil by precipitation reduced oven stability. Thus, differences in the relative amounts of polar lipids extracted by different solvents might explain some variation in oven stability. Stability and resistance to oxidation due to sterols and phospholipids are not well documented and warrant further investigation. The concentration of phospholipids in peanut oil is only about 1%. Phospholipids or membrane lipids have been recognized for some time in the form of lecithin materials (primarily phosphatidylcholine (PC)) as a byproduct of oil and fat processing. Phospholipids, especially PC, were found to be important in the treatment of neurological diseases, respiratory distress, liver diseases, and many others. This class of compounds has been shown to be synergistic with tocopherols in delaying onset of lipid oxidation. The major phospholipids of peanut oil are phosphatidic acid (PA), phosphatidylglycerol (PG), phosphatidylethanolamine (PE), phosphatidylinositol (PI), and PC. Phospholipid content and concentrations have been shown to be affected by maturity and postharvest treatment, as shown in Table 6. The higher concentrations of PA and PC in immature peanuts might be explained on the basis that these phospholipids are precursors to other phospholipids. Excessive heat and freezing both affect membrane stability with the result of significant

Table 6 Effect of postharvest treatment on total phospholipid

Treatment	*Phospholipid (% area)*					*Total phospholipid (mg per 100 g DWT)*
	PA	*PG*	*PE*	*PI*	*PC*	
Control	2.2	2.5	13.3	15.7	66.4	500
Immature	4.5	2.3	14.0	7.6	71.7	700
Heat cured	9.5	1.1	16.0	15.4	58.1	900

differences in the phospholipid content and distribution. The large increase in PA and great decrease in PC with freezing of nondried peanuts may be related to the fact that freezing induces phospholipase-D activity, with PC being the most susceptible to action of the enzyme. (*See* **Phospholipids**: Properties and Occurrence.)

Sterols

Peanut oil contains several sterols, which are secondary alcohols with 27–29 carbon atoms, and unlike short-chain alcohols, they are crystalline solids at room temperature. Peanuts contain β-sitosterol, campesterol, stigmasterol, Δ5 avenasterol, Δ7 stigmasterol, Δ7 avenasterol, and brassicasterol (Table 7). β-Sitosterol (SIT), the major component in peanut sterols, has been shown to inhibit cancer growth. SIT may offer protection from colon, prostate, and breast cancer. Unrefined peanut oil contains approximately 200 mg of SIT per 100 g of oil, and this value is comparable with soybean oil, which contains approximately 183 mg of SIT per 100 g.

Antioxidants

Few studies on the relative quantity of antioxidants in peanuts have been published, and studies on the relationship of antioxidant content to shelf-life potential are even less abundant. Data on tocopherol content and individual fatty acids from 31 cultivars for 4 years used in a multiple regression equation for the prediction of stability of cold pressed oil revealed that 87% of the stability could be correlated with total tocopherol/percent linoleic acid. A 3-year study of oil composition factors of peanuts from several origins indicated that tocopherol content was consistently different in peanuts from various origins. Peanuts produced in the USA had a consistently higher tocopherol content than peanuts produced in China or Argentina. The highest levels reported in US peanuts were almost 250 p.p.m. in whole seed, whereas the lowest levels were about 100 p.p.m. The tocopherol content of peanut oil has been demonstrated to be as high as 650 p.p.m., depending on the variety of peanut and growing conditions. Vitamin E intake has been shown in numerous studies to be inversely related to the risk of heart disease. The 3-year study on peanuts from the USA, China, and Argentina reported on levels of copper and iron. The copper content was always significantly lower in US peanuts, and the iron content was generally lower. These factors were related to higher O/L ratios, and oil oven stability studies indicated the overall longer shelf-life potential of peanuts produced in the USA. These data, without consideration of the areas of production, demonstrated the consistent close relationship of oil quality factors such as FFA, O/L ratio, peroxide value, total carbonyls, tocopherols, copper, and iron to most measures of shelf-life stability. The data may be extrapolated to the end that any factor that generates inappropriate levels of these compounds will then contribute to a shorter shelf-life of resulting products. (*See* **Antioxidants**: Natural Antioxidants; Synthetic Antioxidants.)

Properties of Peanut Oil

General

The general properties of peanut oil have been compiled from several references and are provided in Table 8. Crude peanut oil has a bland, but slightly beany, nut-like flavor that is removed during refining. Oxidized oil may have a wet cardboard or painty (oxidized linseed oil) flavor.

Acetyl Value

The acetyl value is the number of milligrams of KOH required to neutralize the acetic acid produced by the hydrolysis of 1 g of acetylated fat and is a measure of the free hydroxyl groups present in the oil. The acetyl number of peanut oil (8.5–9.5) is lower than other vegetable oils but higher than coconut oil, palm oil, and the animal fats and oils.

Table 8 Chemical and physical characteristics of peanut oil

Characteristic	*Value*
Flavor and odor	Bland
Acetyl value	8.5–9.5
Color (visual)	Light yellow
Color (Gardner, maximum)	4
Free fatty acid (as oleic acid, maximum)	0.05%
Heat of fusion (unhydrogenated)	21.7 cal g^{-1}
Melting point	0–3 °C
Peroxide value (maximum)	10 meq of peroxides oxygen per kilogram of oil
Refractive index (n_D 40 °C)	1.46–1.465
Smoke point (minimum)	229.4 °C
Specific gravity (21 °C)	0.915
Unsaponifiable lipids	0.40%

Percent Free Fatty Acid (FFA)

Peanut oil generally has low levels of FFA. The highest natural percentages are found in very immature seed (0.8), and the percentage decreases to *c*. 0.05 in fully mature seed. Improper handling, moisture, fungal invasion and other factors contribute to hydrolysis of triacylglycerols and cause significant increases in FFA. Saponification in the refining process removes FFA, but crude oil used in many parts of the world may contain high levels of FFA with resulting rapid deterioration in quality, flavor, and stability.

Iodine Value (IV)

The iodine value is a measure of the relative degree of unsaturation in oil components, as determined by the uptake of halogen. Because the melting point and oxidative stability are related to the degree of unsaturation, IV provides an estimation of these quality factors. The greater the iodine value, the more unsaturation and the higher the susceptibility to oxidation. Peanut oil (IV 82–107) is more saturated than corn (IV 103–128), cottonseed (IV 99–113), or linseed (IV 155–205) oils; however, it is considerably less saturated than coconut (IV 7.7–10.5), palm (IV 44–54) or butter (IV 25–42) oils.

Color

The light yellow color of peanut oil is due to β-carotene and lutelin, and becomes lighter as peanuts mature. Although oil color may be used to assess maturity, other methods are preferred because many factors such as curing temperature and duration influence oil color. Color measurement is frequently done by visual comparison under a CIE standard light source. The Gardner color is determined using a Gardner-delta color comparator, which has a scale between 1 and 18.

Heat of Fusion

The heat of fusion, or latent heat, is the quantity of heat required to change 1 g of solid to a liquid with no temperature change. This latent heat increases with increasing molecular weight. The heat of fusion of peanut oil is 21.7 cal g^{-1}.

Melting Point

At refrigeration temperatures (0–3 °C), peanut oil sets to a gel. In contrast to safflower, soybean, corn, and olive oils, peanut oil is not filterable during winterization.

Peroxide Value

Elevated peroxide values indicate that lipid oxidation has taken place and is measured as reactive oxygen content in terms of milliequivalents per 1000 g of fat. In raw peanuts, once the cell structure is disrupted by pressing, lipoxygenase reacts with linoleic, linolenic, or arachidonic acid to form hydroperoxides. These oxidation products are correlated with reduced flavor scores and cardboard or painty flavor defects. The peroxide value is often used as an indicator of peanut quality related to oil oxidation.

Unsaponifiable Lipids

The unsaponifiable matter in peanut oil is largely sterols (mainly β-sitosterol and campesterol).

Health Issues

Early work with animals suggested a high atherogenic potential when peanut oil was fed in relatively high doses. Because chemical treatment to randomize peanut oil resulted in a decrease in atherogenicity, the triacylglyceride structure was believed to be involved. However, recent numerous human epidemiological studies have indicated an amazingly high 30–50% reduction in cardiovascular disease in people who ate nuts, including peanuts, four to five times a week. In a recent 4.2-year study, researchers found that compared with those who rarely or never consumed them, study participants who consumed two or more servings of peanuts and nuts per week, decreased their risk of heart disease by 25%. These significant data align with the numerous research studies that have shown that diets high in mono- and polyunsaturated fats and low in saturated fat can be heart-healthy. Recent studies have been conducted in which healthy subjects consumed one of five diets: a low fat diet; one including olive oil; one including peanuts and peanut butter; one including peanut oil, and a typical American diet. Results show that the diet including peanuts and peanut butter, the

diet including peanut oil, and the diet including olive oil (all low in saturated fat and cholesterol, and high in monounsaturated fat) lowered total cholesterol and low-density lipoprotein cholesterol. Further, each of these three diets lowered triacylglycerol levels, but did not lower the beneficial high-density lipoprotein cholesterol.

New Developments – High-oleic Peanut Oil

Peanut lines with a high-oleic acid trait have been identified, and this trait has been incorporated into commercial peanuts. The original two lines identified had approximately 80% oleic and 2% linoleic acid. The lines developed with the high oleic acid trait have O/L ratios of approximately 30, and the lines do not show any meaningful differences in oil content, flavor, color, or texture. Oxidative stability comparisons made on extracted, neutralized, and bleached oil from high oleic (76.3% oleic/4.7% linoleic) and conventional (56.6% oleic/24.2% linoleic) lines differing only in fatty acid composition resulted in up to 15 times more stability in the high oleic oil. The use of high oleic oil in roasting of peanuts resulted in slight increases in shelf-life, as measured by the oxidative stability and peroxide value, and the degree of improved shelf-life was related to the O/L ratio of the peanut roasted. Swine fed a diet incorporating high oleic acid peanuts had increased monounsaturates and lower polyunsaturates in backfat relative to use of a feed incorporating standard peanuts or canola oil. Further, the use of high oleic acid peanuts as the fat source in a low-fat and high-monounsaturate diet produced significant and positive changes in blood lipids in postmenopausal women including a reduction in total cholesterol from 264 to 238 mg dl^{-1}.

GROWTH AND DEVELOPMENT

R Tojo and R Leis, Santiago de Compostda University, Hospital Clínico Universitario de Santiago de Compostela, Spain

Introduction

Human growth is a product of continous interaction between inheritance and a large number of environmental variables, which act both in fetal period and in the two first decades of the life. Hormones, growth factors, and nutrition play an important role in growth velocity and the attainment of adult size.

Growth is an excellent indicator of health status or illness. Periodic growth assessment must be an obligatory exploration in the supervision of children and adolescents.

Growth and Development

Growth is a complex process. It is the product of continuous interaction between inheritance and environment from conception to adulthood. Each individual has a genetic basis with a well-defined growth potential, modulated by a wide range of extragenic factors. Therefore, body composition and

predetermined final adult size will only be reached if all factors act harmoniously.

Growth and development refer to the transforming process of a fertilized ovum into an adult individual. Growth basically implies an enlargement of body dimension originated by an increase in cell number and size, that is, a process of cell hyperplasia and hypertrophy. Development is a physiological process which makes possible – from a pluripotential and undifferentiated cell – the differentiation, maturation, and function of all the tissues, organs, and apparatus which make up the human organism.

Cell-Growth Stages

Each tissue, organ, or apparatus growth process, in spite of having a development program of its own, is conditioned by cell division and size. This process of tissue growth generally is in three stages:

1. Cell hyperplasia: the initial stages of growth, mainly during organogeny and the fetal period, are characterized by cell division and proliferation, by hyperplasia.
2. Hyperplasia-hypertrophy: as the organ or tissue approaches its predetermined cell total, cell division and increase in cell number are less, whilst cell size rises.
3. Hypertrophy: when total adult cells are reached, cell division stops and cell growth exclusively depends on the increase in existing cell size.

Types of Tissue According to their Growth and Maturation: Tissular Specialization

There are three types of tissue, according to their life span and cellular cycle.

Permanent or Static Tissues

These tissues, once they have reached the adult cell number – which happens precociously – remain theoretically invariable. Their subsequent renovation does not occur, or is only minimal. That is, dead cells cannot be replaced, and cell size and structures can only change or renew their subcellular constituents. Nerve cell, cardiac muscle, and retina cells are the paradigms for this behavior.

Renewing Tissues

These are characterized by a high rate of continuous cell proliferation throughout life. They have a very active turnover of cell populations, which are continously eliminated and renewed, but keep a stable mass. Epidermis, intestinal mucus, seminiferous tubules and hematopoietic tissue are renewing tissues.

Expanding Tissues

Once they have attained adult growth and development level, expanding tissues do not vary unless damaged, in which case a regenerative compensatory phenomenon of cell hyperplasia and hypertrophy takes place. Liver and kidney are typical expanding tissues.

Patterns for Organic and Tissular Growth

General Pattern for Human Growth, or Scammon's General Curve

Scammon's general curve is the curve followed by the whole organism. A good example is size, which, expressed in adult-size percentages, follows a sigmoid curve with two periods of rapid increment (first, prenatal and immediately postnatal ones, and second, pubertal growth) and, between both, a curve of slow and stable growth corresponding to preschool and school age. Many other corporeal components follow roughly this growth pattern (respiratory and digestive systems, kidney, spleen, muscles and osteal system) (Figure 1).

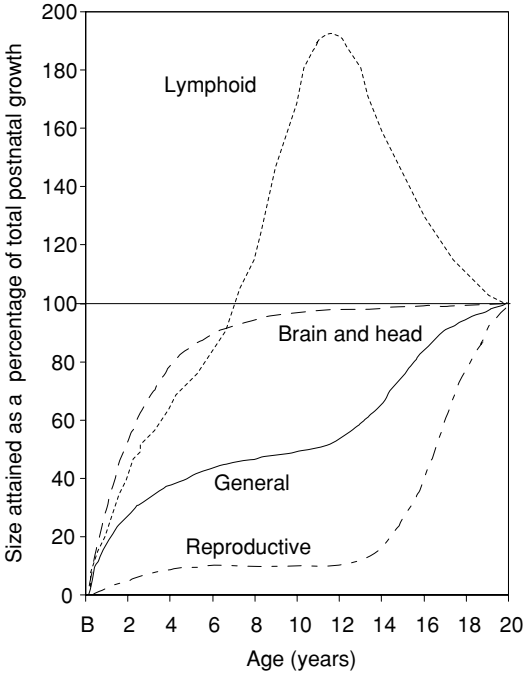

Figure 1 Growth curves of different parts and tisúes of the body. All the curves are of the size attained and plotted as a percentage of total gain from birth to 20 years. Reproduced with permission from Tanner JM (1962) *Growth at adolescence*, 2nd edn. Oxford: Blackwell.

Neural, Cerebral, or Cranial Growth Pattern

The growth of the central nervous system is extremely quick during the prenatal period and in the first years of life, reaching 90% of adult weight at the age of 5.

Lymphoid Growth Pattern

The growth processes of some lymphoid structures, such as thymus, lymphatic nodes, and adenoid glands or tonsils, undergo great development in early life. Thus, at the age of 5, they will have already reached 100% of their adult size, following their enlargement up to 180%, which is achieved at 12–13 years of age. From that time onwards, size nearly halves so that, roughly at 20, it reverts to the 5-year-old size.

Growth Pattern of the Reproductive System

Gonad and external genital growth takes place in two stages: embryonic–fetal stage, permitting sexual difference, followed by a long period when growth is very slow, without significant changes from birth to the end of prepuberty. At the beginning of puberty, and within a 3-year period, the second stage of growth, takes place when gonad and external sexual character growth is completed and reproductive capacity is achieved.

Growth Pattern of Adipose Tissue

This is characterized by rapid growth during the first year of life. Then it decreases, and from 10 years onwards there is a new increase, which is more evident in women's case, which continues in puberty. In contrast, in men it decreases, so that at the end of the growth process women's rate of body fat is almost twice that of men.

Growth and Variation of Body Proportions

After 2 months of fetal life, craniofacial section represents 50% of total body length. This decreases to 25% in the newborn, whilst in adulthood it is only one-eighth of total size. Leg proportion undergoes an opposite evolution to that of the cranium. Trunk proportional changes are much more limited. They affect the superior/inferior body segment ratio, which ranges from 1.7 at birth to 1.0 at 10 years.

Critical or Sensitive Periods of Cell Growth

Teratogens, infections, and nutrient deficiency have different effects on the growth and function of organs, depending on growth speed. That is, during the growth process there are critical or sensitive periods which are characterized by an increase of vulnerability to a specific stimulus. This phenomenon occurs along periods of maximum cell proliferation (cell hyperplasia), mainly in the fetal period and the first year of life, and in puberty, to a lesser extent.

In line with this is the 'programming phenomenon.' Poor nutrition and other adverse biological and environmental influences in the critical periods of fetal development and the first year of life may cause permanent changes in gene expression, cell replication, organic function and structure, hormone action and secretion, and growth factors. These factors, apart from affecting growth and body composition, will also favor the development of degenerative diseases such as cardiovascular disorders, high blood pressure, diabetes or hyperlipidemia (X-syndrome) during adulthood, and these diseases are nowadays the main cause of morbid mortality. Fetal growth is a significant predicting factor for postnatal growth and adult size (Figure 2).

Human Growth Pattern: The Infancy–Childhood–Puberty Model

Currently, the most accurate model for the relationship between growth and the biological factors responsible for growth at different stages of life is Kalberg's ICP (infancy–childhood–puberty) model. Based on experimental data, this model shows a general growth curve representing the additive and partially overlapping effect of its biological basis, from the fetal period to the end of puberty (Figure 3).

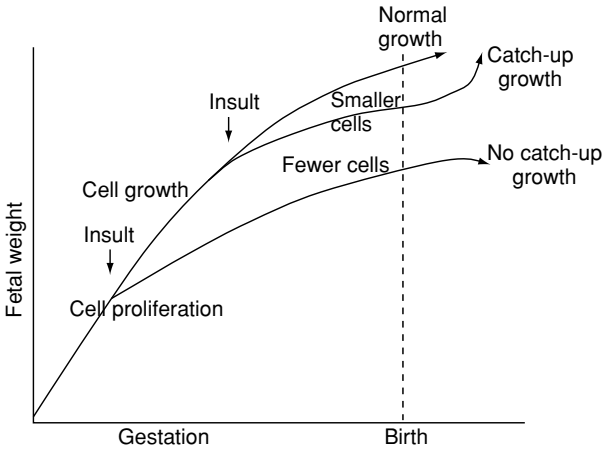

Figure 2 This diagram illustrates how fetal growth is predominantly by cell proliferation in early pregnancy and later by cell growth. For this reason, an early insult may result in a permanent reduction in cell number, whereas one later in pregnancy may reduce cell size and be reversible after birth. Reproduced with permission from Holmes R and Soothill PW (1998) Normal fetal growth. In: Kelmer ChJH, Savage MO, Stirling HF and Saenger P (eds) *Growth disorders*, pp. 143–157. Cambridge: Chapman & Hall.

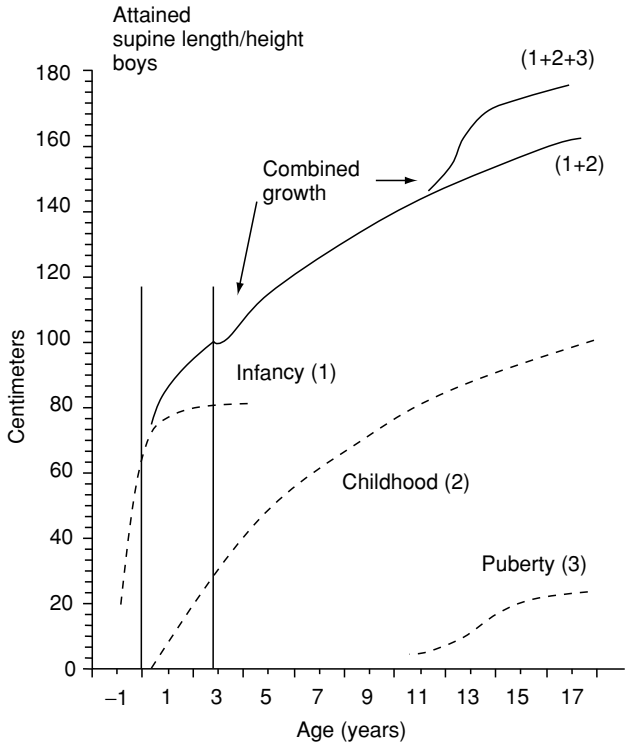

Figure 3 The infancy–childhood–puberty (ICP) model of growth: the infancy component is initially rapid but decelerates as the influence of growth hormone appears by the end of the first year. The effect of growth hormone is sustained through childhood but, in the absence of adequate sex steroid secretion, the pubertal growth spurt is blunted or absent. The combined input of the three components results in the normal pattern of growth until final height is achieved. Reproduced with permission from Karlberg J (1989) A biologically oriented mathematical model (ICP) for human growth. *Acta Paediatrica* 350 (suppl.): 70–78.

Infancy Component (I)

Infancy is from the second half of gestation to the second to third year of life. It is represented by an exponential function ($y = a + b(1-\exp(-ct))$. Therefore, it covers an accelerated period of fetal growth and one of high-speed postnatal deceleration. Growth during the fetal period and the first stage of life depends on the mother to a great extent, since her size, health, nutrition state, placental structure and function, and nutrient contribution to her child exert a great influence. In this sense, growth is mainly 'nutrition-dependent' as growth hormone (GH)-receptor scarcity and tissular insensitivity to their action show their secondary role in fetal growth and during the first period of life.

Childhood Component (C)

Up to the second to third year, the infancy component continues to influence growth. But, from the sixth month onwards, the childhood component starts to exert a progressive influence too, acting in both an additive and complementary way. After the second to third year, the childhood component keeps on exerting this influence until puberty begins. It is characterized by slow and stable growth. The mathematical model for the childhood component is a second-grade polynomial function: $y = a + bt + ct^2$.

In normal conditions, the childhood component starts between sixth and 12th month of life, becoming manifest by means of an increase in growth velocity. Its appearance represents the beginning of a progressive and significant GH effect on linear growth. At this stage, the highest percentage of body growth takes place at the inferior limbs and is related to a greater sensitivity of long bones to GH action in comparison to short ones and vertebrae. The fact that it starts after the 12th month may have a crucial influence on final adult size, as proved by the fact that the biggest difference in adult size between developing and developed countries is established during the very first period of the childhood component. Moreover, socioeconomic, health, and nutritional situation are also involved. Whilst the infancy component is 'nutrition-dependent,' GH action is essential for the childhood component, although nutrition continues to play an important role.

Pubertal Component (P)

The pubertal component is described as a logistic function: $y = a/(1+\exp[b-[t-tv]]$, and is the result of the synergy of two hormonal systems promoting growth, one of them depending on GH and the other one on sexual steroids (estrogens, testosterone). Growth accelerates, ending with a high-speed peak, and then decelerates to adult size.

Growth Velocity According to the following ICP Model

Fetal Growth

The fetal period is the most intensive period of life as regards growth and development. One characteristic is the elevated rate of cell division – there is maximum cell hyperplasia. It is a chronologically short although biologically active time. Let's say that 42 consecutive cell divisions take place in the fetus whilst from postnatal period to the end of growth only five more divisions take place. Thus, from the fertilized cell, the newborn gains 3500 g weight, whereas from newborn to adulthood its weight is only multiplied 20 times (3.5 kg to 70 kg). As regards length, the fertilized cell reaches 50 cm at birth. Subsequently, this length is multiplied 3.5 times (50 cm to 175 cm).

Infant Growth (0–2 years)

Postnatal growth is, essentially, hypertrophic: it is an enlargement of the already existing cells rather than the addition of new ones. The period of maximum postnatal growth corresponds with the first year of life. During the first 12 months of life, size increases 50%, by around 25 cm (50 versus 75–80 cm), weight rises 200%, by around 7 kg (3.3 versus 10 kg), and cranial circumference enlarges by 45%, which is around 11 cm (35 versus 47 cm), relative to birth. During the second year, there is an obvious deceleration of growth: size increases by only 10–12 cm (75 versus 85–90 cm), weight rises 2.5 kg (10 versus 12–13 kg) and cranial circumference enlarges by 2–2.5 cm (47 versus 50 cm).

Growth during Preschool Age (3–5 years)

This is the final stage of neonatal growth deceleration. Growth velocity slows down and becomes more constant; size increases by around 6–8 cm $year^{-1}$. Around the fourth year of life neonatal size has doubled (50 versus 100 cm), weight rises 2 kg $year^{-1}$ and cranial circumference enlarges by 1 cm $year^{-1}$. The increase is in leg length, while subcutaneous fat decreases. This changes the infant's look into a more slender, less rounded one than that of the first 2 years of life.

Growth Velocity from School Age to the Beginning of Puberty (6–10 Years for Girls, 6–12 Years for Boys)

Growth becomes slow and steady. The increment per year is 5–6 cm for size and 3 kg for weight. The child has a proportionally greater increase on leg length. Immediately before puberty, growth velocity reaches its lowest point – 4–5 cm $year^{-1}$. Cranial circumference growth is only 2–3 cm for this whole period.

When they are 6–8 years old, most children experience a slight prepubertal or midchildhood spurt. This mild acceleration (increment 1.5 cm $year^{-1}$) occurs basically at the expense of leg enlargement and coincides with an increase in suprarenal sexual hormone secretion, which may provoke an increase in GH secretion and peak (adrenarchy).

Pubertal Growth

Puberty begins with activation of the hypothalamus–pituitary–gonadal axis, by means of the coordinated action of sex steroids, GH, insulin-like growth factor 1 (IGF-1), and thyroid hormones. It is characterized by growth velocity and acceleration of development of sexual organs. After the slow, steady and prolonged growth stage which takes place in childhood, a progressively accelerating stage (growth spurt) begins, which peaks at maximum speed and then subsequently slows down. Although all body sections take part in the pubertal spurt, it affects trunk size to a larger extent than lower limbs. These stages have been expressed following a using musical system of descriptors (andante, moderato, allegro, lento, lentissimo).

The start of acceleration in pubertal growth happens 18–24 months earlier for girls than for boys. In the first year, growth velocity amounts to 7 cm $year^{-1}$ for boys and 6 cm $year^{-1}$ for girls. During the year of greatest growth (the peak), which happens for girls at 11.5 ± 1 and for boys at 13.5 ± 1 years of life girls gain 8–10 cm and boys 9–11 cm, mainly at the trunk. That is, growth velocity doubles and becomes comparable that which took place in the second year of life. Later on, there is progressive deceleration until adult size is reached. An important increase in weight velocity also occurs: at the peak it is up to 8–9 kg for boys and 7–8 kg for girls.

Before puberty, boys' and girls' size is similar. As girls' puberty begins earlier, they are slightly taller and heavier when aged 11–13. The fact that boys reach puberty 2 years later means that, when they begin it, they are 8–10 cm higher and 6–8 kg heavier than girls. Moreover, 2–5 cm and 2–4 kg must be added to the previously mentioned data because of a more intensive speed peak in boys' case.

Final Adult Height

At the end of growth, which happens 2 years earlier for girls (16 versus 18 years), boys are 10–15 cm taller and 8–12 kg heavier than girls.

Once the closure of long-bone epiphysis occurs, there is still a residual growth of 1–2 cm (no more than 1–2% of total size) which may go on until the 25th year of life, or even longer, when all the spine epiphyses are closed.

Growth Regulation

Growth is neither a constant nor regular linear process, but it is a dynamic one with a chaotic pattern that acts intermittently with static phases when growth is minimal, and jumps about, therefore showing a wide speed range in 1 year.

Determining Factors (Genome)

Growth is genetically determined by means of a polygenic device. Genetic influence on growth is less clear during the prenatal period, when birth weight depends 60% on environmental factors – basically maternal ones – with only 40% due to genetic influence. Nevertheless, the subsequent relationship of adult size with inheritance represents, under ideal health and environment conditions, 80% of

determining factors, so that environment only represents 20%. The fact that to a great extent genetic burden defines size becomes obvious in studies on twins. In the case of monozygotics the difference in their adult size is just 2.5 cm, with a correlation coefficient of 0.99, whilst in the case of dizygotics it is 12 cm, with a coefficient of 0.66. The variability rank between brothers rises to 16 cm, with a coefficient of 0.55, reaching a rank of 25 cm in the general population. Another sample of genetic influence is sexual maturation, since the difference of menarche appearance age in monozygotics is 2 months, in dizygotics is 1 year, while in the general population it is more than 1 year. The correlation between the parents' size and children's adult size is 0.55 when compared to both parents' size, 0.45 for mother and children and 0.42 for father and children. Regarding the correlation between birth size and adult size, this is low in the newborns case ($r = 0.25$–0.30), but increases rapidly and significantly so that in the second year it is already 0.80.

Regulating Factors (Hormones and Growth Patterns)

Each cell is controlled by an enormous variety of hormones, growth patterns, and their carrier proteins. This is accomplished in different ways and by different pathways: endocrine, paracrine, autocrine, juxtacrine, intracrine, and neuroendocrine ones. However, all pathways are necessary to express the whole genetic potential of growth (Table 1).

Prenatal growth regulation Hormonal regulation of fetal growth shows important peculiarities in connection with postnatal growth. GH exerts scarce influence. In contrast, human placental lactogen (hPL) plays a more important role. Although its structure is similar to GH, its growth-promoting action is lower than that of GH.

IGFs play an important role in regulating fetal growth. IGF-2, with insulin-like actions, as well as actions on fetal, placental, and uterine growth, is very important during the fetal period. IGF-1, especially in the last months of pregnancy, keeps a close correlation with birth weight and size, as shown by serum levels. Newborns suffering a delay in their intrauterine growth show significantly lower levels at birth and in their first year of life, especially those whose fetal growth delay was more intense and with a lower adjusting index. This means that IGF secretion is sensitive to nutrient availability, particularly that of energy and proteins. Other growth factors, such as neural growth factor-β (NGF-β), epidermal growth factor (EGF), and transforming growth factor-α (TGF-α), also play a role in cell growth and differentiation. Insulin has an important function, not only in protein synthesis, but also in cell transport and use of amino acids and glucose, in enzymatic induction, in lipogenic activity, and in somatic growth. It also plays a part in the regulation of IGF-1 synthesis. Thyroid hormones, glucocorticoids, and sexual hormones exert a bigger influence on the development of specific organs than on longitudinal growth. The role of thyroxine in the development of the central nervous system is to be noted (Table 2).

Postnatal growth regulation The role of hormones during the postnatal period as executors of the predetermined genetic program for growth is a crucial one. GH is essential for normal linear growth from the end of the first stage of life, when the quantity of receptors and tissular sensitivity to GH becomes evident.

Table 1 Modes of cellular regulation

Mode	*Agent*	*Source*	*Vehicle*	*Target*	*Modulators*
Endocrine	Hormone	Gland	Circulation	Heterologous tissue	Neurons Hormones Growth factors
Paracrine	Growth factor	Local site	Diffusion	Heterologous cell	Hormones Growth factors
Autocrine	Growth factor	Local site	Diffusion	Autologous cell	Hormones Growth factors
Juxtacrine	Growth factor precursor	Local site	Cell contact	Adjacent cell	Proteases
Intracrine	Hormone Growth factor Nutrient	Intracellular	Cytoplasm	Intracellular receptor	?
Neuroendocrine	Neurotransmitter Growth factor	Neuron	Axon	Heterologous tissue	Hormones Growth factors Neurons

During puberty, the increase in sexual hormone secretion – in males this is testosterone while in females it is estrogen – stimulate GH and IGF secretion as well as their local action on growth cartilage. The pubertal growth spurt is, therefore, closely connected with the interaction of GH, IGF-1, and sexual hormones.

GH actions imply a complex interaction of factors, including cerebral neurotransmitters and hypothalamic peptides; genes, receptors, and GH-carrier proteins; IGFs and their receptors; carrier and inhibitor proteins, and nutritional signs. GH exerts direct actions on cell division, protein synthesis, lipolysis, enzymatic induction, and the stimulation of cellular transport of amino acids and glucose. Its effects in promoting longitudinal growth affect growth cartilage directly, inducing maturation of the most undifferentiated and indirect chondrocytes, facilitating the expression of IGF-1 gene, which for its part stimulates chondrocyte maturation and multiplication. The importance of GH, GHBP (growth hormone binding protein), IGF-1 and IGFBP-3 (insulin-like growth factor binding protein-3) carrier proteins is notable in the activity and function on the GH–IGF-1 axis growth (Figure 4, Table 2).

Table 2 Insulin-like growth factors and binding proteins

	Functions
IGF-I	Fetal growth and especially postnatal one Insulin-like actions Important sensitivity to undernutrition
IGF-II	Fetal growth Important insulin-like actions Limited sensitivity to undernutrition
BP-1	Transport of IGFs from vascular space
BP-2	Transport of IGFs from vascular space
BP-3	Sequesters the circulating IGF in an inactive form. Component of 150 kDa serum IGF complex intravascular reservoir
BP-4	Blocks IGF action in cells
BP-5	Potentiales IGF action in cells

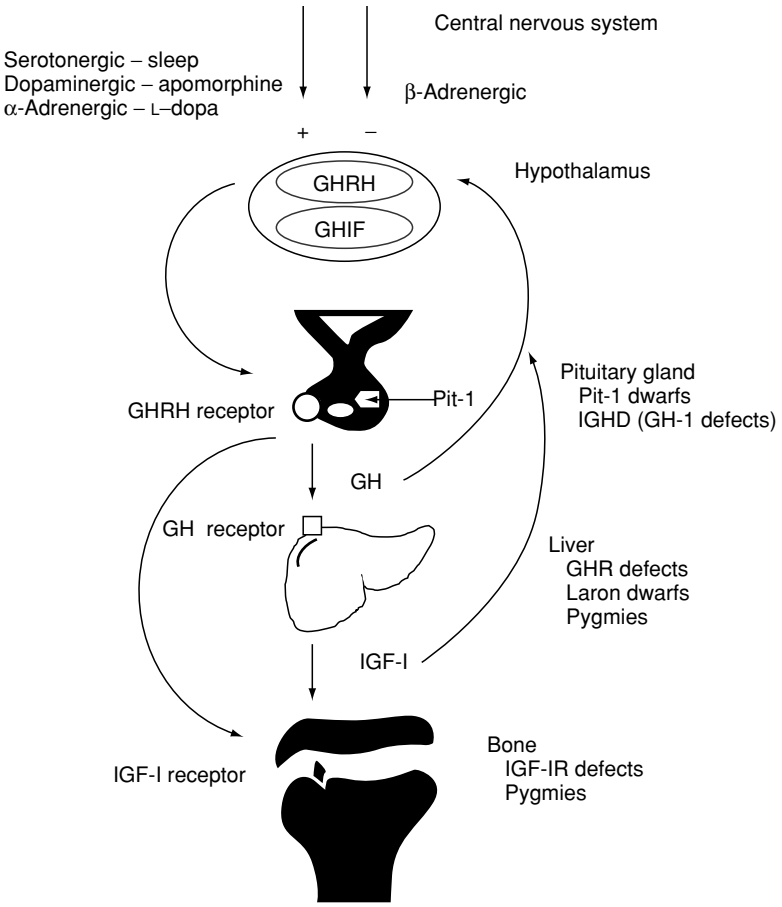

Figure 4 Regulation of growth hormone (GH) secretion: this is regulated by various factors. The sites of derangements responsible for various familial disorders of the GH axis are indicated on the right. GHRH, growth hormone-releasing hormone; GHIF, growth hormone-inhibitory factor, Pit-1, specific pituitary transacting factor; GHR, growth hormone receptor. Reproduced with permission from Mullis PE (1998) Genetic control of growth. In: Kelmer ChJH, Savage MO, Stirling HF and Saenger P (eds) *Growth disorders*, pp. 39–61. Cambridge: Chapman & Hall.

There is a close relationship between IGF-1 and GH. GH, diet, and nutritional state are the main factors regulating IGF-1 synthesis. Although the contribution of proteins and essential amino acids is important for IGF-1 regulation, it is essential in accurate energy input. Liver is the most important source of plasma IGF-1, which acts as an endocrine factor, but many other organs and tissues also synthesize IGF-1 by a local action where it is synthesized or in adjacent tissues, that is, with autocrine and paracrine action. This suggests a diffuse biological action: not only a metabolic but also a mitogenic one, with effects on cell proliferation, protein synthesis, and body enlargement processes.

Thyroid hormones have a role in bone maturation, metabolism, and central neural system (CNS) development. Apart from their direct effect on the cartilage, they are necessary in adequate GH secretion and as a complete expression of their effect on cartilage and bone formation. They stimulate IGF-1 production, while a lack of thyroid hormones restricts the effects of IGF-1 on the cartilage, independent of the effects it exerts.

Insulin favors protein and hepatic glycogen synthesies, as well as lipogenesis. In addition, it exerts an action promoting mitogenic growth mediated by IGF and other growth factors. Sexual hormones play an important role in sexual maturation and pubertal growth, and together with GH are responsible for the pubertal spurt. They exert direct anabolic action and an effect modulating GH and IGF-1 secretion and function.

Peptide growth factors Quite recently a group of messengers has been discovered inducing cell growth, proliferation, and differentiation. Unlike classical hormones, they are delivered in multiple cell types and act in more locally, exerting their actions on a wide variety of cell types or on specific tissues. Epidermal growth factor (EGF) mostly acts on cells of ectodermal origin cells and activating the mitosis of epithelial cells, conjunctive tissue, glial cells, and granulosum ovarian cells. Alfa transformant growth factor (TGF-α) shows similar actions to EGF, and shares the same membrane receptors. Platelet-derived growth factor (PDGF) is a mitogen for many types of mesodermic cells such as fibroblasts, smooth-muscle cells, and glial cells. Fibroblastic growth factors (FGF) stimulate the proliferation of cells of endodermic and mesodermic origin. Together with these growth-stimulating factors, there is an inhibitory system, which is quite unknown so far.

Permissive, External, or Environmental Factors

Nutrition is the main permissive factor, but at the same time socioeconomic, health and psychoemotional levels, environment, habitat, and iatrogenic factors will make it possible or not to achieve the highest genetic potential for growth.

Nutrition has a direct influence on the expression of genes controlling growth and metabolism. It is indispensable for the adequate function of regulating factors and, for their part, these influence nutrient transport and use. Most hormones and growth factors join cell receptors and their ability to influence the genome requires a 'cascade' of reactions, involving proteins, lipids, and ions as secondary messengers. Hormonal control of growth is highly sensitive to nutritional mean, so that intracellular availability of nutrients is the last regulator of growth. Therefore, malnutrition has important negative effects on growth, affecting the GH–IGF axis.

Together with malnutrition, low socioeconomic, and familiar educational levels, the number of children and home characteristics have a negative added influence on growth, not only on prenatal but also postnatal growth. Differences in adult size are due, to a large extent, to the growth delay accumulated during fetal stage and during the first 3 postnatal years, since this is not effectively made up later on. So, in the case of those individuals short for gestational age (SGA) – mainly in symmetric factors (size, weight, and cranial circumference within the same percentile) – who manifest a situation of prolonged malnutrition, their adult size is lower.

Any disease, especially a chronic one, interferes with normal growth and development. The degree affected depends on age at onset, duration, and seriousness. A growing social phenomenon is growth failure due to a serious emotional deprivation producing a lower GH secretion (psychosocial growth delay). An adverse familiar environment and ill treatment are two examples of this condition.

Growth Velocity Secular Trend

Over the last 150 years, since the beginning of the Industrial Revolution, growth velocity has speeded up, producing a significant increase in average adult size in developed countries. The existence of better socioeconomic, hygienic, sanitary, and nutritional conditions has had an important influence. In Spain, the socioeconomic, sanitary, and nutritional changes occurring in the twentieth century marked the evolution of an increase in secular growth. The situation in 1900–50 was that of a developing country nowadays. In 1950–99 the Spanish economic miracle took place, accompanied by a spectacular improvement in lifestyle, medical care, and the availability and accessibility of food of high nutritional value. During the period 1900–55 the height of Spanish soldiers

Table 3 Secular trend in Spain

	Mean Height of Spanish recruits (1956–1996)		
	Height (cm)		
Autonomous Community (regions) CC.AA.	*1956*	*1996*	*Δ1956–1996*
País Vasco	168.7	175.2	6.5
Cataluña	168.6	175.0	6.2
Canarias	167.3	175.1	7.8
Baleares	167.1	174.9	7.8
Madrid	166.8	175.1	8.3
Navarra	166.8	175.6	8.8
Cantabria	166.8	174.8	8.0
Valencia	166.3	174.8	8.5

Asturias	165.9	174.5	8.6
La Rioja	165.3	175.0	9.7
Murcia	164.4	174.8	10.4
Castilla-León	164.3	174.8	10.5
Castilla-La Mancha	164.2	174.7	10.5
Andalucía	164.2	174.5	10.3
Galicia	164.2	174.0	9.8
Extremadura	164.0	174.0	10.0
Difference Between (CC.AA.)	4.5	1.6	
Spain	165.9	175.1	9.2

increased only 1.7 cm (0.3 cm per decade), whereas in 1955–95, it increased by 9.2 cm (2.3 cm per decade). A remarkable fact is that differences in adult size among recruits from different regions over the last 40 years have significantly decreased, ranging from 4.5 cm in 1956 to just 1.6 cm in 1996. Those regions which were less developed in 1955 showed a far superior increase with relation to most developed ones, as their income per capita approached the most developed regions (Table 3).

'Catch-Up,' 'Catch-Down,' and Channeling

Birth size reflects maternal environment rather than fetus genotype. Thus, during the first 2 years of life many children suffer some changes in their growth velocity as maternal factors are progressively losing influence and genetic forces determining postnatal growth pattern are gaining in importance. Children born shorter or larger than they should be according to their genetic growth potential gradually change their weight and size percentile upwards or downwards until they reach the most appropriate one, corresponding to their genome. At this point they standardize their growth velocity. These acceleration and deceleration processes, occurring during the postnatal adaptation period, are known as 'catch-up' and 'catch-down,' or 'lag-down,' respectively.

From 2 years onwards, growth becomes quite a steady process, following an extremely regular pattern. It is unusual that a healthy infant changes the channel determined by its genetic antecedants by more than one percentile. So, from this age, size is closely correlated with adult size. This pattern or growth curve has been defined as 'a guided missile' and as a ship led along a channel, so that the infant undergoes a 'canalized' growth process. 'Channeling' has been defined as the capacity of reverting to the original growth curve after moving away from its pattern because of a disease and/or malnutrition. 'Catch-up' is the recuperation growth, which can be three to four times higher than average until the original channel is reached. The earlier and longer an insult is, the more difficult complete recuperation of growth becomes.

Methods for Growth Assessment

Anthropometric Study

The assessment of somatic growth is based on the analysis of those changes produced in time in body size, shape, and composition. In order to value the most important aspects of growth, one of the most reliable methods is the anthropometric study, that is, the application of biomedical techniques expressing quantitatively body shape, which is called 'auxological anthropometry.' The validity of the method depends on a precise and exact measurement with an accurate device or material and by means of a right technique.

Height and size Body height measurement is the best parameter of skeleton growth, since, unlike weight, this is not influenced by fat or water accumulation. Over the first 2 years of life, it is preferable to measure height in the supine position. Ideally, mechanical instruments (Harpender's infantometer, ranging from 300 to 940 mm) should be used to get an exact measure. Size is used instead of height from 2 years onwards, and the chosen instrument is Harpender's stadiometer.

Cranial circumference This one of the most anthropometric measures in children, since it is related to intracranial volume and makes possible an estimate of brain growth velocity. To make this measurement, a nonextensible metal tape measure is used.

Estimate of weight and body mass Weight is not as specific a growth measure as size, since it shows body composition (water, fat, muscle, bones, viscera), that is, a mixture of tissues. But weight, mainly in infants, is a better reflection of health and nutritional state. Precision balances must be used, not only

electronic (which are better for infants), but also manual ones. They should be periodically balanced and calibrated.

Subcutaneous fat is a measure that correlates adequately with body fat content, being higher than weight for adiposity assessment. It is, therefore, an important measure of nutritional state. Triceps subcutaneous fat represents accurately limb fat, and subscapular one shows trunk fatty deposit. The assessment of the deposit of subcutaneous fat tissue must be done with a thickness compass (Holtain calliper).

The weight (kg)/size (m^2) index, or Quetelet's index, or body mass index (BMI) is nowadays considered the most accurate indicator of weight/size.

Bone maturation The most useful way to measure biological maturity is to estimate skeleton age. This is because the changes bones suffer during maturation are very similar in all individuals, and each ossification center undergoes a series of morphological changes which are easily identifiable. Conventionally, an X-ray of the left hand and wrist is used to calculate skeleton maturity simply, because there is a great proportion of long and rounded bones in an easily accessible area.

Atlas methods assess quantitatively the maturity of epiphyseal nuclei. The most widely used one is that of Greulich and Pyle. Numerical methods are ahead of atlas ones, since by transforming a simply qualitative evaluation into a quantitative phenomenon, they allow more precise assessment of the normal process of bone maturation and pathological set of symptoms by means of the mathematical analysis of data. The most widely used method is that of Tanner and Whitehouse (RUSTW2).

Adult Height Prediction

Adult height prediction according to parents' height: genetic potential for height Since genetic constitution is the main determining growth factor, parents' height is of special importance in their children's growth assessment. Each parent's height contributes equally to their children's growth, so their mean height must be a reference. Garn and Rohman, using the data in Fels' longitudinal studies, made tables of mean parental height, which are useful to predict the most probable child's height at a determined age and final height. Tanner constructed some graphics for 2–9-year-old children in which their height is expressed as a percentile of the expected standard, adjusted to mean parental height. A calculation of the expected target size based on mean parental height (genetic growth potential) is achieved like this:

For a boy :

$$\frac{\text{Father's height} + (\text{mother's height} + 13\text{cm}) \quad 10 \times 2}{2}$$

For a girl :

$$\frac{\text{Mother's height} + (\text{father's height} - 13\text{cm}) \quad 8.5 \times 2}{2}$$

Kalberg proposes a new model to estimate target height. It is a simple linear function of mean parents' size (y = estimate of child's height, x = mean parents' size (cm)). It is $y = 45.99 + 0.78x$ for boys, and $y = 37.85 + 0.75x$ for girls. This new model gets better results than the equation of corrected parental height, especially in the case of children whose parents' height is short.

Methods of adult height prediction These methods are based on, or use, skeletal maturation, not only to determine growth velocity but also to make a prediction of adult size. The three predicting models most widely used are:

1. Bayley-Pinneau's method: this uses tables from bone-age data taken from Greulich and Pyle's atlas. These are based on total growth percentage achieved at different ages: there are three subgroups according to whether bone age is advanced, slowed, or accurate in relation to chronological age. These tables can only be applied to bone aged over 6 years.
2. Roche, Wainer and Thissen's method: this uses correlation coefficients existing in different age periods between final size and height, weight, and bone age, according to Greulich and Pyle's atlas, and parental size. This method can be used for 1–16-year-old boys and 1–4-year-old girls.
3. Tanner's method: based on a mathematical equation relating a number of coefficients established for each age and sex under the following parameters: height, bone age, according to the RUSTW2 method, and chronological age. In 1983 the method was revised and more exact predicting equations were proposed.

Graphics and Limits for Normality

As human growth shows a strong tendency to remain 'channeled,' the successive points of a curve are strongly correlated. So, the best method of assessing growth is to measure it regularly and represent it on standard graphics. In this sense, periodic measurement of growth is a sensitive, easy and economical indicator of the state of health and quality of life of children and the population.

Distance graphics Distance graphics are useful to understand a specific growth situation, the height achieved at an individual's age or by the children of any community, by comparison. Distance graphics come from the study of a sample of children of different age who are examined just once ('cross method'). Therefore, it is useful to assess growth, nutrition, health or socioeconomic state, and differences and to monitor height variations in groups or in the whole society. In contrast, the longitudinal method allows the follow-up of a population sample during part or all growth periods. Each child is measured at regular intervals of time. This method is the only one that permits the analysis of individual circumstances and the inflections produced in growth velocity, as well as creating curves for growth velocity. Therefore, it is essential for clinical analysis, diagnosis, and treatment of growth disorders.

To analyze variations, increments, or inflections in the speed of children's growth, it is necessary to have velocity standards in velocity graphics. These can express growth increments experienced in a specific time interval. So, to assess velocity, height increment is divided into the time which has passed between two measurements. The time between two measurements is more easily calculated by means of a decimal calendar.

To assess if a child is within the normal variation limits for growth, percentiles or standard deviations must be used. The third and 97th percentiles define the cutting point between normal and pathological risk, and the first and 99th percentile define pathological risk. Standard deviation, calculated by means of a score standard deviation or *Z*-scoring, allows one to evaluate multiple or fraction standard deviations of a subject separated from the average, by means of the formula: $Z = a - x/\mathrm{TD}$, where a = value to compare, x = mean of standard group and TD = typical deviation. When it is $\pm$ 2 SD, the risk area starts, and $\pm$ 3 SD would be pathology.

The most widely used graphics from an international point of view are Tanner's (longitudinal) and those from the National Centre of Health Statistics (cross ones). However, the most accurate procedure will be to use individual country standards.

GUAVAS

S Yusof, Universiti Putra Malaysia, Selangor, Malaysia

Introduction

Guava has long been established in many tropical and subtropical countries of the world, although its origin was from Central America. Much of the interest in guava has been due to its extremely high vitamin content. Nutritionally, it is a healthy fruit, containing relatively high amounts of vitamin C and total fiber. Guava has the potential to become a commercially important tropical fruit crop not only for processing, but also for fresh consumption. Improved propagation techniques have produced fruits with better quality and thus increased the commercial importance of the fruit in many countries, especially in the Far East.

Morphology and Anatomy of Fruits

Guava is the most important fruit plant in the large family, Myrtaceae, which also includes strawberry guava, *Psidium cattleianum sabine*; the rose apple, *Engenia jambos*; Surinam cherry, *Engenia uniflora*; the mountain apple, *Engenia malaccensis*; the Java plum, *Engenia cumini* Merr.; and the spices cinnamon, clove, allspice, and nutmeg. Guava is classified under the genus *Psidium* which contains 150 species, but only *Psidium guajava* has been exploited commercially. Guava is a shrub but under high moisture conditions can grow up to 6–9 m in height and spread, with trunk diameters of 30 cm or more. The trunk is short, freely branching from the base. Branches are pliable and hence are rarely broken by winds. Leaves are usually opposite and simple, arranged in pairs; oblong or oval in shape measuring about 10–18 cm in length; smooth on the upper surface but finely pubescent on the undersurface and prominently veined. Flowers occur singly or in clusters of two to three at the leaf axils of current and preceding growth. The flowers are bisexual or called perfect flowers. They are white in color, 2.5–3.5 cm in diameter, with four or five petals, numerous stamens, and one style. Flowers open between 5 and 7 a.m., depending upon the cultivar and morning temperatures. The tubular calyx encases the bud and splits into four or five segments at anthesis. The ovary is inferior with four or five carpels, each containing numerous ovules in axile placentation. The flowers can be self-pollinated, but cross-pollination takes place most frequently, aided by bees and pollen-carrying insects. After fertilization, the flowers will develop into mature fruits.

Botanically, the fruit is a berry or capsule. It is a many-seeded berry, varying in size from 2.5 to 10 cm in diameter and from 50 to 500 g in weight. The shape of the fruit can be globose, ovoid, elongated, or pear-shaped. The color of the skin of some varieties may turn yellow when ripe; the flesh color may be pink, salmon, white, or yellow. Skin texture may be smooth or rough. The inner walls of the carpels are fleshy and of varying thickness and seeds are embedded in the pulp. The fruits may have thick flesh with only a few seeds in a small center cavity, or thin flesh with numerous seeds embedded in a large mass of pulp. The seeds are small, bony, kidney-shaped, flattened, light yellow or yellowish brown, measuring about 3–5 mm long by 2–3 mm wide. It occupies about 1.6–4.4% of the weight of fruit. Fruit growth follows a simple sigmoid curve and pulp growth parallels total fruit growth. The days from anthesis to harvest can vary from about 120 to over 220 days, depending upon temperature during fruit development. The variation between different cultivars can be up to 60 days.

Cultivars

Guavas can be classified into three types depending on their end use, namely the dessert type, the processing type, and those suitable for both dessert and processing (Table 1). In India a low-acid dessert cultivar, such as Allahabad Safeda an 'apple color,' with white flesh was developed. South Africa's Malherbe and Fan Ratief are mild, sweet, dessert types, with light pink color. They are also suitable for canning as halved fruit. For processing, Beaumont, Ka Hua Kula, and Waiakea are recommended in Hawaii. Beaumont was the first processing cultivar introduced to Hawaiian industry and was the only recommended processing guava until the introduction of Ka Hua Kula. Beaumont produces fruits ranging from 145 to 235 g, averaging about 170 g. Fruits are mildly acid with total titratable acidity ranging from less than 1.0% during the summer to about 1.25% in winter. Soluble solids range from about 7% in winter to 10% during summer. Fruit characteristics of Ka Hua Kula are similar, with a slightly stronger pink color and somewhat higher acidity. Both varieties are good yielders, exceeding 227 kg tree^{-1} year^{-1}. Florida has developed both dessert and processing cultivars of excellent quality. Ruby, Supreme and the hybrid Ruby × Supreme, are excellent dessert types. Pink Acid and Patillo are

two acid cultivars with dark pink color suitable for processing. Other varieties that have been developed in various countries are as shown in Table 1.

Certain guava cultivars exhibit a change of skin color from green to yellow during ripening, whereas in others the color remains green and this is dependent on the cultivar. The flesh color may change from white to either creamy white, yellowish pink, deep pink, or salmon-red upon ripening. The presence of carotenoids, lycopene, and β-carotene may influence the intensity of the flesh color of ripe fruit. Fruit texture may differ between cultivars and it varies with position of the tissue. For example, the Beaumont cultivar is significantly softer when ripe, and its firmness decreases more rapidly during ripening than that of the Vietnamese guava. Irrespective of the cultivar type, outer mesocarp tissue of the fruit is consistently firmer than inner mesocarp tissue.

Fruiting Cycle

The fruiting peaks can deviate with prevailing weather conditions and cultural practices. Since flowers are produced on new growth, factors that stimulate new growth, such as irrigation, fertilization, pruning, and defoliation stimulate flowering. The practice of pruning, fertilizing, and irrigation at the end of harvest is essential. Pruning is repeated every 8–9 months. Initial flowering after pruning occurs in about 5–6 weeks. Defoliation can be accomplished using urea plus ethephon and a detergent. Following defoliation, new leaves appear in about 3–4 weeks, with a peak of flowering occurring 9–12 weeks after defoliation. This is followed by fruit set and a peak of abscission of young fruit. The percentage fruit abscission is correlated with number of fruitlets set per tree. In Hawaii, a small harvest peak occurs between April and November.

Guava plant grows best in warm areas with abundant moisture. The ideal rainfall pattern for guava is alternating dry and wet conditions. The optimum temperature is reported to be between 23 and 28 °C. Temperatures lower than 23 °C and higher than 27 °C during flowering would reduce fruit set significantly.

Chemical Composition

The chemical composition of guava fruits is shown in Table 2. As in most fruits, moisture constitutes a fairly large portion of guava fruit (85%); the energy content is relatively high (230 kJ); the protein and fat contents are low (0.3% and 0.1%, respectively). Carbohydrates are the principal nonaqueous constituents of guava. Of the total carbohydrates (15%), 5.82 g are the sugars fructose, glucose, and sucrose.

Fructose is the predominant sugar, constituting about 58.9%, followed by glucose (35.7%), and sucrose (5.3%). During development and maturation the sugars increase gradually and then decrease in overripe fruits (Figure 1). The fiber and ash contents are considered high, with values of 2.4 and 0.5 g respectively. Refer to individual nutrients .

Nutritional Value

Guava is an excellent source of ascorbic acid (Table 3). It is mainly located in the skin and a slightly lower concentration is found in the flesh. The content of ascorbic acid, which is also cultivar-dependent, varies from as low as 60–100 mg 100 g^{-1} in some cultivars to about 200–300 mg 100 g^{-1}, or to even higher levels (800–1000 mg 100 g^{-1}) in other cultivars. Ascorbic acid level generally increases with ripening, and also with decreasing depth of the mesocarp tissue. The fruit has an appreciable amount of minerals such as calcium, phosphorus, iron, potassium, and sodium as well as vitamins like vitamin A, thiamin, riboflavin, and niacin. (*See* **Vitamins**: Overview.)

Table 3 Ascorbic acid content of several guava varieties

Location	*Variety*	*Ascorbic acid (mg 100 g^{-1})*

Important Biochemical Composition

Acid Content

Glycolic, malic, ascorbic, and citric acids were the major organic acids detected in guavas. Also present is fumaric acid. Total acid level calculated as citric acid ranges from 0.2 to 1.1% fresh weight. The level of ascorbic acid is quite substantial, those of malic and glycolic acids are relatively low, while fumaric acid is only found in trace amounts. The presence of these acids in guava is responsible for the tart flavor and also for its relatively low pH of 3.2–4.1. (*See* **Acesulfame/Acesulphame**.)

Flavor

Flavor and aroma vary widely among the different cultivars. There are low-acid, sweet types, bland types that are low in both sugars and acidity, and high-acid types. The musky aroma is more pronounced in the fully ripened, low-acid, sweet types. The flavor of guava is determined by the types and amounts of sugars, acids, phenolics, and volatile compounds that are present in the fruit. The proportions of these chemical constituents may vary with the fruit age and with the cultivar. Depending on the cultivar, these flavor compounds may accumulate to different extent during ripening and thus may result in guava fruits having a distinctive aroma and taste.

The volatile flavor constituents of guava have been isolated and separated. There are 22 compounds in Hawaiian guavas, of which methyl benzoate, hexanol, *p*-phenylethyl acetate, methyl cinnamate, cinnamyl acetate, and β-ionone are believed to play predominant roles in the flavor and odor of the fruit. More recently, 154 compounds were identified, of which 116 were described in guava for the first time. Later on, 122 volatile compounds in guava were identified. Among the identified compounds were 13 aldehydes, 17 ketones, 31 alcohols, 10 acids, 28 esters, 10 hydrocarbons, and 13 miscellaneous compounds.

Tannins

Tannins or polyphenols are another group of compounds that have been considered in many fruits and lately in guavas. The function of these compounds in plants is unknown, but their ability to combine with proteins has often caused problems for food scientists. Their role in the browning of fruit and fruit products, and a cause of cloudiness in many fruit juices, has long been recognized. Tannins have also been associated with astringency in many fruits, especially in less ripe ones. Changes in polyphenols and polyphenoloxidase activity have been reported during fruit development in guavas. There were decreases in seven categories of phenolics (total phenols, nontannin phenols, tannin phenols, hydrolyzable tannins, simple phenolics, nontannin flavans, and condensed tannins) during ripening; insoluble leucoanthocyanins were the major components. At the mature stage, polyphenolase activity was barely detectable in both pink and white-fleshed guavas. However, at the ripe and fully ripe stages, polyphenolase activity increased dramatically, and this change was stated to be responsible for the decrease in polyphenolics during ripening and the subsequent decline in astringency. (*See* **Dietary Reference Values; Tannins and Polyphenols**.)

Pectin

Several workers demonstrated the potential of guava as a source of pectin. Pectic substances are contained in the intercellular spaces of cell walls where they function as bonding and lining materials. The significance of pectin is in contributing to the rigidity of plant tissues. The pectin content in guavas is highest in the mature stage. The value decreases in the ripe and overripe stage. The methoxyl content is an important factor in evaluating the gelling property of pectin. The values obtained from fresh white and pink cultivars were 3.23% and 3.03% respectively. The equivalent weight of guava pectin varied from 2181 to 3173, which is considerably higher than that reported for mangoes. The presence of pectin in guava impart a viscous property to the guava purée or juice. The pectic substances have been shown to combine with protein or polyphenolic compounds to form a cloud suspension. During the extraction of juice from fruit, pectin is released from the cell wall and since the pH of the juice is lower than the isoelectric point of protein, the positively charged protein is surrounded by the negatively charged pectin. Due to the interruption of the negative charge of the outer pectin molecule, the cloud suspended in the juice is more stable. The pectin contains neutral sugars, rhaminose, arabinose glucose, and fructose in branched chains that can bind to the protein with a hydrogen bond and make the cloud more stable. The content in guava purée was found to be between 5 and 8%.

Stone Cells

Guava contains a considerable amount of stone cells which contribute to an undesirable gritty texture to the processed purée. The number of stone cells that is tolerable varies from region to region. In Brazil, the presence of stone cells is considered a positive quality factor. According to a recent report, there are two types of stone cells in guava: an irregular-shaped type, abundant under the epidermis, and a smooth type found in the core region of the fruit.

Stone cells are developed from parenchyma cells by secondary thickening of the wall. Cell differentiation occurs when fruits are about 14 weeks old. As the fruits increase in maturity, cell wall thickening appears to be more prominent. The stone cells are found in clusters, each measuring approximately 300 μm in length. The presence of stone cells in the flesh of fruits has no specific function. In leaves or other parts of the plant, stone cells may help to give rigidity to the plant part or may act as a protective covering, as in the testa of seeds. The composition of stone cells is reported to be as follows: 0.92% fat; 1.05% ash; 1.50% protein; 37.1% lignin; 53.9% cellulose; 5.49% soluble carbohydrates.

Harvesting

Guavas produce varying amount of fruit throughout the year in the tropics. Fruit yields depend upon cultivar potential, plant density, weather conditions, and all the factors involved in management. On the average the yield ranges from 25 to 40 t ha^{-1} $year^{-1}$. Guava fruit generally takes about 17–20 weeks from fruit-set to reach maturity. The recommended optimum stage for harvesting is about 2–3 weeks before attaining full growth, because guava fruits will experience changes associated with ripening such as skin yellowing, and decrease in tissue firmness and in detachment force while they are still actively growing. It was reported that the Ka Hua Kula guava entered the ripening phase when the fruit was only half the maximum size while in Allahabad Safeda ripening changes occurred towards the end of the growing period. For green ripe guava cultivars, fruit size, moisture content, or chemical attributes such as total soluble solids, titratable acidity, sugar and tannin contents, may also be adopted as additional maturity indices.

Guava fruit must be harvested with great care because of their soft and thin skin. Harvesting is normally done manually to avoid physical injuries, although tests with machine harvesting have been conducted in some countries. Subsequent handling and transportation of the fruit also need extra precautions to reduce bruising. Dessert fruit are hand-harvested mature green and carefully handled to avoid injury, graded to size, and packed carefully in cartons for shipment. Processing fruit should be picked at the firm yellow to half-ripe stage. Overripe fruit and those severely infected with fruit flies and diseases should be destroyed rather than left to fall and rot in the field. When only fully ripe fruits are harvested on a 3-day cycle, losses between 35 and 40% can occur. Harvesting fruits showing some yellow to the half-ripe stage allows the interval between harvest cycles to be lengthened to about 3 days and this would minimize losses. Fruits are harvested into plastic buckets or packing bags worn by the harvester with bottom delivery. The fruits are transferred into larger bins or small wooden boxes and placed in the shade until delivered to processing plant.

Storage and Handling

The common guava (*P. guajava*) is a climacteric fruit. If full-size pale-green fruits are stored at 20 °C, the peak in carbon dioxide and ethylene production occurs about 5–6 days after harvest. Biochemical and color changes accompany the ripening process. Storage of two processing guava cultivars at 20 °C, showed that the fruit developed eating ripe quality after 5 days. After 7 days at 20 °C, the skin was discolored and some rotting occurred. Storage at 0–10 °C extended the postharvest life for about 2 weeks. Storage at 0 °C reduced rotting, but caused chilling injury to the pulp, resulting in darkened flesh. The optimum storage temperature was 5 °C since pulp injury occurred least at that temperature. Several trials have been carried out to prolong the storage life of guavas. Recent experiments indicate that the storage life of mature fruit may be extended up to 1 week at room temperature by using modified atmospheres. Waxing accompanied with low-temperature storage (8–10 °C) increased storage life to 21 days. The use of carnauba-paraffin emulsion imparted a gloss to the fruits that is normally lost during storage. Fully ripe guava should be processed without delay, but if necessary, they can be held for about a week at 2–7 °C with only a small loss in vitamin C content. Storage at 0 °C for up to 2 weeks is used commercially in Hawaii.

Guava fruit is highly perishable; therefore, it is important to select the right type of fruit and the right packaging material for transport. Shallow wooden boxes should be used to protect the fruit from external hazards and from internal crushing of lower fruits if containers are too deep. For long-distance shipments, soft filling or cushioning materials should also be used. Good ventilation is important to prevent build-up of heat and humidity, which promotes microbial spoilage. If ripe fruits need to be shipped, it might be better to hold them in a cool or shady area and transport them during the cooler night temperatures. The best practice would be to ship unripe fruit and ripen it under controlled conditions at the processing plant.

Diseases

Some diseases and causal organisms are specific to certain countries and others are widespread where

guavas are grown (Table 4). Anthracnose is widespread and is considered an important disease in most countries. Algal spots are very common but are not usually serious, except they are of concern in fruits for dessert. Other types of fruit rots are attributed to a number of organisms. *Guignardia* fruit rot becomes serious in Hawaii when fruit is left to overripen on the tree or on the ground. Wilting of guava trees is reported from South Africa and India and attributed to different organisms.

Mucor fruit rot first appears as a water-soaked area and later becomes covered with yellowish, fuzzy mycelia and fruiting bodies. Infection rate can be as high as 80–90% and, as a wound parasite, it is commonly associated with fruit fly oviposition wounds. Culture control is possible by removing fallen fruit from the field at 2–4 days' intervals. Low-acid sweet cultivars are more tolerant to this disease than acid types. Blossom end rot of fruit appears to be widespread. In Hawaii, no organism has been isolated and fungicidal sprays have been ineffective. Calcium application to guavas largely alleviates this disease.

Pests

The types of pests that are common to all guava growing areas are as indicated in Table 5. Report of work done in Hawaii found a list of approximately 45 species of insects and six species of mites attacking guavas. Included among them are species of aphids, thrips, scales, mealy bugs, beetles, moth larvae, false spider, eriophyid, and spider mites. There are several species of parasitic wasps and predators that keep scale insects and mealy bugs under reasonable control. Fruit flies cause serious damage and fruit rot within a day or two upon ripening. Fruit bagging along with thinning 30–40 days after anthesis can significantly reduce the problem and produce high-quality blemish-free dessert fruit.

Thrips can cause silvering of leaves and scarification of the fruit. When young developing fruits are severely damaged, they often fail to develop and become mummified. Natural enemies can keep thrips under fair control, although outbreaks do occur, especially during the fruiting season. Skin of scarred fruit becomes russeted by disruptions of the

epidermal layer and corky tissue development in the subepidermal area. This corky tissue must be screened out during the processing; otherwise the purée from russeted fruit appears muddy pink in color. Several sweet cultivars such as Allahabad Safeda, Ruby × Supreme and Lucknow-49 have a higher degree of resistance to thrips than others. This resistance increases somewhat with increasing foliar levels of nitrogen and potassium.

Industrial Use

Guava is one of the easiest fruits to process since it does not show many problems of physical or biochemical nature in relation to texture and shape of fruit or pulp browning during processing. However, compared to other fruits, guavas have found very limited use in the fruit-processing industry. Guava purée, which is also known as guava pulp, is a liquid product prepared by puréeing or pulping whole guavas. A guava-puréeing process, which was developed in Hawaii, and is in commercial use today is similar to that shown in Figure 2. Fruits for processing are placed in a dump tank which serves to soak and wash the fruit. The fruit which then floats is picked up on to a moving conveyer belt; it is inspected and sorted for decay, insect damage, and foreign materials such as leaves and dirt. Clean fruits are then passed through a chopper or slicer to be broken up, and are then fed into a pulper. The pulper removes the seeds and fibrous tissues and forces the remainder of the product through a perforated stainless-steel screen. The puréed material coming from the pulper is next passed through a finisher which removes the stone cells from the fruit. The finisher is equipped with a perforated screen of approximately 0.051-cm-sized holes. Alternatively, the guava purée can be passed through a mustard mill which effectively grinds up the stone cells so that smooth guava purée is obtained. However, the incorporation of an excessive amount of milled stone cells into the purée can discolor it. Other methods of removing stone cells include the use of a finer screen in the finisher, or using a centrifuge. The average yield of purée is approximately 85%. The prepared purée may be used directly for preparation of various guava beverages, or frozen for export. The purée is most commonly manufactured into nectars, various juice drink blends, syrups, icecream toppings, jams, and jellies.

GUMS

Contents

Properties of Individual Gums

P A Williams and G O Phillips, The North East Wales Institute, Wrexham, UK

Introduction

The term 'gums' is commonly used to describe a range of polysaccharides that are nowadays widely used in food products to perform a number of functions including, thickening, gelling, stabilization of foams, emulsions, and dispersions, inhibition of ice and sugar crystal formation, and in the controlled release of flavors. The commercially important gums and their source of origin are given in **Table 1**.

The choice of gum for a particular food application is dictated by the functional characteristics required but is inevitably influenced by price and security of supply. It is for these reasons that starches are the most commonly used thickening agents. It is interesting to note, however, that xanthan gum, since its introduction in the early 1970s, has become the thickener of choice in many applications, despite its high price. This is due to the fact that xanthan gum has unique rheological behavior (see later). Gelatin (a protein but commonly considered as a gum) is by far the most widely used gelling agent. However, with the increasing demand for nonanimal products and in particular the recent bovine spongiform encephalopathy (BSE) outbreak in the UK, prices have increased significantly over the last few years. There is currently much activity in the development of a gelatin replacement. The carrageenan market has also been unstable over recent years due to the introduction of cheaper lower-refined grades (processed euchema seaweed or PES) which can compete effectively with the traditional purified grades in applications where gel clarity is not important. The gum arabic market has been particularly erratic due to extreme price fluctuations and security of supply and much effort has been directed at finding alternatives. A number of starch-based substitutes are now available. Gellan gum was approved for food use in Japan in 1988 and later in the USA. More recently it has been approved for food use in Europe and is beginning to establish its own niche market. A summary of the functional properties of the individual gums and the value and volume of the gums market is given in **Table 2**.

Gellan gum (*Auromonas elodea*)
Animal
Gelatin (collagen from animal skins and bones)
Chitosan (shells of shrimps, crabs)

Functional Characteristics

Gums will dissolve or swell in water, although in many cases high temperature and vigorous agitation are required before complete dissolution is achieved. The solutions formed are usually thick and viscous, even at very low concentrations (1%). There are, however, notable exceptions, for example gum arabic solutions only become viscous at concentrations >50%. The viscosity of polymer solutions generally shows a marked increase at a critical polymer concentration, commonly referred to as C^*, which corresponds to the concentration at which the polymer molecules start to touch and interpenetrate due to molecular crowding. C^* decreases with increasing hydrodynamic volume of the gum molecules which in turn is influenced by their molecular mass, shape, and the presence of charged groups. Hence high-molecular-mass linear molecules possessing ionizable groups tend be good thickeners. The main thickeners used in food products are listed in Table 3.

Gum solutions normally exhibit Newtonian behavior at concentrations well below C^*, i.e., their viscosity is independent of the rate of shear. However, above C^* non-Newtonian behavior is usually observed and the viscosity–shear rate profiles show three distinct regions, i.e., a high-viscosity low-shear Newtonian plateau (at shear rates typically $< 1\,s^{-1}$); a shear thinning region ($\sim 1 - 1000\,s^{-1}$), and a low-viscosity high-shear Newtonian plateau (typically $> 1000\,s^{-1}$).

Some gums, notably xanthan gum, have a tendency to undergo weak intermolecular chain association in solution, leading to the formation of a three-dimensional network structure, thus giving rise to a very high viscosity. The junction zones formed can be readily disrupted even at very low shear rates, resulting in a dramatic drop in viscosity. Other polysaccharides self-associate and form stable junction zones and as a consequence strong gel structures are produced. The gels are referred to as 'physical gels' because the junction zones are formed through physical interaction, for example, by hydrogen bonding, hydrophobic association, and cation-mediated cross-linking and differ from synthetic polymer gels which normally consist of covalently cross-linked polymer chains.

Some gums form thermoreversible gels and examples exist where gelation occurs on cooling or heating. Some form nonthermoreversible gels. In such cases gelation may be induced by cross-linking polymer chains with divalent cations. Gels may be optically clear or turbid and a range of textures can be obtained. Gel formation occurs above a critical minimum concentration, which is specific for each gum. Agarose, for example, will form gels at concentrations as low as 0.2%, while for acid-thinned starch, a concentration of ~15% is required. Typically, however, concentrations of less than 1% are required. Gel strength increases with increasing concentration. The main gelling agents are listed in Table 4.

Mixtures of gums are commonly used to impart novel textural characteristics to food products and an added incentive is a reduction in costs. Classic examples include the addition of locust bean gum to kappa-carrageenan to yield softer, more transparent gels and also the addition of locust bean gum to xanthan gum to induce gel formation.

Gums are effective at either inducing or preventing flocculation in particulate dispersions. If insufficient gum is present to coat all the particles fully, aggregation occurs owing to polymer adsorbing on to two or more particles simultaneously, thus inducing bridging. If the particles are fully coated, particle aggregation is prevented by steric repulsion, which arises as a result of interaction between the adsorbed polymer layers. Although nonadsorbed gum is

Table 3 Thickeners

Xanthan gum
Very high viscosity at low shear rates (yield stress), highly shear thinning, maintains viscosity in the presence of electrolyte, over a broad pH range and at high temperatures

Carboxymethyl cellulose
High viscosity but reduced by the addition of electrolyte and at low pH

Methyl cellulose and hydroxypropylmethyl cellulose
Viscosity increases with temperature (gelation may occur) not influenced by the addition of electrolytes or pH

Galactomannans (guar and locust bean gum)
Very high viscosity at low shear rates and strongly shear thinning. Not influenced by the presence of electrolyte but can degrade and lose viscosity at high and low pH and when subjected to high temperatures

generally considered to enhance the stability of dispersions (and emulsions) by increasing the viscosity of the aqueous phase, it can have the opposite effect and give rise to depletion flocculation. This phenomenon occurs as a consequence of polymer molecules being excluded from the space between approaching particles. The difference in osmotic pressure between the depleted region and the bulk solution results in weak interparticle attractive forces, which induce aggregation.

Some gums, such as gum arabic, methyl cellulose and propylene glycol alginate, show amphiphilic character which has led to their use in the stabilization of emulsions and foams owing to their affinity to adsorb at the oil–water or air–water interface.

In systems containing sugar or ice crystals, gums can retard crystal growth either by adsorbing on to the crystals or by competing for available water molecules.

Although gums have primarily been used in foods to control texture, organoleptic properties, and stability, consumers are now being made increasingly aware of their nutritional and health benefits. Many gums (e.g., locust bean gum, guar gum, konjac mannan, gum arabic, xanthan gum, pectin) have been shown to reduce blood cholesterol levels. Others (e.g., inulin, gum arabic) have been shown to have prebiotic effects. They are resistant to our digestive enzymes and pass through the stomach and small intestine without being metabolized. They are fermented in the large intestine to yield short-chain fatty acids and stimulate the specific growth of beneficial intestinal bacteria, notably bifidobacteria, and reduce the growth of harmful microorganisms such as clostridia.

Properties of Individual Gums

Tree Gum Exudates

The four main tree gum exudates are gum arabic, gum karaya, gum tragacanth, and gum ghatti, with gum arabic being by far the most important commercially. Gum arabic occurs as a sticky liquid that oozes from the stems and branches of acacia trees (*Acacia senegal* and *A. seyal*) which grow across the Sahelian belt of Africa, principally Sudan. The gummosis process occurs when the tree is subjected to stress conditions such as heat, drought, or wounding. The liquid dries in the sun to form glassy nodules, which

Table 4 Gelling agents

Thermoreversible gelling agents

Low-methoxyl (LM) pectin	Gels formed in the presence of divalent cations, notably calcium at low pH (3–4.5)
Gellan gum	Gels formed on cooling in the presence of salts
Methyl- and hydroxypropylmethyl cellulose	Gels formed on heating
Xanthan gum with locust bean gum or konjac mannan	Gels formed on cooling mixtures
Thermally irreversible gelling agents	
Alginate	Gels formed on the addition of polyvalent cations, notably calcium or at low pH (< 4)
High-methoxyl (HM) pectin	Gels formed at high soluble solid (e.g., 50% sugar) content at low pH < 3.5
Konjac mannan	Gels formed on addition of alkali
Locust bean gum	Gels formed after freezing due to association of galactose-deficient regions

are collected by hand. The gum from *A. senegal* (traditionally the main source of gum arabic) is a complex polysaccharide consisting of galactopyranose (~44%), arabinopyranose, arabinofuranose (~25%), rhamnopyranose (~14%), glucuropyranosyl uronic acid (~15.5%) and 4-*O* methyl glucuropyranosyl uronic acid (~1.5%). It also contains a small amount (~2%) of protein as an integral part of the structure. Analysis of the carbohydrate structure has shown that it consists of a core of (1,3)-β-D-galactose units with extensive branching at the C6 position. The branches consist of galactose and arabinose and terminate with rhamnose and glucuronic acid (Figure 1a). As a consequence of the highly branched structure, viscous solutions are only formed at high gum concentrations (~50% w/w). It has been shown by gel permeation chromatography that the gum consists of three molecular mass fractions which have also been shown to differ principally in their protein contents. Most of the gum (~90%) contains very little protein and has a molecular mass of $\sim 2.5 \times 10^5$. A second fraction (~10% of the total) contains ~10% protein and has a molecular mass of $1–2 \times 10^6$ and has been shown to have a 'wattle-blossom'-type structure where blocks of carbohydrate of molecular mass $\sim 2.5 \times 10^5$ are connected to a common polypeptide chain. The third fraction (~1% of the total) contains up to 50% protein and has a molecular mass of $\sim 2 \times 10^5$. Fraction 2 has been shown to be responsible for the gum's excellent ability to stabilize oil-in-water emulsions. It has been proposed that the hydrophobic polypeptide chains adsorb on to the oil droplets and anchor the molecules to the surface, while the hydrophilic carbohydrate blocks protrude out into solution and prevent droplet aggregation and coalescence due to electrosteric repulsions. Its ability to act as an emulsifier has led to its use in stabilizing flavor oil emulsion concentrates for the soft drinks industry and also in the production of spray-dried encapsulated flavors for use in dry packaged products such as soup and cake mixes. In the latter case the gum forms a film around the flavor particle, preventing oxidation and evaporation, and the gum's high solubility facilitates rapid flavor release. The ability of gum arabic to form concentrated solutions of low viscosity has led to its widespread use in confectionery products, particularly those with a high sugar content such as pastilles where it functions by reducing sugar crystallization.

Gum tragacanth consists of a water-swellable fraction called tragacanthic acid (or bassorin) (60–70%) and a water-soluble fraction called tragacanthin. The former consists of a main chain of (1,4)-α-D-galactopyranosyluronic acid residues with branches linked through (1,3)-β-D-xylose units terminating in L-fucopyranose, as illustrated in Figure 1b. The latter is a highly branched arabinogalactan with a main chain of D-galactopyranosyl units either (1,6)- or (1,3)-linked with side chains consisting mainly of L-arabinofuranose but with a small proportion of D-galacturonic acid and L-rhamnose. Gum tragacanth gives rise to high-viscosity solutions even at 1% concentration. The viscosity decreases irreversibly on heating. The gum solution is stable under acid conditions and shows good emulsification characteristics, which has led to its use in salad dressings and sauces. Its cost and availability, however, have meant that it has been largely replaced in these products by other gums, notably xanthan gum.

Gum karaya is a heavily acetylated polysaccharide composed of chains of α-D-galacturonic acid and α-L-rhamnose. The acid groups are glycosylated with

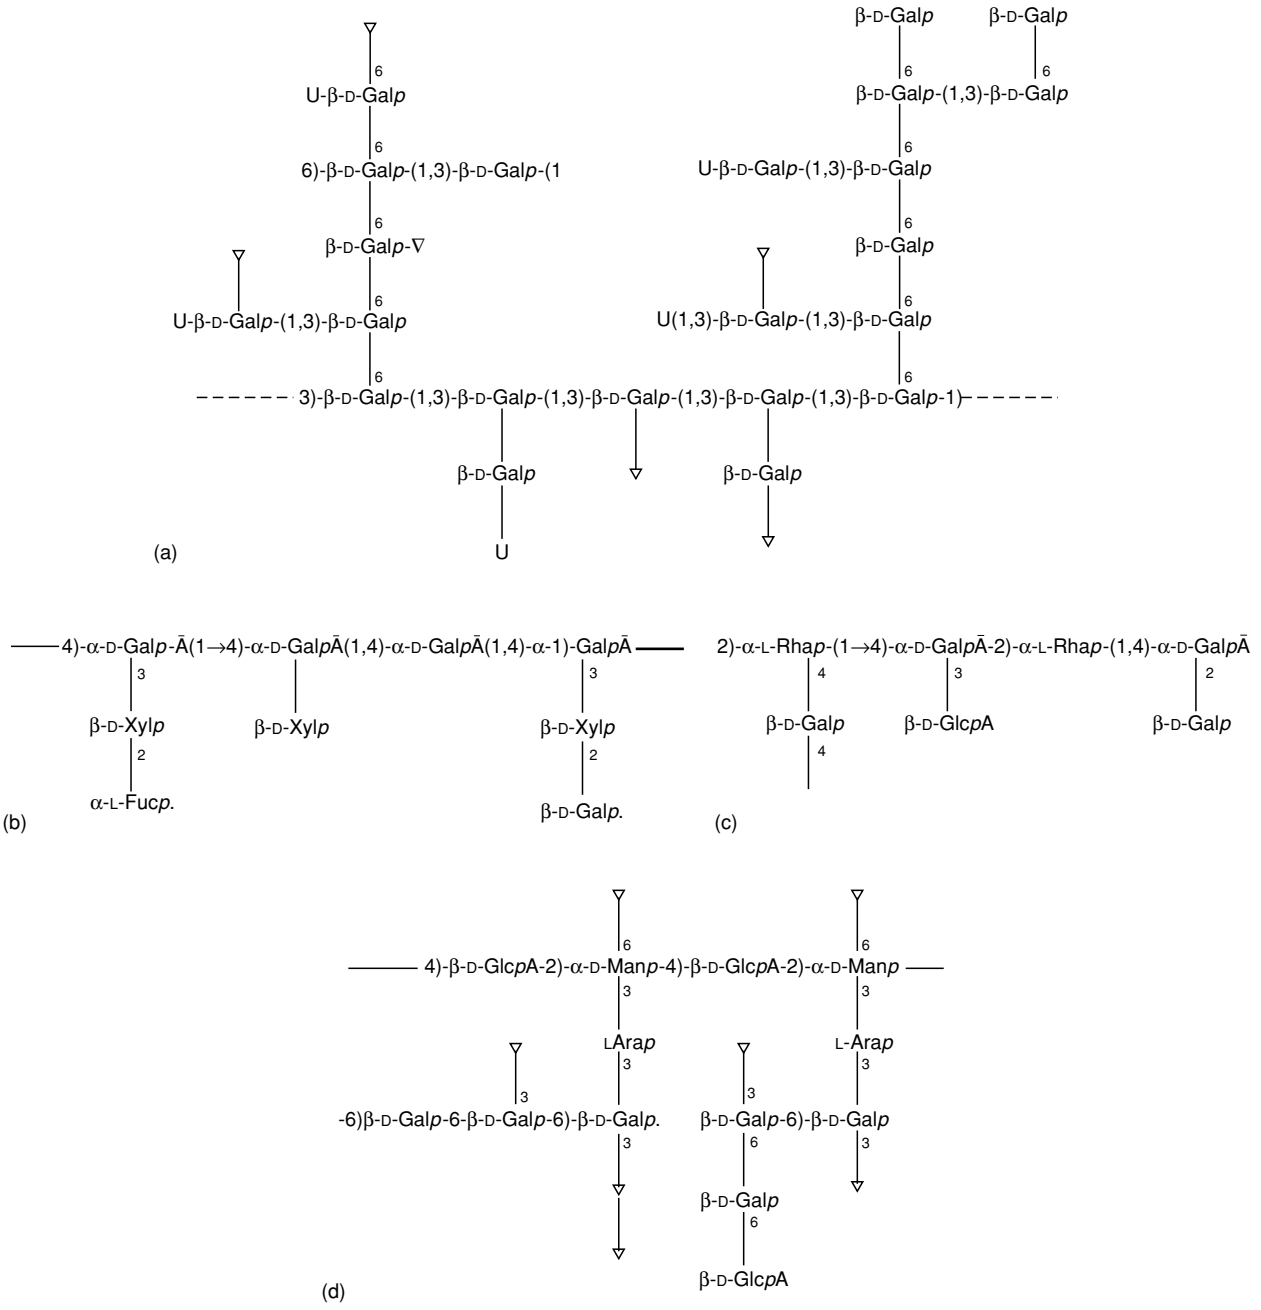

Figure 1 (a) *Acacia senegal* representative segment. β-D-galactose or β-D-glucuronic acid residues, whereas about half of the rhamnose groups carry β-D-galactose units as side chains (Figure 1c). Gum karaya swells in water to yield highly viscous solutions, however, solutions show a permanent loss in viscosity on heating. The gum finds some application in salad dressings.

Gum ghatti has a main chain of alternating (1,4)-β-D-glucopyranosyluronic acid and (1,2)-α-D-mannopyranose units and contains numerous side chains of L-arabinose, D-galactose, and D-glucuronic acid (Figure 1d). It contains a water-soluble (> 80%) and water-swellable fraction and was originally developed in the early 20th century as replacement for

gum arabic since it forms solutions of low viscosity at high concentrations and is also a good emulsifier.

Cellulosics

Cellulose is the most abundant of all the polysaccharides, being the structural component of land plants. It is composed of linear chains of (1,4)-β-D-glucopyranose units which are associated through hydrogen bonding, giving rise to a number of crystalline forms. Although it is insoluble in water, it can be chemically modified to form a number of water-soluble derivatives with valuable functional properties. Derivatization usually involves etherification of the reactive hydroxyl groups on the glucose residues. The most common water-soluble cellulose derivatives used in food applications are carboxymethyl (CMC), methyl (MC), and hydroxypropylmethyl (HPMC) cellulose. Derivatization is carried out following conversion of the cellulose to the sodium form by treatment with concentrated alkali. This process destroys the crystalline structure and yields alkali cellulose. The alkali cellulose is then reacted with the appropriate reagent, namely sodium monochloroacetate for CMC, methyl chloride for MC, and methyl chloride/propylene oxide for HPMC. Since the reactions are heterogeneous, substitution can be very irregular.

CMC is the most widely used of the cellulose ethers and can be obtained in various grades, which vary in molecular mass and degree of substitution (DS). The minimum DS is ~ 0.4 (i.e., 4 hydroxyls substituted per 10 glucose residues), since below this the CMC is insoluble. Above this CMC dissolves readily in water to form viscous solutions but, since it is anionic, the viscosity of dilute solutions ($< 1\%$) is reduced on addition of electrolyte and at low pH due to compaction of the polymer chains. A synergistic increase in viscosity occurs in blends with guar gum and locust bean gum. CMC finds widespread use in icecream and other frozen desserts as well as salad dressings, sauces, and gravies.

The nonionic cellulose ethers, MC and HPMC, are also supplied in a range of molecular sizes and DS. For HPMC, since the substituted moieties contain hydroxyl groups they may also participate in the reaction. Hence a molar substitution (MS) is also quoted to characterize the polymers. MC and HPMC dissolve readily in water to produce viscous solutions which on heating form thermoreversible gels. The gelation temperature is dependent on the degree of substitution. For MC containing 30% methoxyl groups, gelation occurs at ~ 50–$55\,^{\circ}C$, whereas for HPMC containing 20% methoxyl and 8% hydroxypropyl, gelation occurs at $\sim 85\,^{\circ}C$. Gelation is believed to be a consequence of molecular association through the hydrophobic methyl and hydroxypropylmethyl substituents. This functional characteristic has led to their use in combination with starch in soups and gravies to prevent undesirable loss of viscosity on heating. A further application is their use in fried foods, where gelation on heating helps retain the structural integrity of the product and additionally serves to prevent moisture loss and oil absorption. Since MC and HPMC are also surface-active they are used in baked goods to aid uniform gas cell formation and in salad dressings to stabilize emulsion droplets.

Plant Extracts

Starch is also a very abundant material and is derived commercially principally from corn and potato and, to a lesser extent, from waxy corn, wheat, tapioca, rice, cassava, sorghum, pea, and sago. It is obtained in the form of granules, which have varying degrees of structural order and consist of two polysaccharides, namely amylose and amylopectin. The proportions of each depend on the source, for example, corn and potato starch contain $\sim 27\%$ and 21% amylose respectively, while waxy corn contains $< 2\%$ amylose.

Amylose consists of linear (1,4)-α-D-glucopyranose chains with very little branching (10 branch points per molecule) and has a molecular mass of typically 2×10^5–2×10^6. Amylopectin also contains sequences of (1,4)-α-glucopyranose units; however, it has extensive branching via (1,6) linkages and has a molecular mass of $\sim 5 \times 10^7$–4×10^8. The starch granules are insoluble in water but on heating they swell and burst, releasing amylose, forming a viscous paste. The temperature at which the granules burst is very characteristic of the source of the starch and is (perhaps inappropriately) referred to as the gelatinization temperature. Typical values for corn and potato starch are $67\,^{\circ}C$ and $60\,^{\circ}C$ respectively. On cooling, the amylose molecules readily self-associate, a process known as retrogradation, and it is then that a gel is formed. Natural starches form turbid gels which are prone to syneresis. Hence most of the commercial starches used are derivatives which have a lesser tendency for retrogradation. Derivatives include hydroxypropyl starches, starch phosphates, oxidized starch, acid, or enzyme-degraded starches.

Pectin is the general term for a group of polyuronans that occur as the structural components of plants. Commercial pectins are obtained from the pomace of apple or the peel of citrus fruits following hydrolysis, which renders the pectin water-soluble. Pectin molecules consist of linear chains of (1,4)-α-D-galacturonic acid residues, up to 80% of which occur as the methyl ester. The hydroxyls in the C2 and C3 positions may be acetylated. The chains also

contain up to 4% (1,2)-α-rhamnopyranose units which give rise to kinks. L-Arabinose, D-galactose, and D-xylose (10–15%) are linked to the rhamnose units forming ramified side chains which are referred to as 'hairy regions' along the otherwise smooth galacturonan backbone. If the degree of esterification (DE) is > 50% it is referred to as high-methoxyl (HM) pectin. Deesterified pectin with DE < 50% is produced by mild acid or alkali treatment and is referred to as low-methoxyl (LM) pectin. If the alkali used is ammonia, amidated pectin is formed. Pectin is soluble in water and is most stable at pH 3–4. At lower pH, the glycosidic bonds are hydrolyzed. In alkaline conditions the glycosidic and ester linkages are cleaved, yielding the free acid. Both HM and LM pectins form gels. For HM pectin (DE 60–75%) gelation occurs at high soluble solids content (typically 50–75% sugar) and at pH < 3.5 over a period of time. The gels are not thermoreversible. Junction zone formation is believed to be as a consequence of hydrophobic association between ester groups coupled with intermolecular hydrogen bonding between hydroxyl groups on the galacturonan backbone. For LM pectin (DE typically 20–40%) gelation is brought about by the addition of divalent cations, and a high solids content and low pH are not a prerequisite. Gelation is rapid and is thermoreversible.

Pectins are mainly used for the production of jams and jellies. High-ester pectins find widespread use in normal jams, whereas low-ester pectins are preferred for low-sugar jams. LM amidated pectin is used to stabilize fruit pulp which is incorporated into products such as yogurt.

Konjac mannan is the soluble extract of konjac flour obtained by pulverizing the dried tuber of *Amorphophallus konjac*. It is a glucomannan and consists of a main chain of (1,4)-β-D-mannopyranosyl and D-glucopyranosyl units with (1,3) linked branches approximately every 10 sugar residues. The ratio of mannose to glucose is 1.6:1. Approximately 1 in 19 sugar residues is acetylated. Konjac mannan forms highly viscous solutions on dissolution in water following heating. In the presence of alkali, thermally irreversible gels are formed as a consequence of deacetylation and aggregation of the glucomannan chains. In Japan, konjac mannan is made into noodles. The process involves pumping a solution of the gum through a spinneret into a hot alkaline bath (e.g., calcium hydroxide solution) which results in the formation of long gel threads. The gum is also sold in blocks of gel, known as konnyaku, for use in traditional Japanese dishes and also as a dessert jelly. Konjac mannan has recently been approved for food use and is now finding application as a thickener and gelling agent. It forms thermoreversible gels with xanthan gum and also increases the gel strength, elasticity, and clarity of kappa-carrageenan gels. For both mixtures it has been argued that the synergistic behavior is due to association of carrageenan and xanthan helices with the glucomannan chains.

Galactomannan Seed Gums

Locust bean (or carob), tara, and guar gums are storage polysaccharides obtained from the endosperms of leguminous seeds of *Ceratonia siliqua*, *Caesalpinia spinosa*, and *Cyamopsis tetragonoloba* respectively. They have a molecular mass of the order of 10^6 and consist of a linear main chain of β-(1,4)-linked D-mannopyranosyl units with galactopyranosyl units linked α-(1,6) to varying degrees. The mannose-to-galactose ratio is approximately 4.5:1, 3:1, and 2:1 for locust bean, tara, and guar gums respectively. The galactose residues are distributed nonuniformly along the mannan chain. The presence of galactose tends to inhibit intermolecular association between the galctomannan chains, hence, whereas guar gum is readily soluble in cold water, tara, and locust bean gums have to be heated to high temperatures to disrupt the aggregation and achieve complete dissolution. Once dissolved, all three yield highly viscous solutions even at 1% concentration and as a consequence their main application is as thickeners.

Locust bean gum will self-associate in solution and will form thermally irreversible gels on freezing. It is commonly used in combination with other polysaccharides, particularly kappa-carrageenan, since it leads to the formation of stronger, more elastic gels, which have improved transparency and are less prone to undergo syneresis. Locust bean gum also forms strong thermoreversible gels with xanthan gum. It is believed that interaction occurs between the carrageenan and xanthan helices and mannose sequences along the backbone which are devoid of galactose residues. This model also explains why guar gum is not as effective.

Algal Polysaccharides

The carrageenans are a family of sulfated galactans obtained from red seaweeds (Rhodophyceae) where they have a key structural function. The traditional method of extraction is by treatment of the seaweed with hot alkali for 10–30 h followed by precipitation with alcohol and then drying. The three major types are kappa-, iota- and lambda-carrageenan. Kappa is obtained from a species of seaweed called *Euchema cottonii* and occurs together with lambda-carrageenan in *Chondrus crispus*. Iota-carrageenan is obtained from *E. spinosum*. They differ essentially

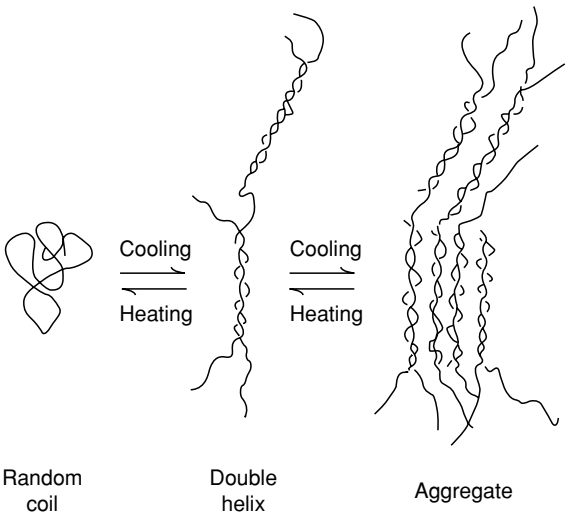

Figure 2 Gelation process for agarose and carrageenan involving double helix formation and aggregation. Reproduced from Gums: Properties of Individual Gums. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

in their degree of sulfation. The idealized structure for kappa-carrageenan is a disaccharide repeat unit consisting of (1,3)-β-galactopyranose-4-sulfate and (1,4)-α-3,6-anhydrogalactopyranose residues. Iota-carrageenan differs only in that the latter residue is sulfated at the C2 position. Lambda-carrageenan is further sulfated and consists of (1,4)-α-galactopyranose 2,6 disulfate and (1,3)-β-linked galactopyranose which is 70% substituted at the C2 position. The carrageenans are all soluble in water but whereas lambda forms viscous solutions, kappa and iota form thermoreversible gels. In solution the molecules undergo a thermoreversible coil-to-helix transition and the helices self-associate, giving rise to a three-dimensional gel structure (Figure 2). The temperature of gelation increases with increasing electrolyte concentration. It has been shown that potassium, rubidium, and cesium ions specifically bind to the helical structure of kappa-carrageenan and hence promote helix formation and gelation at much lower concentrations than other electrolytes. As a consequence, kappa-carrageenan gels are much stronger in the presence of potassium chloride compared to, say, sodium chloride. This ion specificity is not observed for iota-carrageenan, which forms weaker more elastic gels compared to kappa. This is probably due to the fact that the increased charge on the iota-carrageenan chains reduces the extent of helix self-association. Self-association results in the melting temperature being greater than the gelation temperature and this hysteresis is more pronounced in kappa-carrageenan.

Kappa-carrageenan gels are more brittle and turbid than iota-carrageenan gels and are more prone to syneresis. As discussed above, incorporation of locust bean gum or konjac mannan into kappa-carrageenan gels reduces turbidity, brittleness, and syneresis and also increases gel strength.

Kappa-carrageenan is widely used in dairy products because it interacts synergistically with kappa-casein and prevents wheying-off. Carrageenans are also used extensively in meat products such as cooked hams, poultry products, and sausages because of their ability to bind water and control the texture and structural integrity.

Agarose (the major component of agar) is also obtained from red seaweeds, notably *Gelidium* and *Gracilaria* spp. It is a linear neutral polysaccharide and has a similar structure to the carrageenans, consisting of alternating (1,3)-β-D-galactopyranose and (1,4)-linked 3,6-anhydro-α-L-galactopyranose units. It dissolves in near-boiling water and gels on cooling to $\sim < 40\,^{\circ}C$. The gelation mechanism is as described for the carrageenans but, since the agarose chains are nonionic, extensive helix aggregation occurs, resulting in the formation of very strong gels. The gels show pronounced hysteresis and melt only on heating to 80–90 °C. The use of agar is far more restricted commercially than that of carrageenan owing to availability and cost considerations.

Alginate is obtained from brown seaweeds (Phyophyceae) and is a linear (1,4)-linked polyuronan consisting of β-D-mannuronic and α-L-guluronic acids. The acids are present as blocks of separate or mixed sequences along the chain depending on the seaweed source. *Macrocystis pyriferia* and *Ascophyllum nodosum* have a high mannuronic acid content (61% and 65%, respectively), whereas *Laminaria hyperborea* has a high guluronic acid content (69%). Sodium alginate dissolves readily in water to form viscous solutions and forms thermally irreversible gels in the presence of divalent cations (notably calcium). It is the guluronic acid residues that are responsible for gel formation and their proportion and distribution along the polyuronan chain have a major influence on the properties of the gels produced. Adjacent diaxially linked guluronic acid residues form a cavity which acts as a binding site for cations which interact with the carboxyl and hydroxyl groups. Intermolecular cross-linking of sequences results in the formation of junction zones and a three-dimensional gel network. This mechanism is referred to as the 'egg-box model' (Figure 3).

If a sodium alginate solution is added dropwise into a solution containing a calcium salt, gel beads are produced and this process is used for the production of 'artificial fruit' for use in pie fillings. In order

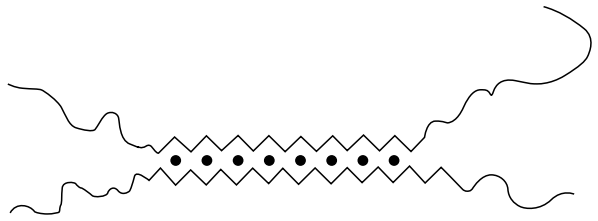

Figure 3 Schematic representation of junction zone formation in calcium alginate gels (egg-box model). The calcium ions are represented by •. Reproduced from Gums: Properties of Individual Gums. *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

to produce homogeneous gels, a common practice is to generate the calcium ions slowly *in situ*. Sparingly soluble salts such as calcium phosphate are used and the release of ions is controlled by sequesterants and adjustment of pH. This process is used in the preparation of structured or fabricated foods such as fruit and meat products.

Microbial Gums

Xanthan gum was first discovered in the 1950s and is now finding extensive application in the food industry since its introduction in the early 1970s. The gum is obtained from the genus *Xanthomonas*, notably *X. campestris* by aerobic fermentation. The xanthan molecules have a (1,4)-β-D-glucopyranose backbone as in cellulose, but in addition have a trisaccharide side chain on every other glucose residue linked through the C3 position. The side chain consists of two mannopyranosyl residues linked on either side to a glucuropyranosyl uronic acid group. The inner mannose residue connected to the backbone may be acetylated while the terminal mannose residue may be pyruvated. The molecular mass of the xanthan molecules is very high ($> 3 \times 10^6$) and the gum dissolves in water to yield highly viscous solutions. The xanthan molecules are reported to undergo a thermoreversible coil-to-helix transition in solution, which is shifted to higher temperatures by the addition of electrolyte. In the disordered coil form the side chains are envisaged as protruding away from the backbone into solution, while in the ordered form the molecules form a stiff five-fold helical structure with the side chains folded in and associated with the backbone. Most workers now believe that the helix is double-stranded. The stiff xanthan chains tend to associate in solution, giving rise to a very high viscosity at low shear rates, which is sufficient to prevent particles from sedimenting or oil drops from creaming. The associations are readily broken on applying shear, giving rise to a dramatic drop in viscosity and hence the solutions readily flow. Unlike other polyelectrolytes the viscosity of xanthan solutions is relatively insensitive to addition of electrolyte since the electrolyte will promote helix formation. The helices are also stable over a broad range of pH. The high apparent yield stress and pronounced shear thinning characteristics have led to a large increase in the use of this gum, which now finds application in a broad range of food products such as sauces, salad dressings, and mayonnaises.

Gellan gum has only recently been commercialized. It is produced from *Pseudomonas elodia* by aerobic fermentation and consists of a linear tetrasaccharide repeat unit of (1,3)-β-D-glucopyranose, (1,4)-β-D-glucopyranose uronic acid, (1,4)-β-D-glucopyranose and (1,4)-α-L-rhamnopyranose. In the native form the (1,3)-linked glucose residues contain glycerate and acetate moieties. X-ray fiber diffraction studies indicate that the gellan molecules form a threefold double helical structure and in solution undergo a thermoreversible coil-to-helix transition. The transition shifts to higher temperatures in the presence of electrolyte. Once formed, the helices tend to self-associate, leading to the formation of a gel, as is the situation for agarose and carrageenan. Gels formed in the presence of monovalent ions are usually thermoreversible, although the melting temperature is normally much greater than the gelation temperature – a consequence of the extensive aggregation. If gels are formed by the addition of divalent ions then they can be thermally irreversible. The native form produces soft elastic gels whereas the deacetylated material, which is sold commercially, forms hard brittle gels. The gum is used in fruit fillings.

Food Uses

P A Williams and G O Phillips, The North East Wales Institute, Wrexham, UK

Introduction

Gums have a major influence on the structural characteristics, texture, organoleptic properties, and overall appearance of foods, even though they are present often at concentrations of less than 1%. On food labels they are commonly referred to as 'stabilizers,' 'thickeners,' or 'gelling agents' and in fact may serve a number of functions, such as enhancing viscosity, preventing particle sedimentation or droplet creaming, inducing gelation, emulsifying oils, stabilizing foams, and inhibiting ice or sugar crystallization. The various food sectors where gums are commonly used are shown in **Table 1** together with an estimate of their usage levels. The high levels of modified starch, gelatin, and guar gum used reflect their relatively low cost.

The use of gums in food products is steadily increasing due to the rapid rise in the consumption of ready-made meals and novelty foods and also because of consumers' growing awareness of the need to increase the amount of fiber and reduce the amount of fat in the diet. Gums are considered as soluble fiber and there is evidence to indicate that they assist plasma cholesterol reduction and promote fermentation in the large bowel. The latter yields short-chain fatty acids, mainly acetate, proprionate, and butyrate, which have a beneficial effect on the colon through stimulation of blood flow and enhancement of electrolyte and fluid absorption and muscular activity. Gums are nowadays widely used for fat replacement in a wide range of low-calorie products. They may be added in their natural form or as specifically fabricated microparticulates and serve to enhance the rheological properties of the lower fat products. Rheological enhancement can also be achieved by incorporating two or more gums. In such systems, phase separation can occur and, if one or more of the gums is able to form a gel, can lead to the development of novel gel structures.

Safety of Gums used in Foods

The Joint Expert Committee on Food Additives (JECFA) was first established in the mid-1950s by the Food and Agricultural Organization (FAO) and World Health Organization (WHO) to assess chemical additives in food on an international basis. The Codex Alimentarius Commission (CAC), an international intergovernmental body, was set up in the early 1960s with the primary aim of protecting the health of the consumer and to facilitate international trade in food commodities. When CAC was formed, it was decided that JECFA would provide expert advice to Codex on matters relating to food additives.

While CAC is the ultimate specification and can provide for approval throughout the world, each country is free to adopt its own standards.

The international numbering system (INS) for food additives is intended as an identification for food additives for use in one or more countries. The

Table 2 International numbering system (INS) and E numbers for food gums

Hydrocolloid	*INS/E number*[a]	*Function*
Carrageenan (including furcelleran)	407	Thickener, gelling agent, stabilizer, emulsifier
Processed euchema seaweed	407a	Thickener, gelling agent, stabilizer, emulsifier
Xanthan gum	415	Thickener, stabilizer, emulsifier, foaming agent
Gellan gum	418	Thickener, gelling agent, and stabilizer
Guar gum	412	Thickener, stabilizer, and emulsifier
Locust bean gum	410	Thickener, gelling agent
Gum arabic	414	Emulsifier, stabilizer, thickener
Pectin	440/E440 (i)	Gelling agent, thickener, stabilizer
Amidated pectin	E440 (ii)	Gelling agent, thickener, stabilizer
Microcrystalline cellulose	INS460 (i)	Anticake, emulsifier, stabilizer, and dispersing agent
Powdered cellulose	INS460 (ii) / E460	Anticake, emulsifier, stabilizer, and dispersing agent
Cellulose	460	Anticake, emulsifier, stabilizer, and dispersing agent
Tragacanth gum	413	Emulsifier, stabilizer, thickening agent
Karaya gum	416	Emulsifier, stabilizer, and thickening agent
Konjac mannan	E425	Gelling agent, thickener, emulsifier, stabilizer
Propylene glycol alginate	405	Thickener, emulsifier
Sodium alginate	401	Thickening agent, stabilizer
Potassium alginate	402	Thickening agent, stabilizer
Alginic acid	400	Thickening agent, stabilizer
Calcium alginate	404	Thickening agent, stabilizer
Ammonium alginate	403	Thickening agent, stabilizer
Methyl cellulose	461	Thickening agent, emulsifier, stabilizer
Hydroxypropyl cellulose	463	Emulsifier, thickener, stabilizer, binder, suspension agent, film coating
Hydroxypropylmethyl cellulose	464	Emulsifier, thickening agent, stabilizer
Sodium carboxymethyl cellulose	466	Thickening agent, stabilizer, suspending agent
Agar	406	Thickening agent and stabilizer
Oat gum	411	Thickener, stabilizer

[a]Where no distinction is made, the INS and E numbers are identical. When only an E number is given, there is no equivalent INS number. From Phillips GO, Williams PA (2000) *Handbook of Hydrocolloids*. Cambridge: Woodhead.

criteria for INS inclusion are: the compound must be approved by a country as a food additive, it must be toxicologically cleared for use by a country, and it must be identified on the final product label.

In the European Union, gums accepted for food use are classified by so-called E numbers. Where both INS and E numbers are available they are interchangeable. INS and E numbers for gums used in foods are given in Table 2, together with their functional characteristics.

Food Applications

Condiments, Mayonnaise, and Dressings

Gum tragacanth was traditionally used in thick sauces, pickles, and relishes because of its ability to maintain the desired rheological properties in the acidic conditions normally associated with these products. However, because of its uncertainty of supply and increasing high cost, modified starches are nowadays the thickeners of choice. Novel products are continually being introduced into the marketplace and some examples of sauces in which gums are incorporated are shown in Figure 1. The choice of gum is dependent on the nature of the product. The tartare sauce, smokey barbecue sauce, and horseradish relish, for example, contain xanthan gum and this acts to thicken the sauces and is stable in the acid conditions found in these products. The creamed garlic sauce contains both xanthan gum and guar gum and these are known to interact synergistically to give enhanced rheological properties. The seafood sauce has a higher oil content than the other sauces and, therefore, propylene glycol alginate is included with xanthan gum. The propylene glycol alginate functions as an emulsifier, preventing droplet coalescence, while the xanthan gum enhances the viscosity of the aqueous phase, thus preventing droplet creaming. The apple sauce, cranberry sauce, and mint jelly all contain pectin, which gives the products gel-like characteristics.

Traditional mayonnaise is a concentrated, oil-in-water emulsion containing about 65% vegetable oil, acidifying ingredients (vinegar or lemon juice) and egg yolk, which acts as an emulsifying agent. The semisolid characteristics associated with this food product are principally controlled by the concentration of oil and the size of the emulsion droplets. Spoonable products can be made at much lower oil content (30–50%) by the incorporation of gums at concentrations as low as 0.5%. The gums used are xanthan gum (sometimes in

Figure 1 Typical sauces incorporating gums.

combination with guar gum or locust bean gum), which functions as a thickener, and propylene glycol alginate, which aids emulsification.

Xanthan gum is widely used nowadays in place of gum tragacanth in pourable dressings because of its stability at low pH, its ability to slow down the separation of the oil-and-water phases, and suspend particulate ingredients, and because of its pronounced shear thinning characteristics.

Coleslaws, potato pasta and Florida-style salads are now commonly available ready-prepared and xanthan gum, perhaps in conjunction with guar gum or locust bean gum, is often incorporated as a thickener.

Icecream, Yogurt, and Other Dairy Products

Icecream Icecream is a complex food system consisting of a liquid phase incorporating fat particles, air bubbles, ice crystals, milk proteins, sugars, and soluble and insoluble salts. Gums are commonly used in combination with emulsifiers in icecream formulations to control the stability of the product. The level of gum used depends on the type and overall composition but is typically in the range of 0.1–0.35%. Even at these very low levels, the gums can have a profound effect, serving to enhance the viscosity of the icecream mix, thus increasing the whipping properties and allowing incorporation of a greater proportion of air prior to freezing. The amount of air incorporated is termed the overrun and it can be 100% or more by volume. The use of gums also has a considerable influence on the organoleptic properties of the product, affecting the body, texture, and mouth feel. Icecreams made without gums also tend to melt much faster. The major influence on texture comes from the ability of gums to inhibit ice crystal growth, which occurs as a result of the phenomenon known as Ostwald's ripening. This process arises from the fact that 'small' ice crystals have a greater solubility than 'large' ice crystals. Hence, the continual melting and freezing of the crystals as a consequence of the temperature fluctuations experienced on prolonged storage in a freezer result in the formation of increasingly large ice crystals. It has been argued that the gums act by binding water molecules, thus preventing them from freezing. However, since they are used in such small quantities, it is more likely that they act by adsorbing on to the ice crystals, thus inhibiting crystal growth. Gums can also reduce 'sandiness' which is found in some icecreams as a result of lactose crystallization.

For batch processing the gum can be added to the cold or hot mix, but for high-temperature, short-time (HTST) pasteurization the gum is dispersed in the mix when cold and should be cold-water-soluble. The gums are usually blended with a proportion of the sugar before incorporation into the mix in order to aid dispersibility.

Today the most widely used gums are alginates, carboxymethyl cellulose, guar gum, and locust bean gum. Serum separation can sometimes occur in the mix before it is frozen and this is avoided by incorporation of kappa-carrageenan as a secondary stabilizer (at, say, 10% of the total stabilizer content). It is believed that the carrageenan interacts with the milk constituents present, notably the kappa-casein, to form a weak gel structure. Microcrystalline cellulose has been shown to be particularly effective at reducing ice crystal formation and enhancing the body, and has application in reduced-fat icecreams.

Yogurt Yogurt is produced from milk following lactose fermentation induced by the action of

microflora. These include *Lactobacillus acidophilus*, *L. bulgaricus*, and *Streptococcus thermophilus*. *Bifidobacterium longum* is also used in the 'bioyogurts' which have now become popular. A culture containing the bacteria is added to the milk after it has been homogenized and undergone heat treatment. The formation of lactic acid causes the milk proteins to coagulate, forming a semisolid gel which entraps the fat globules and the serum containing the dissolved components. For 'set' yogurts, coagulation is carried out directly in retail cartons, resulting in a gel-like product. For 'stirred' yogurts, coagulation is carried out when transferring through a cooler and then packaging. A variety of gums are used in yogurt production in order to reduce syneresis and enhance the rheological and organoleptic properties. It should be noted, however, that legislation in some countries prohibits their use. It is important that the gums do not mask the natural flavor of the yogurt and that they are effective at the product pH of about 4.3. Gums reportedly used are carboxymethyl cellulose, guar gum, locust bean gum, pectin, alginate, agar, carrageenan, and xanthan gum. However, the most common are pectin, gelatin, and modified starch. They are normally used at levels of 0.2–0.5% depending on the gum and the milk solids content. They are often added to the warm milk prior to pasteurization in order to insure complete dissolution. In some cases the gum is added to the coagulum after incubation, in which case its microbiological quality needs to be assured. Fruit-flavored yogurts are produced by adding fruit pulp, consisting of fruit purée (~ 50%), sugar (~30%), and a suitable stabilizer to the yogurt prior to packaging. Low-ester pectins (and low-ester amidated pectins) are particularly effective stabilizers since they are able to provide the optimum rheological properties at low pH and are incorporated at typical concentrations of ~0.6%.

Cheese In cheese manufacture, lactic acid-producing bacteria are added to milk and the mixture is stirred at a constant temperature. When sufficient acidity has developed, rennet, which is a natural enzyme, can be added and this hydrolyzes the kappa-casein in the milk, causing the casein micelles to coagulate and form a gel. The gel is commonly referred to as curd and is separated off from the liquid (known as whey) and may be pressed, salted, and left to ripen according to cheese type. Addition of gums such as guar gum, locust bean gum, and carrageenan increases the rate of coagulation and aids the recovery process, thus increasing the yield of curd. In soft cheeses, where there is a high water content (> 80%), gums can lead to improvement in the body and texture of the product and are also reported to reduce water loss. Blends of carrageenan and galactomannan are particularly effective. Carrageenan is also used in some processed cheeses, and this allows the cheese content to be reduced whilst maintaining good mouth feel and melting properties and improving grating and slice integrity. The use of gums in cheese is, however, subject to food additive regulations and they are generally only allowed in composite cheese products and spreads.

Whipped cream Whipping cream has a high milk fat content (> 30%) and its functional requirements include its ability to incorporate air (i.e., whippability), foam stability, and resistance to serum separation. Sodium alginate, carrageenan, and modified starches can be used to improve these characteristics.

Bakery Products

Bread In the process of bread making, flour, yeast, salt, shortening, water, and so-called 'improvers' are mixed together to form a homogeneous dough. During the process the glutenin and gliadin proteins present in the flour interact to form gluten, giving the dough its elastic characteristics. On standing, the yeast ferments the sugar components present in the flour, producing carbon dioxide which distends the dough, giving it a cellular structure. During baking the starch granules dispersed within the gluten matrix swell irreversibly (gelatinize), releasing amylose and absorbing water, which adds to the structure. The gluten is coagulated by the heat.

Although it is not common practice, gums such as guar, locust bean gum, carboxymethyl cellulose, and xanthan gum can be used in bread manufacture at levels of up to 2%. They have been reported to speed up the development of gluten during mixing, giving a significant reduction in mixing time. In addition, it is claimed that they enhance moisture retention, thus retarding the staling process, which results from the aggregation of amylopectin chains, a process referred to as retrogradation.

Xanthan gum has been used in the preparation of gluten-free bread. It is believed that the xanthan interacts with the starch to form a matrix, allowing structure development comparable to normal bread to occur during baking.

Cakes Gums such as xanthan gum, guar gum, and carboxymethyl cellulose can be used in the production of cakes and they have two major functions. First, they can control the rheological properties of the batter, which is important in large-scale manufacture, where mixing, pumping, and filling stages are encountered. Their shear thinning characteristics are important since a low viscosity is preferable when

mixing and pumping, whereas a high viscosity is required after filling the baking pans in order to prevent splashing and to suspend any particles such as fruit in the batter. The second function is to facilitate more even hydration of the dry ingredients and to control the moisture of the finished product. A more even moisture distribution assists in the stabilization of air cells formed during mixing and this gives rise to a finer, more uniform cell structure, thus improving the volume and texture of the finished cake. Control of the moisture content is of utmost importance since this will influence not only the texture and appearance but also the shelf-life.

Fruit pie fillings Fruit pie fillings usually contain modified starches, which thicken the acidic juices associated with the fruit. Gums such as carrageenan, carboxymethyl cellulose, and low-methoxy pectin and locust bean gum blends are sometimes used in combination with the starch to improve heat stability, to give increased clarity, and to reduce syneresis.

Sodium alginate can be used to produce fruit analogs for pie fillings utilizing the so-called 'internal setting procedure.' In this process a sodium alginate solution containing an insoluble calcium salt (e.g., calcium phosphate) is combined with a fruit purée which contains a sequesterant (e.g., sodium citrate) and acid (citric acid). On mixing, the insoluble calcium salt begins to dissolve in the presence of the acid, releasing calcium ions which initially interact with the alginate, inducing gelation. The uniform gel formed is then cut and a thickened fruit syrup is added to give the finished pie filling.

Sodium alginate can also be used to prepare structured fruits using a coextrusion technique and this is particularly appropriate for fruits such as blackcurrants, which have an outer skin and liquid center. In the process a sodium alginate solution and fruit purée mix are fed separately through nozzles consisting of coaxial tubes positioned above a bath containing a solution of calcium salt (e.g., calcium lactate). The flow of alginate solution is kept constant while that of the fruit purée is intermittent. As each drop of purée breaks away from the nozzle it is coated with a film of the alginate solution which gels instantly, forming a hardened skin on hitting the calcium bath below. The fruit gels formed are then collected and a thickened syrup is added to produce the pie filling.

Gellan gum is now also finding some applications as a gelling agent in fruit fillings for pies and cakes.

Icings, Frostings, and Glazes The icings, frostings, and glazes used for bakery products consist of a saturated solution of sugar in water. Gums such as carboxymethyl cellulose and sodium alginate are used to inhibit sugar crystal growth and to control the rheological and film-forming properties. Such coatings show improved adhesion to the product, have less tendency to crack, and have reduced stickiness.

Gum tragacanth is used in decorative icings for wedding cakes.

Batter Coatings Thickeners such as guar gum, locust bean gum, and xanthan gum are often used in the large-scale production of batter coatings for seafood and poultry. They provide the required rheological properties to the batter and assist in its adhesion to the product.

Desserts

Specialty desserts There is a vast assortment of dessert products available today for the consumer to choose from, and gums are widely used to control the characteristics of the various components, which make up each product. Carrageenan, for example, is often used in milk-based desserts since it interacts with the milk proteins present, giving rise to the formation of a weak gel structure and thus preventing serum separation. Thickeners such as guar and locust bean gum or gelling agents such as pectins are used to control the viscous or gel-like characteristics of the liquor associated with fruits, while sodium alginate is often used to stabilize whipped-cream toppings. Examples of typical dessert products, with details of the additives incorporated into each, are given in Figure 2.

Gums are also commonly used in frozen gateaux in order to confer the desired properties on the individual components and, in particular, to enhance freeze–thaw stability.

Table jellies Jellies are traditionally prepared using gelatin. The material is dissolved in hot water and gelation occurs on cooling in a refrigerator. The gelatin molecules in solution undergo a coil-to-helix transition, which occurs at about 25 °C, and the helices aggregate to form a gel. The gels formed have high clarity and on heating melt at 37 °C, which corresponds to body temperature. The jelly, therefore, melts in the mouth, providing rapid flavor release and a smooth texture, but they are prone to toughening on storage.

Jellies can also be prepared using gums such as carrageenan, alginate, and pectin. Iota-carrageenan gives rise to compliant gels similar to those of gelatin. However, they have a higher melting temperature and hence do not have the same attractive organoleptic properties but since they also have a higher gelling temperature, the gels form without the need for refrigeration. Kappa-carrageenan itself forms very

Figure 2 (see color plate 80) Typical desserts incorporating gums. The additives contained in each dessert include the following: chocolate delight: modified starch, carrageenan, sodium alginate; caramel dessert: modified starch, carrageenan, pectin; raspberry royale: amidated pectin, sodium alginate; pineapple cheesecake: modified starch, gelatin, pectin, guar gum; strawberry fruit fool: gelatin, sodium alginate.

brittle gels but can be used in conjunction with (purified) locust bean gum, which improves the clarity and makes the gels more elastic (less brittle) and less prone to syneresis. Jellies can also be prepared using alginate with a high mannuronic acid content. Soft-textured, nonbrittle gels can be produced with calcium ions under controlled conditions.

Low-acyl gellan gum can be used to prepare dessert jellies with a firm brittle texture. Mixtures of low- and high-acyl gellan gum can be used to produce jellies with a range of textures. Low-acyl gellan can also be used to modify the texture of gelatin gels. In Japan, konjac mannan is commonly used to produce dessert jellies.

Syrups, toppings, and dry dessert mixes Gums are commonly used to enhance the viscosity of syrups for use on pancakes and icecream. They provide the necessary flow characteristics and cling and, in addition, retard sugar crystallization. Xanthan gum and carboxymethyl cellulose give products of higher clarity than those prepared using guar gum or locust bean gum. Propylene glycol alginate is used in some buttered syrups because of its emulsifying characteristics. Xanthan gum, guar gum, and locust bean gum are often used in whipped nondairy dessert toppings in order to control the viscosity of the system prior to whipping. Methyl cellulose and hydroxypropylmethyl cellulose can also be used in this application and they have the added benefit of promoting emulsification of the oil, although other emulsifiers can also be present. Microcrystalline cellulose has been found to be particularly effective at stabilizing foams. The toppings are normally sold frozen and the gums present inhibit ice crystal formation.

Gums are often used in dry dessert mixes. Xanthan gum, carboxymethyl cellulose, and guar gum are particularly effective since they are soluble in cold water. Pectins and alginates are included in some dessert mixes, such as mousses and cheesecakes, in order to provide a gel structure. Xanthan gum is particularly useful in dry sorbet mixes because of its good solubility and stability in acid conditions and also because it can form a weak gel structure, which traps air bubbles formed during mixing.

Carrageenan is widely used in dry milk pudding mixes because it interacts with the casein present, leading to the formation of a gel structure.

Jams, Jellies, and Marmalades

The formulations of jams, jellies, and marmalades in Europe are controlled by a European Union directive which dictates the minimum fruit and sugar solids required for the various categories. Manufacture consists of blending the ingredients, raising the temperature, and evaporating to the correct soluble solids content either at 100 °C at atmospheric pressure or at temperatures down to 60 °C under vacuum. Vacuum boiling avoids heat damage, caramelization, and loss of fruit volatiles, but an additional pasteurization step is required.

The primary characteristic of all preserves is that they are gelled systems, and for conventional preserves pectin is used as the gelling agent. For preserves with a high total soluble solids (TSS) content (> 60%, mainly sugar), one or more high-methoxyl pectins are

used to control gelation. At TSS content of 20–55%, either an amidated or a nonamidated low-methoxyl pectin is used. Gelation of high-methoxyl pectins is pH-dependent and a pH of < 3.5 is required for gelation to occur. This may require the addition of fruit acids to the recipe to reduce the pH, with most jams having a final pH of 2.8–3.4. For low-methoxyl pectins, gelation is controlled by the presence of calcium ions and a high soluble solids content is not required. Gelation is optimized at pH 3–4.5.

In high-sugar preserves the sugar stabilizes the structure and immobilizes the water, thus reducing syneresis. This becomes much more of a problem in low-sugar preserves.

A number of reduced-sugar products are available with TSS contents of < 25%. In these systems gelation is achieved using carrageenan or carrageenan and low-methoxyl pectin blends. Other gums such as guar and locust bean gum may be added to modify the texture and reduce syneresis.

Meat, Stews, Gravies, and Soups

Gums, notably carrageenan and guar gum, are often incorporated into meat products such as sausages, cooked hams, and poultry products where they serve as binders to control the texture and structural integrity and to retain water.

Methyl cellulose is used in fryable products since it gels on heating and hence helps to retain the product's shape during frying.

Gums such as modified starches, guar gum, and carboxymethyl cellulose are used to thicken the gravies for meat pies, canned meats, and stews and to reduce fat migration and water separation during storage.

Modified starches are used to thicken canned soups, while guar gum is commonly used in instant dry soup mixes to add body and aid dispersion of the various ingredients.

Confectionery

Gelatin, modified starch, gum arabic, and pectin are the main gums used in confectionery products. Gum arabic is the major component in traditional wine gums and is present at concentrations of ~50%. Production involves dissolving the gum in water, keeping the temperature as low as possible (< 60 °C) in order to avoid precipitation, and it is then added to a preboiled sugar/glucose solution (70%) followed by flavorings and colors. After standing the liquid is deposited into starch trays and placed in a stoving room for 4–6 days. The gums are then removed from the starch molds, brushed to remove starch, and often glazed with oil or wax. Softer gums or pastilles can be obtained by reducing the stoving time. In view of shortages in gum arabic and severe price fluctuations, considerable efforts have been made to find alternative gums. Nowadays pastilles are commonly made with gum arabic in combination with other gums, notably, starch, maltodextrin, gelatin, pectin, and agar.

Slow-setting, high-methoxyl pectin is used in the preparation of fruit-flavored acidic confectionery jellies and is usually present at concentrations of less than 2%. Some flavors, such as liquorice and vanilla, are unstable in the acid conditions necessary for the gelation of the pectin, and low-ester pectins which gel in the presence of calcium are used instead. These pectins are also used in the manufacture of Turkish delight.

Dietary Importance

C A Edwards, University of Glasgow, Glasgow, UK

Background

The dietary importance of gums is related to their effects at various sites in the gastrointestinal tract from the stomach to the large intestine. Most of their actions in the upper gut have been related to

the development of a high viscosity in the gut lumen. However, gums in natural foods may not be released in sufficient quantities to increase luminal viscosity. Isolated gums or foods fortified with gums, however, can have very significant effects of nutrient absorption and postprandial plasma nutrient levels. Other important effects relate to the fermentation of the gums by the microflora in the large intestine. A high intake of particular gums may help in the treatment of constipation and diabetes, and in the prevention of colon cancer. However, only the benefits for treating constipation have been well established, and more research is needed in their use for other conditions.

Physiochemical Properties and Physiological Action

In this context, the term 'gum' covers a wide range of polysaccharide molecules that have varied structures, physical properties and physiological actions. The term, for the most part, could be interchanged with 'soluble nonstarch polysaccharide' or soluble dietary fiber (*See* **Dietary Fiber**: Properties and Sources). There are many different dietary sources of gums. They are found naturally in plant cell walls (pectins and hemicelluloses), as plant exudates (gum arabic) or mucilages (ispaghula[1]) as well as being produced by some bacteria (xylan) and algae (alginates). The effects of gums on human physiology will depend on whether the gum is ingested as part of a plant cell wall, as part of a food complex, or as an isolated polysaccharide.

Most, but not all, gums produce viscous solutions in their isolated form, and some (such as pectin) have cation exchange properties. The extent of the viscosity or cation exchange depends on the length of the molecule and the constituent sugars. The physiological action of such gums in the diet can therefore vary enormously and may differ from one dietary source to another. If the gum is ingested within the framework of a plant cell wall, as with pectin in carrots, the pectin may not be released in sufficient amounts to have a significant action on small intestinal function but may still be available for fermentation in the large intestine. In addition, the cation exchange properties of an isolated pectin may be greater than pectin contained in a food because the potential binding sites may already be taken up by minerals or other charged molecules found in the food matrix.

Another important consideration is the amount of gum ingested. The amount in foods, or added as stabilizers, emulsifiers, and fat substitutes, is small, and most of the effects described below require a substantial intake of isolated gum. For example, the standard dose of ispaghula for treatment of constipation is 3–11 g per day. The dose recommended for the action of guar gum on small intestinal absorption is 15 g per day, whereas the amount of pectin in carrots is 1.5 g per 100 g, and there is only a trace of gums in icecream.

[1]The terms 'ispaghula' and 'psyllium' (used later) are interchangeable.

Table 1 Properties of gums that affect human physiology and health

Property	*Consequence*	*Main examples*
Viscosity	Slower absorption Lower blood glucose Reduced cholesterol Increased satiety	Guar gum, pectin, ispaghula (psyllium), oat gum
Cation exchange	Binding of minerals Binding bile acids Reduced cholesterol	Pectin
Fermentability	SCFA production Low colonic pH Altered microflora	Oat gum, pectin, guar gum
Butyrate production	Colonic fuel Colonic health Possibly anti cancer	Oat gum
Stool bulking	Reduced constipation Dilution of carcinogens	Ispaghula (psyllium), gellan

The physical characteristics of each gum are determined by sugar composition as well as the order of sugars and degree of modification, e.g., the degree of methylation of pectin. Viscosity results from the entangling of free carbohydrate chains. This requires a disorganized network, and so the viscosity of gums is determined by their molecular weight and the degree of irregular versus regular sugar patterns, the latter allowing more ordered cross-linkage between chains.

The gums have a range of physiological and nutritional effects (Table 1) mediated mostly through effects on transit through the stomach, small intestine, and colon, by reducing mixing actions in the gut, by their actions on the interaction between nutrients, enzymes, and mucosal cells, and finally as a result of their fermentation by the colonic microflora.

Effects in the Stomach and Small Intestine

The effects of isolated gums on gastric emptying and digestion and absorption have been well studied. The effects of the same gums in foods are less well established. Viscous gums eaten as part of a mainly liquid meal can slow gastric emptying by making the liquid meal of a more solid consistency. Guar gum, which has one of the highest viscosities, can delay gastric emptying half time by 60%. However, it has also been shown that increased viscosity can facilitate the emptying of discrete solids. In this case, they may

act as lubricants and ease passage through the small 2-mm opening of the pyloric sphincter.

In the small intestine, the main impact of increased viscosity is to resist the movement of the intestinal contractions, reducing the mixing of the digestive enzymes with their substrates and inhibiting the movement of the nutrients to the absorptive epithelium. This can give the impression of an increase in the thickness of the unstirred water layer adjacent to the intestinal mucosa, through which nutrients must pass by diffusion. These two effects, along with slowed gastric emptying, can delay the process of digestion and absorption, resulting in decreased postprandial glycemia and potentially reducing fat absorption.

In addition, the viscous matrix of a gum solution can trap endogenous molecules such as bile acids. Bile acids are essential for the emulsification of fats to allow digestion, and for the formation of micelles to facilitate movement of the products of fat digestion to the mucosa for absorption. A decrease in bile acid concentration will therefore disrupt and delay fat digestion. If cation exchange properties persist, then the bile acids may be bound to the charged gum, and this will have an additional impact in fat digestion. The trapped bile acids, if not released in the large intestine during fermentation, are excreted in feces, which will result in reduced plasma cholesterol as replacement bile acids are synthesized from this precursor.

There are, however, some problems with this simplistic explanation of the effects of viscous gums on postprandial glucose and fat absorption. The viscosity shown in *in vitro* models to delay digestion and reduce mobility of nutrients may not be achieved in the part of the small intestine where most digestion and absorption occurs.

Most digestion occurs in the duodenum and jejunum. When foods enters the duodenum, pancreatic secretion of large amounts of bicarbonate and enzyme rich juice is stimulated. This relatively large volume of fluid will dilute the small intestinal contents and considerably reduce the concentration and therefore the viscosity of the food gum. The relationship between concentration and viscosity is not linear but exponential, and changes in concentration can have a major impact on the viscosity maintained. Experiments in rats have failed to find any large increases in upper small intestinal viscosity after ingestion of large amounts of guar gum. The gums are not digested, however, so the viscosity is regained as the nutrients and fluid are absorbed. Thus, the viscosity in the ileum where bile acids are reabsorbed, as part of the enterohepatic circulation, will be much higher. It is well established, however, that postprandial blood glucose is reduced considerably after ingestion of gums. Bread containing lower-molecular-weight guar still has the action of reducing postprandial glycemia, again suggesting that viscosity may not be the critical factor.

Blood Glucose and Diabetes Mellitus

In the past, the use of gums such as isolated solutions of guar gum to reduce the rise in postprandial blood glucose was thought to be of some therapeutic use in diabetes mellitus. Although the effects of guar gum reducing postprandial hyperglycemia and insulinemia are well established, this approach in treating diabetics was not very successful, as the gum solutions used had poor organoleptic properties with an undesirable mouth feel and aftertaste. Since then, the incorporation of gums such as guar and oat gum in bread products has been explored. It has been found that very palatable breads with proven effects on intestinal absorption rate can be produced, but their use in the diabetic diet has still to be established. There has also been much recent interest in the production and action of cereal products containing oat β-glucans, ispaghula (psyllium), and Konjac Mannan.

Therapeutic Enteral Diets

Sometimes, patients, including children, have a problem in dealing with normal foods and are fed a simplified synthetic fluid diet of easily assimilated nutrients. These diets often have to be liquid to allow administration through tubes directly into the gastrointestinal tract. Until recently, these elemental or polymeric diets have contained no source of dietary fiber. This can result in constipation and, after prolonged use, produce atrophy of the colonic mucosa. Some of these liquid diets have now been formulated with soluble gums as a source of dietary fiber to prevent these symptoms and to maintain a healthy microflora. The gums used include soy polysaccharide, pectin, and carboxymethylcellulose.

Effect of Gums on Plasma Cholesterol

Heart disease is one of the major killers of the developed world, and one of the main risk factors is high plasma low-density lipoprotein (LDL) cholesterol coupled with low high-density lipoprotein (HDL) cholesterol. HDL cholesterol is associated with clearance of sterol from the peripheral tissues to the liver. Many of the viscous food gums (oat, pectin, guar, psyllium, and others) have been shown to have a significant and long-term effect in reducing LDL cholesterol while having little effect on, or increasing, HDL cholesterol. The effect of the gums is modest but may be of significance in reducing the risk of heart disease.

Table 2 Possible mechanisms for the effect of gums on serum cholesterol

Inhibition of fat digestion
Viscosity inhibits mixing of enzymes and lipids
Viscosity/cation exchange traps/binds bile acids
Viscosity inhibits formation of micelles
Viscosity inhibits movement of micelles
Increased bile acid synthesis from cholesterol
Binding of bile acids by cation exchange, viscosity
Increased fecal bile acid losses
Increased fecal cholesterol losses
Inhibited cholesterol absorption
Increased intestinal cell losses
Decreased cholesterol synthesis
Inhibition of hepatic cholesterol synthesis by propionic acid (probably only a pharmacological effect)

It is not clear by which mechanisms the gums act (Table 2). They could reduce fat digestion either directly or by interfering with micelle formation. Although there is likely to be only a small increase in total fat losses, the delaying of fat absorption can result in a change in the type of chylomicra or lipoproteins produced. For those gums like pectin with cation-exchange properties, the bile acids may be bound to the carbohydrate molecule, which are then excreted in the feces. Viscous fibers without cation exchange may also trap bile acids within their matrix. Several gums, including guar, pectin, and ispaghula (psyllium) have been shown to increase fecal bile acid losses, and this has been associated with reduced cholesterol. However, if the fiber is fermented, the bile acid would be released in the large intestine where they could be converted to secondary bile acids and returned to the bile acid pool. Moreover, low-molecular-weight (and therefore low-viscosity) guar gum in bread still reduced cholesterol and not all studies demonstrating an effect on cholesterol show an increase in fecal bile acid. If fecal bile acid losses are increased, cholesterol in the liver is used to replace them, and hence plasma cholesterol falls.

Cholesterol levels could also be decreased due to the higher fecal losses of cholesterol from increased intestinal cell loss seen with viscous fibers, and there has been much discussion about the potential actions of propionic acid produced from the fermentation of the gums. However, the inhibitory effects of propionic acid on hepatic cholesterol synthesis appear to require pharmacological levels of propionate rather than those that are produced from the fermentation of food gums under normal conditions. Acetate is a precursor of fat synthesis and lactulose a highly fermentable saccharide increased serum LDL cholesterol when fed to healthy volunteers. This was associated with higher levels of serum acetate in some subjects. It is evident that the actions of gums on serum cholesterol are mediated by different mechanisms for individual gums and for the same gums under different circumstances.

Satiety and Obesity

If gums had a major effect on satiety, they could be a useful adjunct to the prevention and treatment of the increasing public health problem of obesity. However, although highly viscous gums such as guar have been shown to increase satiety and even promote some weight loss in short-term studies, the unpalatability of such gums and the moderate effects they have on weight make them of unlikely benefit in weight-loss or weight-maintenance programs.

Gums and Mineral Bioavailability

Some food gums with cation-exchange properties have been shown *in vitro* to bind minerals such as calcium. Even those gums without direct binding sites may still entrap these minerals and delay or inhibit their absorption. *In vivo* human studies have shown an increase in fecal mineral output, but the overall mineral balance is not affected in adults. The effect in young children is unknown and is one of the reasons why a high dietary fiber intake has not been encouraged in the under fives. However, there is no evidence of significant mineral imbalance in children on high-fiber diets, and the effects are unlikely to be great. Moreover, there are several studies now suggesting increased calcium absorption in the large intestine, perhaps encouraged by the reduced pH from the bacterial fermentation of soluble fiber.

Effects of Gums in the Large Intestine

Most food gums are readily fermented in the large intestine of man by the diverse and dense microflora. The products and consequences of this fermentation may have a major influence on human health, and these effects may outweigh the impact of the food gums in the small intestine.

Colonic Fermentation

The human colonic microflora is thought to contain over 400 different species (perhaps even more as new molecular techniques, which measure bacterial DNA and rRNA, are discovering that the majority of bacterial groups have never been cultured (*See* **Microflora of the Intestine:** Probiotics). The mainly anaerobic bacteria use the carbohydrates to produce short-chain fatty acids (SCFA), mostly acetic, propionic, and butyric acids, and the gases CO_2, H_2, CH_4,

and H_2S. Colonic pH is also determined by the balance between the rate of fermentation and the buffering of the SCFA by bicarbonate exchanged when the SCFA are absorbed.

The fermentability of each gum depends on its structure and water solubility. The presence of bacteria with the required enzymes for each step of gum degradation is also essential. The degradation and fermentation of a complex carbohydrate structure may be the result of a synergy between several bacterial species, and some of the enzymes may take time to be expressed either by induction of enzymes, in originally predominant bacteria, or by an increase in dominance by new groups. It has been shown in rats that it can take many weeks before the colonic microflora is truly adapted to the introduction of a new gum into the diet.

The extent and rate of fermentation of food gums are important. The rate of fermentation may determine the site of SCFA production. Most colonic disease occurs in the distal colon, and yet most fermentation occurs in the proximal colon. Therefore, food gums that are slowly fermented may encourage prolonged fermentation and SCFA at more distal sites.

The pattern of SCFA produced from each gum also differs. Pectin increases the proportion of acetic acid produced, guar gum and ispaghula tend to promote the production of propionic acid, and oat gum increases production of butyric acid.

Health Impact of Increased Colonic Fermentation

The colonic fermentation of carbohydrates including food gums can result in a substantial fall in colonic luminal pH. There are several benefits of reduced colonic pH, which include the inhibition of undesirable bacterial activities such as 7α dehydroxylase, which forms secondary bile acids that can help to promote cancer. Reduced colonic pH can also lead to precipitation of fatty acids, sterols, and other molecules, which have been implicated as procarcinogens. Low pH also reduces the rate of colonic cell proliferation, thought to be a risk factor for colon cancer. However, the SCFA produced during fermentation can stimulate cell proliferation, and so under normal conditions, the effects of pH here may be canceled out. It has been noted, however, that populations in South Africa with a low risk of colonic cancer also have a lower colonic and fecal pH than those from high-risk populations.

The side-effects of increased colonic fermentation and of ingestion of large amounts of food gums include flatulence and abdominal distention. These are usually associated with eating large amounts of fermentable material but may reduce over time as the colonic flora adapts to the new carbohydrate substrate supply and adopts a more efficient fermentation process. This may take over a week.

The SCFA have many potential actions that are generally beneficial for health. They promote the absorption of water and electrolytes and inhibit the growth of pathogens, reducing the risk of diarrhea. They all stimulate cell proliferation throughout the gut, even though they are produced in the large intestine, and this may be important for wound healing after gut surgery or after gastrointestinal disease. In addition to these general effects, each fatty acid has its own idiosyncratic actions.

Actions of Individual SCFA

Acetic Acid

Acetic acid is always the main SCFA produced, usually making up 50–70% of the SCFA. Acetic acid is the only SCFA to reach the systemic circulation in significant amounts. It can provide energy for muscles and other tissues and is noninsulinogenic. Acetate has less effect on the colonic enterocytes in terms of proliferation and motility than the other SCFA. Pectin has been shown to increase the proportion of acetate when fermented by fecal bacteria *in vitro*. Acetate produced during pectin ingestion may also beneficially affect fibrin network architecture in patients with hypercholesterolemia, reducing the risk of heart disease.

Propionic Acid

Propionic acid is usually the second most abundant SCFA produced during fermentation. Propionic acid is absorbed into the portal vein but is mainly removed by the liver. It is gluconeogenic, unlike the other SCFA, and was previously thought to inhibit cholesterol synthesis by the liver. However, although this effect has been well demonstrated under experimental conditions, it is now thought that not enough propionic acid is formed in the colon and absorbed into the portal vain to have this effect. However, it is worth noting that those gums that are associated with cholesterol-lowering effects are often those that promote propionate production.

Butyrate

Butyric acid is the preferred fuel for the colonic enterocyte. It has also been associated with several potential anticancer properties. An increase in the rate of colonic cell proliferation is believed to be a risk factor for cancer. However, all cells in the colon are

programmed with a time to die by a controlled process called apoptosis. It is probably the balance between the levels of proliferation and apoptosis that determine whether a cancer will or will not develop. Although butyrate has been shown to stimulate cell proliferation of normal colonic cells, it has been shown to stimulate apoptosis in cancer cells *in vitro*. It may also affect other important stages in carcinogenesis such as the promotion of cell differentiation and inhibition of histone deacetylase, which may promote DNA repair.

Gums as Prebiotics

There has been much recent interest in the beneficial health effects of certain strains of lactic acid bacteria or probiotics believed to have various health benefits. These include reducing the duration of rotavirus diarrhea, reducing eczema in atopic infants, and potentially having protective actions against intestinal diseases, including colitis and cancer (*See* **Microflora of the Intestine:** Probiotics). These probiotics are usually bifidobacteria, lactobacilli or streptococci but may include certain strains of *E. coli*. The survival of these bacteria in the gut can be enhanced by the presence of certain fermentable carbohydrates. These are called 'prebiotics,' but to fulfill the definition, carbohydrates must selectively increase the populations of the probiotic organisms. The most accepted prebiotics are fructo-oligosaccharides and resistant starch, but some gums may also increase bacterial populations.

Calories from Fermentation of Gums

SCFA produced from fermentation can be used by the colonic cells and other body tissues for fuel. It is now recognized that dietary fibers, including gums, contribute energy, but the exact amount depends on the fermentability and any increased fecal nitrogen losses. After absorption, the SCFA have to be acylated before entering the major metabolic pathways, and this also has an energy cost. It is now estimated that, on average, fermentation provides 8.4 kJ (2 kcal) per gram of carbohydrate.

Constipation

If a dietary gum is poorly fermented, it may have sufficient residual water-holding capacity to increase stool output. Ispaghula (psyllium), which has a water-holding capacity of approximately 7 g g^{-1}, has been used successfully to treat mild to moderate constipation for many years. Gellan, a bacterially produced gum, has also been shown to be a potent stool bulker but is not used therapeutically. Other gums such as karaya and xanthan, which are slowly fermented, may increase stool wet weight and fecal SCFA without increasing stool solids.

Nutritional Role of Guar Gum

P Rayment* **and P R Ellis**, King's College London, London, UK

Introduction

It has been recognized for many years that guar gum, a galactomannan-rich legume flour, has considerable potential as a therapeutic agent in the dietary management of diabetes and hyperlipidemia. For example, it is now well established that guar gum can reduce the postprandial rise in blood glucose and insulin concentrations in response to glucose drinks and starch-rich meals in both healthy and diabetic subjects. Furthermore, the addition of guar gum to a normal diet can elicit long-term improvements in metabolic control in people with type 1 (insulin-dependent) and type 2 (non-insulin-dependent) diabetes mellitus. The ease of isolation and purification of guar gum explains why it is frequently used as a

*Now at Unilever Research Colworth, UK.

'model' non-starch polysaccharide in physiological and clinical studies. Also, the fact that it is well characterized with respect to other sources of dietary non-starch polysaccharides makes it an ideal candidate for clinical use. This article highlights the nutritional and therapeutic role of guar gum, but mainly focuses on its blood glucose- and cholesterol-lowering actions. Also included is a brief discussion of the physicochemical properties of guar gum, including its rheological behavior in model systems and its influence on the properties of human and animal digesta *in vivo*, which has an important, if not crucial, influence on gut function and metabolism.

Extraction and Composition of Guar Gum

Guar gum, a type of dietary fiber, is extracted from the seed endosperm of a leguminous plant (*Cyamopsis tetragonoloba* (L.) Taub.) indigenous to the Indian subcontinent. Figure 1 shows the pods, seeds, and endosperm extract of the guar plant. To recover guar gum from the seed, the endosperm halves (splits)

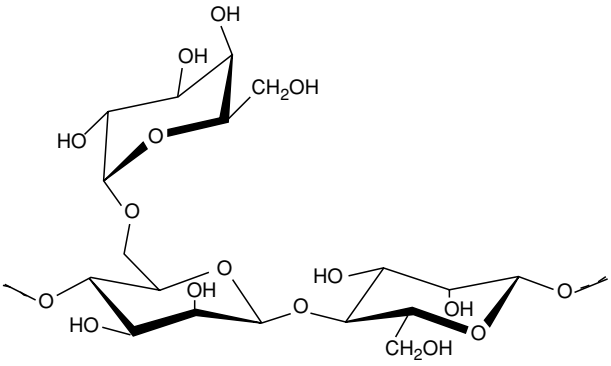

Figure 2 Structure of guar galactomannan showing the mannose backbone and galactose side chains.

must be separated from the hull and the cotyledon. The splits are ground to a fine flour and may then be purified by repeated alcohol washings. In this way guar gum is commercially produced as a flour and is frequently used as an additive (E412) in the food industry for its thickening and stabilizing properties.

Chemically, guar gum mainly consists of a high-molecular-weight polysaccharide, namely galactomannan, which is based on a mannan (M) backbone with galactose (G) side groups, as shown in Figure 2. The ratio of the two components (G:M) seems to vary slightly depending on the origin of the seed, but the gum is generally considered to contain approximately one galactose unit for every two mannose units. The linkages between the sugar groups cannot be hydrolyzed by human digestive enzymes in the small intestine but are fermented by bacterial enzymes in the large intestine. The products of this fermentation include short-chain fatty acids, mainly acetic, propionic, and butyric acids, which have important nutritional implications, notably in relation to colonic function.

The Food Chemicals Codex specifies a standard of not less than 66% of galactomannan in food-grade guar gum in the USA, although generally most samples contain more than 80% (w/w). The other components of guar gum, including fat and protein, which are considered to be impurities, vary between different sources. Table 1 lists the typical composition of a commercially available guar gum flour.

Table 1 Chemical composition of a commercially available guar gum flour

Component	*Concentration (g 100 g^{-1})*
Galactomannan	73.0–86.7
Protein	3.0–6.0
Crude fiber	1.0–4.0
Ash (total minerals)	0.8–2.0
Fat (petroleum ether extractables)	0.5–1.0
Moisture	8.0–14.0
Total impurities[a]	13.3–27.0

[a]Calculated as total nongalactomannan components.

Potential Adverse Effects of Guar Gum

In the food industry, guar gum is normally added to foods in concentrations of $< 1\,g\,100\,g^{-1}$ to provide a thickening, binding, or stabilizing function. Since guar gum is derived from a normal food material, it is classified by the Food and Agricultural Organization/World Health Organization as a substance of low toxicity. The safety of guar gum is substantiated by the results of a number of long-term studies in human subjects. In general, adverse effects, observed in some but not all subjects, appear to be associated with gastrointestinal disturbances. These effects, which sometimes appear to diminish with regular consumption of guar gum, include flatulence, gastrointestinal pain or discomfort, nausea, and diarrhea. Some of these side-effects probably result from bacterial fermentation of guar gum in the large intestine. The extent of the problems is generally related to the dose given, with more adverse gastrointestinal effects occurring when guar gum consumption is excessive (~ 15–$30\,g\,day^{-1}$). It has also been suggested that guar gum may reduce the bioavailability of a number of micronutrients (e.g., vitamins), although there is no evidence to indicate that this is of nutritional significance.

There is more concern about the use of macroaggregates of guar gum that have the potential for causing obstruction in the esophagus and gastrointestinal tract. This concern has arisen from reported incidents of esophageal obstruction and rupture in patients ingesting guar granules. There have also been a number of cases of esophageal and small-bowel obstruction in patients ingesting a particular type of guar-containing diet pill. The USA and Australia have banned such products. In the European Community (EC), food additive legislation prohibits the use of guar gum and other gums for the production of 'dehydrated foodstuffs that will rehydrate on ingestion.' However, the selling of guar products as medicine under license and administered to patients under medical supervision is permitted under EC legislation.

Physicochemical Properties of Guar Gum

Solution Properties

The ability of the galactomannan component of guar gum to hydrate and increase the viscosity, or thickness, of the intestinal contents is an important determinant of its physiological effects. The majority of polysaccharides used in nutritional studies exist in solution as 'random coils' and the number and

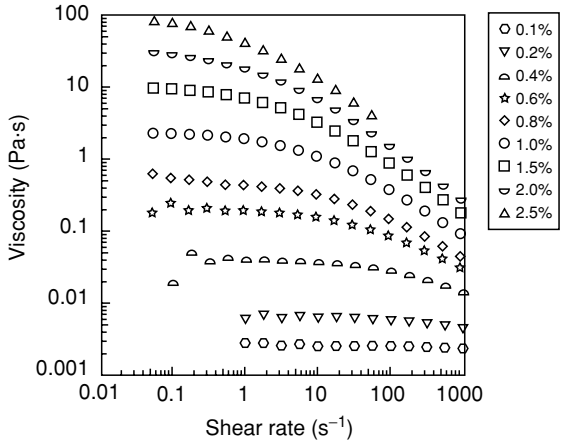

Figure 3 Shear rate and concentration dependence of viscosity for guar galactomannan solutions. Data taken from Rayment P (1996) PhD thesis, University of London.

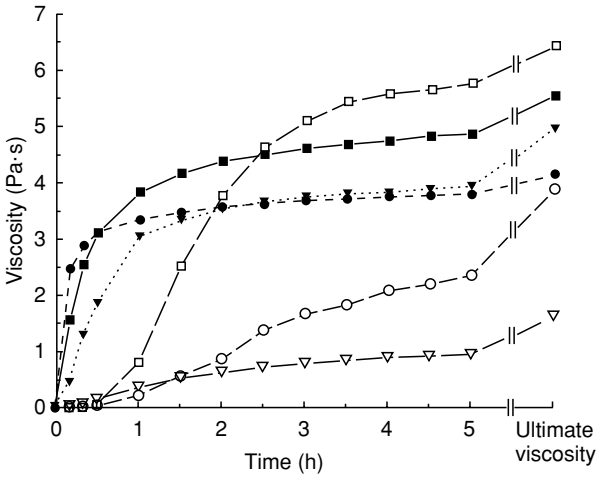

Figure 4 Hydration rate profiles of guar gum samples presented as viscosity (Pa · s) versus time. Experimental points are mean values from measurements on 4 replicate solutions of native guar gum flours M150 (—■—) and RG30 (- -●- -), pharmaceutical granule preparations Guarina (. . .▼. . .), Guarem (—□—) and Lejguar (—○—), and Glucotard minitablets (—▽—). The 'ultimate viscosity' is the measurement of viscosity taken after 24 hours of hydration following homogenisation of the guar solution with an ultra-turrax mixer. The final viscosity is taken only when a consistent maximum reading is recorded on the viscometer (usually after homogenising for 4–6 min). Data taken from Ellis PR & Morris ER (1991) Importance of the rate of hydration of pharmaceutical preparations of guar gum; a new in vitro monitoring method. *Diabetic Medicine* 8, 378–381.

molecular size of the polymer chains are critical determinants of viscosity and thus physiological activity. The high levels of viscosity associated with water-soluble polysaccharides originate predominantly by interpenetration of individual polymer chains to form entangled networks. At low guar gum concentrations, the individual polymer coils occupy a separate domain within the solution with little or no interpenetration. These solutions are described as Newtonian because their viscosity is independent of the rate of stirring or mixing (i.e., related to shear rate). At higher concentrations, where the polymer coils begin to overlap, the system becomes non-Newtonian and viscosity then depends on the shear rate. The more common type of non-Newtonian flow in food systems is shear-thinning (or pseudoplastic) behavior, where viscosity decreases with increased mixing. Figure 3 shows the effect of shear rate and concentration on the viscosity of guar gum solutions.

The viscosity or flow properties of guar gum can be determined by using various rheological techniques. Rheology (from the Greek word *rheos*, meaning stream) is a branch of physical science concerned with the study of the flow and deformation of materials under externally imposed forces. However, to predict the rheological behavior of guar gum in the human intestine, several factors require consideration. These factors include dependence on the mode of administration, the size of the dose and the physicochemical characteristics of the sample used as well as the physical state of the galactomannan in the gut lumen.

Hydration Kinetics of Guar Gum

The realization that viscous polysaccharides can be used for therapeutic benefit has led to the development of various pharmaceutical preparations containing guar gum. These include capsules or macroaggregates of guar gum, such as granules and minitablets, which have been designed to hydrate slowly in the mouth to improve palatability. However, their beneficial effects have been reported to be extremely variable, most probably due to their lack of hydration in the stomach and small intestine. Consequently, the hydration rate of guar gum in the gut lumen is a critical factor. Figure 4 compares the hydration rate profiles of a range of commercially produced samples of guar gum. These samples were hydrated in water and viscosity was measured over a 5-h period. Unsurprisingly, the marked differences observed are mainly attributed to the physical nature of the guar gum preparations. Thus, samples with a smaller particle size (flours < 150 μm) hydrate much more quickly than those with a larger particle size (> 1 mm), e.g., Glucotard minitablets. The results of many clinical trials have shown that the latter types are often physiologically ineffective.

Some research workers have also reported that the clinical efficacy of guar gum is improved when it is incorporated directly into a food rather than when taken as a pharmaceutical premeal supplement. Thus, a key factor in optimizing the glucose-lowering action

of guar gum is to insure that the polymer is in intimate contact with the starch, the main source of dietary glucose.

Nutritional and Physiological Effects of Guar Gum

Many research groups have reported the efficacy of guar gum in attenuating the postprandial rise in blood glucose and insulin concentrations in healthy and diabetic subjects (Figure 5). One reasonable explanation of these postprandial effects is that guar gum reduces the rate (and perhaps the extent) of digestion and absorption of available carbohydrate in the gastrointestinal tract. (Here available carbohydrate is defined as carbohydrate that is digested by α-amylase in the upper gastrointestinal tract and absorbed into the portal blood (mostly as glucose); this includes starch, dextrins and simple sugars (e.g., sucrose, lactose).) There are however problems with obtaining quantitative estimates of glucose absorption in humans; for example, access to the hepatic portal vein is very difficult. Nevertheless, studies in pigs, a useful animal model for studies on dietary polysaccharides, have provided the first direct evidence that guar gum decreases the rate of glucose absorption. In these types of experiment, glucose concentrations were measured simultaneously in the hepatic portal vein and peripheral blood (via the mesenteric artery) and the flow rate of the portal blood was measured also. Significant reductions in glucose absorption over 4 h were observed in the experimental animals given guar gum doses equivalent to those consumed by humans in clinical studies. In the same studies, insulin secretion was significantly decreased over the same period in response to the guar diet. This suggests that the attenuation in the plasma insulin levels seen in humans is attributed to a reduction in insulin secretion from the pancreatic islet β-cells in response to a lowered rate of glucose absorption. Also, a number of human studies have shown that guar gum decreases the postprandial rise in the insulinotropic hormones, plasma gastric-inhibitory polypeptide and glucagon-like peptide-1, which may partly explain the insulin-lowering action of guar gum. Another interpretation of data showing decreases in the peripheral blood insulin concentrations is that there has been an increase in hepatic extraction of insulin, a normal process by which insulin is removed from the blood circulation. Studies carried out to substantiate this have been largely contradictory, however.

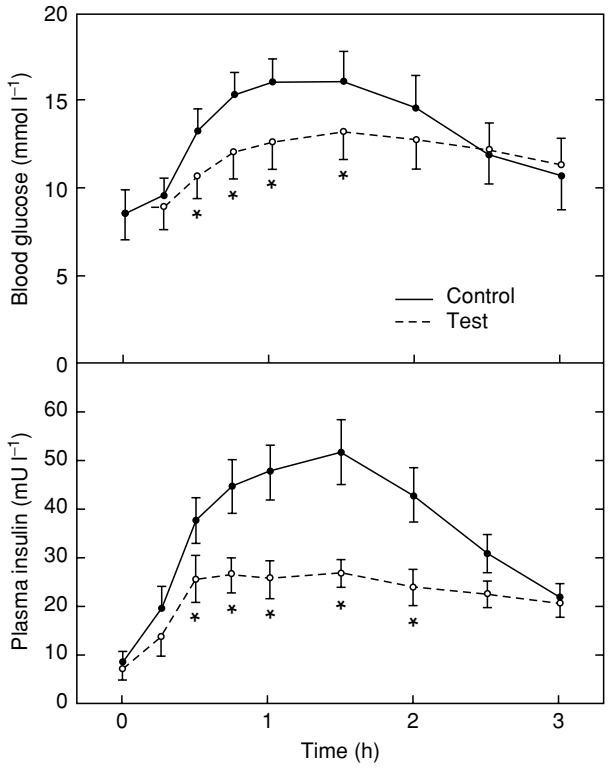

Figure 5 Postprandial blood glucose and insulin concentrations of patients with type 2 (noninsulin-dependent) diabetes mellitus in response to control and test breakfast meals of bread and marmalade (total available carbohydrate, mainly starch and sugars, was 106 g). The test contained 16 g of guar gum (in the bread) and 10 g of pectin (in the marmalade). *Statistically significant differences between control and test meals at individual time points. Figure redrawn from data published by Jenkins DJA, Leeds AR, Gassull MA *et al*. (1976) Unabsorbable carbohydrates and diabetes: decreased post-prandial hyperglycaemia. *Lancet* 2: 172–174.

In relation to long-term studies of insulin action in experimental animals and humans, it has been reported that guar gum increases (improves) insulin sensitivity. A reduction in sensitivity to insulin (i.e., 'insulin resistance') is seen as a decrease in the response of tissues to insulin stimulation and is considered to be an important risk factor for both coronary heart disease (CHD) and type 2 diabetes.

Mechanism of Action of Guar Gum

There is little doubt that the consumption of guar gum, whether mixed in a drink or solid food, can significantly modify digesta properties at all sites of the gastrointestinal tract. One important feature is the capacity of guar gum at relatively low concentrations to form a highly viscous network in solution. As mentioned previously, the behavior of guar gum in a food material is highly complex. In such systems there is unlikely to be one mechanism to explain fully the effects of guar gum in the human gut. A number of physicochemical mechanisms may be

involved, which are largely dependent on the type and form of the guar gum ingested. Much of the literature indicates that guar gum decreases the rate of glucose absorption into the hepatic portal vein by inhibiting the processes associated with digestion and absorption of available carbohydrates. These processes include gastric function, intestinal transit and mixing, α-amylase–starch interactions, and the movement of products of starch hydrolysis to the gut mucosa.

A number of experiments in humans and animals have shown that guar gum reduces the rate of gastric emptying of a meal. However, there are also studies that have shown no effect or even sometimes an acceleration in gastric emptying after the ingestion of guar gum. These contradictory results probably arise from differences in the type of guar gum used, the way in which it was administered, the proportion of solids and liquids in the meals, and the techniques used to measure gastric emptying. In general, it is considered that guar gum may reduce the rate of gastric emptying under some conditions, but this action is unlikely to be the only mechanism. Other groups have shown guar gum has additional effects on gastric function. In studies in dogs, guar gum was reported to impair gastric trituration and sieving by increasing the viscosity of the stomach contents. It was shown that there was a significant increase in the proportion of larger particles of food entering the small intestine when guar gum was incorporated into the diets. Possible explanations for these findings include suggestions that the increased viscosity stabilizes the suspension of larger food particles, which are likely therefore to escape maceration in the antrum of the stomach, and/or that the guar gum alters the contractile pattern of the terminal antrum, thus impairing the ability of the stomach to retain large particles.

There is evidence from human and animal studies that guar gum delays the transit of digesta in the small intestine. The postprandial pattern of gut motility also seems to be influenced by guar gum and other types of dietary fiber. Thus, whereas wheat bran and cellulose-supplemented diets were reported to produce prolonged bursts of intestinal contractions, guar consumption caused continuous contractions with a 50% reduction in amplitude compared with the other types of fiber. The effect of guar gum on the mixing behavior of digesta at different sites of the gastrointestinal tract has yet to be investigated, but it is likely to be extremely complex. It has been suggested that an increase in the viscosity of digesta will produce laminar or 'streamline' flow, rather than turbulent or disorderly flow, which is characteristic of less viscous fluids and facilitates efficient mixing of digesta in the gut. An inhibition of the digesta flow rate will inhibit physical mixing of nutrients and enzymes (e.g., pancreatic amylase). Also, laminar flow behavior would almost certainly have an effect on the rate at which nutrients are exposed to the epithelial surface and then absorbed into the hepatic portal vein.

However, an explanation of the precise mechanism by which guar gum modifies gut function is still elusive, despite the plethora of clinical and physiological studies that have been undertaken. The problem is that researchers understand little about the behavior of guar gum in the human gastrointestinal tract. Digesta is an extremely complex heterogeneous material and the effects of guar gum on this system have not been studied in great detail. Much of the work that has been done has involved investigating digesta in the stomach and small intestine, since it is assumed that guar gum has negligible effects on viscosity in the large intestine due to depolymerization by bacterial fermentation. There are a number of problems associated with measuring digesta rheology *in vivo*. In human subjects, there are obvious practical difficulties in gaining access to the sites of interest in the gut. Notwithstanding the initial problems involved with sampling intestinal contents, particularly in humans, the rheological properties of digesta will depend on the precise location of the sampling site. Thus, digesta is subjected to dilution by gastric secretions and then concentration by absorption of water, by both the intestine and the guar gum, at it passes further along the intestinal tract. Also the samples collected need to be tested quickly to prevent drying or dissolution of particulate materials. In the case of animal experiments, this requires access to rheometers or other measuring devices in the animal house.

Many factors complicate the interpretation of the rheological behavior of digesta containing guar gum. These include a lack of information on the hydration kinetics of guar gum *in vivo* and the contribution of undissolved food particulates to viscosity. Therefore, to enhance our understanding of the physical properties of digesta it is important to study model systems of entangled networks filled with particulates, although *in vivo* other factors such as gastrointestinal motility and fluid secretion/absorption also play a crucial role. In recent years, the rheological properties of guar gum solutions with increasing particulate concentrations have been investigated. The particulates studies included materials that were essentially spherical and rod-like in shape (i.e., starch granules and microcrystalline cellulose, respectively). The effect of particulates or 'fillers' is primarily to increase the viscosity above that of the pure guar gum system, as shown in Figure 6. The initial Newtonian flow

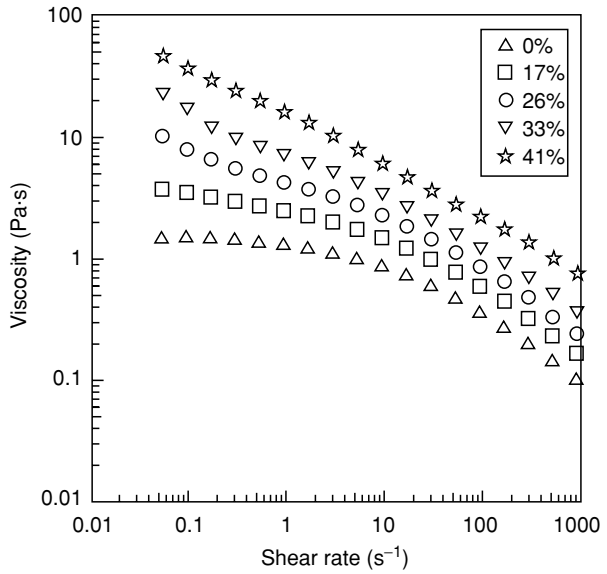

Figure 6 Effect of increasing rice starch concentration on the viscosity–shear rate flow curve of a 1% guar galactomannan solution. Data taken from Rayment P (1996) PhD thesis, University of London.

properties of the pure system at low shear rates become more rate-dependent on increasing particulate concentration – the so-called power-law behavior.

The flow data have been fitted to mathematical equations, which incorporate parameters that describe the shear-thinning nature of guar gum and the increasing solid-like behavior of these filled systems. The model also seems to work well with a more heterogeneous food material containing wheat starch. The extrapolation of such models to real food systems and even digesta is fraught with difficulty, however. The inherent problems with studying digesta have been mentioned already, but to make any real progress in this area, at the very least, information is needed on the fractional volume of particulate material at different sites of the gastrointestinal tract. These data could be obtained by recovering ileal effluent from ileostomy patients and by the recovery of digesta from cannulated animals at appropriate sites of the gut. Further work on the development of more heterogeneous models and techniques to study such systems is crucial if we are to increase our understanding of how guar behaves in the gut environment.

The mechanism by which guar gum reduces plasma cholesterol is still uncertain but, again, the discussion about the effects of guar gum on digesta viscosity and glucose absorption is important here also. The level of viscosity generated in the gut has been suggested as an important determinant of the hypocholesterolemic effect of guar gum in animal studies. The ingestion of guar gum appears to enhance fecal bile acid and neutral sterol excretion, reduce the rate of digestion and absorption of lipids, and inhibit synthesis of cholesterol. *In vitro*, guar gum has been shown to reduce lipid emulsification and the rate of lipolysis of emulsified triacylglycerols, although these effects have not been substantiated *in vivo*. Also, guar gum has been shown to inhibit both the rate of diffusion of cholesterol mixed micelles and hepatic cholesterol synthesis; the latter has been attributed to propionic acid, one of the products of guar fermentation in the large intestine. However, the inconsistency between *in vivo* and *in vitro* studies prevents any conclusive statements being made about the precise mode of action of guar gum.

Dietary Management of Disease

Although guar gum has frequently been used in clinical trials, interpretation of the results can be problematic. There are problems resulting from variable study design, lack of adequate controls, and heterogeneity of subject groups. Furthermore, many nutritional studies reporting the therapeutic effects of guar gum provide very limited information about the type and physicochemical properties of the sample tested, e.g., molecular weight and particle size. Moreover, sometimes it is not even known whether the guar was administered as a pre-meal supplement or incorporated directly into the subjects' meal. Despite these problems, there is sufficient evidence to show that guar gum can be used effectively in the treatment of diabetes and hyperlipidemia, although its role in weight control management has yet to be defined.

Diabetes Mellitus and Hyperlipidemia

The plasma cholesterol-lowering properties of guar gum have been known since the 1960s. Most of the numerous clinical trials published since then have shown reductions in plasma concentrations of cholesterol, mainly the low-density lipoprotein (LDL) fraction, and occasionally triacylglycerols, in both healthy and hyperlipidemic individuals, in some studies for periods of up to 1–2 years. Similar results have been reported in people with diabetes, who are also likely to benefit from any improvements in lipid metabolism given their increased risk for CHD. Currently, although some pharmaceutical preparations are available in the UK, for the management of diabetes, no such products are available for the treatment of hyperlipidemia. In addition to evidence showing the blood glucose-lowering effect of guar gum in response to a starchy meal, long-term improvements have been demonstrated in patients with

type 1 and type 2 diabetes. In one study of a group of type 2 diabetic patients, a 7-g daily dose of guar gum, which had been incorporated into wheat bread, improved glycemic control (as seen by a significant reduction in glycated hemoglobin) and lowered plasma total and LDL-cholesterol levels (Table 2).

As discussed previously, some of the pharmaceutical preparations of guar gum, usually taken as a premeal drink, have been shown to be clinically ineffective due to impaired hydration. Moreover, when guar gum flour is incorporated directly into a meal, the clinically effective dose seems to be significantly lower than that recommended for the pharmaceutical preparations. This has led to the development of a number of everyday foods enriched with guar gum, such as bread, pasta, biscuits, and breakfast cereals. The recommended dose for pharmaceutical preparations of guar gum in diabetes therapy is usually 5 g with each meal (i.e., 15 g day^{-1}). However, it is not known what the precise dose and molecular weight of guar gum should be used in the diet to optimize clinical benefits. A lower and upper daily dose range of 6–15 g of native guar gum has been suggested for use in diabetes therapy. This has been suggested on the basis that doses of guar gum above 15 g day^{-1} may cause side-effects, such as flatulence, and there is a lack of reliable long-term studies at doses of less than 6 g day^{-1}. The average molecular weights of guar galactomannan samples used in nutritional studies are in the range of 2.0–3.0 million. However, more recent studies have shown therapeutic benefits with samples of lower molecular weight (0.5–1 million), produced commercially by partial depolymerization. For example, one such product of approximately 1 million molecular weight has been used to lower plasma cholesterol levels in hypercholesterolemic human subjects (Table 3). Further work is required to define the lowest molecular weight and optimum dose that can be used without a loss in clinical efficacy. Such knowledge would have a number of advantages for any future product development, since low-molecular-weight grades are easier to incorporate into foods and are more palatable.

Obesity

Obesity is associated with an increased risk of diabetes, insulin resistance, CHD, and hypertension. Most short-term studies (often single-meal tests) have shown that guar gum reduces feelings of hunger

Table 2 Mean values (± SEM) of fasting plasma glucose, glycated hemoglobin (HbA_{1c}), and plasma lipid concentrations in 16 patients with type 2 (noninsulin-dependent) diabetes after consuming control wheat bread and bread containing guar gum flour for two 6-week periods, respectively. Control and guar bread were taken by each patient in randomized order

	Control period		*Guar bread period*	
	Start (0 weeks)	*End (6 weeks)*	*Start (0 weeks)*	*End (6 weeks)*
Fasting glucose (mmol l^{-1})	9.7 ± 0.8	9.4 ± 0.7	9.7 ± 1.0	9.1 ± 0.8
HbA_{1c} (%)	11.3 ± 0.8	11.2 ± 0.8	11.5 ± 0.8	10.7[a] ± 0.8

[a]Values after 3 weeks significantly different from control and baseline (start) values at $P < 0.001$.
LDL, low-density lipoprotein; HDL, high-density lipoprotein.
Data taken from Blake DE, Hamblett CJ, Frost PG *et al*. (1997) Wheat bread supplemented with depolymerised guar gum reduces plasma cholesterol concentration in hypercholesterolaemic human subjects. *American Journal of Clinical Nutrition* 65: 107–113.

and appetite and increases feelings of satiety and satiation in all subjects, whether they be normal-weight, overweight, or obese. However, there are problems in designing experiments to investigate feeding behavior, since it is very difficult to make the control food (placebo) look and taste like the test food. One study showed that breads containing high concentrations of guar gum were significantly less palatable than the control breads and this may explain why the subjects were less hungry after consuming the guar-containing bread meal. The energy value of the control and test meals should also be identical in such experiments. Despite the positive effects of guar gum in the short term, many of the long-term intervention studies are contradictory and suggest that a therapeutic role for guar gum in weight control management has yet to be established.

Conclusions and Final Comments

There is now overwhelming evidence to indicate that guar gum has therapeutic benefits for a range of metabolic disorders. At doses of guar gum that are likely to be consumed for therapeutic purposes, there is little evidence that it adversely affects human health. On the contrary, the cholesterol-lowering property of guar gum is of benefit to those who are at an increased risk of CHD, including people with hyperlipidemia and diabetes. Furthermore, the use of guar gum in decreasing postprandial glycemia and insulinemia and in improving long-term glycemic control in diabetic patients is now well established. Any improvement in glycemic control is likely to reduce the risk of microvascular complications (e.g., nephropathy), which are common in people with diabetes, and develop over a number of years.

Recent epidemiological studies have also indicated that diets comprising low-glycemic-index foods may have a protective effect in the development of type 2 diabetes. Guar-containing foods could play an important role in such diets and should be tested in the future for their possible prophylactic benefits. In view of possible beneficial effects of guar gum on insulin resistance, which in itself is a risk factor for both CHD and type 2 diabetes, the role of guar foods needs to be evaluated here also. The effects of guar gum on weight reduction in the long term have yet to be demonstrated, although its use in maintaining weight in weight-reduced subjects merits further study. Obese individuals are likely to benefit however from the consumption of guar gum in terms of improvements in glycemic control, insulin sensitivity, and lipid metabolism.

To assist in the development of new low-glycemic-index foods using guar gum as a major ingredient, it would be advantageous to have a detailed understanding of its behavior in the gut environment. Fundamental information about the way in which guar galactomannan influences the rheological behavior of digesta, through its effects in solution, as an entangled network, or on the swelling of food particles, is of paramount importance. This would need to be closely linked to the effects of galactomannan on nutrient digestion and absorption, including, for example, starch and lipids.

The initial attempts to produce palatable guar foods for the management of diabetes and hyperlipidemia were disappointing. However, the technological difficulties were exacerbated by the perceived need to use high doses of guar gum (15–30 g day^{-1}), since the results of early clinical trials suggested that such doses were needed to elicit metabolic benefits. More recent studies have shown that much lower doses (6–12 g day^{-1}) and partially depolymerized guar gum are not only clinically effective, but have significantly less detrimental effects on sensory qualities of food. From a food technology perspective, it is now possible to produce guar-enriched foods that are both clinically effective and palatable.

HAZARD ANALYSIS CRITICAL CONTROL POINT

J Slatter, RSSL, Reading, Berks, UK

Introduction

The Hazard Analysis Critical Control Point (HACCP) system is a program of preventative food safety assurance originally developed in the USA by the Pillsbury Company working with the National Aeronautics and Space Administration (NASA) and the US army laboratories at Natick in order to insure the safety of astronauts' food. In the three decades since then, HACCP has been internationally recognized and accepted as a proven method for food safety assurance. Its original purpose was to insure microbiological safety of foodstuffs; it has since been further broadened to include physical and chemical hazards for a wide variety of food and associated industries.

The role of HACCP in food production and quality management systems is described and legal and training aspects are discussed in this article.

Definition of Hazard Analysis and Critical Control Point

HACCP is a systematic approach to the problems and food safety issues associated with all points of food production, from raw material through to end use by the consumer. HACCP aims to identify the source and potential risk of a hazard occurring at these points and put controls or preventative actions in place, so eliminating the problem before it occurs or reducing it to a safe level and more effectively protecting the consumer from harm.

The HACCP Principles have international acceptance and have been published by the Codex Alimentarius Commission and National Advisory Committee on Microbiological Criteria for Foods (NACMCF). The system of Hazard Analysis, of which HACCP is one method, is part of legislation, through the European Community (EC) directive 93/43/EEC which was implemented in the UK in 1995 through the Food Safety (General Food Hygiene) Regulations. Several industry guides exist which help suppliers and manufacturers to apply the legislation and to comply with the requirements of HACCP.

Principles of the HACCP System

Different food processes are vulnerable to different hazards. There is no single hazard analysis which covers all cases. Each HACCP program must be specific to the operation and take into account every factor that might affect food safety. Although details vary, there is a general sequence of events involved in completing a HACCP program (Table 1).

What are the Principles of HACCP?

The HACCP system consists of seven principles which outline how to establish, implement, and maintain a HACCP plan (Table 2). These principles make up the Codex standard (*See* **Legislation**: Codex), which has become the reference for international food safety and identified as the baseline for consumer protection under the Agreement on Sanitary and Phytosanitary Measures agreed at the General Agreement on Tariffs and Trade (GATT) negotiations in 1995.

Table 1 Glossary of HACCP Terminology

Hazard	A biological, chemical or physical agent in, or condition of, food with the potential to cause an adverse health effect
Risk	The probability that a given hazard will occur and cause an adverse health effect
Critical control point (CCP)	A step at which control can be applied and is essential to prevent or eliminate a food safety hazard or reduce it to an acceptable level
Critical limit	A criterion which separates acceptability and unacceptability
Monitor	The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a CCP is under control
Corrective action	Any action to be taken when the results of monitoring at the CCP indicate a loss of control
Control measures	Any action and activity that can be used to prevent or eliminate a food safety hazard or reduce it to an acceptable level. These were previously known as preventive measures

Table 2 The seven principles comprising the Hazard Analysis Critical Control Point (HACCP) system

1 Conduct a hazard analysis
2 Determine the critical control points (CCPs)
3 Establish critical limit(s)
4 Establish a system to monitor control of the CCP
5 Establish corrective action to be taken when monitoring indicates that a particular CCP is not under control
6 Establish procedures for verification to confirm that the HACCP is working effectively
7 Establish documentation concerning all procedures and records appropriate to these principles and their application

Table 3 The 12 stages of a Hazard Analysis Critical Control Point (HACCP) study

1 Assemble the HACCP team
2 Describe the product
3 Identify the intended use
4 Construct a flow diagram
5 Carry out on-site confirmation of flow diagram
6 Carry out hazard analysis
7 Determine critical control points (CCPs)
8 Establish critical limits for each CCP
9 Establish a monitoring system
10 Establish corrective action
11 Establish verification procedures
12 Establish documentation and record keeping

These seven principles can be broken down into 12 different stages, which can logically be used to develop the HACCP Plan.

Stages in a HACCP study (Table 3)

Assemble the HACCP Team

The HACCP study is best carried out by a multidisciplinary team. This usually comprises individuals covering all aspects of production, e.g., manufacturing, buying, quality assurance, technical, and engineering. Occasionally it may be necessary to enlist the help of an expert to cover specialist topics such as microbiology or toxicology. A person experienced in the HACCP technique should be responsible for leading the team and for managing the study.

Describe the Product

A full description of the product should be drawn up, including any relevant safety information such as composition, processing, durability, storage conditions, and method of distribution.

Identify the Intended Use

The intended use should identify the potential consumer. In some cases, at-risk groups may have to be considered, such as the elderly.

Construct a Flow Diagram

The process must be accurately defined from start to finish and this is normally done in the form of a flow diagram. This a simple stepwise sequence of events, which enables the HACCP team to understand the process.

Carry Out On-site Confirmation of Flow Diagram

It is important to check that the flow diagram is accurate by physically checking it against activities and that it includes exceptional items such as breakdowns, rework, and cleaning. The team should also check that the flow diagram is correct for any shift patterns.

Carry out Hazard Analysis

The terms of reference or scope for the HACCP study need to be set. Ultimately all types of hazards (biological, physical, and chemical) will be examined but in the initial stages it may be useful to examine only one category of hazards or even to concentrate on one type of hazard such as glass or *Salmonella*. The HACCP team will have to consider whether to cover the whole of the process or just part of it and if the process is common for a number of products, then these products must be included in the scope.

The next stage of hazard analysis is not easy, but it can be carried out in a structured way.

Hazard analysis consists of an evaluation of all procedures and raw materials to:

- identify potential hazardous materials or pathogens and their severity
- identify potential sources and points of contamination at each stage of the food chain
- determine the potential for microorganisms to survive or multiply in the food
- assess the likelihood of the hazards occurring

A hazard may be biological (e.g., microorganisms), chemical (e.g., pesticides, cleaning chemicals) or physical (e.g., metal, glass, stones). In order to identify correctly the control for the hazard, the source or cause of the hazard must also be examined. For example, glass from a light fitting would be controlled in a different way to glass from a broken bottle on the filling line. In terms of microorganisms, the hazard may be more adequately explained by identifying either the named organism (e.g., *Salmonella*) or group of organisms (e.g., spore formers) and whether they will be present, survive, or grow at the stage.

There are many ways of identifying hazards based on previous knowledge of the product or process, customer complaints, and information from literature or experts. The team must take care to include not just problems which have previously occurred but also new potential hazards, which can be identified by brainstorming.

Obvious sources of hazards are:

- raw materials
- plant and equipment design
- formulation
- processing
- personnel
- packaging
- storage and distribution

Once the potential hazards have been identified, the severity and possibility of the hazard occurring, i.e., the risk, should be assessed. This will identify the significant hazards. The risk assessment is often a judgment by the HACCP team based on knowledge and information; however, some risk assessment schemes have a scoring system or a weighting of high, medium, or low.

When all significant hazards have been identified, the associated controls for each hazard can be assigned. Controls are the factors that are required to prevent, eliminate, or reduce the occurrence of hazards to an acceptable level. These may be controls that are already in place or it may be that new controls will need to be devised. Also, more than one control may be needed for effective reduction of each hazard.

Determine CCPs

For each step (where a hazard exists) CCPs must be evaluated. A CCP is a stage in a process where food safety hazards must be controlled. They are essential to prevent, eliminate, or reduce hazards to an acceptable level. There may be previous stages where the hazard is controlled or reduced and these are sometimes called control points, but the CCP will be the point where, if control is lost, a health hazard will occur.

Understanding the CCPs can help to focus on the efforts and finances on the key areas of food safety and save money by preventing effort in exercising control at a point of less importance.

Information established by the HACCP team may be sufficient to identify a CCP using judgment and prior knowledge; however, to assist in finding where the CCPs may be, a decision tree is a useful tool (**Figure 1**).

Establish Critical Limits for each CCP

Once the CCPs have been identified, the critical or safety limits need to be established. These define the difference between safe and potentially unsafe foods and of acceptable and unacceptable products.

In the work place, target limits may be required to provide a buffer zone to allow the hazard to be brought back under control before it exceeds the critical limit.

Establish a Monitoring System

The means of testing to insure that the control is adequate must be established for each CCP. This assessment may be chemical, physical, sensory or, rarely, microbiological. Criteria usually include measurements of time, temperature, moisture level, water activity, available chlorine or sensory parameters such as visual appearance, flavor or texture.

Monitoring is a scheduled measurement or observation of a CCP. The monitoring procedure will assess whether there is a loss of control from the critical limits, in which case corrective action will be needed.

Establish Corrective Action

Specific corrective actions are required for each CCP. The actions must insure that the consumer is protected and the CCP is brought back under control. It is effective also to assign responsibilities to individual members of staff for the corrective actions in the

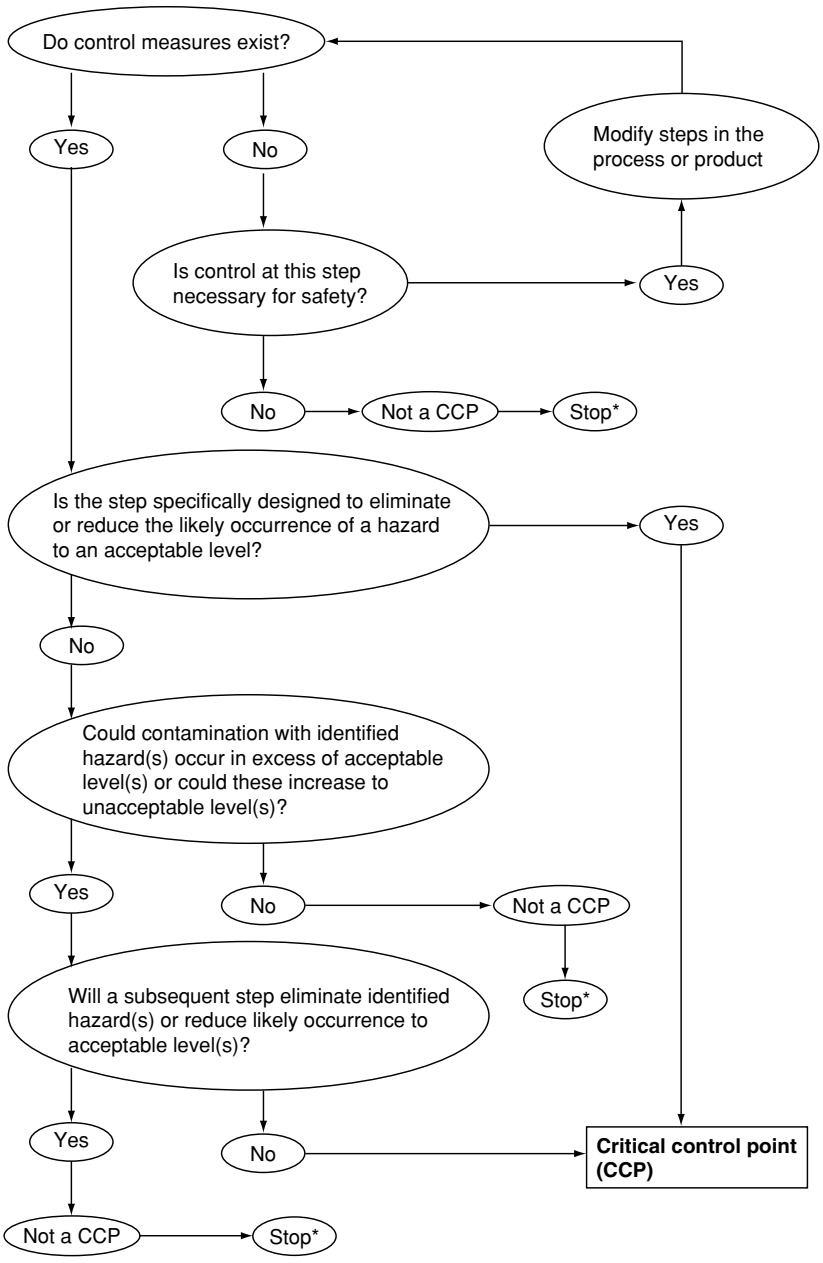

Figure 1 Example of a decision tree for identifying critical control points (CCPs). Reproduced from *Codex Alimentarius Food Hygiene Basic Texts*. (1997).

HACCP plan. All corrective actions should be recorded and reviewed by the HACCP team as part of the verification process.

Establish Verification Procedures

The verification process checks that the HACCP Plan is an accurate record of the activities taking place. The main method of verification is by audit, but other methods may also be used, such as document review and analysis of data.

Establish Documentation and Record Keeping

Documentation and record keeping should be appropriate to the size of the operation. The HACCP will incorporate documents such as the following:

- the HACCP Plan
- hazard analysis
- CCP determinations
- CCP monitoring sheets
- corrective actions
- audit records

- HACCP team meeting minutes
- calibration records

Figure 2 shows a HACCP plan format recommended by Codex Alimentarius. It can be adapted for different operations and size of business and easily facilitates verification.

Implementation

Once developed, the HACCP Plan must be implemented and established in the work place. To be successful the plan must be absorbed into the day-to-day running of the operation with effective training of all personnel, especially those directly involved in the HACCP Plan. The Plan must also stay current and up-to-date if it is to be used as an effective management tool.

Maintenance

Any changes in the product or process which may affect the HACCP system must be identified and the HACCP changed accordingly. This may mean a change in raw material supply, change in process or factory layout, or emergence of further information indicating a health risk associated with the product. Otherwise, the HACCP should be routinely checked annually to ascertain that it is still an accurate reflection of the working environment. This may be done by auditing the HACCP Plan and flow diagrams but can also be carried out by checking process control documents, hygiene audit reports, and customer complaints.

It is also important that the HACCP team remain up-to-date with issues of hygiene and safety affecting other food companies from information in the newspapers, trade press, and membership of trade associations. New technologies may also emerge, providing better controls, and these should be reviewed by the HACCP team.

Prerequisite Programs

The HACCP system will incorporate other existing management systems into its procedures. Typical areas are personal hygiene, good manufacturing practice, supplier quality assurance, and maintenance schedules. These have been given the term 'Prerequisite Programmes' and are normally in place before the HACCP Plan is developed (Figure 3). Prerequisites are systems in their own right and will support the HACCP by taking the control of the general hygiene and good manufacturing practice out of the HACCP Plan.

HACCP and International Quality Systems

Many food companies are using standards such as the ISO 9000 series. There are many similarities between the two systems. Both HACCP and ISO 9000 are concerned with prevention and detection of food safety problems in areas such as calibration, training, document control, control of nonconforming product, and verification through internal audit.

The ISO 9000 standard was updated in March 2001, to ISO 9000:2000 and has guidance notes for the food and drink industries (BS ISO 15161). This includes a requirement for HACCP and provides assistance for incorporating the principles of HACCP into the ISO system.

4. Verification

Figure 2 Example of a Hazard Analysis Critical Control Point (HACCP) worksheet. CCPs, critical control points.

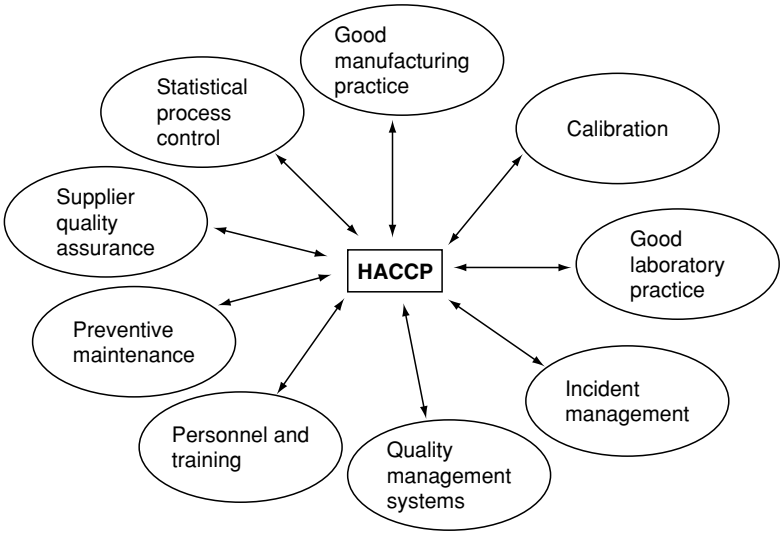

Figure 3 Prerequisites of Hazard Analysis Critical Control Point (HACCP). Reproduced by kind permission of Mortimore and Wallace (1998).

HACCP Training

Training is essential for the effective implementation of HACCP. Staff must understand why the HACCP plan was developed, as well as their role within HACCP, and should be encouraged to suggest any modifications to the HACCP team.

Staff should have an understanding of:

- what hazards are and their importance in food safety
- CCPs and their role in the assurance of product safety
- critical limits which must be met
- corrective actions and responsibilities
- record-keeping requirements
- the objective of verification procedures

It may be necessary to give more specific training to staff involved in CCP monitoring.

Formal training qualifications exist, with examinations introduced by the Royal Society of Health (RSH), the Chartered Institute of Environmental Health Officers (CIEH) and the Royal Institute of Public Health (RIPH). These courses are run by training organizations registered by the above bodies at levels 1, 2 and 3.

A training standard is available from the RIPH steering group to provide a syllabus for training to an advanced level in the principles of HACCP. Training programs have been specified by the World Health Organization to cover the recommended skills and problem encountered in training for HACCP, together with proposed programs for food-processing and manufacturing industries, small food enterprises, and small operations.

HEAT TRANSFER METHODS

J Varley, Imperial College London, London, UK

Introduction

Heat transfer is an essential stage of many food-processing operations, e.g., cooking, sterilizing, freezing, baking, and drying. The fundamental principles of heat transfer and a review of methods for the addition and removal of heat are considered in this article.

Principles of Heat Transfer

There are three fundamental types of heat transfer: conduction, convection, and radiation; these can occur individually or simultaneously.

Heat transfer may be steady-state or unsteady-state. The equations considered here are for steady-state heat transfer and can be solved easily. More complicated solutions arise for unsteady-state heat transfer (i.e., when temperature varies with time), but solutions are available for simple geometries, e.g., slab, cylinder, and sphere.

Conduction

Conduction is the transfer of heat by exchange of molecular energy from hotter to colder regions, under conditions in which there is no turbulent motion of particles. Heat transfer by conduction can take place in a solid, liquid, or gas. Rates of heat transfer by conduction are given by Fourier's law:

$$q = -kA(\mathrm{d}T/\mathrm{d}x) \qquad (1)$$

where q is the heat transfer rate in the positive x direction, k is thermal conductivity, A is the area perpendicular to direction of heat flow, T is temperature and x is distance.

For example, for conduction through a slab the rate of heat transfer is given by the following equation:

$$q = -kA[(T_1 - T_2)/x] \qquad (2)$$

where $(T_1 - T_2)$ is a steady temperature difference maintained across the slab and x is the thickness of the slab (Figure 1).

Thermal conductivity (k) is influenced by temperature, pressure, and composition of the food, including such factors as moisture content and amount of air trapped between cells. Values of thermal conductivity are available for some food materials.

Fourier's law indicates that the rate of heat transfer by conduction is proportional to the driving force for transfer, and inversely proportional to the resistance to heat transfer. For conduction in a slab, the driving force for transfer is the temperature difference, and the resistance to heat transfer is given by x/k.

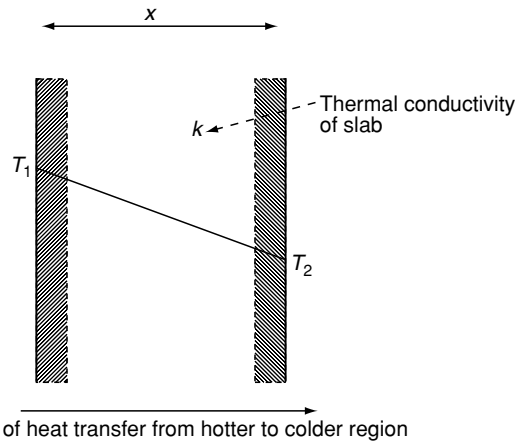

Figure 1 Heat transfer by conduction through a slab. Reproduced from Heat Transfer Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Convection

Convective heat transfer occurs when molecules or groups of molecules in a fluid are mixed. In a solid, molecules are not free to move, and convective heat transfer will therefore only occur in a liquid or gas. Natural convection arises when mixing is a result of density differences caused by temperature gradients. For forced convection, mixing is brought about by mechanical means. Forced convection provides higher rates of heat transfer than natural convection and is therefore more commonly used in the food industry, e.g., in air blast freezers, heat exchangers, agitated retorts, and forced convection ovens. Examples of natural convection include heat transfer in domestic freezers or ovens with natural air circulation (i.e., unaided by fans) and heating below boiling in unstirred, steam-jacketed pans in the food industry.

For heat transfer from a fluid to a surface, rates of convective heat transfer can be calculated from the following equation:

$$q = hA(T_f - T_s) \tag{3}$$

where h is the heat transfer coefficient, T_f is the temperature of the fluid and T_s is the temperature of the surface.

For convective heat transfer between a surface and a fluid, a film (layer of fluid) exists between the bulk fluid and the surface. At the surface, the velocity of the fluid will be zero and there will be minimal mixing of fluid elements. Heat transfer in this film will therefore be by conduction only, and the film will provide the main resistance to heat transfer. The rate of heat transfer can thus be written in terms of the conduction equation:

$$q = (k_f/x_f)A(T_f - T_s) \tag{4}$$

where k_f and x_f are the thermal conductivity and effective thickness of the film, respectively. The film heat transfer coefficient is therefore equal to k_f/x_f for the film, and the resistance to heat transfer is $1/h$.

Typical values of film heat transfer coefficients are available in the literature.

Determination of heat transfer coefficients The heat transfer coefficient can be written in terms of the dimensionless Nusselt number (Nu):

$$(Nu) = (hD)/k \tag{5}$$

where D is a characteristic linear dimension of the heat transfer system, e.g., diameter of a cylinder.

For natural convection, the heat transfer coefficient is found to depend on the temperature difference, acceleration due to gravity, and the physical properties of the food (e.g., density, viscosity, thermal conductivity, and specific heat). The dependence of heat transfer coefficient on these factors can be represented by the following equation:

$$(Nu) = a(Pr)^b(Gr)^c \tag{6}$$

where a, b, and c are constants. Pr and Gr are the Prandtl and Grashof number, respectively:

$$Pr = (c_p\mu)/k \tag{7}$$

$$Gr = (D^3\rho^2 g\beta\Delta T)/\mu^2 \tag{8}$$

where c_p is specific heat at constant pressure, μ is viscosity, D is the linear dimension of the system, ρ is density, g is acceleration due to gravity, and β is the coefficient of thermal expansion. Values for the constants, determined experimentally for some foods at certain conditions, are available in the literature.

For forced convection, gravity and the coefficient of thermal expansion are much less significant than for natural convection. Therefore the heat transfer coefficient does not depend to any great extent on the Grashof number. Of more importance is the influence of forced circulation velocities, which can be represented by the Reynolds number (Re). For forced convection the heat transfer coefficient can, in general, be evaluated from the following dimensionless equation:

$$(Nu) = a(Re)^b(Pr)^c \tag{9}$$

As for natural convection, values for the constants (a, b, and c) in the above equation have been determined for a range of experimental conditions.

Composite Heat Transfer

The equations given above for heat transfer by conduction and convection show that the rate of heat transfer is given by the ratio of the driving force for heat transfer (temperature gradient) and the resistance to heat transfer offered by the material. The resistance to heat transfer for conduction and convection is given by x/k and $1/h$, respectively.

If heat is transferred through a composite material, the heat transfer resistances behave in a similar manner to electrical resistances in series. Consider, for example, heat transfer to a food material from the surroundings, first through a surface (surface 1), then through several composite layers (layers 1 and 2) and, finally, through a further surface film (surface 2). The overall resistance to heat transfer would be given by the following equation:

$$(1/U) = (1/h_{s1}) + (x_1/k_1) + (x_2/k_2) + (1/h_{s2}) \tag{10}$$

where $1/U$ is the overall resistance to heat transfer, U is the overall heat transfer coefficient, h_{s1} and h_{s2} are the surface heat transfer coefficients for surface 1 and 2, x_1 and x_2 are the thicknesses of layers 1 and 2, and k_1 and k_2 are the thermal conductivities of layers 1 and 2.

The overall rate of heat transfer can then be written as follows:

$$q = UA\Delta T \tag{11}$$

where ΔT is the overall temperature difference.

Radiation

Radiation is the transfer of heat by electromagnetic waves. Radiant heat transfer is often found in the food industry, especially in baking and drying operations. Heat transfer by radiation depends on temperature, surface area, and surface properties of the body. Rates of heat emission by radiation can be determined from the Stefan–Boltzmann law:

$$q = A\sigma T^4 \tag{12}$$

where A is the surface area, σ is the Stefan–Boltzmann constant (5.67×10^{-8} W m^{-2} K^{-4}) and T is the absolute temperature of the body.

The Stefan–Boltzmann law determines the maximum amount of radiation that would be emitted at a particular temperature by a perfect radiator (a black body). However, most surfaces do not emit this maximum amount of energy, but many do emit an amount of energy which is directly proportional to the maximum value. The proportionality constant is known as the emissivity of the body (ε) and has a value between 0 and 1. Bodies with emissivities between 0 and 1 are known as gray bodies. For a gray body, the heat transfer equation for radiation is as follows:

$$q = \varepsilon A\sigma T^4 \tag{13}$$

Bodies not only emit radiation but also absorb and reflect radiation. Absorption can be evaluated from the Stefan–Boltzmann law for black bodies, and from the modified equation for gray bodies, with the emissivity replaced by the absorptivity (α). For gray bodies, it can be shown that $\varepsilon = \alpha$. Any radiation which is received by a body but is not absorbed must be reflected. For a gray body, the reflectivity is equal to $(1 - \alpha)$ and the amount of heat reflected can be evaluated by replacing the emissivity in the above equation with the reflectivity.

Radiative heat transfer can take place between bodies and also between a body and its surroundings. As an example, radiative heat exchange between a body and its black surroundings would be given by the following equation:

$$q = A_1\varepsilon_1\sigma(T_1^4 - T_2^4) \tag{14}$$

where A_1 is the surface area of body 1, ε_1 is the emissivity of body 1, T_1 is the temperature of body 1, and T_2 is the temperature of the surroundings.

If the temperature difference $(T_1 - T_2)$ is small, the above equation can be written as follows:

$$q = A_1\varepsilon_1\sigma T_1^3\Delta T \tag{15}$$

The above equation shows that the rate of heat transfer for radiation is directly proportional to the temperature difference and inversely proportional to the resistance to heat transfer (as is the case for convection and conduction). The resistance to heat transfer is given by $1/(A_1\varepsilon_1\sigma {T_1}^3)$. If convection and radiation are occurring simultaneously, this radiative heat transfer resistance can be used to calculate an overall heat transfer resistance (as described above for simultaneous convection and conduction).

Heat Transfer Rates in Heat Exchangers

There are a wide variety of heat exchangers in use in the food industry. These include direct steam injection, plate heat exchangers, and swept-surface heat exchangers. The variety in design of heat exchanger available reflects the wide range of physical properties of food requiring heat treatment. Most heat exchangers can be used for both heating and cooling. Heat transfer rates will, in general, be higher for heating than for cooling, because the viscosity of a liquid film will be higher during cooling than for heating. (*See* **Heat Treatment**: Ultra-high Temperature (UHT) Treatments.)

The surface area of a heat exchanger required to provide a certain heat transfer rate can be determined from the equation for the overall rate of heat transfer (eqn 11), if the overall heat transfer coefficient and the relevant value of the temperature difference are known. In general, two fluids are flowing on opposite sides of the walls of a heat exchanger, either cocurrently or countercurrently (Figure 2). The relevant temperature difference for heat transfer calculations in this case is the log mean temperature difference (ΔT_{lm}), which is defined as follows:

$$\Delta T_{lm} = \frac{(T_1 - T_2) - (T_1' - T_2')}{\ln(T_1 - T_2)/(T_1' - T_2')} \tag{16}$$

where T_1 and T_2 are the temperatures of fluids 1 and 2 at one end of the heat exchanger and T_1' and T_2' are the temperatures of fluids 1 and 2 at the other end of the heat exchanger.

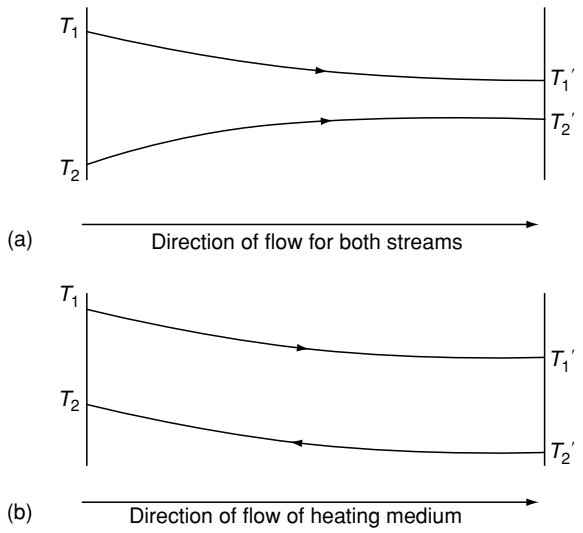

Figure 2 Temperature differences for heat transfer in heat exchangers: (a) co-current flow; (b) countercurrent flow. Reproduced from Heat Transfer Methods, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Addition and Removal of Heat

For addition or removal of heat to a food material, an energy source is required. Sources of energy for bulk generation of heat include gas, oil, solid fuels, electricity (microwave or dielectric heating), or infrared energy. These energy sources may be used directly or indirectly.

Direct methods of heating involve direct contact between the food material and the source of heat energy. The food material therefore comes directly into contact with the products of combustion of the fuel. Direct methods may be used for the addition of heat in food processing, e.g., baking ovens, but they are rarely used for the removal of heat.

In indirect methods, the food material is separated by a barrier from the primary source of heat energy and does not come into contact with the products of combustion. Heat is generally transferred to the food via a heat exchanger. The primary energy source may be used as the heating medium, or it may be used to heat a secondary medium, which will then be passed through the heat exchanger. The heat transfer medium may be a vapor or gas (e.g., steam or air), a liquid (e.g., water), or electricity (as for resistance heating systems). Heating of the secondary heat transfer medium is usually accomplished by means of a boiler, in which the source of fuel is burnt to generate heat. Once the heat transfer medium has been heated, it is pumped to a heat exchanger where heat transfer takes place between this fluid and the food material. In some systems, the secondary heat transfer medium is passed directly over the food, e.g., steam blanching.

Removal of Heat

Removal of heat is commonly referred to as refrigeration or chilling. Removal of heat can be accomplished by mechanical or nonmechanical refrigeration. Mechanical refrigeration is dealt with elsewhere. Typical methods of nonmechanical refrigeration include heat removal using ice, chilled brine, or cryogens. (*See* **Freezing**: Principles; Cryogenic Freezing.)

Heat removal using ice Ice, at 0 °C, is capable of removing large quantities of heat (the heat capacity of ice is 68 kJ kg^{-1}, K^{-1} at 0 °C) and has therefore been used as a means of heat removal for many years. In recent years, the use of ice for heat removal has declined as mechanical refrigeration has grown in popularity. Ice is still used for some chilling applications, particularly when refrigeration is only required for a short period of time (e.g., marine fishing operations) or as a secondary refrigeration system which may be required to deal with peak loads. There are several ways in which ice can be employed as a heat transfer medium. These include the following:

1. Packing crushed ice around the food material.
2. Circulating air over ice blocks before passing it over the food product.
3. Circulating water over ice blocks prior to flow of water through a heat exchanger.

The freezing temperature of ice can be reduced (and hence the potential for heat removal increased) by the addition of salts. However, corrosion can become a problem when ice and salt mixtures are used.

Heat transfer using chilled brine Brine, a solution of salt and water, can be used to remove heat from food materials, e.g., on fishing vessels. As with ice, mechanical refrigeration has largely superseded the use of brine in refrigeration. Sodium chloride and calcium chloride are the most widely used brines for heat removal. The freezing point, and hence capacity to remove heat, depends on the concentration of the brine solution. For typical concentrations used for refrigeration, the minimum freezing point of sodium chloride and calcium chloride solutions are −15 °C and −51 °C, respectively. Problems with corrosion will arise when employing brine solutions, if precautions are not taken. Calcium chloride is much more corrosive than sodium chloride. Appropriate precautions to reduce corrosion include elimination of air, neutralization to pH 7 or 8 with caustic soda or hydrochloric acid, and addition of corrosion retardants, e.g., sodium bichromate. A typical system which

uses brine to remove heat would consist of the following steps:

1. The brine is cooled to the required temperature in direct expansion coils.
2. The brine is then passed through a heat exchange system which is in contact with the food.
3. The brine is returned to the expansion system where heat is removed.

Other media that have been used for chilling include glycol–water mixtures and methylated spirits.

Heat removal using cryogens In cryogenic systems, heat is absorbed by the cryogen as it changes phase. Cryogens commonly used for removing heat include solid and liquid carbon dioxide, and liquid nitrogen. Halogenated hydrocarbon refrigerant gases are also used to a limited extent.

Addition of Heat

Heat can be added by direct or indirect methods (in direct methods the food material comes into direct contact with the energy source, whereas for indirect methods the food material and energy source are separated by a barrier). (*See* **Drying**: Theory of Air-drying.)

Heat transfer media used in indirect heat addition to food materials include vapors, gases, and liquids. Only the most commonly used heat transfer media will be considered in this article.

Heat transfer using air Air is used to a limited extent as a heat transfer medium in indirect heating systems, e.g., in some baking processes, fluidized-bed cooking, and hot-air driers. Air has the advantage of being odorless and nontoxic, although it also has low specific heat and thermal conductivity, which are disadvantageous for efficient heat transfer.

Heat transfer using steam Saturated steam is a widely used heat transfer medium in food processing. Maximum temperatures and pressures of typical steam supplies generated for heat transfer in food processing are 200 °C and 1.7 MPa respectively. Steam is used in a wide variety of heating processes which include steam blanching, pasteurization, heat processing of food in containers, extrusion cooking, and evaporation.

Saturated steam has several physical properties that make it attractive for use as a heat transfer medium, including the following:

1. High heat capacity.
2. Nontoxicity.
3. Stability.
4. No odor.
5. Low cost.

Adverse properties of steam for use as a heat transfer medium include the following:

1. High vapor pressure.
2. Low critical point.
3. Corrosion, formation of scale, or foaming (during steam generation) may occur as a result of impurities being present in the raw material, i.e., the water supply.

Heat transfer using hot water and other liquid media Hot water is used as a heat transfer medium up to temperatures of 200 °C in a wide variety of food processes, including blanching, pasteurization, and in-container sterilization. Advantages of hot water as a heat transfer medium include the following:

1. High specific heat and thermal conductivity.
2. Stability.
3. No odor.
4. Simplicity and ease of control of associated equipment.
5. Abundance and low cost.
6. Limited corrosion, scale formation, and foaming, as compared to steam systems.

Limitations include, for example, the possibility that if hot water comes into direct contact with the food material there may be substantial loss of water-soluble nutrients (vitamins, salts, and minerals).

Other liquids that are used as heat transfer media include mineral oil, chlorinated diphenyls, organosilicate, *o*-dichlorobenzene, and diphenyl or diphenyloxide. All these liquids have the disadvantage of giving off odors, but with the exception of diphenyl and diphenyloxide they have the advantage of possessing low vapor pressures, which allows design of high-temperature, low-pressure systems.

HEAT TREATMENT

Contents

Ultra-high Temperature (UHT) Treatments

K R Swartzel, North Carolina State University, Raleigh, USA

Introduction

Commercially sterile foods are processed and packaged in a manner that leaves the food free of microorganisms of public health significance, and inhibits the growth of any microorganism under normal nonrefrigerated storage and distribution. Process methods include both thermal and nonthermal. These are accomplished by either: (1) heating the product in a hermetically sealed container so that the package and contents are sterilized at the same time; or (2) separately sterilizing the food and the container and then aseptically filling and sealing the sterile product in the sterile container.

The former sterilization process relates to conventional in-can or in-bottle processes, while the latter refers to ultrahigh-temperature (UHT) processing. By heating product during continuous flow, product temperatures of 130–150 °C are achieved. Due to the relatively high sensitivity of vegetative bacterial cells and spores to these high temperatures, less chemical change occurs than with conventional canning to achieve the same sterilizing effect. This results in increased retention of nutrients, color, flavor, and texture. Time needed for UHT processes is short, in the order of seconds. By understanding product constituent temperature-dependent changes, equipment performance and process design, the desired balance between desirable effects (inactivation of biological materials, i.e., enzymes, microorganisms, and their spores), and undesirable effects (loss of product quality, i.e., flavor, color, and flow properties) can be achieved.

This section discusses thermal aseptic process equipment, processing with and without particulates, temperature measurement, and control considerations. Product quality, microbiological considerations, and aseptic packaging are discussed in separate sections.

Equipment

Equipment required for continuous thermal sterilization of foods includes the following: product supply pump, heat exchanger for preheating product, metering pump, product sterilizer, holding section, heat exchangers for cooling product, and aseptic optional surge tanks (**Figure 1**). Components which may be incorporated into a continuous sterilization system include orifice plate or backpressure valve for maintaining the pressure necessary to prevent the product from boiling; homogenizer; and steam seals on pumps, valves, connection or access ports; and a monitoring and control system to insure the proper thermal treatment.

The product supply pump and preheat exchanger can be conventional food-handling equipment since product has not been sterilized when it moves through these components.

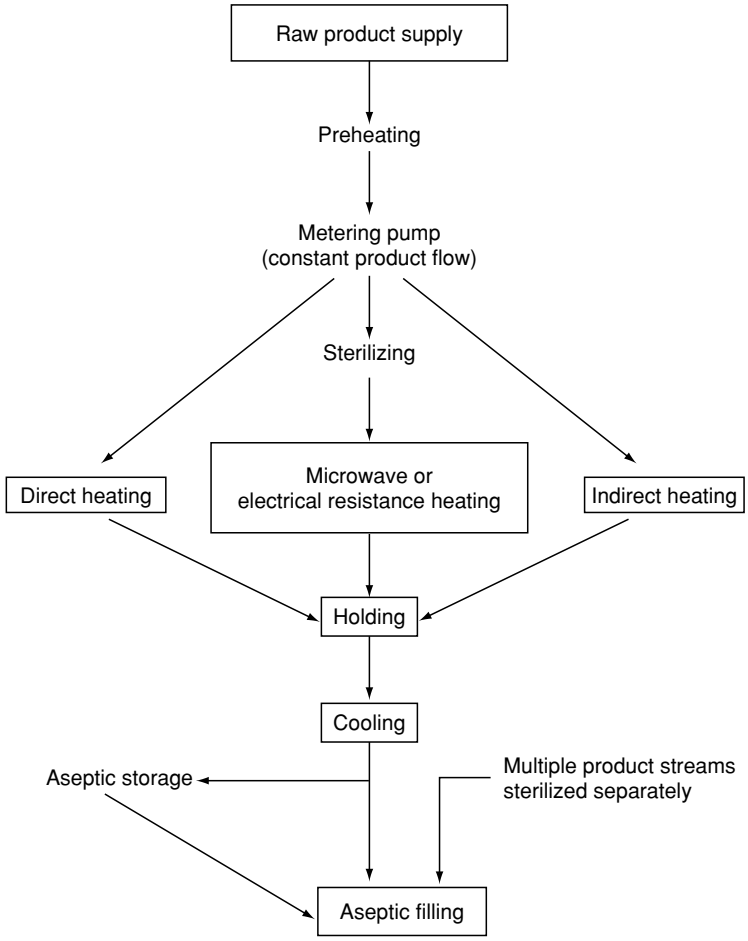

Figure 1 Flow chart of continuous-flow aseptic processing.

Metering Pump

The metering pump determines the flow rate of product through the holding tube. A positive displacement pump is employed to maintain a constant flow rate that is relatively independent of the load on the pump. Rotary pumps are normally specified for pressures up to 68.94 kPa. For higher pressures, plunger or piston pumps are used. The metering pump is located upstream from the holding section. (The holding section will be described in detail later.) If the pump has a speed control device for changing the flow rate, some mechanism is employed to insure that the pump does not operate at a speed higher than that needed to give product the required thermal treatment time in the holding section. A lock on the speed control is the most satisfactory method of preventing unauthorized changes which would reduce residence time.

Direct and Indirect Heaters

The sterilizer is a heat exchanger used to heat product to the sterilization temperature. There are two basic types of commercial sterilizers available: direct and indirect units. Sterilizers may be categorized as direct contact heaters (steam injectors and steam infusers) and indirect heaters (tubular heaters, plate heaters, and scraped surface heaters).

Steam or hot water is normally the source of heat for continuous thermal sterilization. Direct contact heating involves mixing steam and product together. As steam condenses, its latent heat is transferred to the product. When no wall separates the steam and product, the heat transfer rate is high and product is heated rapidly. Product is diluted by the steam condensate and vacuum equipment is generally used for partial cooling and removal of excess moisture. Steam is injected into a continuous stream of product in the steam injector. The steam infuser introduces product with a large surface area into a steam atmosphere under sufficient pressure to achieve the desired sterilization temperature. Steam for direct contact heating must be produced from potable water in a culinary steam generator or in a boiler using accepted boiler treatment compounds.

In the injector steam enters the product in pulses, and excessive vibration, pressure fluctuations, and temperature variation may result. To stabilize operation, orifices may be installed in the product entrance and discharge ports of the injector to isolate the injection chamber. The orifices are approximately equal in size and designed to produce at least a 68.94 kPa pressure drop across the injector during normal operation.

In indirect heating, product is heated by transferring heat from water or steam through a heat exchange wall. The wall may be a tube, a plate, or a scraped surface with each having its own time–temperature profile. Tubular and plate heaters used as sterilizers have relatively small flow channels for product. This gives a large surface area to product volume ratio for rapid heating. The high temperatures used for sterilization require heat exchangers to be built to handle the associated high pressures required. Plate and tube designs incorporate varying machining (plate patterns, tube dembling, tube helical patterns) in an effort to promote mixing, resulting in more uniform product thermal treatment.

Tubular and plate sterilizers lend themselves to regenerative heating and cooling as an energy-saving feature. Regenerative heating uses the heat of the hot product to heat cold incoming product. Longer times are required to heat product to the sterilization temperature than in direct contact heaters, and deposit of product on hot heat exchange surfaces sometimes severely limits the operating time and makes cleaning more difficult. (*See* **Cleaning Procedures in the Factory**: Overall Approach.)

Scrape surface heat exchangers (SSHEs) provide a moving blade inside an elongated circular chamber which scrapes the outer heated surface. SSHEs are used with highly viscous products or products with particulates.

In the direct heating systems (steam injection or infusion), the heating and cooling at higher temperatures take place very rapidly compared with indirect systems (tubes, plates, SSHE). In the direct systems, virtually all of the thermal effects on product occur in the holding section after the product has reached the scheduled process temperature. In the indirect system, substantial thermal effects can occur during heating and some additional effects may occur during cooling. For public safety reasons, however, usually only the heating effects in the holding tube are considered.

Holding Section

The holding section is a pipeline section located immediately downstream from the sterilizer. It is designed to insure that all product is held at, or above, the sterilization temperature for the time equal to, or greater than the scheduled process time. The tube is sloped upward toward the discharge end. The upward slope insures that vapor cannot be trapped. A vapor pocket in the holding tube would permit product to move through the tube faster than if the holding tube contained product only.

For public safety (destruction of pathogenic organisms, mainly *Clostridium botulinum*), regulatory specification calls for a holding tube to be sized to hold the fastest-moving particle in laminar flow for the minimum specified time. (*See* ***Clostridium***: Botulism.)

Heat Exchangers for Cooling Product

Product is cooled either by evaporative cooling in a vacuum chamber or in indirect heat exchangers similar to those used for product heating and sterilization. A vacuum chamber is often used when the sterilizer is a steam injector or infuser. In addition to cooling product, the vacuum chamber removes moisture. When vacuum chamber pressure (or temperature) is controlled properly, the same amount of moisture added during heating by the condensing steam can be removed. The operating pressure or temperature is a function of product flow rate and properties, steam properties and heat losses from the sterilizer, holding tube, and vacuum chamber. The correct pressure (or temperature) must be established for each system.

Since the vacuum chamber is normally controlled at pressures below atmospheric pressure, aseptic seals are used on all ports for pipeline connections, sensors, sight glasses, and manholes. Steam seals are commonly employed.

The heat exchangers used for cooling, whether plate, tubular, SSHE, or vacuum chamber, are designed to withstand temperatures and pressures required for equipment sterilization before product flow is initiated. (*See* **Sterilization of Foods**.)

Aseptic Surge Tank

The function of the aseptic surge tank is to act as a reservoir for product between processing and packaging. This may or may not be a part of all systems. Operation of the tank is as critical as any other part of the aseptic system.

Sterilization of the surge tank is independent of the rest of the system. Four modes are utilized: steam and vent, sterilizing, cooling, and tank sterile. The steam and vent cycle allows the previously cleaned and sanitized tank to be vented of any gases and drained of any liquids or condensates during heat-up. This cycle continues until predetermined sterilizing conditions (temperature and pressure) are met. The sterilization cycle maintains this temperature and pressure for the

sterilization time. The tank is then cooled, but kept pressurized with filtered sterile air or inert gas (i.e., nitrogen). The air pressure also provides a means to move the sterile product to the filler without the use of pumps.

Processing Considerations

Thermal Evaluation

Techniques for evaluating thermal systems have been the subject of elaborate developments in process calculation procedures. Continuous-flow thermal processing offers new challenges to the traditional batch (retorting) process.

Backpressure Requirements

For process temperatures above the boiling point of the liquid, backpressure devices must be used. The backpressure system assures proper pressure to achieve and maintain the desired temperature. For direct steam heating, condensation of the steam may not be complete. Lack of complete condensation inside the injector would cause temperature variations in the holding tube that could lead to some fluid particles being processed below the desired process thermal treatment.

For steam injection units, the product and the steam flows must be isolated from pressure fluctuations inside the injection chamber. Supplementary orifices on the product inlet and the heated product outlet is one method of isolation. The orifices are approximately equal in size and yield a minimum product pressure drop of 68.94 kPa across the injector during normal operations.

For holding tubes in all systems, the product pressure must be of sufficient magnitude to keep heated product in the liquid phase. If this pressure is too low, the resultant vaporization in the holding tube will substantially reduce residence times. A minimum product pressure in the holding tube of 68.94 kPa for operating temperatures from 88 °C through 100 °C is satisfactory. For temperatures above 100 °C, a minimum pressure of 68.94 kPa above the product saturation value pressure is needed to keep the heated product in the liquid phase.

No noncondensable gases can be tolerated in the holding section. Any two-phase flow caused by the noncondensable gases would displace the product in the holding tube, resulting in reduced residence times.

Holding Tube Calculations for Direct Systems

As with the indirect systems, holding tube lengths for direct systems are calculated as twice the length required to hold the average measured flow. However, with the steam injection process, the holding time is adjusted because the product volume increases as the steam condenses to water during heating in the injector. This surplus water is evaporated as the product is cooled in the vacuum chamber. With as much as 60–70 °C increase by steam injection, which is probably the maximum temperature rise that will be used, a volume increase of 12% would occur in the holding section. For holding time calculations, the volumes per unit time are adjusted accordingly.

Consideration for Processing Fluids with Particles

Special equipment is usually incorporated for the processing of fluids containing particles. As with all UHT systems, the required minimum heat treatment for the system must be achieved for all parts of each particle. This means that for systems with particles, the spot receiving the least thermal treatment (the 'cold spot') is generally in the center of the largest particles with the lowest heat of conduction traveling with a minimum of residence time (fastest particle). To achieve this, the carrier fluid is often overprocessed for the desired end result. For many products, this is not a problem and SSHEs are the equipment choice. For heat-sensitive carrier fluids, systems have been developed that keep the particles and final carrier fluid separate during heating. In these systems the solids are processed in a processing carrier fluid. The end carrier fluid is heat-treated in a conventional manner. After the particles have been properly processed the processing fluid is drained off and the end carrier fluid is then added. This also provides for minimum mechanical damage. In other systems, other means of heating are incorporated for rapid, uniform heating, such as electrical resistance heating, microwave heating, and/or radiofrequency heating. With these systems, due to the unique form of heating with conventional cooling, the surface of the particles may define the cold spot.

Numerous special pieces of equipment have been developed for moving the two-phase material and controlling the flow. One such item relates to reciprocating piston pumps capable of pumping 2–3-cm-diameter particulates. Moving chamber devices have been developed to allow for different holding times for different-size particles.

Product Deposition

During the heating of foods, product may deposit on the heat exchange surface. The deposit fouls the heat exchange surface and is undesirable for several reasons. First, the deposit acts as an extra layer of resistance to heat transfer. Product temperature is

raised enough to compensate for the increased resistance. In several cases, the deposit can effectively reduce the cross-sectional area available to flow. Thus, not only is product temperature affected, but so is residence time. Second, flakes of fouled material can break off from the wall of the heat exchanger and be carried and deposited elsewhere by the product flow (i.e., homogenizing values, product packages, etc.). Finally, the burnt material can give off undesirable flavors to the product.

Direct systems are not as susceptible to fouling, though fouled material may be deposited in the holding tube, and sometimes in the vacuum chamber.

Temperature Sensing and Utilities

Temperature sensors are installed at appropriate locations in the product flow stream for controlling and/or recording temperatures to insure sterilization of all contact surfaces. During equipment sterilization, hot water under pressure is circulated through the processing system and interconnecting piping with the aseptic filler.

The sterilization temperature is monitored at the coldest point in the system that must be sterilized. This point is usually in the return line from the filler.

The proper temperature in the holding section is very important in achieving the commercial sterility of a product. It is important that this temperature be closely controlled, monitored, and recorded.

Steam requirements for aseptic systems vary with the type of system being used. Steam supply must be of the proper pressure and flow rate to satisfy process needs. Product heating and steam seals make up the two major uses of steam in UHT processing. Steam that comes in contact with product must be culinary (food-grade).

Steam seals provide a safety barrier at fittings, valves, and other locations on the sterile side of the system. They protect against microbiological contamination from the environment. The seal assembly provides a steam channel between two gaskets, allowing live steam to enter and fill the groove, thus forming a microbial barrier. These seals are located on the potential problem areas of UHT systems. Usually they are found in low-pressure areas (i.e., vacuum chambers) and around moving system components.

Compressed air is used in pneumatic systems such as controllers, recorders, valves, and sensors. Manufacturers of processing and pneumatic systems specify compressed-air requirements for their equipment. Because processing plants have existing air supply systems, it must be determined whether sufficient air volume and pressure are available. If not, corrective procedures should be implemented. Pneumatic systems are very susceptible to entrained particles of moisture, oil, or dirt. Proper filtering devices should, therefore, be installed so specifications for particulates can be adhered to. A pneumatic system jammed by dirt or oil can cause expensive and frustrating shutdown of equipment.

Compressed sterile air or inert gas is also used by manufacturers to maintain positive pressure in aseptic tanks. This positive pressure serves two purposes. First, it acts as a barrier to contamination. Should there be a crack or failure in the tank or valves, the positive pressure would blow sterile air out of the tank, tending to prevent entrance of microorganisms. Second, the pressure is used to push the product from the aseptic tank to the filler.

Since the air is in contact with sterile product, it must also be sterile. Air is sterilized by using filters and/or heaters. Air, to be sterilized, must itself be of good quality so removal of moisture, oil, and particulates is essential. The filters used have filter pores of a size smaller than microorganisms, thus preventing their passage through the filter. In addition, an air-sterilizing assembly consisting of a heater, holding tube, and cooler can be used to sterilize the air.

Safeguards must be developed to insure that product is rejected if all conditions for sterile-aseptic processing are not achieved. These conditions include maintenance of scheduled process time and temperature, correct functioning of steam seal and/or sterile air pressurization systems, or sufficient product pressure downstream from the sterilizer to eliminate any possibility of sterile product contamination. All important and necessary aspects of UHT processes must be documented, with proper records maintained to demonstrate safe operation.

The following sections will examine kinetic aspects of product processing, including quality retention, microbial destruction, and aseptic packaging.

Chemical and Microbiological Changes

C James and S James, University of Bristol, Langford, North Somerset, UK

Introduction

Temperature controls the rate of all physicochemical reactions and consequently has a profound effect on all biological systems. It influences such fundamental properties as hydrogen bonding, solubility of solute molecules, viscosity, density, and osmotic properties of cell membranes.

The prime purpose of most heat treatments is to make the food safe to eat by reducing the numbers of pathogenic organisms present in the food, if not completely eliminating them. Many food sterilization and pasteurization processes have been developed to achieve this aim without unacceptable changes to the structure or flavor of the food. However, in many cooking processes the aim is to cause structural and chemical changes that will make the food more palatable.

Every operation has, however, side-effects which adversely influence product properties. This is because during every heat treatment many types of process take place simultaneously, i.e., mechanical, physical, chemical, biochemical, and microbial.

Chemical

The adverse chemical effects of heat treatment may be classified as:

- Enzymic and nonenzymic browning reactions
- Vitamin destruction
- Destruction of amino acids
- Oxidation of lipids, flavor components, etc.
- Hydrolysis of carbohydrates, etc.
- Destruction of pigments, such as chlorophyl, carotenoids, and flavonoids
- Development of undesirable flavors by reaction products
- Destruction of carbohydrates and proteins
- Retrogradation of starch
- Cross-linking reactions of polymers, including proteins and carbohydrates, which adversely affect the water uptake of the product.

Changes in Proteins

Heating causes dramatic changes in most foods. The heating of meat is accompanied by changes in appearance, flavor, texture, and nutritive value. The most drastic changes in meat during heating, such as shrinkage and hardening of the tissue, release of juice, and color changes, are caused by changes in the muscle proteins. It is difficult to investigate heat-induced changes in the complicated and highly organized protein structure found in meat. Therefore, many of the experiments have been carried out by heating isolated proteins. These studies show that the most drastic changes of the myofibrillar proteins occur between 30 and 50 °C, reaching almost completion at 60 °C. These changes are characterized by an unfolding of the protein molecules, accompanied by an association of molecules and resulting in coagulation and loss of enzyme activity. At temperatures above 70 °C more severe changes such as oxidation of sulfhydryl groups occur.

Home cooking and commercial canning procedures have little effect on the nutritive value of food proteins. However, other industrial processes that involve the use of excessive heat at low moisture levels, such as drying, and subsequent storage of these products may result in severe nutritional damage. Milk is the only important naturally occurring protein food that has a high content of reducing sugar. Liquid milk appears virtually unaffected by industrial pasteurization and only slightly affected by autoclaving and canning. However, the protein in dried milk can deteriorate during manufacture and storage.

Maillard reactions occur during the baking of bread and biscuits and during the production of breakfast cereals. A 10–15% loss of lysine can occur during the baking of bread with the loss occurring mainly in the crust. Biscuits are an attractive product to enrich the protein content of diets, but are subjected to high temperatures and baked to low moisture contents. Losses of up to 50% reactive lysine can occur during the production of biscuits enriched with 15% skimmed milk powder.

Lysine is the most sensitive amino acid to Maillard damage but all amino acids can be reduced in availability when the heat process is increased.

Changes in Carbohydrates

Heat affects the properties of different carbohydrates in foods to different extents, and not always in the

same direction. The effect can best be considered under four areas – taste, caramelization, pyrolysis, and interaction with other food components. These naturally are not independent but are related to a greater or less extent, depending on chemical structure.

It is important when considering the effect of temperature on taste to distinguish between relative and absolute sweetness. The former is usually determined with reference to sucrose, and the relative sweetness of most sugars decreases with increasing temperature. However, the absolute sweetness of sugars usually increases with increasing temperature.

Caramelization or scorching of carbohydrates is a result of the partial thermal breakdown of carbohydrates. The brown product produced, caramel, consists of dehydration products and colored substances, the proportion of which depend on the extent of heating.

After polymerization, depolymerization, and dehydration reactions, secondary thermal reactions cause carbon–carbon bond cleavage and many pyrolysis products of low molecular weight are produced in a similar way from both mono- and polysaccharides.

The most important reaction of carbohydrates with other food components is the so-called nonenzymic browning or Maillard reaction. This occurs between reducing sugars and nitrogenous compounds, in particular amino acids and proteins. The reaction is highly temperature-dependent and may increase two to three times for each 10 °C rise in temperature in model systems and even more in real foods.

Changes in Vitamins

Three vitamins, vitamin E in its ester form, riboflavin, and niacinamide, are extremely heat-resistant, whereas thiamin is the most labile of the vitamins. Some vitamins show a gradual degradation as the temperature is raised from 100 to 130 °C (vitamins A, D, B_{12}, and C). Other vitamins show a sudden drop above a critical temperature – folic acid at 110 °C, and pyridoxine and pantothenic acid at 120 °C.

Vitamin A and carotene lose activity when heated in the presence of oxygen, but are fairly stable to ordinary cooking. Insignificant losses are found in milk during pasteurization, sterilization, and spray-drying.

Carotene is well retained during the dehydration of vegetables if enzymes have been inactivated by blanching. Synthetic β-carotene has good stability when used as a coloring agent in canned soups. Retention in cakes baked at 175–200 °C was 90–95%, whereas in white bread it was only 50–80%.

Frying of oils and fats may lead to a considerable loss of carotene and vitamin A. Vitamin A appears to be retained as long as water is present but after 40 min at 130–160 °C or 20 min 175–200 °C about 90% had been destroyed. It has been reported that a 40% loss of carotene occurs during the frying of margarine for 5 min with the loss increasing to 60% after 10 min.

Less information is available on the thermal stability of vitamin D in foods but it is though to be similar to vitamin A. Its retention during smoking of fish, spray-drying of eggs, and pasteurization and sterilization of milk is satisfactory.

Vitamin E in food products occurs in the form of free tocopherols. These survive domestic cooking processes far more than commercial processing. Losses of up to 95% have been measured in canned vegetables (Figure 1). However, oils and cereals are a more important source of vitamin E than vegetables. Almost 100% of the free tocopherols were destroyed when vegetable oil was heated for 3 h at 200 °C, whilst 47% of tocopherols in unbleached flour were destroyed during the baking of bread.

High losses occur in water-soluble vitamins during slow heating, long cooking, and slow cooling processes. Much of the loss is due to leaching of soluble matter into the cooking water. When processing of vegetables prior to freezing, steam blanching followed by air-cooling is recommended.

Blanching of fruits and vegetables inactivates the ascorbic acid oxidase and stabilizes vitamin C. Under the most favorable conditions, blanching losses can be less than 10%; however, under severe conditions they can exceed 50%. Similar differences in vitamin C content can result in domestic cooking (Table 1).

The thermal degradation of thiamin vitamin (B_1) results in numerous reaction products from the cleavage of the vitamin molecule to its pyrimidine and thiazole moieties. Vitamin B_1 losses in high-temperature, short-time (HTST) canning processes are far less than in conventional canning. Losses in vegetables are in the 13–16% range compared with

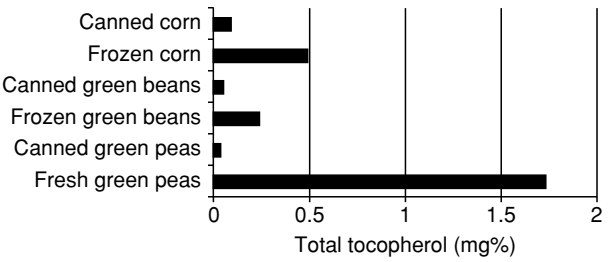

Figure 1 Total tocopherol content after processing of vegetables.

Table 1 Typical vitamin C losses during cooking

Method	Vitamin C (%)		
	Destroyed	Extracted	Retained
Green vegetables	–	–	–
Boiling (long time, much water)	10–15	45–60	25–45
Boiling (short time, little water)	10–15	15–30	55–75
Steaming	30–40	< 10	60–70
Pressure cooking	20–40	< 10	60–80
Root vegetables			
Boiling	10–20	15–25	55–75
Steaming	30–50	< 10	50–70
Pressure cooking	45–55	< 10	45–55

over 40% in conventional systems. With meat, losses are under 10%, compared with approximately 20% conventionally.

Less severe heat treatments such as sous-vide processing have been shown to increase retention of vitamin B_6 and folate acid. After 5 min of boiling, vitamin B_6 and folate losses were 55 and 39% respectively. Steaming for the same time reduced the losses to 17 and 12% and sous vide to 3 and 3% respectively.

Overall, vitamins C, B_1, B_6, and folic acid are the most vulnerable vitamins in thermal processing. However, major losses of vitamins during thermal processing can be taken as a sign of poor treatment methods.

Changes in Enzymes

The purpose of most pasteurization processes is to kil microorganisms and inactivate deteriorative enzymes. Often the inactivation of certain enzymes is used as a processing index to verify that the food has been subjected to the desired heat treatment.

Different heat treatments have different effects on enzymes and within processes, process temperature is critical (Table 2).

Microbiological

The use of heat to inactivate vegetative cells in pasteurization processes and to inactivate both vegetative cells and endospores in sterilization processes is the basis of many food production systems. The aim of thermal processing is to deliver sufficient heat to a food to reduce the chance of survival of an organism that will grow in the food to an acceptably low level. The rational for deciding what is an acceptably low level has developed over many years since initial studies on the thermal inaction of *Clostridium botulinum* in the 1920s.

Table 2 Effect of different heat treatments on enzymes

Process	Influence on enzymes
Sterilization	Extremely thermostable enzymes survive
Pasteurization	Thermostable enzymes survive
Blanching	Quality-changing enzymes inactivated
Cooking/frying/baking	Most enzymes inactivated
Drying	Dependent on process temperature
Extraction/concentration/ distillation	Dependent on process temperature

Heat Activation Kinetics

It is generally observed that the number of viable organisms in a uniformly heated population of a single strain of microorganisms decreases exponentially with time, and over many orders of magnitude, with a slope usually designated as D in minutes. It is also generally observed that the rate of inactivation increases exponentially with rise in temperature, with a slope usually designated z in degrees.

Much careful experimentation has shown that there are clear departures from these simple log: linear relationships in practice. The two most common types of deviation are shown in Figure 2. When large inactivations have been achieved and survivor curves followed down to very small surviving fractions, 'tails' are commonly reported. Rising counts or 'shoulders' during the initial heating periods are also common. A number of reasons for these deviations have been put forward. They include assumptions that they are artifacts caused by counting colony-forming units rather than actual survivors. Alternatively, heterogeneity of resistance within the population or changes in resistance during heating have been suggested to cause deviations from the log:linear relationship.

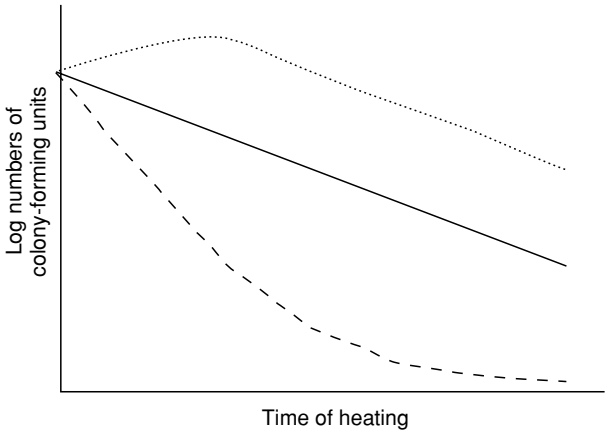

Figure 2 Commonly observed deviations from classical heat-inactivation kinetics. Continuous line, log:linear; dashed line, tail; dotted line, shoulder.

Deviations from the log:linear relationship are more often reported and occur to a greater degree in vegetative cells than in endospores. This is particularly prevalent during lower-temperature, longer-time treatments during which vegetative cells continue to metabolize. This may result in changes in composition and structure and hence thermal tolerance during the heating process.

In vegetative cells the shoulders and tails can be greatly influenced by the heating menstruum and the conditions of growth prior to heating.

Mechanism of Heat Inactivation and Injury

DNA, RNA and ribosomes, cytoplasmic membranes, and specific enzymes are the primary sites for lethal and nonlethal injury of microorganisms.

Studies on spores as well as vegetative cells have been inactivated by heating and have shown single strand breaks in DNA. There is a substantial difference between dry and moist heating. Higher temperatures are needed in dry heating but very high levels of mutants in spore populations are generated. Because of this, heat-injured spores may require additional nutrients for recovery and the production of colony-forming units. It is thought that recovery, in particular with respect to DNA repair, plays an important role in determining the overall resistance of bacterial spores to thermal stress.

Mild heating accelerates the degradation of ribosomal RNA, but this often precedes loss of viability and is not therefore thought to be a prime cause of cell death.

Much early work showed that after heating vegetative cells generally became leaky, losing ions, amino acids, and low-molecular-weight nucleic compounds. The rapid loss of such materials from heated cells has long suggested that heating interferes with the permeability of cytoplasmic membranes. Procedures that minimize leakage have been shown to reduce the level of injury. However, correlations between cell death and leakage are poor. Therefore, membrane damage as a major site of the lethal effects of heat is unlikely.

After some heat treatments, it has been observed that a fall in the rate of germination is preceded by a reduction in colony count. Since DNA is not involved in the initiation of germination this would support the view that damage to DNA is a prime cause of heat inaction. Conflictingly, there are also data that show that in some cases some part of the germination system itself may be especially heat-sensitive and the key site of heat inactivation. The strong inference from such data is that heat inactivates the spores by destroying the activity of an enzyme(s) on the germination pathway. Unfortunately, since the mechanism of germination is not completely understood, the identity of the heat-sensitive step(s) is not known.

Overall, heat is assumed to cause inactivation by destroying a key lethal target in the cell. This is most often directly or indirectly the functionality of the DNA. At the same time, the heat is also destroying many other targets that may be present in larger numbers in the cell. Destroying these targets is therefore less critical unless their numbers are reduced to very low levels or unless the cell becomes further stressed. A heat-treated cell may therefore have a reduced probability of growth after treatment.

Practical Processing

The prime purpose of cooking or other heat treatment is to reduce, if not completely eliminate, any pathogenic bacteria present in the food. To quote from the Chilled Food Association guidelines: 'The heat process must be validated and critical parameters must be controlled and recorded. These must take account of the worse conditions likely to occur with respect to heat transfer (for instance, the use of frozen raw materials or the use of large pieces of meat). All parts of the product must receive a minimum heat process appropriate to the target organism to be controlled and for the targeted shelf life.'

From a pathogenic survival view, heat treatments are divided into three types:

Table 3 Time required to produce a 10^6 reduction in *Listeria monocytogenes* and *Clostridium botulinum* type B at different temperatures

Temperature	*Time (min) to produce 10^6 reduction*	
	Listeria monocytogenes	Clostridium botulinum *type B*
60	43.5	
62	23.3	
64	12.7	
66	6.8

70	2.0	
72	1.0	
74	0.6	
76	0.3	
78	0.2	
80	0.09	270.3
82	0.05	138.9
84	0.03	71.9
86		37.0
88		19.2
90		10.0
92		6.3
94		4.0
96		2.5
98		1.6
100		1.0

Table 4 Thermal inactivation rates (*D*-value) of *Listeria monocytogenes* in meats determined using different media for enumeration of surviving *L. monocytogenes*

Type of meat	*Temperature (°c)*	D-*value (min)*	
		Tryptose agar	*LPM agar*
Ground-beef roast	54.4	22.4 ± 1.1	19.3 ± 4.3
	57.2	15.7 ± 4.1	17.6 ± 9.8
	60.0	4.47 ± 1.60	3.5 ± 1.13
	62.8	2.56 ± 1.04	2.82 ± 1.29
Naturally	54.4	12.5 ± 6.5	6.84 ± 1.79
contaminated	57.2	3.41 ± 1.42	1.97 ± 0.80
ground beef	60.0	1.62 ± 1.10	1.11 ± 0.44
	62.8	0.73 ± 0.32	0.47 ± 0.35

1. If the food temperature is less than 70 °C for 2 min then there is a possibility that all pathogens present will survive.
2. In foods heated to 70 °C for 2 min (or equivalent) then all pathogens present will be reduced to an acceptable level (6 log reduction), e.g., *Listeria monocytogenes, Staphylococcus aureus*, salmonella, verocytotoxigenic *Escherichia coli*. However, spores and preformed toxins may persist.
3. In foods heated to 90 °C for 10 min (or equivalent) in addition to vegetative pathogens, spores of psychotrophic *Clostridium botulinum* will be reduced to an acceptable level (6 log reduction). However, more heat-resistant spores, e.g., strains of *Bacillus cereus* and some preformed toxins, may persist.

The equivalent times at different temperatures are shown in Table 3. However, care must be taken when using these equivalent values. Values for temperatures above 70 °C for *Listeria* have been extrapolated from the measured data. The *Clostridium* values have been calculated using a *z*-value of 7 °C below 90 °C and 10 °C above 90 °C.

Rates of thermal inactivation of a five-strain mixture of *L. monocytogenes* were determined in ground-beef roast (Table 4). *D*-values for *L. monocytogenes* Scott A in naturally ground beef were also determined. Large differences in *D*-values were found when using different media for enumeration of the surviving bacteria.

Comparing the results of this study with those obtained for salmonella at similar temperatures in ground-beef roast it was noted that *L. monocytogenes* is about four times more heat-tolerant than salmonella (Table 5).

Although *Salmonella* spp. in general are not as heat-resistant as *Listeria monocytogenes*, one species, *S. senftenberg* 775W (Table 6), has been found to be more heat-resistant than *L. monocytogenes*.

Concern about the manufacture of 'rare' roast beef in the USA (a process requiring relatively low temperatures, usually below 60 °C) initiated studies into the effect of low temperatures on the survival of salmonella in meat systems. Results (Figure 3) showed that adequate processing of meats at temperatures below 60 °C required substantially longer processing times than at temperatures greater than 60 °C.

Campylobacter is the most significant source of food poisoning in the UK, with the number of cases now exceeding those caused by salmonella. In the USA it was found that *Campylobacter jejuni* was present in 38% of pigs, 24% of sheep, and 2% of the beef carcasses examined. Studies carried out in New Zealand found that *C. jejuni* was commonly present in the feces of unweaned calves and from two of four groups of sheep. Poultry is also a major reservoir of *Campylobacter* species. *Campylobacter* species have a low heat resistance, with a *D*-value of 2.12 min at 55 °C and 0.79 min at 57 °C, and should be destroyed by adequate cooking.

Table 5 Comparison of heat tolerance of salmonella with that of *Listeria monocytogenes* in ground-beef roast

Temperature (°c)	D-*value (min)*	
	Salmonella	L. monocytogenes
57.2	3.8–4.2	17.6
62.8	0.6–0.7	2.6–2.8

Table 6 Comparison of heat tolerances (*D*-values) of *Salmonella typhimurium* and *S. senftenberg* 775 W

Temperature (°C)	D-*values (min)*	
	S. typhimurium	S. senftenberg 775W
60		6.3

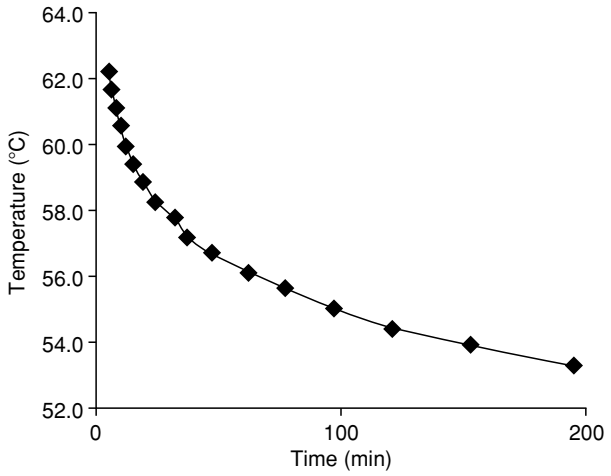

Figure 3 Thermal death curve for a 7-*D* kill of salmonella in cooked beef.

Table 7 US Food and Drug Administration temperature–time recommendations for cooking ground-beef patties to control *Escherichia coli* O157:H7

Temperature (°C)	*Cooking time*
60.0	8 min 20 s
62.2	2 min 7 s
62.6	32 s
68.3	8 s

E. coli is a common organism found in the gut of animals and humans. *E. coli* is mostly harmless in humans, but enterohemorrhagic *E. coli* and, in particular, *E. coli* serotype O157:H7, is recognized as being of significance to human health. Many food-poisoning outbreaks and a number of deaths have been associated with its survival after poor cooking. The US Food and Drug Administration temperature and time recommendations for cooking ground-beef patties to control *E. coli* O157:H7 are shown in Table 7.

Overall

Most heat treatments for food have been established to increase the safe high-quality storage life of the product. The severity of the treatment should be sufficient to reduce, if not completely, eliminate pathogenic organisms likely to be present in the food of interest.

Cooking is a heat treatment with a dual role. Cooking should render the food safe by reducing pathogen levels. At the same time, it facilitates chemical changes that improve the flavor and texture of the food.

Chemical changes in proteins, carbohydrates, vitamins, and enzymes occur in all heat processes. In many cases these changes are undesirable and careful control of the heating regime is required to minimize thermal changes.

Electrical Process Heating

P J Fryer, University of Birmingham, Birmingham, Edgbaston, UK

Introduction

In electrical process ('ohmic') heating of foods, heat is generated by the passage of electrical current through a food. Heat is generated within the food; this overcomes the limitations of slow thermal conduction

within solids, and makes it possible to process solids and liquids at similar rates. This article reviews the principles that govern electrical heating, the factors which control the heating rate, and the design of processes.

Electrical Heating

Thermal processing aims to reduce contamination so that the food will not cause a health hazard during its shelf-life. Each part of the material must be processed to a level prescribed to insure product safety. Heat transfer to solids is slow, however; by the time enough heat is conducted to the centre of a solid to insure sterility, much of the rest is overcooked.

Several sets of reactions occur when a food is heated: those which reduce the level of bacterial contamination, those which result in losses in product quality, in terms of nutrition, taste, and texture, and some that improve taste and texture. The reactions which reduce the number of bacterial spores have a higher activation energy than those which lower product quality: to maximize quality for a given level of sterility it is best to process at as high a temperature as possible. Continuous ultrahigh-temperature (UHT) or high-temperature, short-time (HTST) processes exploit this to produce food of a higher quality than canning. In these processes, food is rapidly heated to *c*. 140 °C, held there for a short period and then rapidly cooled. At 140 °C, food can be sterilized in a few seconds, rather than the several minutes needed at canning temperatures. This requires rapid heating rates to minimize time spent at high temperatures, and thus quality loss, and is best done in a continuous process.

Processing single-phase liquid foods this way is straightforward, because they can be heated and cooled rapidly. High heating and cooling rates ($>1\,^{\circ}\mathrm{C\,s^{-1}}$) are possible. This type of process can efficiently cook liquids such as milks, fruit juices, soups, and sauces, but cannot readily be applied to foods which contain particles, because of the slowness of thermal conduction into the solid. Conduction heating requires a temperature driving force between particles and liquid, and for particles larger than about 2 mm, rapid heating is not feasible. It is possible to use conduction/convection methods to process foods with a high solids fraction (for example, in scraped-surface exchangers), but low heating rates and long hold times are needed, giving poor product quality.

The need to conduct heat is the limiting factor in the thermal processing of particles, and thus for solid–liquid mixtures. Volumetric heat generation techniques can solve this problem. Various techniques are available which use electric fields. In microwave or RF (radio frequency) heating, a high-frequency electric field excites the water molecules within the material, whilst in electrical resistance heating (ohmic heating), however, the passage of electrical current results in heating throughout the material. The process is more energy-efficient than microwave heating, because nearly all of the electrical energy goes to heat the food. It requires the passage of electric current through the material; electrodes that make good contact with the food are required, unlike microwave heating which needs no physical contact. When an electric current flows through a material, heat is generated according to the familiar Ohm's law:

$$W = I^2 R \qquad (1)$$

Here W is power, I is current, and R is the resistance. Heat is generated throughout the material as a result of its inherent electrical resistance.

If the electrical conductivities and thermal capacities of different components of a food are similar, they can heat at similar rates. In practice, as a result of their thermal capacities and electrical conductivities, solids can heat faster than liquids, a result which is impossible by conventional means. Figure 1 shows that rapid heating rates are possible for real foods. Short process times thus make it possible to apply UHT techniques to particulate foods.

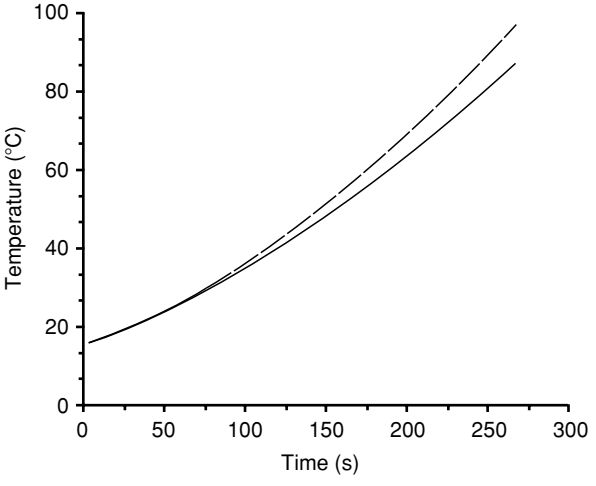

Figure 1 Electrical heating of a piece of lamb meat 20 × 20 × 15 mm, electrical conductivity 0.45 S m^{-1} at 15 °C, in a saline solution, conductivity 0.454 S m^{-1} at 15 °C. Applied voltage gradient 11 V cm^{-1}. Dashed line, solid; continuous line, liquid. Reproduced from Heat Treatment, Electrical Process Heating, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Electrical Heating Processes

The advantages of electrical heating are such that many attempts have been made to commercialize it, in areas such as baking, thawing, and as alternatives to conventional heating processes. An electrical pasteurization process was successful in the USA in the 1930s, and applications have been found in areas such as fish processing. For a process to be commercially acceptable, a number of process and safety criteria must be satisfied:

- electrical design to avoid electrolysis and product contamination;
- effective control of food heating and flow rates;
- efficient aseptic packaging techniques for a two-phase mixture;
- overall cost-effectiveness.

A number of early processes did not meet these criteria, for example, by using direct current supply (which leads to electrolysis), or by using packages containing expensive electrode material. The absence of efficient packing plant also limited success.

The resurgence of interest in the process in the last 15 years is due to the development of a commercial system by APV Baker, which incorporates solutions to the problems described above. The APV Baker ohmic heater was originally developed by EA Technology at Capenhurst, UK. In 1984, APV Baker secured a license for the heating system and then developed a commercial process. Commercial-scale systems are available with power outputs of 75 and 300 kW, corresponding to product capacities of *c.* 750 and 3000 $kg\,h^{-1}$. A schematic process flowsheet is given in Figure 2. The system incorporates heat, hold, and cool sections. Food passes from a product pump into a vertical or near-vertical pipe containing a series of electrodes between which current flows. Sufficient pressure is maintained to insure that the material does not boil; this can be up to 4 bar for sterilization at 140 °C.

The process was originally designed to sterilize foods of high solids fraction, up to about 60%, at heating rates in the region of 1 $°C\,s^{-1}$. Large particles, up to 25 mm in diameter, can be processed, and the technique has found commercial application in the UK, the USA, Europe, and Japan. It has been developed for a number of different applications:

- aseptic processing of high-added-value ready-prepared meals for storage and distribution at ambient temperatures;

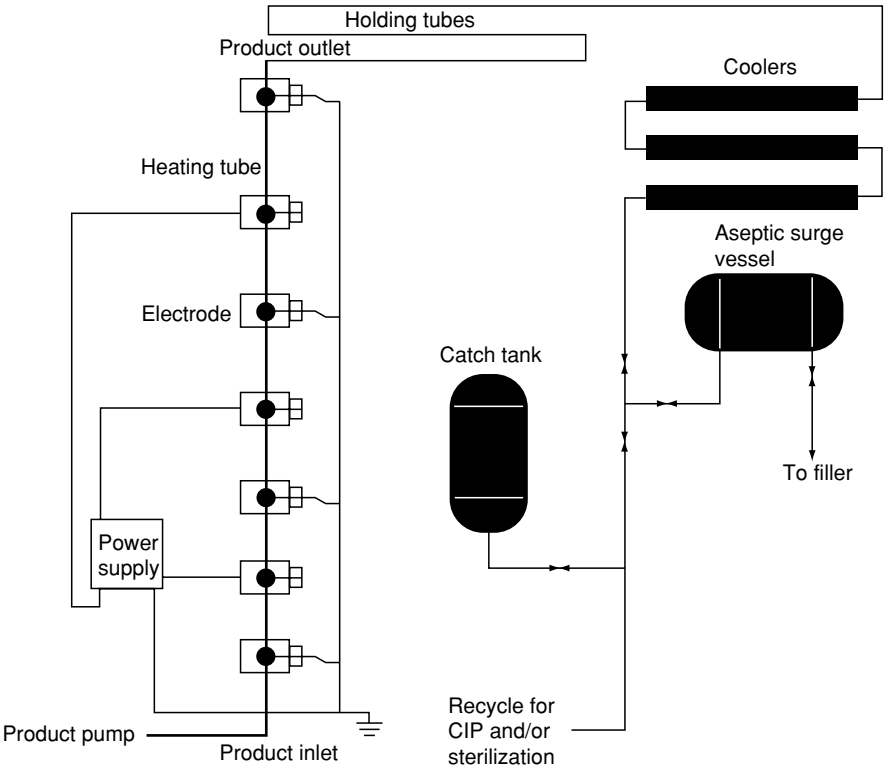

Figure 2 Schematic process flowsheet for the APV Baker ohmic heater. CIP, cleaning in place. Adapted from: Parrott DL (1992) Use of ohmic heating for aseptic processing of particles. *Food Technology* 46: 68–72 with permission.

- pasteurization of particulate food products, for example fruit pieces;
- preheating of food products prior to in-can sterilization;
- the hygienic production of high-added-value ready-prepared meals for storage and distribution at chilled temperatures.

Rapid pasteurization of particles gives very high product quality and has proved very successful. Electrical heating involves short process times: different parts of a meal may require different pretreatments. For example, to produce tender meat and crisp vegetables in the same formulation it will probably be necessary to precook the meat. It is important to prove that an ohmic heater carries out the required treatment. Understanding the principles of electrical heating is necessary both for process design and for proving that it is acceptable to regulatory bodies.

Factors that Control Electrical Heating

Ohmic and conventional processes differ significantly. The process is also significantly different from microwave heating, which has a finite penetration depth of energy into any food; electrical heating has no such limitation. Ohmic heating offers the possibility of rapidly heating solid–liquid mixtures on a commercial scale. The process does however lead to problems for formulation designers and food engineers. Some of these are conceptual; many of the situations possible in ohmic heating are not generally encountered in food processing.

To design a food formulation to exploit the advantages of electrical heating requires understanding of the process and the factors which affect product sterility and quality. The process is controlled by the rate of heat generation, which is governed by a number of factors, the most important of which is the electrical conductivity of the food material. However, temperature is also affected by the way food flows through the heater, and thus the residence time within the plant. To design a food and process requires the factors which affects the heating rate of the material, and the time that it spends in the heater, to be understood.

The heating rate can be found from eqn 1; a more useful form of Ohm's law considers voltage gradients, where the heating rate is given as:

$$Q = \kappa E^2 = \kappa(\text{grad V} \cdot \text{grad V}) \qquad (2)$$

where E is the voltage gradient (V m^{-1}) and κ the electrical conductivity (S m^{-1}). The voltage field within a system in which the electrical conductivity varies with position is found by solving Laplace's equation:

$$\nabla(\kappa \nabla V) = 0 \qquad (3)$$

throughout the material with appropriate boundary conditions, such as constant voltage on the electrodes. The distribution of electrical conductivities thus controls the voltage distribution, and critically affects the heating rates of the different phases. Local voltage gradients may well be different to global ones because of local conductivity changes.

The temperature field that results from heating can be found by solving the equation for thermal transport; for example, in a solid:

$$\frac{\partial T}{\partial t} = \frac{Q}{\rho c_p} + \frac{\lambda \nabla^2 T}{\rho c_p} \qquad (4)$$

where ρ is the density, c_p the specific heat, and λ the thermal conductivity of the material. Eqns 2–4 are coupled through the temperature dependence of the physical properties, particularly electrical conductivity.

Figure 3 demonstrates the interaction between particle shape and alignment of the electric field using experimental results; the same particle will underheat the fluid if placed parallel to the electric field or overheat if placed at right angles to the field. This arises because the solid is less conductive than the liquid: current is diverted past the particle when it is parallel to the field, but has to pass through the solid when it is at right angles to the field. The reverse is seen when the particle is more conductive than the surrounding liquid. Particles with a smaller aspect ratio, such as cubes, will have less heating rate variation with orientation, but some effect will always be seen around sharp edges.

Electrical Conductivity of Foods

In electrical heating it is obviously necessary to know the overall electrical conductivity of the mixture. This is key in determining the power consumption and mean heating rate of the process. It is also necessary to know the local conductivity of the different components of the food. Foods generally have electrical conductivities in the region of $0.01–10\ \text{S m}^{-1}$; these often increase linearly with temperature, with about 2% increase per degree increase. However, where there is a physical or chemical change in the food, complex changes in conductivity can occur, such as when there is a phase change (such as melting of fats) or a change in the structure of the food (such as the breakdown of cell walls).

For a commercial situation, electrical conductivity needs to be measured experimentally for all the components of a mixture. Care should be taken

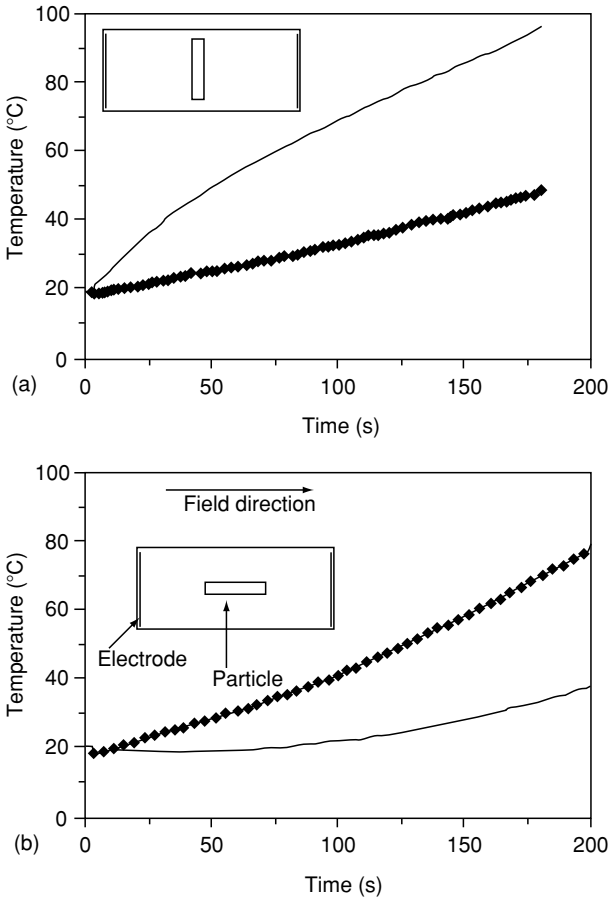

Figure 3 The electrical heating of potato particles, 3 × 4 × 0.75 cm, as a function of orientation to the applied field. Overheating and underheating of a particle (circles), in liquid (continuous line), in different orientations to the electric field (shown in insets). Reproduced from Heat Treatment, Electrical Process Heating, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

here; electrical conductivity can be a strong function of the frequency of the supply, and can be strongly anisotropic, because of the structure of food. For example, the electrical conductivity of carrot at 25 °C was found to be 0.025 S m^{-1} along the axis of the carrot, and 0.02 S m^{-1} perpendicular to the axis. Table 1 shows typical electrical conductivities for foods; these are guides only. It is possible to change the conductivity to some extent, for example by salt infusion, but the result may not be acceptable to consumers. Insulators (such as glass or plastic) and conductors (such as metals) have electrical conductivities several orders of magnitude different to those of foods. In each case, these inclusions will not heat at a significant rate in an electric field; metal has too low a resistance to heat, whilst no current flows through insulators to give rise to heating. Care must be taken to avoid the presence of these inclusions to eliminate cold spots in the system.

Table 1 Electrical conductivity data for typical foods

Product type	*Conductivity at 25 °C (S m^{-1})*
Pickles and chutnies	2.0–3.0
Savory sauces	1.6–1.8
Soups	1.4–1.8
Meats	0.8–1.2
Full-cream milk	0.52
Desserts; vanilla, rice, custard	0.38–0.5
Beaten egg	0.4
Vegetable pieces	0.06–0.1
Fruit pieces	0.05–0.15
Margarine	0.027 (too low for successful heating)

Heating of Solid–Liquid Mixtures

The equations show that the distribution of temperature in a food mixture depends on the distribution of electrical conductivity. This depends on the electrical conductivities of the individual phases, the shape of the particles, and their orientation to the field. Figure 3 has shown this effect for materials where the electrical conductivity of the two phases is significantly different. In practice, if the electrical conductivities of the two phases are within about 10%, then the temperatures will be reasonably uniform.

Eqn 2 can only be solved analytically in very simplistic situations, such as when the physical properties are constant. In practice the commercial ohmic heater involves a flowing mixture where the electrical conductivities vary with temperature: flow through the heater must also be considered in detail. Full solution of the electric, temperature, and flow fields is not feasible given the complexity of the problem and the coupling of the equations via the variation of viscosity and electrical conductivity with temperature.

Various approximations have been tested to predict how flowing particle–liquid mixtures behave. Finite element models have been used to develop solutions for ohmic heating of solid–liquid mixtures: this type of model can simulate both complex shapes and temperature-dependent physical properties. Such models solve the Navier–Stokes equations for flow, but can also solve energy and potential field equations to predict temperatures. In each simulation, the vessel geometry can be discretized by a mesh, and the material properties and boundary conditions given as input data.

In flow situations, the full Navier–Stokes equation for fluid flow must be solved together with the temperature and voltage field. The assumption of no fluid motion can simplify modeling considerably,

shortening the computational run, and gives insight into the 'worst-case scenario': when there is little convective heating, then the temperature differences between different regions of a food mixture will be more pronounced. A number of computational models for the heating of two-phase mixtures have been developed and validated; if the physical properties of the materials are known, it is possible to predict the heating rates and patterns that will result.

The aim of simulations is to demonstrate the nature and extent to which effects might arise in real situations. The finite element method is expensive in computer time, although advances in hardware have made it possible to use high-end personal computers rather than workstations. It is best as a design and research tool rather than as the basis for a control system.

Design of Formulations and Processes

Using electrical heating it is possible to heat a solid–liquid mixture very rapidly. The key physical parameter is electrical conductivity, both of the mixture and of the individual phases. The overall electrical conductivity governs the power that can be supplied to the system. In any given system there will be limits on the voltage and current density that can be sustained. Voltage limits arise through the cost of transformers. Current is limited by the acceptable current densities on the electrode, recommended as $< 4000\ \mathrm{A\ m^{-2}}$ for the APV system. Locally, however, the electrical conductivity of individual regions of the system controls the heating rate.

Once it has reached the required state, it is vital to cool the food as rapidly as possible to avoid loss of product quality. From the heater, material will pass to the holding section and then to cooling. In a conventional process the holding section allows thermal equilibration between particle and liquid and holds the material at temperature long enough for the required level of sterility. In electrical heating equilibration may not be needed because particle and liquid temperatures are closely matched. For process control, it is useful if the particle temperature at the end of the heating section exceeds the liquid, as the liquid temperature is simplest to measure. However, any overheating of particles may impair quality, because it is necessary to remove heat by conduction during cooling. Any design should thus consider the effect of the whole process on the product.

Care must be taken in the design of formulations to eliminate temperature variations, and quality assurance protocols developed to insure that the electrical conductivity of the ingredients lies between acceptable limits. All the physical properties of the system must be known over the whole range of process temperatures, and the heating rates checked under batch conditions. The successful application of electrical heating produces a product of very high quality: developments in electrical equipment design and in process understanding will enhance the ability of food processors to use the technique.

HEAVY METAL TOXICOLOGY

G L Klein and W R Snodgrass, University of Texas Medical Branch, Galveston, TX, USA

Introduction

This article deals in brief with the toxic effects of the heavy metals, including **Cadmium**: Properties and Determination; **Lead**: Properties and Determination; and **Mercury**: Properties and Determination – each covered in depth in other articles – as well as nickel and bismuth. The latter two, although not obviously dietary toxicants, are nevertheless considered to be heavy metals; they do enter the body and can cause toxicity.

Lead

Toxic Effects

Children appear to be more susceptible to the effects of lead than adults. Manifestations of lead poisoning are neurological, hepatic, hematological, renal and endocrine, and genetic and reproductive.

Neurological Overt lead encephalopathy, consisting of delirium, truncal ataxia, irritability, lethargy, visual disturbances, vomiting, and coma, is less frequently seen than in the past. Peripheral neuropathy and paralysis are still reported in adults as a late sign of lead intoxication. Most striking, however, are the reports of learning difficulties and a small but widely confirmed and apparently irreversible reduction in intelligence quotient in children, leading to poor school performance. Contributing to the learning disability is a lead-associated hearing loss, especially of the high frequencies. These learning disabilities occur with blood lead concentrations previously thought to be safe. Adults also manifest behavioral changes at low blood lead levels. These include fatigue and impaired concentration.

Animal data, primarily but not exclusively from studies using rats, show that exposure to lead from birth can lead to hemorrhages, neuronal edema and necrosis, and mitochondrial dysfunction in both cerebrum and cerebellum. Rats exposed to lead beginning on day 10 of life had these changes only in the cerebellum. Rats exposed to lead beginning on days 20–24 of life had none of these alterations in histology. Other documented effects of lead on the nervous system include inhibition of calcium-stimulated neurotransmitter release at presynaptic terminals while stimulating spontaneous release of neurotransmitters, resulting in mini end-plate potentials. When combined with manganese, lead has produced increased peroxidation in rat brains. Lead has also recently been shown to inhibit nitric oxide synthase activity in mouse brain. In addition, lead has produced necrosis of photoreceptor cells in the rat retina and swelling of endothelial cells lining the retinal vessels, with consequent luminal narrowing. Lead can also cause hearing reduction and possible auditory nerve damage in rats. Moreover, there is a report describing disruption of brain microtubular assembly by organic but not inorganic lead.

Hepatic Animal studies have shown that when lead acetate is added to rat hepatocytes, there is decreased binding of L-tryptophan to hepatocellular nuclei, suggesting that lead may alter certain aspects of hepatocyte function as well.

Hematological Lead produces a microcytic anemia, primarily by interference with two enzymes necessary for heme biosynthesis, δ-aminolevulinic acid dehydratase (ALAD) and ferrochelatase. The latter enzyme catalyzes the incorporation of iron into protoporphyrin. Increased erythrocyte protoporphyrin results from this inhibiting effect of lead. With prolonged elevation of blood lead levels, erythrocyte survival time decreases.

The hematological effects of lead are similar in animals and humans, with the exception that in animals lead has been reported to inhibit the pentose phosphate shunt and glucose-6-phosphate dehydrogenase, thus providing a possible explanation for decreased erythrocyte survival seen with chronic lead poisoning. Also of interest is a lead-binding protein in kidney, which limits lead inhibition of ALA activity in kidney but not in liver.

Renal and endocrine At low blood lead levels, lead may contribute to hypertension. It may also produce proximal tubular dysfunction, leading to glycosuria, aminoaciduria, and hyperphosphaturia. Recent studies by the US National Institute of Occupational Health and Safety (NIOSH) suggest that lead exposure altered glutathione *S*-transferase expression in rabbit kidney, suggesting that the kidney may be more susceptible to peroxidative damage. Gout may develop as a result of hyperuricemia. Furthermore,

lead impairs the function of the renal enzyme 25-hydroxyvitamin D-1α hydroxylase, which converts 25-hydroxyvitamin D to the biologically active compound 1,25-dihydroxyvitamin D.

Renal and endocrine effects in animals include not only the enhancement of lead absorption in calcium deficiency but also the involvement of 1,25-dihydroxyvitamin D_3 in the increased absorption of lead as well as calcium. Furthermore, osteoclasts develop pyknotic nuclei and nuclear and cytoplasmic inclusion bodies that may lead to reduced bone resorption. Lead accumulated in bone can be released by resorption, increasing the local tissue lead concentration. This may be a mechanism by which calcium influx into osteoblasts is blocked by lead. Also, lead appears to reduce the natriuretic response to extracellular volume expansion and reduces binding of follicle-stimulating hormone to receptors in the Sertoli cells of the testes. Lead crossing the placenta in hamsters, chicks, and rats has produced urogenital, rectal, and vertebral malformations in the fetus.

Genetic and reproductive Lead has recently been shown to affect chromatin in cells by inhibiting DNA binding to zinc finger proteins, thus altering transcription. It is also possible that transplacental lead gives rise to congenital anomalies in humans as well as in animals, although the data are inconsistent. There is no convincing documentation of male reproductive organ toxicity of lead in humans, although this has been reported in animals. Similarly, there is no convincing evidence that lead is a carcinogen in humans.

Dietary and Environmental Sources of Lead

Although there is no known biological requirement for lead in humans, it is ubiquitous in an industrial environment. Ingestion or inhalation by children or adults occurs as a result of environmental contamination, including food and water. Children, especially underprivileged inner-city children, may ingest chips from lead-based paint surfaces and can mouth items containing lead from paint, dust, or soil. High levels of lead in soil and house dust have been associated with elevated blood lead levels in children. Lead is still present in unleaded gasoline; thus lead continues to be released into the atmosphere by all gasoline-burning vehicles. Lead from vehicle exhausts may be retained by crops, especially leafy vegetables. Acidic foods may leach lead from lead solder in cans; lead from soldered water pipes can contaminate tap water. The US Environmental Protection Agency (EPA) estimates that 20% of the American population consumes drinking water containing $>20\,\mu g$ of lead per liter ($0.1\,\mu mol\,l^{-1}$); this includes more than 3.8 million children.

Significance of Levels in the Diet

Individuals who are also subject to dietary iron deficiency, calcium and/or zinc deficiency risk increased lead absorption. Adults may absorb approximately 15% of ingested lead, while pregnant women and children may absorb up to 50%. Once in the blood, 99% of lead associates with erythrocytes, while 1% remains in plasma and is not available for tissue entry. Blood lead not retained is excreted in urine or bile. In single-exposure studies, lead has a biological half-life in blood of 25 days, in soft tissue of 40 days, and in bone up to 25 years. The latter pool can be mobilized without further intake under conditions of stress, such as pregnancy, lactation, and chronic disease. The significance of dietary and experimental exposure to lead is the impact these exposures have on blood lead concentrations and their effect on enzymes. Thus inhibition of ALAD occurs at a blood lead concentration of $5–10\,\mu g\,dl^{-1}$ ($0.25–0.5\,\mu mol\,l^{-1}$); decreased erythrocyte ferrochelatase occurs at blood lead concentration of $15\,\mu g\,dl^{-1}$ ($0.70\,\mu mol\,l^{-1}$). Inhibition of the renal enzyme 25-hydroxyvitamin D-1α hydroxylase occurs at $25\,\mu g\,dl^{-1}$ ($1.2\,\mu mol\,l^{-1}$) of blood lead, and subtle neurobehavioral changes will occur with blood lead concentrations of $10–15\,\mu g\,dl^{-1}$ ($0.5–0.7\,\mu mol\,l^{-1}$).

Intake Limits

Because of the neuropsychological changes that can occur with blood lead concentrations between 10 and $15\,\mu g\,dl^{-1}$ ($0.5–0.7\,\mu mol\,l^{-1}$), several states in the USA require physicians to report blood lead concentrations greater than $25\,\mu g\,dl^{-1}$ ($1.2\,\mu mol\,l^{-1}$). The US Occupational Safety and Health Administration has made mandatory the periodic blood lead determinations of workers exposed to ambient air lead concentration of $\geq 50\,\mu g\,m^{-3}$ for over 30 days per year. If workers have blood lead levels exceeding $40\,\mu g\,dl^{-1}$ ($1.9\,\mu mol\,l^{-1}$), the employer is obliged to remove the employees from excessive exposure until blood lead concentrations fall below $40\,\mu g\,dl^{-1}$ ($1.9\,\mu mol\,l^{-1}$). The US EPA requires that the lead content of air be less than $1.5\,\mu g\,m^{-3}$, of unleaded petrol $0.01\,g\,l^{-1}$ (0.05 g per US gal), and of leaded petrol $0.03\,g\,l^{-1}$ (0.10 g per US gal). In the USA the maximum amount of lead permitted in water is $50\,\mu g\,l^{-1}$, but this may be reduced to $5\,\mu g\,l^{-1}$. The US Food and Drug Administration Advisory Panel suggests that no more than 100 μg of lead per day be consumed from food, and the Consumer Product Safety Commission suggests that the lead content

of paint be no more than 0.06% (600 p.p.m.) dry weight.

Management of Lead Poisoning

Management of lead poisoning involves separation of the patient from the lead source, identification and treatment of anyone exposed to the source, and identification and correction of other nutrient deficiencies such as those of iron, zinc, and calcium. Aggressive screening of the population is also required. A recent survey of blood lead levels in Galveston, Texas in 1570 children 6 months to 8 years of age revealed that 19% of them had blood lead concentrations $\geq 10\,\mu g\,dl^{-1}$ ($0.5\,\mu mol\,l^{-1}$). Chelation therapy with oral dimercaptosuccinic acid should be started in anyone with a blood lead concentration of 25–55 $\mu g\,dl^{-1}$ (1.2–2.65 $\mu mol\,l^{-1}$). Two more recent oral chelating agents are dimercaptosuccinic acid and 2,3-dimercaptopropane-1-sulfonate; the latter is not commercially available in the USA. Both are water-soluble derivatives of dimercaprol, a chelating agent. A mobilization test using a chelator and noninvasive measurement of bone lead content by K-type X-ray fluorescence may be performed in selected patients above 18 years of age due to reproducibility of measurements based on bone calcium. (*See* **Lead**: Properties and Determination; Toxicology.)

Cadmium

Toxicity in Humans and Animals

Humans can be exposed to cadmium through either diet or industrial contact. The placenta is generally an efficient barrier against transmission of cadmium from an occupationally exposed mother to fetus. However, exposed mothers may exhibit hypertension during pregnancy and give birth to small-for-gestational-age infants with high blood cadmium concentration. Placental function may also be adversely affected as the presence of cadmium in human placental cultures decreases microvillous vesicle uptake of α-aminoisobutyric acid, a neutral amino acid. In addition, there is increased placental cadmium in women smokers. Thus cadmium may be one of the factors involved in the relationship between low-birth-weight babies and maternal smoking.

In the Jinzu river basin in Toyama Prefecture in Japan, primarily premenopausal women consuming a low-calcium diet were exposed to excessive cadmium as a contaminant of water and rice. These women developed itai-itai disease, manifested by bone pain, osteoporosis, pseudofractures, and a higher incidence of renal disease, including proteinuria (α- and β-microglobulin) and glycosuria. Other nonindustrial exposures have occurred in the past from leaching of cadmium from cadmium-plated containers by acidic drinks such as fruit juices. Cadmium-plated containers are now banned by public health laws in many American states.

Among the symptoms of chronic cadmium food poisoning are increased salivation, persistent vomiting, abdominal pain, and diarrhea. Also of concern is renal tubular damage. Since cadmium absorption is only 2–8% of dietary intake, and acute cadmium ingestion is almost always followed by vomiting, most clinically significant cadmium exposure occurs by inhalation of fumes or dust. Respiratory absorption of cadmium has been reported as anywhere from 12 to 30%. However, it is the total inhaled cadmium that is most likely to result in toxicity. Symptoms of acute toxicity include dyspnea, uncontrollable cough, cyanosis, followed by fever, gastrointestinal symptoms including abdominal pain, diarrhea, and vomiting, emphysema, and heart failure. In nonfatal cases the first symptoms are often throat irritation and chest soreness. Also experienced are headaches, nausea, vomiting, diarrhea, chills and weakness. In chronic respiratory exposure, fatigue, anosmia, dyspnea, weight loss, anemia, renal tubular dysfunction, hepatic dysfunction, and bone marrow involvement have been reported. The most prominent features are emphysema and proteinuria. Urinary cadmium excretion of approximately 200 μg (1.78 μmol) per day and a concentration of 200 μg of cadmium per gram of renal cortical tissue is associated with tubular proteinuria. Chronic rhinitis, osteoporosis, and pseudofractures may also be seen. A recent study in rats suggests that cadmium-associated nephrotoxicity may be mediated by oxidative stress-induced proteolysis of sodium–potassium adenosine triphosphatase. Mouse studies have shown that cadmium administration reduces the erythrocyte count and interleukin-1β and tumor necrosis factor, both of which would play a role in producing osteoporosis.

There is epidemiological evidence that cadmium exposure may be carcinogenic. A study of a cohort of 600 workers exposed to cadmium in a smelting plant for at least 6 months between 1940 and 1978 revealed a higher mortality rate from respiratory tract cancers than the rate in the general US population. Workers exposed for more than 2 years had an even greater mortality rate.

In animals, the range of toxic effects is greater. They include the following: testicular necrosis; placental destruction; abortion; fetal resorption or teratogenic malformation, including exencephaly, renal tubulopathy and glycosuria; liver damage; dental changes; deficiencies of calcium iron, copper, and zinc; skeletal decalcification; anemia; haemorrhagic

lesions of sensory ganglia; hypertension; pulmonary edema; and emphysema. In animals, cadmium is transiently bound to an unidentified plasma component and then appears in erythrocytes as whole blood concentration rises.

After ingestion or injection, cadmium is taken up by most tissues, but liver and kidney contain 50–75% of total body burden. Among the chief histopathological changes are peribronchial and perivascular fibrosis and emphysema in the lungs, and fatty infiltration of kidney and liver. Chronic exposure in rats is manifested by weight loss, anemia, leukocytosis, and infertility. Sarcomas have been observed at the site of subcutaneous injection of cadmium powder to rats.

Cadmium also produces neurological toxicity in some species. Cadmium crosses the blood–brain barrier more readily in neonatal rats than in adult rats. *In vitro* cadmium serves as a blocking agent at both adrenergic and cholinergic synapses. Adult rats given an intraperitoneal injection of cadmium show decreased exploration responses up to 9 days after cessation of cadmium dosing. A single intraventricular injection of cadmium to rats causes alterations in neurotransmitter levels throughout the brain. In addition, some fish show abnormal behavior after cadmium exposure via water contamination. In kidney and liver, cadmium binds to metallothionein. When intracellular accumulation exceeds metallothionein-binding capacity, toxicity is thought to occur. There is also a recent report suggesting that metallothionein may be protective against various toxic effects of cadmium.

Place in the Food Chain

Cadmium is found primarily as cadmium sulfide in ores containing zinc, lead, and copper. Cadmium volatilizes more rapidly than other metals when the ore is being smelted, and it condenses to form fine airborne particles that react immediately with oxygen to form cadmium oxide fumes. Cadmium is used industrially to plate other metals, in pigments, batteries, stabilizers for plastics, metallurgy, nuclear reactor rods, and semiconductors. Cadmium is deposited in soil and water near the industrial source. It is taken up by various marine organisms, especially plankton, molluscs, and shellfish. Brown meat of edible crabs may contain as much as 5–15 μg of cadmium per kg. Certain sea birds, both plankton-eating and fish-eating, have high liver cadmium levels – 20–50 μg per kg wet weight. Otherwise, there is no significant cadmium concentration in marine food chains since cadmium is toxic to fish and fish embryos.

Cadmium is a normal plant constituent and can be absorbed through both leaves and roots. Plants have no excretory mechanism for cadmium. Cadmium from soil is freely exchangeable, especially from acid soils, but its concentration there is normally low – 0.02–0.5 $\mu g\,kg^{-1}$. However, cadmium may be high in plants grown near the contaminating industrial site. Accumulation is greater at the roots than at the top of the plant, restricting the movement of cadmium through food chains. In domestic animals reared for human consumption the cadmium burdens are low. In cattle and other mammals the mammary gland is an efficient barrier to cadmium since only small amounts (1 $\mu g\,dl^{-1}$) are excreted in milk.

Significance of Levels in the Diet

In foodstuffs of animal origin, cadmium is present bound to metallothionein. Its bioavailability after exposure to gastric acid is unknown. Plankton and shellfish have the highest levels of cadmium. After absorption, cadmium is transported to tissue, where it binds to metallothionein, leaving the blood concentration less than 1 $\mu g\,dl^{-1}$ (0.1 $\mu mol\,l^{-1}$). Estimates of biological half-life are 17–33 years in human kidney and approximately 7 years in liver. The absorption of cadmium antagonizes, and is antagonized by, zinc, copper, ferrous and ferric ions, and calcium. Zinc and selenium protect against many acute effects of cadmium in animals, including testicular necrosis, placental damage, and teratogenicity. Copper prevents cadmium-induced anemia. Conversely, with marginal copper intake (3 mg kg^{-1} diet), low cadmium levels (1.5 $\mu g\,kg^{-1}$ diet) interfere with copper metabolism in rats and reduce plasma ceruloplasmin activity. Higher intakes of cadmium (6–18 $\mu g\,kg^{-1}$ diet) exacerbate those effects and reduce bone density. The presence of cadmium at a concentration of 12 $\mu g\,kg^{-1}$ in the maternal diet reduces copper storage in newborn lambs. The mechanism of cadmium antagonism to zinc and copper is unknown but may involve competition for transport sites on metallothionein. Iron transport in chicken duodenum is significantly reduced by dietary cadmium. In addition, calcium deficiency may increase dietary cadmium uptake. Furthermore, cadmium may inhibit conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, the biologically active form which acts as a steroid hormone.

Intake Limits

A lethal dose of cadmium following dust or fume exposure is 0.1 $mg\,m^{-3}$ of air for 1 h. The US NIOSH occupational exposure limit is 5 $\mu g\,m^{-3}$ air level per 40-h week. The amount of atmospheric cadmium inhaled by chronically exposed workers varies widely and cannot be correlated at any one

time with atmospheric cadmium. A study of 53 jig solderers in the UK showed that 32 workers employed (exposed) for more than 5 years and 11 of 21 exposed for less than 5 years had elevated blood and urine cadmium levels. Thirty of the 43 workers with elevated cadmium levels had urine cadmium concentrations exceeding 10 nmol $mmol^{-1}$ creatinine. Normal daily urinary cadmium excretion is 2–5 μg (0.02–0.045 μmol), while in unexposed individuals normal blood cadmium is less than 1 μg dl^{-1} (0.1 μmol l^{-1}).

Kidney cadmium, as measured *in vivo* by neutron activation, increased linearly to 15 years of exposure and then reached a plateau. Liver cadmium content increased linearly up to 20 years of exposure. Urinary β_2-microglobulin and retinol-binding protein were greater than the 95th percentile in 20 of 51 subjects. In 9 of the 20, urine protein values were less than twice the upper normal limit, suggesting tubular dysfunction. Both proteins remained within the normal range for up to 15 years of exposure and then increased dramatically. Urinary albumin concentration, a marker of glomerular function, was normal in 48 of 51 subjects. Blood and urinary cadmium concentrations by themselves are only indications of recent exposure, not of cadmium toxicity. Thus *in vivo* neutron activation measurements of tissue cadmium may be a better indicator of toxicity.

Management

The dithiocarbamates appear to be more effective than either dimercaprol or calcium disodium ethylenediaminetetraacetic acid (EDTA) in chelating cadmium in animals. In humans, calcium disodium EDTA has been used, as have dimercaprol, D-penicillamine, and diethyldithiocarbamate (a metabolite of disulfiram). Diethylenetriaminepentaacetic acid also increases renal cadmium excretion. (*See* **Cadmium**: Properties and Determination; Toxicology.)

Mercury

Toxic Effects in Humans and Animals

Mercury may enter the body in two forms: inorganic mercury, absorbed through skin, or from vapor escaping from mercury-containing 'silver' dental amalgam, or through the gastrointestinal tract as an organic salt, primarily of methyl mercury. In children, a symptom complex called acrodynia develops, consisting of redness of lips, throat, and tongue, loss of teeth, swelling, and redness of the skin with pink-red fingertips, palms, and soles. Redness of the conjunctival membranes of the eye and photophobia, enlarged cervical lymph nodes, joint pain, anorexia, and vascular thrombosis are also described. Effects on the nervous system include irritability, withdrawn behavior, proximal muscle weakness, loss of muscle tone, and reduced tendon reflexes.

Occupational exposure to mercury vapor in adults can give rise to acute respiratory distress and renal failure, as well as flu-like symptoms. With more prolonged exposure the chief manifestation is proteinuria resulting from renal tubular damage. This is thought to be caused by a mercury-induced autoimmune response. With long-term mercury vapour exposure in some workers, neurological symptoms develop, including reduced muscle strength and coordination, decreased sensation, and an increase in abnormal reflexes. In individuals who consumed fish contaminated by mercury from an industrial plant near Minamata Bay in Japan and those in Iraq who consumed bread made from wheat contaminated by a mercury-containing fungicide, symptoms of methyl mercury poisoning were primarily neurological, severe, and irreversible.

Exposed infants developed cerebral palsy-like symptoms, including psychomotor retardation, microcephaly, flaccid or spastic paralysis, unsteady gait, abnormal hand motions, visual field narrowing, and tonic convulsions. Exposure of pregnant women led to fetal toxicity, including low birth weight, cerebral and cerebellar histopathology, and severe mental retardation. Mercuric chloride can produce DNA damage in a human fetal hepatic cell line, as can lipid peroxidation.

In animals, mercury toxicity is much the same as in humans. Additional insights into the pathophysiology of mercury have been obtained. Thus mercuric chloride injection into rats can produce renal proximal tubular necrosis. However, in the brown Norway rat, mercuric chloride produces antiglomerular basement membrane antibodies, antiproximal tubular basement membrane antibodies, alterations in helper and suppressor T lymphocytes, and appearance of autoantibodies in peritubular capillaries. With regard to neurotoxicity, injection of pregnant rats with methyl mercuric chloride resulted in appearance of methyl mercury in the fetal nervous system within 2 h. Early changes included mitochondrial degeneration of the endothelium of cerebral capillaries, leading to hemorrhaging, which distorts the pattern of neuron development and migration. Methyl mercury is also believed to disrupt neuronal microtubular assemblage and to interact with sulfhydryl groups of tubular and membrane proteins, causing peroxidative injury. Inhaled mercury can cause respiratory distress and death in mice who lack metallothionein; the latter may be protective, as it is with lead.

Sources of Mercury

Inorganic mercury is primarily inhaled as dust or vapor from dental amalgams or industrial processing. When inorganic mercury is released into either fresh or salt water, it is converted to methyl mercury by methanogenic bacteria and enters the aquatic food chain. Two major epidemics of methyl mercury poisoning in Japan occurred as a result of consumption of contaminated fish from Minamata Bay in Japan following release into the bay of mercury-contaminated waste from an acetaldehyde plant. Agricultural contamination may occur as a result of the use of mercury-contaminated pesticides, such as occurred in Iraq. Finally, poultry products and eggs from hens raised on mercury-contaminated fish meal have varying quantities of mercury. Most of the poultry products fall within the Food and Agriculture Organization/World Health Organization (FAO/WHO) limits for acceptable mercury contents of foods other than fish.

Recently, the adjuvant of the hepatitis B vaccine as well as hepatitis B immune globulin were identified as being contaminated with mercury. Corrective measures are now being taken.

Significance of Levels in the Diet

Dietary intake of mercury is generally not well documented outside of major epidemics. FAO/WHO limits for dietary mercury intake are 0.3 mg mercury per person per week, of which no more than 0.2 mg mercury should be present as the methyl mercury ion. Seafood is probably the primary source of dietary contamination with mercury. Acid rain has increased mercury concentration in the edible tissues of fish, resulting in the closure of many American lakes and rivers to sport fishing. Furthermore, shark and swordfish sales have been restricted because of the high mercury content of these fish. Most poultry products fall below FAO/WHO acceptable limits of mercury of 50 p.p.b. In addition, children, especially toddlers, mouth objects contaminated with soil or household dust, either of which might be mercury-contaminated.

Intake Limits

Whole-blood mercury levels greater than 50 nmol l^{-1} (1 μg dl^{-1}) or urinary mercury concentration of greater than 100 nmol l^{-1} (20 μg l^{-1}) indicate recent mercury ingestion or inhalation. Symptoms of acrodynia have been reported in toddlers with urinary mercury concentration of 249 nmol l^{-1} (50 μg l^{-1}). Whole-blood mercury levels in cases of acute occupational exposure, with nephrotoxicity and neurotoxicity, have been reported to be 24 and 27 μmol l^{-1} (48 and 54 μg dl^{-1}). Hair mercury content is reported to be a reliable indicator of methyl mercury load. Distribution of hair and whole-blood mercury concentrations are in equilibrium, with hair mercury being about 250 times greater than whole-blood mercury. Treatment of choice at present is chelation with dimercaptosuccinic acid to reduce the body burden of mercury. (*See* **Mercury**: Properties and Determination; Toxicology.)

Other Heavy Metals

Nickel

Toxicity Nickel is a heavy transition metal, atomic weight 58.69, to which the general population is exposed primarily as an industrial emission rather than as a dietary component or contaminant. Its concentration in the ambient air in the vicinity of industrial plants is generally less than 1 μg m^{-3}, and this is not considered dangerous to the general public. However, workers exposed to nickel dust in industries such as stainless-steel and nickel alloy production, electroplating, and battery and coinage manufacture are at risk of developing respiratory or nasal neoplasms. Extensive epidemiological studies of cohorts of nickel workers suggest that prolonged exposure to oxides and sulfides of nickel in ambient concentrations exceeding 1 mg m^{-3} is associated with increased risk of lung and nasal tumors. Pulmonary tissue nickel concentration in one study in Germany showed that in high nickel-emission areas in the Ruhr valley pulmonary nickel was threefold greater than in a low-exposure population. Pulmonary nickel concentration in 6 patients who developed bronchial carcinoma ranged from 0.6 to 20.6 μg g^{-1} dry weight, compared to concentrations in low-exposure control lungs of 0.04–0.36 μg g^{-1} dry weight of lung tissue. Half-life studies performed in rats exposed to nickel monosulfide by aerosol inhalation revealed a 20-h half-life in the rat lung. This contrasted with a 221-month half-life for green nickel oxide. No malignancies were seen with the shorter half-life. The mechanism for the causation of respiratory malignancies is uncertain, but may involve nickel induction of chromosome abnormalities and oncogene amplification, as occurs in the production of experimental renal tumors in rats given nickel subsulfide. It has also been shown in rats that nickel administration results in a decreased number of antibody-forming cells in lung-associated lymph nodes, suggesting that alteration of the immune response may play a role in tumorigenesis. In another study, administration of nickel to women showed an increase in serum levels of interleukin-5 4 h after ingestion and a decrease in

CD4 and increase in CD8 lymphocytes 24 h after nickel inhalation. Antioxidants may have a protective effect.

Bismuth

Bismuth is primarily ingested as an antiulcer medication in the form of colloidal bismuth subcitrate or colloidal bismuth subsalicylate.

Toxicity in humans There have been many reports of neurotoxicity in Europe and Australia in individuals ingesting large quantities of bismuth subcitrate or subgallate. There have been isolated cases of patients taking large doses of bismuth subsalicylate and subcitrate, both without impaired renal function. Although bismuth is reported to be poorly soluble in biological fluids, solubility in digestive secretions is increased by the presence of urine or ascorbic acid. Neurotoxic manifestations include numbness and tingling of the extremities, irritability, insomnia, poor concentration, impaired short-term memory, tremors, ataxia, and abnormal electroencephalographic tracings. These symptoms are reversible with discontinuation of the bismuth compounds and with the use of a chelating agent, such as 2,3-dimercapto-1-propane sulfonic acid. Nephropathy following bismuth overdose has also been reported, as has osteoarthropathy. One case of acute reduction in blood platelets has also been reported with bismuth subcitrate. This effect may have been the result of an idiosyncratic drug reaction.

Distribution and toxicity in animals Animal studies indicate that most absorbed bismuth accumulates in the kidneys and only trace amounts in the brain. Tissue distribution of bismuth in humans is unknown. Experimental bismuth neurotoxicity has been produced in mice. Reproduction of tremors, ataxia, myoclonus, and convulsions was associated with hydrocephalus and an average of 8 μg bismuth per gram of brain tissue. Animals with brain bismuth concentration of $4\,\mu g\,g^{-1}$ did not show evidence of neurotoxicity but did manifest hydrocephalus with no other histopathology. When brain bismuth concentration was $1\,\mu g\,g^{-1}$ there was no evidence of hydrocephalus, neurotoxicity, or histopathology.

Sources of bismuth Average dietary intake in humans is not well quantified, but is probably $< 5\,\mu g\,day^{-1}$. It is poorly absorbed from the gastrointestinal tract, but with chronic medication small amounts can accumulate in blood, although generally this amount does not exceed $50\,\mu g\,l^{-1}$. The rate of urinary clearance of bismuth when ingested in the subcitrate form decreases by approximately 2.6% per day and reaches a steady state by 2 weeks after discontinuation of the compound. However, persistence of urinary bismuth concentration of as much as $250\,\mu g\,l^{-1}$ ($1.2\,\mu mol\,l^{-1}$) suggests that there is tissue accumulation of bismuth, and slow mobilization.

Intake limits Data from over 1000 cases of bismuth neurotoxicity in France suggest that a whole-blood bismuth level greater than $180\,\mu g\,l^{-1}$ ($0.86\,\mu mol\,l^{-1}$) is associated with neurotoxicity; if whole-blood bismuth concentration is greater than $100\,\mu g\,l^{-1}$ ($0.48\,\mu mol\,l^{-1}$), bismuth compounds should be discontinued. With whole-blood levels between 50 and $100\,\mu g\,l^{-1}$ ($0.25–0.48\,\mu mol\,l^{-1}$), individuals should be monitored for signs of neurotoxicity, and if less than $50\,\mu g\,l^{-1}$, no monitoring is needed.

HEMAGGLUTININS (HAEMAGGLUTININS)

G P Savage, Lincoln University, Canterbury, New Zealand

Background

The presence of heat-labile toxic factors in plant products, mainly in leguminous seeds, makes them unsuitable as food for humans unless they are properly cooked. There is evidence, however, that leguminous seeds were an important part of the diet of prehistoric man, and the use of fire for cooking must have had an important bearing on the safe use of leguminous seeds in the diet. In the late eighteenth century, it was noticed that plant lectins, or phytohemagglutinins (hemagglutinins) occurred in castor bean seeds and that these compounds could agglutinate red blood cells. (*See* **Legumes**: Dietary Importance.)

The ingestion of raw or incompletely cooked beans regularly leads to incidents that at first appear to be cases of food poisoning. When no causative organism appears to be involved, high concentrations of hemagglutinins are usually implicated. Vomiting and diarrhea usually occur within 2–3 h after consumption. As few as four or five beans are often the cause. In many instances, the beans have been soaked for a few hours and then eaten without further cooking.

General Properties

Hemagglutinins are proteins that possess a specific affinity for certain sugar molecules. Since carbohydrate units exist in most animal cell membranes, the hemagglutinins may attach to these receptor groups. This attachment will occur only if the lectin molecule has at least two active groups. Hemagglutinins are characterized and detected by their action on red blood cell membranes, causing the blood cells to clump together. Other cells can also be affected. The receptor site on the cell surface must be exposed in order to react with a specific lectin. Pretreatment of red blood cells with a protein-digesting enzyme, such as papain, trypsin, or pronase, activates the cells and presumably exposes the receptor sites.

Structure

All plant lectins are proteins. Some contain a range of covalently bound sugars and can therefore be called glycoproteins. Lectins from different legumes show a remarkable range of specificity towards various animal red blood cells, which suggests that there is a considerable range of structures in this group. (*See* **Protein**: Food Sources.)

Location

Most hemagglutinins of higher plants are found in seeds, but tubers and plant sap are also sources of lectins. Lectins are most commonly found in leguminous seeds. They have been observed in potatoes and cereals, but the amounts in these foods do not appear to have any adverse effects.

Lectin Content of Edible Leguminous Seeds (see Table 1)

The seeds of a wide range of edible legumes are known to contain proteins that agglutinate red blood cells. Some of these hemagglutinins have been suggested to contribute to the poor nutritive value of raw beans. The level of toxicity of kidney beans has

Table 1 Hemagglutinin content of a number of legumes

Legume	*Hemagglutinin (units per gram dry wt)*	*Hemagglutinin removed (%) on soaking in water for 18 h*
Phaseolus vulgaris		
Red kidney beans	37 000–53 000	22–66
White kidney beans	17 000–43 000	18–36
Rose coco beans	39 000	18
Lens culinaris		
Red lentils	77 000	22
Green lentils	18 000	19
Split peas	1 000–16 000	11
Pisum sativum		
Garden peas	5 100	65
Vigna sinensis		
Black-eye beans	1 000	100

From Bender AE (1983) Haemagglutinins (lectins) in beans. *Food Chemistry* 11: 309–320.

been shown to be directly related to the lectin content and hence hemagglutinating activity. Using rat growth experiments and hemagglutinin tests on a range of leguminous seed lines available in the UK, leguminous seeds have been classified into four broad groups. In this study, group A seeds from most varieties of kidney (*Phaseolus vulgaris*), runner (*P. coccineus*) and tepary (*P. acutifolius*) beans showed high reactivity with red blood cells from a range of different species and were also highly toxic (none of the rats survived the feeding experiment). Group B contained seeds from lima or butter beans (*Phaseolus lunatas*) and winged bean (*Phosphocarpus tetagonolobus*), and they agglutinated only human and pronasetreated rat erythrocytes. The seeds did not support proper growth, but the animals did survive the feeding experiment. Seeds included in group C were lentils (*Lens culinaris*), peas (*Pisum sativum*), chickpeas (*Cicer arietinum*), black-eye peas (*Vigna sinensis*), pigeon peas (*Cajanus cajan*), mung beans (*Phaseolus aureus*), field or broad beans (*Vicia faba*), and adzuki beans (*Phaseolus angularis*). These generally had a low reactivity with all cells and were nontoxic. Group D contained soya (*Glycine max*) and pinto (*Phaseolus vulgaris*) beans, which generally had a low reactivity with all cells but caused growth depression at certain levels of inclusion in the diet. It was thought that the growth depression in this group was due to antinutritive factors other than lectins. The experiment showed that no single erythrocyte type could be used as a sole indicator of toxicity. The potential toxicity could, however, be predicted from the response to various erythrocytes. The usefulness of animal feeding trials was clearly shown by these experiments. (*See* **Beans; Peas and Lentils**.)

Assay Methods

The detection of lectins in plant extracts is generally performed by a serial dilution technique followed by visual estimation of the end point. Washed red blood cells are activated by pretreatment with a suitable proteinase (pronase, trypsin, papain), and the test is always carried out in saline solution (0.9%). A more quantitative method is based on the photometric measurement of the density of red blood cells that have not been agglutinated by the extracted lectin. Hemagglutinin activity is usually expressed as hemagglutinin units per milligram of sample. One unit is usually defined as the lowest amount of sample required for agglutination under the test conditions, but has also been defined as the amount of material per milliliter in the last dilution giving 50% agglutination.

The rather subjective nature of this test makes it quite difficult to compare results between different research centers, but it gives good results in the hands of experienced workers. Many workers use a standard reference material to calibrate their own experiments. Wide use of a reference sample between research centers would make comparison of published data more feasible.

Biological Effects of Hemagglutinins

The *in vitro* precipitation of red blood cells does not explain the *in vivo* effects of lectins. Lectins cause agglutination or 'clumping together' of cells by binding to the saccharides branching from lipid and protein molecules of the cells' outer surface. A definite relationship between the lectin content of legume-containing diets and the nutritive value has been made. The feeding of lectin preparations from some legumes has been shown to cause definite growth retardation and, in extreme cases, death. In contrast, it has been shown that white pea hemagglutinin has no growth-depressing or toxic effects on rats when fed at a level of 1% in the diet.

Many ingested lectins cause toxicity by binding to the surface of intestinal epithelial cells, which results in the reduced absorption of nutrients across the intestinal wall. Suppression of intestinal disaccharidase activity and proteolytic activity has also been observed. Since the disaccharidases are involved in the breakdown of carbohydrates to monosaccharides prior to absorption in the small intestine, their reduced activity would be expected to lead to reduced digestibility of dietary carbohydrates. The decreased proteolytic activity would also lead to reduced availability of amino acids and peptides for absorption. The growth inhibition caused by lectins can therefore be attributed to the reduction in absorption of

nutrients due to their disruption of the absorptive area of the intestine. (*See* **Carbohydrates**: Digestion, Absorption, and Metabolism.)

Detoxification

The detoxification of plant lectins is usually achieved by traditional methods of household cooking. There are conditions where this type of processing is not completely effective. When leguminous seeds are used in the manufacture of animal feeds, cooking is usually omitted, although steam pelleting of the final mixed feed may have some effect in the degradation of antinutritive factors. The time and temperature of the feed during the pelleting process are clearly insufficient to degrade a significant proportion of the hemagglutinins. As manufacturers do not want reduced food utilization occurring with their products, they usually limit the amount of leguminous seed protein incorporated in their mix.

Lima bean lectin has been observed to be stable between pH 5 and 7 at elevated temperatures. Addition of *N*-acetyl-L-cystine (NAC) inactivated lectin at a lower temperature than in its absence. This suggests that NAC reacted with the disulfide linkage of the lectin to bring about inactivation. NAC had no effect on lectins extracted from soya bean flour; this supports the proposed role of NAC, as it is known that soya bean lectins do not contain any disulfide bridges. Addition of NAC prior to heatprocessing of some legume flours may reduce the amount of heat processing required and improve the overall quality of the final product.

Hemagglutinins are almost completely destroyed by boiling for 60 min at atmospheric pressure. Autoclaving at 105 °C for 30 min is also effective. If leguminous seeds are previously soaked for 18 h, the hemagglutinins can be completely destroyed by boiling for 2–5 min. Other traditional techniques used to improve the nutritional value of legume seeds involve soaking and germinating. It has been shown that germination of lima beans for 6 days results in a 50% reduction in activity. Soaking for the same time results in an overall 34% reduction in activity. It should be noted that soaking, though not as effective as germination, would only be the first step in preparation; normal cooking would destroy further lectin in the beans.

Dry heat treatment (roasting) to destroy hemagglutinins is remarkably ineffective. For example, winged beans (*Psophocarpus tetragonolobus*) heated at 100 °C for 2 h show less than 5% reduction in lectin activity. The generally low but quite variable levels of hemagglutinins in this seed could be easily destroyed by autoclaving at 120 °C for 5 min.

The treatment of whole cow peas (*Vigna unguiculata*) with microwaves (2400 MHz) for 6 min was almost ineffective in destroying hemagglutinins, while dry roasting (160 °C for 50 min) led to between 28 and 47% reduction in lectin content. Treatment of cow peas with mild alkali (0.5% sodium bicarbonate for 12 h) led to an 80% reduction in hemagglutinin content. (*See* **Cooking**: Domestic Use of Microwave Ovens.)

Infrared heating of winged bean (*Psophocarpus tetragonolobus*) for 60 s was remarkably effective in reducing the hemagglutinating activity of this seed, whereas oven and microwave heating had little effect.

Conclusions

Extensive research has been carried out on the chemical, physical, and biochemical properties of hemagglutinins, but the understanding of their toxicological and nutritive properties is limited. These properties are an important aspect of our knowledge as legumes provide a vital source of protein in developing countries. The preparation of protein isolates from leguminous seeds and the use of these in quick cooking food products need careful consideration of the possible antinutritional effects of residual hemagglutinins. It is possible that these toxic effects may be only partially destroyed, and the resulting, slightly reduced food utilization may be difficult to detect. It is not clear what the long-term effect of consuming low levels of these compounds will be.

Hemagglutinins occur in a wide range of leguminous seeds. Lupins are the only common legume that do not appear to contain any lectins. Legumes contain a wide variety of toxins, including hemagglutinins, that are heat-labile and should therefore present no health hazard when properly cooked. Thus, it is surprising that outbreaks of poisoning following the consumption of incompletely cooked leguminous seeds occur in an otherwise well-informed society.

HEMICELLULOSES

M T Holtzapple, Texas A&M University, College Station, TX, USA

Introduction

Hemicellulose is the world's second most abundant carbohydrate (after cellulose). An estimated 45 000 million tonnes are produced annually, a daily production of about 20 kg per person. (*See* **Carbohydrates: Classification and Properties.**)

Hemicellulose comprises 20–30% of plant cell walls, which have a composite structure analogous to fiberglass resins. Cellulose provides cell rigidity and strength (like the glass fibers) and is embedded in a hemicellulose matrix encrusted with lignin which bonds the entire structure together. (*See* **Cellulose; Lignin.**)

Definition

Hemicellulose is defined as the cell wall polysaccharides extractable in dilute ($10 \pm 8\%$) sodium hydroxide solutions. It includes all the cell wall polysaccharides except cellulose and pectin. The term 'hemicellulose' was first used by Schulze in 1891,

who believed these extractable polysaccharides to be cellulose precursors. This is now known to be absolutely false, but the name has remained. Staudinger has proposed the name 'polyoses' to prevent this erroneous association, but it has not gained widespread acceptance.

Hemicellulose is quite distinct from cellulose. Hemicellulose polymers are short, with a degree of polymerization (DP) of 50–200. In contrast, cellulose polymers are much longer, with a DP of 500–15 000. Cellulose is a linear polymer without attached side groups, whereas some hemicelluloses are Y-branched and most have attached side groups. Cellulose is a homopolymer of glucose, whereas hemicellulose generally is a heteropolymer composed of many sugars and modified sugars.

Structure

Monomers

Hemicellulose monomers are shown in Figure 1. Three monomers are hexoses (glucose, galactose, and mannose) and two are pentoses (xylose and arabinose). Some of the sugars are acetylated (glucose, mannose, and xylose). Glucose appears as its uronic acid and also as the methylated uronic acid. Most of the hemicellulose sugars appear as D enantiomers except for three L enantiomers (arabinose, fucose, and rhamnose). Galactose is primarily a D enantiomer, although the L enantiomer is occasionally present. Two 6-deoxy sugars (fucose, rhamnose) may be found in small quantities. (*See* **Galactose**.)

Linear free-aldehyde sugars are unstable and cyclize into a ring structure (Figure 1). In reality, the ring resembles a garden chair, but simpler Haworth projections are commonly used. The ring can have six members (pyranose) or five members (furanose). In hemicellulose, arabinose appears as both a pyranose and a furanose, whereas the others appear only as pyranoses. When the linear sugar cyclizes, C1 becomes chiral. Its axial hydroxyl groups are designated α and its equatorial hydroxyl groups are designated β. Both α and β sugars appear in hemicellulose, although the β forms are more common.

Hemicellulose can be classified into three families (xylans, mannans, and galactans), named here according to the backbone polymer. (Note: the naming conventions for hemicellulose vary widely.)

Xylan

Xylan is known by many names – including glucuronoxylan, araboxylan, glucuronoarabinoxylan, and L-arabino(4-*O*-methyl-D-glucurono)xylan – which reflects its heterogeneous nature. Figure 2a shows the backbone polymer is β-1,4-linked xylose. Numerous side groups can attach to the backbone, as shown in Figure 2b. Generally, 10–20% of the xyloses have side groups (i.e., $n = 4$–9), although 30–40% is sometimes observed (i.e., $n = 1.5$–2.5) in cereal flours. Most of the side-group attachments are made through arabinose, which may occur singly or with additional attached groups (xylose, galactose, or 4-*O*-methyl-D-glucuronic acid). Galactose is generally found in the xylans of annual plants. Glucuronic acid and its methylated form may also attach directly to the backbone at xylose C2, although C3 attachment is sometimes observed. Often, the xylose backbone is partially acetylated, particularly in the C2 position, although C3 acetylation is found. Xylans are generally linear, with a DP of 50–200. In some xylans, there are one to two Y branches in a single molecule.

The following generalizations may be made about xylans from different plants:

- monocotyledons – arabinose side groups attached along with glucuronic acid (or its methylated form);
- dicotyledons (including hardwoods) – 4-*O*-methylglucuronic acid attached every 10th xylose;
- softwoods – 4-*O*-methylglucuronic acid attached every sixth xylose with small amounts of arabinose side groups.

One of the few examples of homopolymer xylan is produced by esparto grass (Figure 2c) that contains Y-branched xylose backbone without attached side groups. (Note: esparto grass also makes some heteropolymer xylan with attached arabinose.)

Wheat flour xylan (Figure 2d) has irregularly attached arabinose on about 30–40% of the xylose backbone. 'Open regions,' consisting of about five sequential bare xyloses, occur about every 20–25 xyloses. Wheat bran xylan is similar, except it has more side groups (65% of xylose has attached arabinose) with glucuronic acid on every seven to eight xyloses. Barley husk xylan (Figure 2e) also has attached side groups of glucuronic acid and xyloarabinose. The xyloarabinose side group also occurs in corn cob xylan and perennial rye grass. Maize seed coat xylan (Figure 2f) has many side groups, including arabinose, xylose, galactose, and glucuronic acid. (*See* **Barley**.)

Hardwood xylan (Figure 2g) has 4-*O*-methylglucuronic acid every 10th xylose. Of these 10 xyloses, approximately 3.5–7 are acetylated primarily at the C3 position, although C2 acetylation is also found. Softwood xylan (Figure 2h) has more side groups because 4-*O*-methylglucuronic acid occurs

every sixth xylose, and it also has arabinose side groups.

Some unusual xylose-containing hemicelluloses have nonxylose backbones. Cress seed hemicellulose (Figure 2i) has an arabinose backbone with attached xyloarabinose side-groups. Runner bean hemicellulose (Figure 2j) has a glucose backbone similar to cellulose with side groups containing xylose, galactose, arabinose, and fucose. (*See* **Legumes**: Legumes in the Diet.)

Mannans

Mannans generally occur with other sugars, including galactose and glucose. Four distinct groups (**Table 1**) are generally recognized depending on the relative amounts of the additional sugars. In some mannans, particularly from softwoods, the sugars are acetylated.

Mannan (Figure 3a) is a relatively pure (> 95%) mannose polymer found in the food reserves of some seeds. The most famous mannan source is vegetable ivory (i.e., tagua palm seed), a hard crystalline material that may be fashioned into buttons. It is not completely pure, because traces of galactose have been isolated with the mannose. Mannan also occurs in coffee beans and orchid tubers.

Glucomannan is a heteropolymer of random-sequence mannose and glucose. Hardwood glucomannan (Figure 3b) has no side groups. Its mannose-to-glucose ratio is 2:1 (common) to 1:1 (infrequent).

Softwood glucomannan (Figure 3c) has side groups with a mannose-to-glucose ratio of 3:1 (common) to 4:1 (infrequent). A galactose residue is attached to approximately every 15th or 30th mannose unit at C6. Some galactose may also be attached to glucose at C3. Approximately 25% of the backbone sugars are acetylated. Glucomannans also occur in the food reserves of some plants, such as iris seeds (mannose-to-glucose ratio 1:1), lily bulbs, bluebell seeds, and orchids.

Table 1 Sugar and acetyl ratios in various mannans

	Mannose	*Glucose*	*Galactose*	*Acetyl*
Mannan	> 19		1	
Glucomannan				
Hardwood	1–2[a]	1		
Softwood	3[a]– 4	1	0·1–0·2	1
Iris	1	1		
Galactomannan				
Legume	1–5	1		
Galactoglucomannan				
Softwood	3	1	1	1

[a]More common.

Galactomannan is common in the seeds of legumes and carob trees. The most famous form is the food thickener guaran (or guar gum), shown in Figure 3d. Galactose side groups are attached to every other mannose unit. (*See* **Gums**: Properties of Individual Gums.)

Galactoglucomannan is similar to glucomannan, except it has about 10 times more galactose and a lower DP. The backbone from western hemlock galactoglucomannan (Figure 3e) has randomly ordered mannose and glucose. Galactose side groups are attached to either mannose or glucose. Approximately 25% of the backbone is acetylated.

Galactan

Figure 4a shows the β-1,3-linked galactose backbone of galactan. Arabinose is a common side group, so the term 'arabinogalactan' is sometimes used. Larchwood has an unusually high galactan content (10–15% typical, but as high as 25–30%), so it is well studied. Larch galactan (Figure 4b) has side groups of galactose, arabinose, and small amounts of glucuronic acid. The arabinose-to-galactose ratio ranges from 1:4 to 1:8, with 1:6 most common. Maritime pine galactan (Figure 4c) contains a small amount of xylose. Tobacco (Figure 4d) and maple sap galactans contain some rhamnose.

Cellular Structure

Hemicellulose is a major component of plant cell walls, which are well described in the **Cellulose** article. Figure 5 shows the distribution of lignin, cellulose, and various hemicelluloses in the cell wall layers for both softwoods and hardwoods. (The distribution in herbaceous crops would be similar to hardwoods.) Hemicellulose is the dominant carbohydrate in the compound middle lamella, whereas cellulose is more plentiful in the secondary layers (S1, S2, and S3). In hardwoods (and herbaceous crops), glucuronoxylan is the primary hemicellulose, whereas glucomannan is more prevalent in softwood.

Properties

Physical

Because hemicellulose is so heterogeneous, its physical properties are not well studied. The higher heat of combustion for xylan is 17.8 MJ kg^{-1}. Hemicellulose begins to decompose above 200 °C, which makes it one of the least thermally stable components of the cell wall.

In the cell wall, most hemicellulose is noncrystalline. (An exception to this is the mannan from

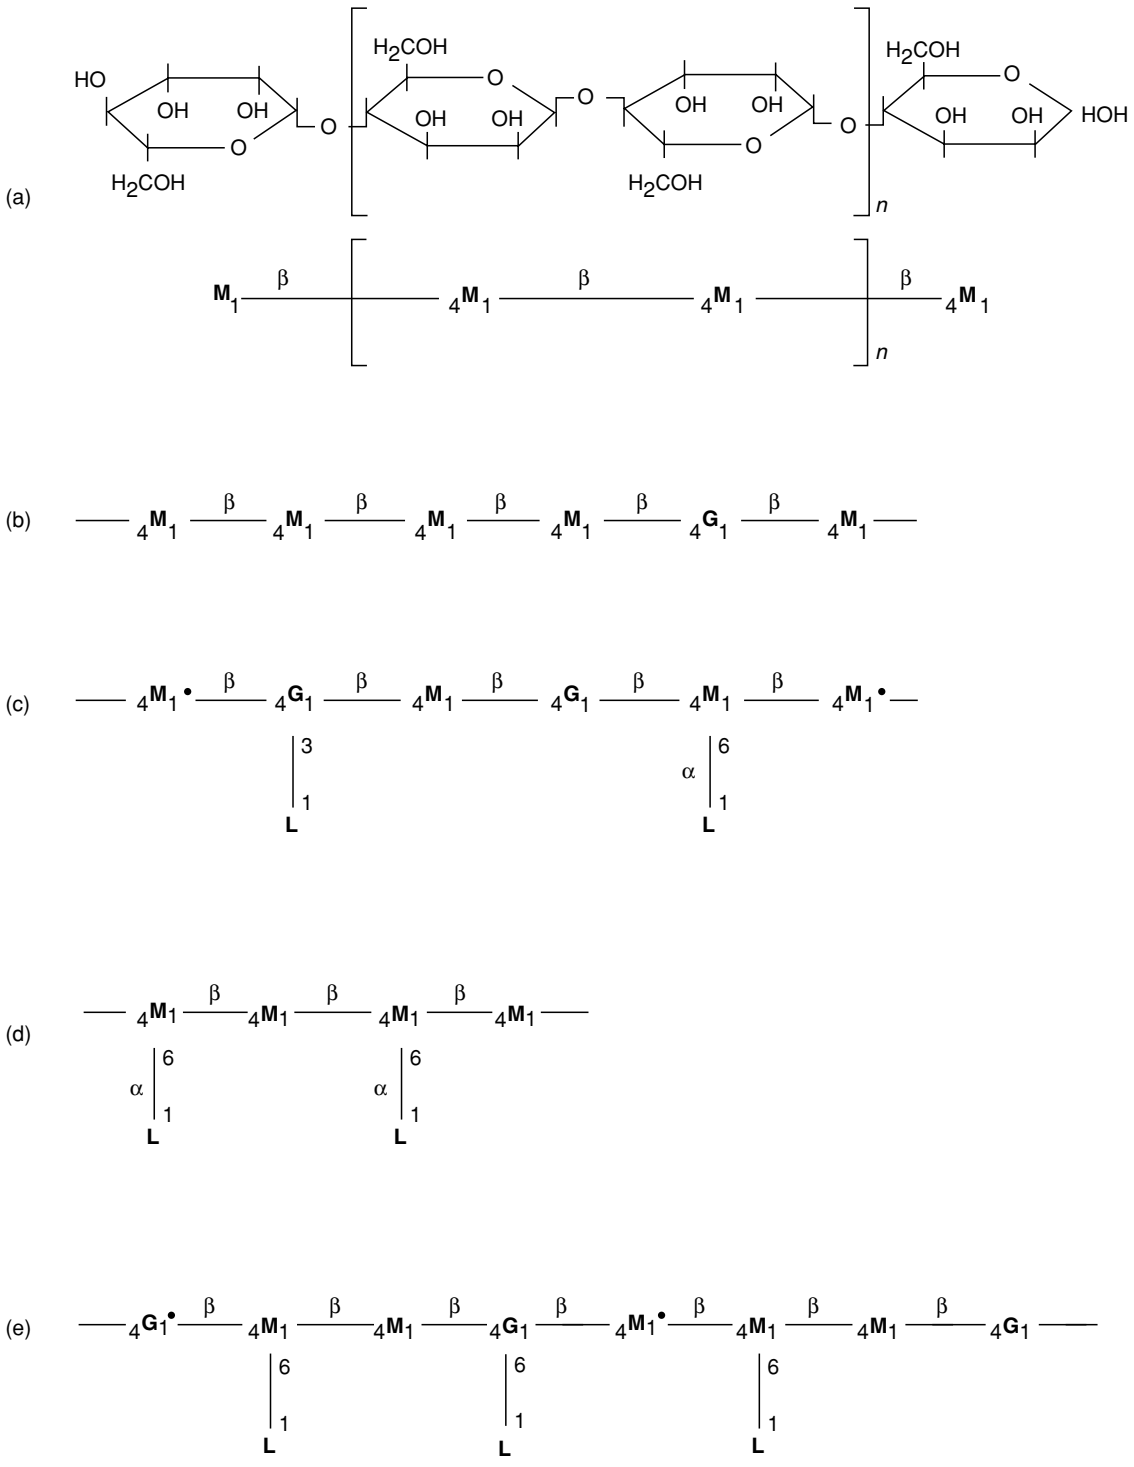

Figure 3 Mannan structures: (a) ivory nut mannan; (b) hardwood glucomannan; (c) softwood glucomannan; (d) guaran; (e) western hemlock. Reproduced from Hemicelluloses, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

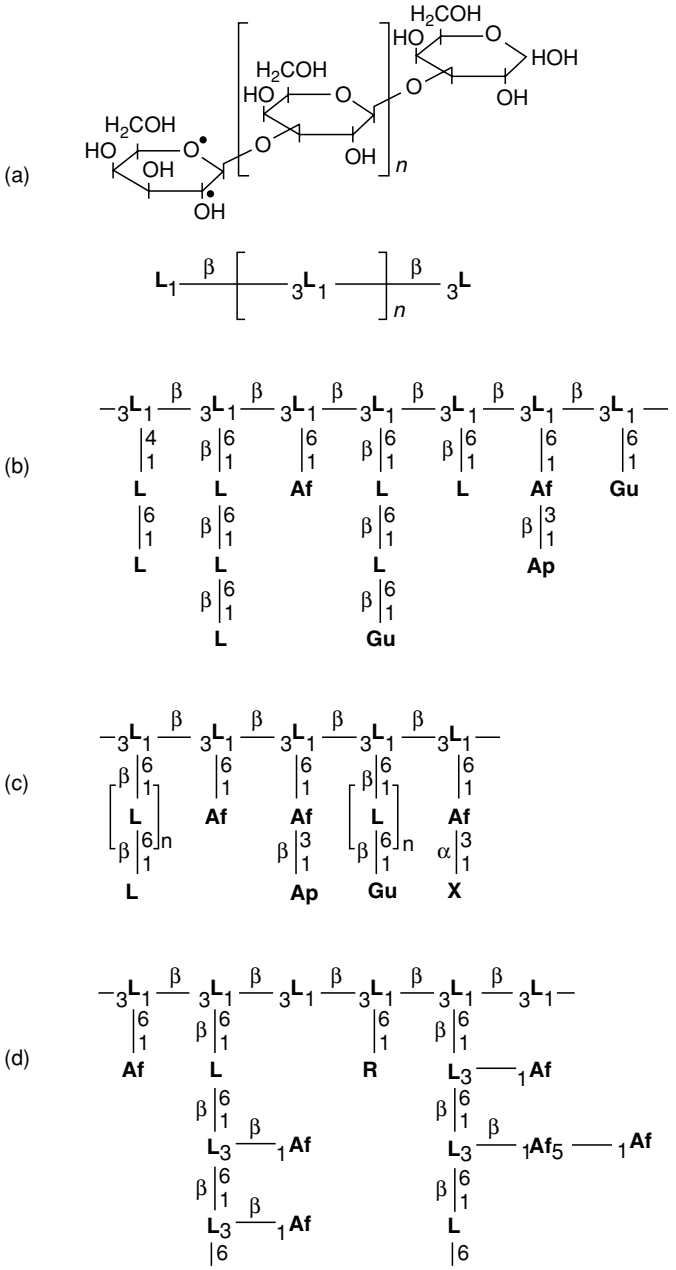

Figure 4 Galactan structures: (a) galactan backbone; (b) larch; (c) maritime pine; (d) tobacco. Reproduced from Hemicelluloses, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

ivory nuts.) Isolated 4-*O*-methylglucuronoxylan is crystalline with a repeating length of 1.48 nm. Adjacent xyloses are rotated 120° with respect to their neighbors in a left-handed helix.

Chemical

Only a few hemicelluloses are water-soluble, such as galactan (from larch) and galactomannan (from guar gum). Most hemicelluloses are soluble in dilute ($10 \pm 8\%$) sodium hydroxide, a property used to define hemicellulose. Alkaline extraction deacetylates hemicellulose, which can be avoided by using dimethyl sulphoxide. The glucomannan *cis*-hydroxyl groups (C2 and C3) impede alkaline solubility, so sodium borate is sometimes added to improve dissolution. A fraction of ivory nut mannan (mannan B) forms microfibrils similar to cellulose. It is insoluble in alkali but, like cellulose, it is soluble in cuprammonium hydroxide solutions.

Dilute acid readily hydrolyzes hemicellulose. The xylose released from xylan degrades to furfural, which further degrades to resins if the hydrolysis conditions are severe.

Alkaline degradation occurs from the polymer 'reducing end', i.e., the end with the free (or unlinked) C1 hydroxyl group. In xylan, successive terminal xyloses 'peel off' and degrade to the saccharinic acid, 2-hydroxymethyl-2,4-dihydroxybutyric acid. The reaction proceeds more readily in calcium hydroxide than sodium hydroxide. This reaction occurs slowly at the usual cold extraction temperatures. At higher temperatures, 4-*O*-methylglucuronic acid loses both its methyl and uronic acid functional groups. Alkaline degradation of hemicellulose can be limited by prereducing with borohydride.

Hemicellulose is much more resistant to oxidation than lignin – a fact exploited in its isolation from natural materials as 'holocellulose.' However, slight changes do occur. Preparing holocellulose using chlorous acid (acidified sodium chlorite) causes depolymerization, oxidation of 2,3-hydroxyl groups, and oxidization of reducing ends to aldonic acids.

Occurrence

A detailed list of the hemicellulose content in various foods and agricultural products is presented in the **Cellulose** article.

Table 2 lists the sugar distribution in various plants determined by acid hydrolyzing the polysaccharides and chromatographically measuring the resulting sugars. Most of the glucose is derived from cellulose, although some comes from hemicellulose mannans. The softwoods have a much higher mannose content because much of their hemicellulose contains mannans rather than xylans. The hemicellulose composition of hardwoods and agricultural residues is similar.

Uses

Furfural can be made by heating xylan in the presence of 12% hydrochloric or sulfuric acid. Oat hulls and corn cobs are traditional sources. Furfural may be used as a solvent in petroleum refining, in manufacturing furfural–phenol plastics (Durite), as a solvent for cellulose nitrate and cellulose acetate, in the manufacture of insecticides, and as a nylon precursor. (*See* **Oats**.)

Xylitol is a sugar alcohol formed by reducing xylose. It is as sweet as sucrose, but is not cariogenic. Its endothermic heat of solution elicits a cool sensation to the mouth, so it has been incorporated into chewing gum. Because it is completely metabolized, it is not a low-calorie sweetener. It has no insulin requirement and has been used for intravenous infusion. (*See* **Sugar Alcohols**.)

Xylose is used as a media ingredient to produce xylose/glucose isomerase which is used in the production of high-fructose corn syrups.

Carboxymethylxylan has been prepared with properties similar to carboxymethylcellulose. It has potential uses in detergents, pigment dispersants, or paper coatings. Other hemicellulose derivatives, analogous to cellulose derivatives, include acetates, butyrates, higher-fatty-acid esters, benzoates, and xanthates. The acetates may be used to form films similar to cellophane.

Bread freshness can be improved up to three times by adding hemicellulose to dough. It also improves water-binding capacity, mixing quality, mixing energy efficiency, and loaf volume. (*See* **Bread**: Chemistry of Baking.)

Dietary fiber contains hemicellulose. Approximately 40–60% is digested by microbes in human large intestines. (*See* **Dietary Fiber**: Properties and Sources.)

Hemicellulose Isolation

Holocellulose is prepared by defatting the fiber with hot azetropic ethanol/benzene and delignifying with hot (70–75 °C) chlorous acid ($HClO_2$). Alternatively, it may be treated with chlorine gas and alcohol pyridine, or chlorine gas and 95% alcohol containing 3% monoethanolamine. If the sample contains a starch, it must be heated in water to gelatinize the starch, with subsequent hydrolysis using α-amylase. After washing, the remaining material (holocellulose) contains cellulose and hemicellulose.

Hemicellulose is removed from holocellulose by extracting with alkali (2–18% sodium hydroxide, although 10% is common). Neutralization of the extract precipitates 'hemicellulose A,' which is composed of linear (or nearly linear), high DP hemicellulose without acidic carboxyl groups. 'Hemicellulose B' remains in solution and tends to be more branched with lower DP and more acidic carboxyl groups. Hemicellulose B can be fractionated by gradually adding ethanol and collecting the various components as they precipitate.

An alternate approach to fractionating hemicellulose from holocellulose is to exploit differences in alkali solubilities. For example, 24% potassium

hydroxide extracts holocellulose xylan and galactoglucomannan from both hardwoods and softwoods, but does not extract glucomannan from the residue. The dissolved galactoglucomannan may be precipitated from the extract by adding barium hydroxide. The insoluble glucomannan remaining in the residue can be extracted using 17·5% sodium hydroxide/4% borate with subsequent precipitation by barium hydroxide addition.

Acidic hemicelluloses can be precipitated and isolated from neutral hemicelluloses by using quaternary ammonium salts (e.g., cetyltrimethylammonium bromide) under neutral or mildly alkaline conditions. Then, the neutral hemicelluloses can be precipitated from solution by increasing the alkalinity in the presence of the quaternary ammonium salts.

Hemicellulose Analysis

Gravimetric Method

The **Cellulose** article describes the Van Soest method for preparing acid detergent fiber (ADF), which contains cellulose, lignin, and insoluble ash (mainly silica). This article describes the procedure for making neutral detergent fiber (NDF), which contains hemicellulose, cellulose, lignin, and insoluble ash. The difference between NDF and ADF is a measure of hemicellulose content.

NDF is prepared by placing in a beaker about 1 g of sample (ground to pass a 30-mesh screen), 100 ml of neutral-detergent solution (30 g l^{-1} of sodium lauryl sulfate 18.61 g l^{-1} of disodium ethylenediaminetetraacetatic acid (EDTA) dihydrate, 6.81 g l^{-1} of sodium borate decahydrate, 4.56 g l^{-1} of anhydrous disodium hydrogen phosphate, 10 ml l^{-1} of 2-ethoxyethanol), 2 ml of decahydronaphthalene and 0.5 g of sodium sulfite. The mixture is boiled for 60 min while refluxing to keep the liquid volume constant and then filtered on a previously tared Gooch crucible. After being rinsed twice with boiling water and twice with acetone, the sample is dried overnight at 100 °C and weighed. (If the sample contains starch, it is incubated with α-amylase overnight before washing with water.)

Colorimetric Method

The Technical Association of the Pulp and Paper Institute (TAPPI) Method T 223 os-78 describes a colorimetric method for measuring pentosans. Because pentose sugars are dominant in most hemicelluloses (except for softwood), this procedure indicates hemicellulose content. The sample is boiled in 3.85 mol l^{-1} hydrochloric acid, causing the pentoses to degrade to furfural which is collected in the distillate. The collected furfural is reacted with orcinol which forms a colored compound measured spectrophotometrically. Because of the complexity of the apparatus, only a few samples can be run daily. Holtzapple describes a colorimetric pentosan assay which is performed in a sealed test tube, which speeds up the assay. (*See* **Spectroscopy**: Visible Spectroscopy and Colorimetry.)

Chromatographic Method

TAPPI Method T 249 pm-75 describes a chromatographic technique for measuring mannan, arabinan, xylan, galactan, and glucan. (In starch-free materials, cellulose is the dominant glucan, although some glucan is also present in hemicellulose.) The sample is hydrolyzed using sulfuric acid in a two-step procedure. Some of the hydrolysate is neutralized and the sugars are reduced to alditols (i.e., sugar alcohols) using sodium borohydride. The alditols are acetylated with acetic anhydride and sulfuric acid. The alditol acetates are precipitated in ice water and extracted with methylene chloride for injection into a gas chromatograph. Because sugars degrade under the acid hydrolysis conditions, internal standards of the free sugars are run under identical treatment conditions. This method is extremely time-consuming and is used only when complete characterization of polysaccharides is required. (*See* **Chromatography**: Gas Chromatography.)

Herbs and Their Uses

K P Svoboda and T Svoboda, The Scottish Agricultural College, Auchincruive, Ayr, UK

Background

The plant kingdom produces a wide range of valuable products. These include numerous aromatic, dye, spice, medicinal, and other useful substances. Such products have contributed to the quality of human life for thousands of years. From ancient texts and scriptures, it is known that some plants have long served as the principal components of seasonings, flavorings, cosmetics, dyes, and medicines.

Herbs generally include plants whose leaves, stems, flowering tops, and roots are used fresh, dried, or frozen in the seasoning of foods, in the beverage industry, in perfumery and cosmetic products, in the pharmaceutical industry, and for numerous other purposes, including ornamental gardening, pot-pourri, moth and general insect deterrents and in dyeing and fabric cleaning. There is no standard definition of the term 'culinary herbs,' and the distinction between culinary herbs and spices is imprecise. The American Spice Association, the most important body in the spice trade, uses the term 'spices' in such a way as to include both herbs and aromatic seeds. Scientific information on herbs, plant drugs, their active constituents, and their therapeutic and health uses is being published worldwide at an unprecedented rate, in many different journals and in various languages. Scientific and regulatory information is systematically presented in various monographs. Recommendations for new crops which can be used as herbs are given for specialty crop growers. In addition, there is growing interest in organically produced herbs, and such herbs have to conform to organic certification standards. Many herbs are now also being used as dietary supplements and ingredients in foods.

Sources of Herbs

Herb material is obtained from both wild and cultivated plants. In most cases, the demand for culinary herbs is such that collection of material from the wild is insufficient to satisfy market requirements. Cultivation of herbs offers numerous advantages, including:

- the development of high-yielding cultivars, which also leads to a product with more consistent properties than would be obtained from plants growing wild;
- the use of mechanization;
- the control of insects and diseases;
- planned harvesting and transport; and
- efficient drying and storage.

Herb production can be undertaken using either labor-intensive techniques, as for example in north Africa and India, or capital-intensive harvesting and processing methods as in the USA, France, and other Western countries.

The quality of herbs is dependent on several factors, including plant variety, growing conditions, cultural practices, drying and processing methods, storage, and packing. Cleanliness, color, flavor, and aroma are the most important considerations in the selection and utilization of herbs. National quality standards have not yet been established for culinary herbs, but as the market grows, the need for specific quality standards is being recognized. The description and chemical composition of a number of herbs are defined in the *British Pharmacopoeia, British Pharmaceutical Codex, British Herbal Pharmacopoeia, New Cyclopedia of Botanical Drugs and Preparations, British Herbal Compendium, ESCOP Monographs in Herbs or Plant Drugs, WHO Herbal Monographs, and German Commission E Monographs on Herbs*.

Production and Consumption

Accurate data on the area of individual herbs grown and their production in any country are very difficult to obtain. An unofficial estimate of total UK herb production in 1999 was about 3000 ha. The UK growing season is usually from April to November, depending on the herb and the weather in any particular year. Outside the season, fresh herbs are imported largely from Mediterranean countries, especially Israel. A significant proportion of marketed herbs are cultivated on smallholdings or collected from the wild, and do not enter the trade statistics. Most sources agree that the total national consumption of herbs is increasing at around 10% per annum. Her Majesty's Customs and the Ministry for Agriculture are the most important organizations for reporting on the trade and production of herbs. Of the various culinary herbs, they report separately only on thyme and parsley, with other herbs being generally categorised under 'other species' or 'dried vegetables'.

Table 1 shows the estimated annual consumption of the major culinary herbs and volatile oils in the UK. These statistics must be regarded as providing orders of magnitude rather than precise measures. Since commercial herb growing is a relatively small part of horticulture, insufficient research has been carried out to permit the use of more than a narrow range of pesticides, most of them with limited off-label use, which causes some difficulty in growing some crops on a large scale. Traditionally, herbs are hand-harvested, but there are now several purpose-built harvesting machines available, and many people have adapted conventional cereal- and grass-cutting and harvesting equipment for use on herbs, the aim being to cut and immediately lift the crop without bruising. The trade estimates that about 50% of the plants traded are used for the food industry, 25% in cosmetics, 20% for medicinal and 5% for other uses such as insecticides.

Herbs and Volatile Oils

There are 31 plant families made up of 93 species representing the major flavor- and spice-producing taxa. Approximately 10% of the world's major economic plants are sources of flavorings. These may be classified into six main groups, according to their principal flavor components (Table 2).

The volatile (essential) oils consist of a complex mixture of chemical compounds, which combine to give the oil distinctive characteristics. The differences in aroma among plant types result from differences in the volatility and quantity of chemicals in the volatile oil. The volatile oils are products of the plant's metabolic processes and are particularly subject to seasonal and climatic changes, and to the care taken in general husbandry, harvesting, and storage. Volatile oils, oleoresins and oleo-gum resins are produced in various types of secretory tissues. The type of

Table 1 Estimated UK production and imports of selected culinary herbs

1	Cineole or eucalyptol	Bay (*Laurus nobilis*)
		Spanish sage (*Salvia lavandulifolia*)
		Rosemary (*Rosmarinus officinalis*)
2	Eugenol	West Indian bay (*Pimenta racemosa*)
3	Thymol or carvacrol	Origanum (*Origanum vulgare*)
		Wild marjoram (*Origanum marjoranum*)
		Summer savory (*Satureja hortensis*)
		Mexican oregano (*Lippia graveolens*)
		Thyme (*Thymus* spp.)
		Basil (*Ocimum basilicum*)
4	Linalool, methyl chavicol, or terpineol	Sweet marjoram (*Marjorana hortensis*)
		Parsley (*Carum petroselinum*)
		English sage (*Salvia officinalis*)
		French Tarragon (*Artemisia dracunculus*)
5	Thujone	Dalmatian sage (*Salvia officinalis*)
6	Menthol, menthone, or carvone	Mints (*Mentha* spp.)

secretory structure is an important character of a plant family and includes various forms, such as oil and oleoresin cells (ginger, pepper, vanilla), secretory glands (bay, clove, eucalyptus), secretory ducts (tarragon, anise, angelica) and glandular trichomes (mint, sage, lavender, rosemary, chamomile) (Figures 1–4). These structures are associated with many different parts of the plant, such as vascular bundles in the leaves, stems and roots, fruit wall, bark, parenchyma, or epidermal tissue. Leafy herbs are normally used in a well-broken state. Following drying and milling, the finer the powder, the more readily available is the flavor.

Three major types of industrial distillation are used to obtain the volatile oil fraction: water, water and steam, and steam. In water distillation, the plant material is placed in a distilling container with water and heated until the volatile compounds have vaporized. The gaseous mixture of oils and water is piped to a condenser for cooling: the oil, being lighter than water, floats to the top and can be collected. Volatile oils used by the perfumery industry are extracted by the use of organic solvents. Although more expensive than distillation, it avoids elevated temperatures, which may cause the loss of highly volatile components and the denaturation of other chemicals in the oil. The solvent system uses petroleum ether or benzene. In a technique known as enfleurage, the plant material is affixed to a thin layer of odorless fat spread on a glass sheet. The volatile oils are absorbed into the fat and can then be extracted with alcohol.

A more recent development in extraction technology, still at the research and development stage, is the use of supercritical carbon dioxide. Liquid carbon dioxide is used at a range of temperatures and elevated pressure. Under these conditions, carbon dioxide behaves like a solvent and removes different classes of compounds from the plant material depending on the running conditions in force. Moderate pressure (< 50 bar) releases volatile oils from plant material, while at a greater pressure (> 200 bar), waxes and resins predominate in the resultant extracts. By careful manipulation of the operational parameters, it is possible to sequentially remove these different groups of compounds from the raw material. It is also possible to deterpinate certain oils, making them less pungent in taste.

Figure 1 (see color plate 89) Chamomile field in Norfolk.

Volatile oils have long been used in industry in place of the dried herbs. Their advantages over the

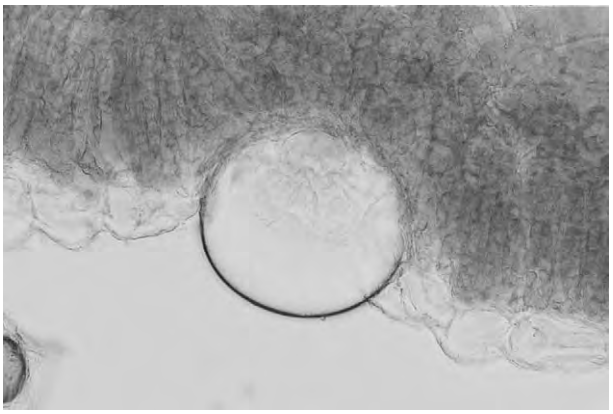

Figure 2 (see color plate 90) Volatile oil gland on the surface of a Greek oregano (*Origanum heracleoticum*) leaf.

plant material include a generally uniform flavor quality and their sterility – they are free from all extraneous contaminants. Oils can be readily incorporated into liquid concentrates and emulsions, the flavor character and strength of which can be standardized. They can be readily mixed with fats and oils which are commonly present in food products and are easily dispersed throughout the mix. Being concentrated, these oils save both storage space and handling costs. They are normally stable and show only a slight deterioration over long periods provided that they are correctly stored.

Cleanliness and Preservation

Spice and herb plants tend to be heavily contaminated with microorganisms and molds, many in spore form. The general negligent and unhygenic way in which they are handled from the time of harvesting until they are eventually presented for sale results in the presence of such contaminants such as rodent hairs and droppings, insect parts, eggs and larvae, hessian sacking fibers, soil, and stones. Cleanliness is regarded as being important by the producer, processor, and consumer, and has to be achieved without detriment to the product itself. In the UK, following the banning of ethylene oxide gas at the end of 1990 as the principle cleaning agent for dried herbs, firms have devised several different methods of reducing the microbial load. In 1991, a licence was granted for including ionizing radiation treatment of dried herbs and spices to a maximum load of 10 kGy. Pesticide contamination and heavy metal content are becoming important issues on the quality market. Some European countries permit irradiation but the laws in the US are different.

Fresh herbs are supplied prewashed, using a sterilized agent such as dilute sodium hypochlorite; frozen herbs are similarly treated, chopped, and then ideally quick-frozen using liquid nitrogen. Freeze-dried herbs go a stage beyond frozen by being subsequently treated at a low temperature in a vacuum, which drives moisture from the herbs without any browning or shrinking, a feature which may occur with conventionally dried herbs. The final product may be stored indefinitely without refrigeration, although packaging requirements are stringent. The process is costly

Figure 3 (see color plate 91) *Agastache* species (Korean mint) at the Auchincruive herb garden.

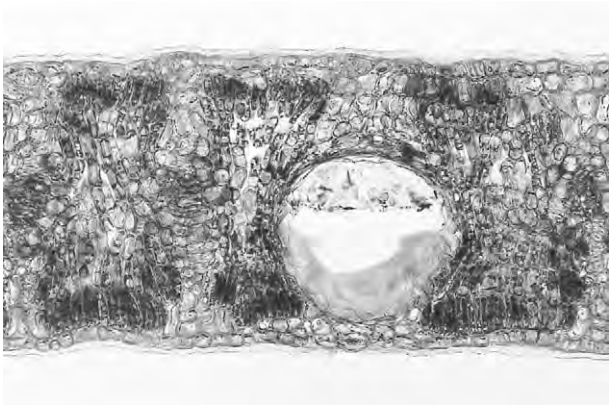

Figure 4 (see color plate 92) Cross-section through a eucalyptus leaf, showing the oil cavity.

and is presently used in commerce to preserve highly degradable substances, such as chopped chives, for which other satisfactory methods of drying are inappropriate. Freeze-drying seems to be better for volatile substances or vitamins but offers no apparent advantage or preservation of certain other substances, such as alkaloids, and may promote the oxidation of fatty acids, especially linoleic and linolenic acid.

Food Industry

Commercially Important Herbs

Commercially important herbs on the UK market include basil, celery, chervil, chives, coriander, dill, marjoram, mint, oregano, parsley, rosemary, sage, savory, tarragon, and thyme. However, many other species are used in cooking, and their range is expanding every year. Mixed herbs usually contain three or four herbs selected from thyme, savory, sage, marjoram, basil, parsley, and rosemary.

Uses of Herbs

Herbs are being incorporated into a variety of different food products: butters, cheeses, biscuits, pastries, popcorn, sausages, salami, meats and stews, fish dishes, soups and sauces, mustards and vinegars, chocolates, and sweets. Herbs can be used fresh, dried, broken, or ground. Alternatively, volatile oils or extracts are readily available on the market. A number of companies have now introduced dehydrated or frozen herbs. Frozen flakes are free-flowing, can be used without any previous defrosting, and have a fresh aroma that is stable for 18 months.

Packaging and Storage

Dried herbs are packaged for the retail trade in a wide variety of small- to medium-sized packs, including glass jars, drums, tubs, cellophane, polythenes, and cartons. Freeze-dried herbs tend to be packed in polyethylene terephthalate. If stored in tubs, the herbs must be free of oxygen and water vapor in airtight, opaque containers and, in the case of freeze-dried material, filled with a dry inert gas. Fresh herbs are usually packed in polystyrene trays with a clear overwrap or in transparent punnets with lids. The wholesale market also accepts polythene bags, open crates, and cartons.

Fresh herbs need to be transported and stored chilled, between 2 and 5 °C, or slightly warmer for more sensitive herbs such as basil. Frozen herbs need to be stored and shipped at temperatures of at least − 18 °C, giving a shelf-life of 12 months, which can be extended to 2 years at − 25 °C. Dried and freeze-dried herbs are stored and transported at ambient temperature, preferably out of direct light.

Pharmaceutical Industry

Although synthetic and semisynthetic organic substances have achieved a substantial share in pharmaceutical applications, plant-derived substances still remain a vital ingredient in modern medicine. As estimated 25% of prescriptions contain one or more active constituents obtained from higher plants. The herbal ingredients are obtained from some 550 different herbs. It has been estimated that about 7000 t of herbs are extracted annually for the ingredients of UK medicines. Some particularly potent plants, such as *Areca catechu, Aconitum napellus, Atropa belladonna*, and others, have been brought under strict pharmaceutical control. Many plant products available to the public are capable of causing serious harm. These include products which can cause allergenic reactions in previously sensitized individuals, preparations which induce gastroenteritis, and products with cardiovascular involvements. Also, many can interfere with anticoagulant treatment due to the presence of substances such as coumarins. A further problem arises from the misidentification of plant products and from contamination of beneficial plant material with toxic species. If the public is to be protected from potentially hazardous plant products available for sale, herbal suppliers must be monitored carefully. Chemical diversity in natural products is a rich source of new pharmaceuticals and other economically important chemicals. A number of new bioassays have been designed to facilitate the isolation of natural products from plants, rapid screening of several thousand samples in one day, and complicated synthesis of complex products based on a natural template. The development of natural product chemistry and the discovery of new natural products from indigenous medicinal plants are becoming increasingly prominent features due to their medicinal, food, and other industrial values.

Product Development and the Future

The herb market has experienced significant growth in recent years, and a considerable amount of product development has taken place, with much input from supermarkets. Despite the effects of economic recession in the early 1990s, this trend is set to continue under the influence of travel abroad, TV cookery programs, and ethnic restaurants. New methods of production and packaging continue to evolve,

offering greater quality and convenience to consumer, caterer, and manufacturer alike. Current developments include new harvesting techniques, improved washing chemicals, and new forms of presentation, such as pelletized frozen herbs. These factors, combined with the demand for more natural flavorings and innovative ideas from all areas of the industry, should ensure a steady growth in the herb market throughout the next decade and beyond.

Research and Development

Research into the biological activity of plant volatile oils has been undertaken for several decades. However, the most interesting results had to await the development of sophisticated analytical instruments such as gas chromatography linked to mass spectroscopy, high-performance liquid chromatography, Fourier-transformed infrared spectroscopy, and Fourier-transformed nuclear magnetic resonance. With such instrumentation available, it is now possible to identify the majority of the chemical constituents in the oils and thus allocate bioactivity to specific compounds. The possibility of synergistic effects should not be overlooked, although the evaluation of such phenomena becomes problematic when many oils have over 100 different constituents. The marked antibacterial and antifungal activities in certain volatile oils provide the food and related industries with a source of natural preservatives. There is some reluctance on the part of the industry to exploit such antimicrobials on a larger scale, owing to the problem of balancing effective antimicrobial activity without rendering food unacceptable because of an overwhelming taste of plant extract. Deterpenation using supercritical carbon dioxide may help to alleviate this aspect.

A number of plant secondary metabolites possess antioxidant compounds in the volatile oil and other fractions. There is now evidence that plant antioxidants taken as diet supplements have a marked beneficial effect upon the lipid metabolism in animal model systems. The long-chained polyunsaturated fatty acids (arachidonic and docosohexaeonic) are well protected by such antioxidants, leading to the reversal of the normal decline in concentration during the ageing process. Many degenerative disease conditions associated with human aging, such as senile dementia and acute memory loss, can be described in terms of lipid inadequacies. Hence, any natural antioxidants capable of slowing down the disease process are of real significance in human health and the quality of life.

Recently, it has become clear that many plant metabolites have potential beneficial effects directly relevant to human diet and health. Some may exert a protective role which reflects similar protective actions like antioxidants, some can prevent cells from mutation (blocking and suppressing anticarcinogens), and certain herbs contain chemicals (isocoumarins, flavonoids, hop acids, and terpenes) which are structural analogs of the natural estrogens. These compounds may interact with the estrogen receptors in human cells. Herbs, by their nature and quality, have the potential to influence both short-term and long-term human health and well-being. An increased level of certain protective factors may be desirable, and both classical plant breeding and biotechnology can provide the improved plant material for human consumption.

Herbs of the Compositae

S G Deans and E J M Simpson, Aromatic and Medicinal Plant Group, South Ayrshire, Scotland, UK

Introduction to the Group

The Compositae represents the largest family of flowering plants, with over 900 genera and 14 000 species comprising examples of various ecological types and life forms, such as trees, shrubs, perennial and annual herbs, aquatic, alpine and desert plants, climbers, succulent, and spiny shrubs. Many species are cultivated as vegetables (lettuce, endive, artichoke, salsify, sunflower) and several genera as culinary and medicinal plants (*Achillea, Aster, Calendula, Helenium, Rudbeckia, Tagetes*).

Special Morphological and Anatomical Features

Flowers from small florets are aggregated into heads (capitula) simulating a single large flower and surrounded by a calyx-like involucre of one or more rows of bracts. These vary greatly in number and arrangement. Florets can be all similar (head homogamous) or with central and marginal florets differing (head heterogamous). Pollination is entomophilus, rarely anemophilous; some genera (*Taraxacum, Hieracium*) contain apomictic species.

The family exhibits several specific features, such as secretory resin canals (*Achillea, Ambrosia, Anthemis, Arnica, Artemisia, Centaurea, Cnicus, Echinacea, Ehlinthus, Eupatorium, Inula, Matricaria, Parthenium, Petasites, Pyrethrum, Senecio, Solidago, Tagetes, Tanacetum*), secretory cavities (*Artemisia, Inula, Tagetes*), lactiferous canals, cells and vessels (*Arctium, Carlina, Silybum*), different types of glandular (*Eupatorium, Haplopappus, Helianthus, Olearia*) and nonglandular hairs, and anomalous secondary thickening (*Artemisia, Helianthus, Taraxacum*).

The volatile oil found in the leaves of *Artemisia dracunculus* is produced partly in schizogenic volatile oil canals and partly in characteristic glandular hairs. Differences have been recorded between the oil found in the canals and the oil produced by the glandular hairs. Primary volatile oils extend from the stem into the root system where they are located between the endodermis and the cortex. Excretion canals are also found in the roots, but do not extend to the stem (**Figure 1**).

A blue volatile oil is extracted from the flowers of German chamomile (*Matricaria chamomilla* L.) produced in secretory glandules and canals localized

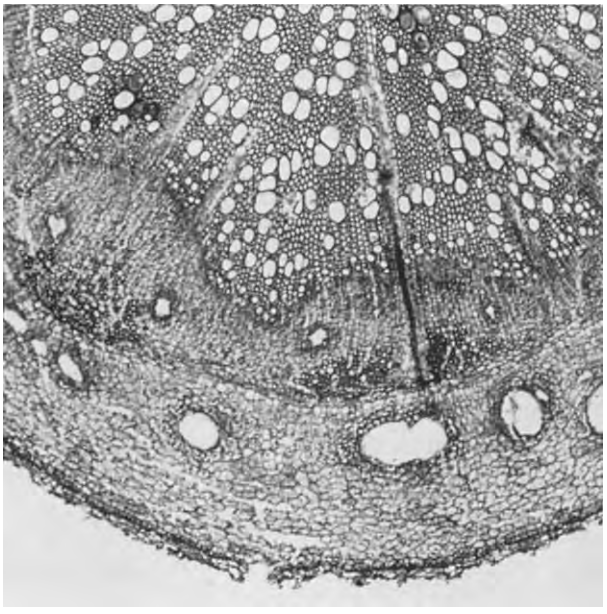

Figure 1 (see color plate 93) Volatile oil canals in root of *Artemisia absinthium* (wormwood). Bright field × 40. Reproduced from Herbs: Herbs of the Compositae, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

mainly in the anthodia. The content of the oil varies considerably during the development of the plant and the flowering of the anthodia. (*See* **Essential Oils: Properties and Uses.**)

Harvesting and Handling Procedures

Harvesting crops at the correct stage of maturity is essential to achieve a product that will be of top quality and meet the buyers' standards. Harvesting of herbs is still carried out by hand in many cases. The development of mechanized harvesting systems has proved to be problematical owing to the wide variety of plant parts to be harvested (roots, rhizomes, stems, leaves, flowers, seeds, and pods) combined with a relatively small crop acreage. Machinery currently in use has either been adapted from equipment constructed to harvest other crops(usually forage, grain, or vegetable products) or specifically designed and constructed for a few herbs or even one specific herb. The construction of new harvesting machinery can only be considered when the market value of the crop or related product is high and the acreage is relatively large, or when large commercial companies finance such equipment development as in chamomile production in Germany.

Drying facilities are essential and may vary from an unused room to an elaborate drying shed. Low humidity is important and using a dehumidifier allows better control over the drying process. The temperature of the drying is critical since many volatile compounds can be lost at elevated temperatures (Table 1).

Use in the Food Industry

Many members of the Compositae are cultivated as edible plants, vegetables, herbs, and spices (Table 2). The edible tubers of the Jerusalem artichoke consist of the parenchyma of the medullary rays and pith, together with the xylem. Fleshy parts of the inflorescence of the globe artichoke are eaten. The roots of scorzonera and salsify are used as vegetable, while dried and roasted roots of dandelion and chicory are used as coffee substitutes and in medicine.

Table 1 Changes in volatile oil yield (%)[a] with rising temperature

Plant	*Temperature (°C)*						
	40	*50*	*60*	*70*	*80*	*90*	*100*
Basil	1.0	0.7	0.7	0.7	0.3	0.3	0.1

Thyme	1.0	1.0	1.0	0.3	0.3	0.2	< 0.01

[a]Percentage of volatile oils expressed as value per gram of dry matter of plant material.

Research and Development

An increasing demand from the food, pharmaceutical, and cosmetic industries calls for the development of new varieties with high levels of active constituents, consistent quality, and safe application. The anatomy and the physiology of each plant have to be investigated in order to elucidate the plant's requirements and adaptation to cultivation. Several species are currently being investigated for their bioactivity and a number of representative genera will be discussed. (*See* **Biotechnology in Food Production.**)

Chamomile

Roman chamomile (*Chamaemelum nobile* (L.) All.) and German chamomile (*Matricaria recutita* L.) are two different species of plant commonly called chamomile. Roman chamomile, formerly classified as *Anthemis nobilis* L., is a creeping, herbaceous perennial native to western Europe and North Africa. German chamomile is an erect-growing annual, native to Europe and western Asia. The volatile oil of Roman chamomile consists mainly of chamazulene, angelic acid, tiglic acid and several sesquiterpene lactones. German chamomile contains chamazulene, α-bisabol, α-bisabol oxides A and B, spathulenol and farnesene. Extracts from both plant species are reported to have antiseptic, antibacterial, antifungal, and antitumor activities.

The breeding of chamomile has been targeted towards increased content of two sequiterpenes: chamazulene and α- and β-bisabolol. The diploid and tetraploid varieties have been introduced on the market in Germany and the former Czech Republic, with high and stable contents of these sesquiterpenes. Other important flavanoid secondary metabolites, namely apigenins, are now being investigated in detail. (*See* **Colorants (Colourants): Properties and Determination of Natural Pigments.**)

Achillea millefolium

Yarrow is a hardy perennial plant, native to Europe and Asia. The chemical constituents include a volatile oil comprised of azulene, caryophyllene, thujone, eucalyptol, α- and β-pinene and borneol, as well as lactones, tannins, and alkaloids. Yarrow extracts

Table 2 Uses of herbs of the family Compositae

Plant species	*Medicinal*	*Food industry uses*	*Colors*	*Others*
Achillea millefolium	✓	Salads, substitute in brewing or tobacco		Cosmetics
Antennaria dioica	✓			
Arctium lappa	✓	Salads, candied stalks, liqueurs

Taraxacum officinale	✓	Salads, wine, beer, coffee substitute		Insect repellent
Tragopogon porrifolius		Salads, cooked vegetables		
Tussilago farfara	✓	Salads, wine		Herbal tobacco

are generally recognized as safe in beverages, but the finished product must be thujone-free. Extracts of yarrow have also been shown to be effective as mosquito repellents. Contact with yarrow has been reported to cause dermatitis. Field plots and experiments have been established with the objective of extracting chamazulene: 24 t of fresh matter per ha has been harvested at full bloom, yielding 0.3% volatile oil and 4.43 kg of chamazulene per hectare.

Artemisia dracunculus, A. afra, and *A. absinthium*

Artemisia dracunculus L., French tarragon or estragon, is a hardy perennial which grows wild throughout central Europe and Asia, but is also widely cultivated owing to the popularity of tarragon-vinegar-based sauces and dressings. The volatile oil of tarragon, produced in oil canals and glandular hairs, is pale yellow to amber in color, with a delicate spicy odor. The oil consists mainly of methyl chavicol,

typically 65%, as well as β-pinene, camphene, ocimene, limonene, menthol, and sabinene. Extracts of tarragon are reported to have antiseptic, stimulant, antibacterial, and antifungal activities. A mixture of flavones and isocoumarins has also been found in the shoots. French tarragon rarely sets viable seeds and must be propagated from cuttings or by root division. Seed is available from Russian tarragon (*Artemisia dracunculoides*) which is markedly inferior since it lacks the distinct odor and taste required for culinary purposes. Recent micropropagation studies on French tarragon have shown that tissue culture techniques could provide an efficient means of propagation. Optimal growth was achieved using sterile shoot tip explants, placed on mineral salts medium supplemented with sucrose and the phytohormones, benzyl amino purine (BAP, a shoot-promoting phytohormone) and naphthalene acetic acid (NAA, a root-promoting phytohormone). Rooting was maximized by dipping new shoots in NAA or indole-3-butyric acid (IBA, a root-promoting phytohormone).

Artemisia afra Jacq, African wormwood, is indigenous to the mountainous regions of South Africa. It is a bushy, branched perennial shrub growing up to 1 m and can be propagated from seeds, cuttings, and root pieces. It has a thin brownish bark and green-gray leaves with a marked aromatic scent when crushed. It possesses characteristic paniculate aggregations of pale yellow inflorescences. *A. afra* is one of the most widely used medicinal plants. Traditionally, extracts have been applied to a whole range of disease conditions, such as common cold, diabetes mellitus, bronchial complaints, and stomach disorders. The antibacterial properties of the volatile oil are summarized in Table 3. The leaves are used in a tea or as a leaf poultice, and the vapors from boiling leaves can be inhaled. It has also been used as an insect repellent and anthelmintic agent. The volatile oil contains α-thujone, β-thujone, 1,8-cineole, camphor, and α-pinene.

Artemisia absinthium L., wormwood or absinthe, is an erect-growing perennial native to Europe and naturalized in northeastern North America. It is also cultivated commercially in central and northwestern USA. The volatile oil extracted from this very bitter herb has a strong odor and acrid taste, and contains mainly thujone and thujyl alcohols, as well as myrcene, α-pinene, nerol, limonene, and 1,8-cineole. The oil, which can be poisonous, due to its high thujone content, finds limited use in fragrance compounding and external analgesics. Recently, essential oil distilled from *A. absinthium* collected in the Spanish Pyrenees was found to contain no thujone, which may be of significant interest to the food industry. The bitter principle of wormwood is made up of the glycosides, absinthin and absinthinin. The plant also contains lignans, oligosaccharides, flavonol glycosides, and tannins. Owing to its bitterness, wormwood has few culinary uses, but extracts are used to flavor bitter drinks such as vermouth, absinthe, and tonic water, as well as being used medicinally, chiefly as an anthelmintic. (*See* **Vermouth**.) More recently, extracts of *A. absinthium* have shown antibacterial activity against both Gram-positive and Gram-negative bacteria, but not against yeasts.

Table 3 Bactericidal properties (zone of inhibition in mm) of *Artemisia afra* volatile oil

Organism	*Dilution of* A. afra *volatile oil*			
	1.1	*1.2*	*1.5*	*1.10*
Acaligenes faecalis	9.8	6.0	5.2	5.2
Acinetobacter calcoacetica	17.8	9.4	6.6	5.7
Aeromonas hydrophila	4.0	4.0	4.0	4.0
Bacillus subtilis	7.5	7.0	5.6	5.0
Beneckea natriegens	16.2	10.4	8.1	6.3
Brevibacterium linens	19.0	20.0	6.1	5.3
Brocothrix thermosphacta	13.3	9.4	7.0	6.6
Citrobacter freundii	11.5	9.6	8.8	7.6
Clostridium sporogenes	6.1	4.9	4.0	4.0
Enterobacter aerogenes	8.4	5.4	5.4	5.4
Enterococcus faecalis	9.9	7.0	6.0	5.3
Erwinia carotovora	7.6	4.0	4.0	4.0
Escherichia coli	6.4	6.2	5.8	5.3
Flavobacterium suaveolens	9.9	6.7	6.3	4.6
Klebsiella pneumoniae	15.5	10.1	8.1	7.1
Lactobacillus plantarum	7.6	6.2	6.2	4.8
Leuconostoc cremoris	9.4	8.2	4.0	4.0
Micrococcus luteus	8.6	5.6	4.0	4.0
Moraxella spp.	6.0	5.0	4.5	4.1
Proteus vulgaris	4.0	4.0	4.0	4.0
Pseudomonas aeruginosa	6.4	4.8	4.8	4.0
Salmonella pullorum	5.3	4.5	4.3	4.2
Serratia marcescens	11.0	7.7	5.1	4.6
Staphylococcus aureus	8.3	6.9	5.0	4.2
Yersinia enterocolitica	8.3	6.5	6.0	5.8

Recent studies on wormwood have examined the transformed or 'hairy' roots produced *in vitro* by the infection of sterile explants with the soil bacterium, *Agrobacterium rhizogenes*. Differences were noted in the volatile oil profile of the transformed material cultured in flasks and the normal field-grown roots. Microscopic examination revealed a lack of maturity in the transformed root which may account for these differences (Figure 2 and 3).

Poisonous Plants

The family Compositae includes one of the most important poisonous plants in the UK, ragwort (*Senecio jacobaea*). It is abundant on wasteland, beside roads, and in pastures, where it is a troublesome weed. The poisonous principles are pyrrolizidine alkaloids, many

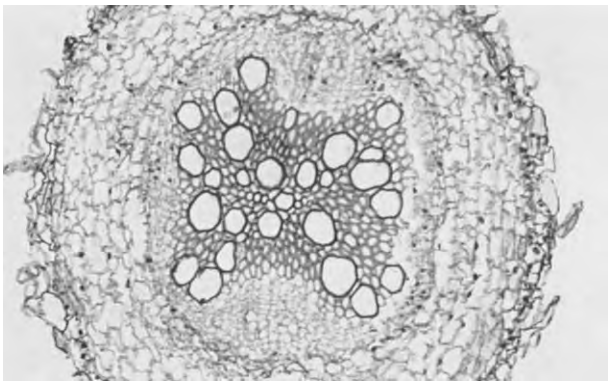

Figure 2 (see color plate 94) Transverse section of *Artemisia absinthium* (wormwood) root showing vascular bundle. × 200. of which have been characterized and named, including senecionine, seneciphylline, jaconine, and jacobine. Poisoning in animals causes disorders of the digestive and nervous systems.

Another group of poisonous substances in the Compositae comprises terpenoid compounds, especially sesquiterpene lactones (present in *Lactua virosa, Artemisia douglasii, Achillea millefolium, Matricaria chamomilla*, and *Cichorium endivia*). These compounds can cause allergic skin reactions. *Arnica montana* and great burdock (*Arctium lappa*) can also cause skin irritation owing to attachment of flower heads by hooked bracts.

Herbs of the Labiatae

S Kokkini, R Karousou and E Hanlidou, Aristotle University, Thessaloniki, Greece

Introduction

The Labiatae (Lamiaceae) family consists of approximately 3500 species centered chiefly in the Mediterranean area, although some small groups have a local distribution in Australia, South-west Asia, and South America. The family contains many culinary or flavoring herbs, which have been widely used, since antiquity, as spices, teas, or traditional medicines. Several members of the family are also used as sources of essential oils.

Morphological Characteristics

The Labiatae are annual or perennial herbaceous plants or shrubs, often densely glandular and aromatic. Their stems are usually four-angled. The leaves are usually simple and always opposite. The flowers are hermaphrodite or male-sterile (functionally female) and form whorls (verticillasters) that are often arranged in spikes, heads, racemes, or cymes. The calyces are usually five-lobed and two-lipped; rarely, the calyx is one-lipped or actinomorphic. The corollas are sympetalous and two-lipped; rarely, they are one-lipped or more or less actinomorphic. They usually have four stamens, rarely reduced to two; the upper (posterior) pair is usually shorter than the lower (anterior). The ovary is superior, doubly carpellate but appearing equally four-lobed when mature. The style is single, usually gynobasic, shortly bifid above. The fruit consists of four dry (very rarely fleshy), one-seeded nutlets.

Besides the non-glandular or clothing hairs, the leaves and other aerial parts of the Labiatae plants bear a great number of glandular trichomes. Two main types of these secretory structures occur in the Labiatae: the glandular hairs (capitate hairs) and the glandular scales (peltate hairs). The former type is very variable in stalk length and head shape, whereas the latter is more or less stable, consisting of a uni- or bicellular foot, a uni- or bicellular stalk, and an (up to) 18-celled head. The bulk of the essential oil is thought to be produced and accumulated in the glandular scales. Because of their size and number, they can be seen as bright yellowish dots when the lower leaf surface is examined with a hand lens (Figure 1).

Chemical Characteristics

The active ingredients, to which the Labiate herbs owe their flavors and aroma, are the essential oils. They are usually obtained by steam- or water-distilling their fresh or dried aerial parts. However, though the Labiatae are generally considered as an aromatic family, they include several genera whose members produce only traces of essential oils and are almost scentless. The genera of the subfamily Lamioideae consist of essential oil-poor species (e.g., *Phlomis*, *Sideritis*), whereas the subfamily Nepetoideae is quite variable. The different Nepetoideae genera may include oil-poor (e.g., *Lycopus*), oil-poor and oil-rich (e.g., *Salvia*, *Micromeria*) or only oil-rich (e.g., *Mentha*) species.

A variety of highly valued constituents have been found as main components of the Labiatae oils. However, the essential oil profile that determines the economic value of a Labiate herb may vary greatly within a species. As a result, plants belonging to a single species may not be used for the same purpose. However, there are numerous examples of similarity in the oils of widely diverse genera, and thus different species are used similarly.

The total essential oil content and the quantitative and/or qualitative oil composition of a single species depend on the season, the local environmental conditions and the genetic differences. The age and the season at which each herb is harvested are often of considerable importance, since the total oil amount and the relative proportions of its active constituents vary throughout the year (seasonal variation). Sage plants, for example, produce in late summer almost double the amount of the essential oil that is present in spring, whereas the highest

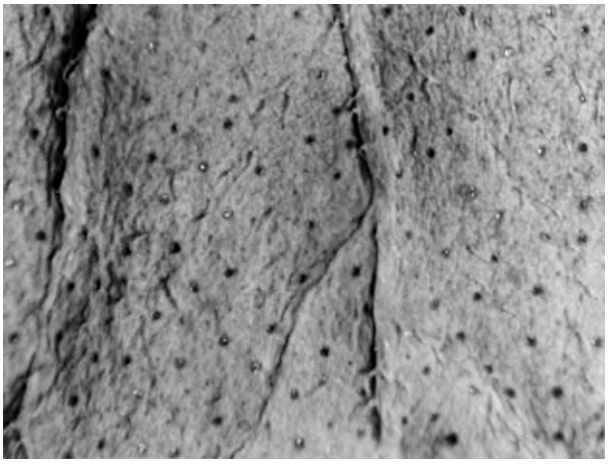

Figure 1 Lower side of *Origanum vulgare* subsp. *hirtum* leaf (Greek oregano) as it appears under the stereoscope (× 32).

thujone content can be obtained in late autumn. Oregano plants grown in areas with mild winter temperatures and a typical Mediterranean summer (low precipitation and high temperature) are much richer in essential oil (up to 30 times more) than those found in areas suffering from low winter temperatures. Similarly, the total phenol content (carvacrol+thymol) of oregano plants is much higher in areas with a Mediterranean type of climate than in areas characterized by a Continental climate (geographic–climatic variation).

Striking differences in qualitative oil composition between individuals of a Labiatae species suggest the presence of chemotypes or chemical races (genetic variation). The different chemical races are distinguished on the basis of the presence or absence of a particular biosynthetic pathway, leading to the formation of a number of compounds and not on the presence or absence of a single compound. Different chemotypes are often encountered in the wild populations of *Mentha*, *Thymus*, and *Satureja* species, and their oils are exploited for different applications. One of the most variable species is *Mentha spicata* with four distinct chemotypes: (1) essential oil rich in linalool and/or linalyl acetate (plants with a fragrant smell), (2) oil rich in carvone/dihydrocarvone (sweet smell), (3) oil rich in piperitenone and/or piperitone oxide (musty smell), and (4) oil rich in methone/isomenthone/pulegone (pungent smell).

It has been established that several of the essential oil constituents are biologically active, with significant antibacterial, antifungal, insecticidal, and antioxidant properties. However, besides essential oils, the members of Labiatae produce other types of biologically active compounds. Diterpenes, which present strong antibacterial and antifungal activities, occur in several genera, such as *Salvia* and *Sideritis*. Iridoids (monoterpene lactones) are mainly found in members of the subfamily Lamioideae (e.g., *Ajuga*, *Phlomis*, *Scutellaria*, and *Leonurus* spp.) and more rarely in Nepetoideae (e.g., *Nepeta*, *Salvia*, and *Satureja* spp.). Several of these show insecticidal, cytotoxic, and cytostatic activities. Among the phenolic constituents, rosmarinic acid is of great interest, especially for its antioxidant and antiinflammatory properties. It is produced by several taxa, including *Rosmarinus officinalis*, *Salvia officinalis*, *Melissa officinalis*, and *Origanum vulgare*.

The commonest Labiatae herbs used in the food industry are listed below under their commercial names. A commercial name may attributed to a specific chemotype or to a particular species or even to a group of species that have a similar oil composition and consequently a similar flavor and use.

Balm

Balm (*Melissa officinalis* L.) is a perennial herb up to 100 cm in height, which is native to South Europe, North Africa, and Anatolia and introduced in almost all temperate regions. It has broadly ovate leaves and white or light pink flowers arranged in axillary whorls. Three subspecies of *Melissa officinalis* are recognized, but only subsp. *officinalis* is cultivated for its aromatic foliage, which has a strong, pleasant, lemon-like odor.

The aromatic balm leaves are often used in beverages and as a seasoning in salads, dressings and sauces, as well as in cooked foods, e.g., in soups and stews. Balm leaves yield a low amount of essential oils, up to 0.5% vol./dry wt. Balm oil is considered as a mild spasmolytic agent and is employed as a flavor ingredient in alcoholic beverages. The main compounds of the commercial oils are citronellal, geranial (citral a), and neral (citral b).

Basil

Basil is obtained from the foliage of *Ocimum basilicum* L. (sweet basil), an annual herbaceous plant up to 100 cm in height. It is native to tropical Asia, Africa and America and widely cultivated in pots and gardens in Europe, South-west Asia and the USA. The leaves are ovate and vary in size, depending on the cultivated variety, from the small leaves of the common basil to the large leaves of lettuce leaf basil. The verticillasters of the white or pink flowers are arranged in terminal racemes. Different cultivated forms, considered distinct by herbalists (e.g., *O. minutum* L.), are not recognized taxonomically.

The dried sweet basil leaves have a sweet, fragrant odor, and their taste is aromatic, warm, and slightly pungent. Basil is considered as the finest of all aromatic herbs and is widely used to flavor cooked vegetables, tomato-paste products, and fish. It is sometimes used with, or as a substitute of, oregano to flavor pizza and spaghetti sauce and is employed together with other spices in the manufacture of vinegar, mustard, and sausages. Though not used in large quantities, sweet basil oil is used quite extensively in the flavoring of several food products, including those for confectionery, alcoholic beverages (liqueurs), baked goods, and condiments. The commercial essential oils are usually methyl-chavicol (an isomer of anethole) and/or linalool rich. However, *O. basilicum* oils are particularly variable and may also have high amounts of methyl-cinammate, geraniol, eugenol, and methyl-eugenol.

Hyssop

Hyssopus officinalis L., an aromatic shrub growing on dry hills and rocky grounds, is native from Portugal and Spain eastwards to India. It is naturalized in the USA, where it grows in gardens and along roadsides. Hyssop plants are up to 60 cm high and have linear or almost linear leaves, actinomorphic calyces and violet–blue, pink, or white flowers in verticillasters, forming a terminal spike-like inflorescence. *H. officinalis* is a morphologically variable species, separated into four subspecies. The cultivated plants belong to subsp. *officinalis*.

The dried aromatic hyssop leaves are considered as a gentle stimulant used in medicines, tonics, bitters, and alcoholic liqueurs. Hyssop oil is employed mostly in the flavoring of beverages, e.g., bitters, tonics, and especially of French-type liqueurs. The essential oils produced by *H. officinalis* have a variable composition, mainly consisting of isopinocamphone (the major component of commercial oils), pinocamphone, pinocarvone, and 1,8-cineole.

Marjoram

The vernacular name marjoram comprises several Labiatae herbs belonging to different species or even genera. The best known are as follows:

Spanish Marjoram

Spanish marjoram is obtained from *Thymus mastichina* L., a dwarf shrub up to 50 cm in height, which grows wild in Spain and Portugal. It has ovate to elliptic leaves, almost actinomorphic calyces, whitish corollas and an inflorescence of somewhat plumose appearance.

Spanish marjoram, also known as wild or forest marjoram, has a different odor from that of sweet marjoram, being harsher and eucalyptus-like, due to the high amount of 1,8-cineole (eucalyptol). Spanish marjoram is used in the manufacture of fragrances, but also in the food industry to flavor canned and processed meats and sauces. The essential oils produced by wild *Th. mastichina* plants may also have high amounts of linalool.

Sweet Marjoram

Sweet marjoram is obtained from *Origanum majorana* L. (syn. *Majorana hortensis* Moench., *M. vulgaris* Miller), a dwarf shrub of dry and rocky places, native on Cyprus and the adjacent part of South Turkey. It is cultivated in several countries in Europe, Africa, America, and Asia. The plants are up to 60 cm high and have ovate, whitish or greyish leaves, one-lipped calyces and white corollas. The flowers are arranged in spikes forming a paniculate inflorescence.

Because of their fragrant odor and pleasant, highly aromatic, slightly sharp and spicy taste, the dried leaves of *O. majorana* are widely used as flavoring agents for dressings, egg and vegetable dishes, soups, stews, cheese, liver, Polish sausages, and fancy meats. The characteristic compounds of the commercially exploited marjoram essential oils are terpinen-4-ol, α-terpinene, γ-terpinene, α-terpineol and *cis*-sabinene hydrate, occurring in variable quantities. *O. majorana* also produces essential oils with different compositions, which are either rich in linalool or *p*-cymene and its biosynthetically related compounds thymol and carvacrol.

Mint

Plants producing essential oils rich in menthane-type compounds are frequently found within the Labiatae, commonly known as the mint family. However, those that today constitute the commercial mint herbs are species of the genus *Mentha*.

Mentha species are perennial herbs up to 150 cm in height, usually growing in damp sites. The white, pink, or lilac flowers are arranged in dense, many-flowered verticillasters, which, in some cases, form a long and spike-like inflorescence or a terminal head. The genus is taxonomically difficult, and the identification of a single plant is often problematic, since, in addition to much morphological plasticity, most of the species are capable of hybridization with each other. Besides the high morphological variability, great differences in chemical composition of the essential oils often occur within a species. As a result, although the genus consists of approximately 25 species and rather fewer hybrids, more than 1000 names of different taxonomic rank have been attributed over the past 200 years to the morphological and/or chemical variants of the mint plants. Among the different *Mentha* species and hybrids, those that have achieved economic importance are as follows.

Cornmint

Extremely menthol-rich essential oils (up to 80% menthol) are produced by *Mentha arvensis* var. *piperascens*, mainly plants cultivated since antiquity in Japan and during recent years in China, India, and Brazil. The cornmint plants are distinguished by their leafy at apex inflorescence, which consists of remote flower verticillasters.

The cornmint oil (also known as Japanese or Chinese or Brazilian peppermint oil) is valued as a source of L-menthol, which is generally obtained by simple

freeze-crystallization. The dementholized oil is used as inexpensive, rather harsh peppermint-like oil.

Pennyroyal

The leaves and flowering parts of *Mentha pulegium* L. (European pennyroyal) plants grown wild in western and central Europe as well as in the Mediterranean region are traditionally used for the preparation of teas and, to a limited extent, for food flavoring (soups, stuffings). *M. pulegium* is distinguished from the other mint species by its inflorescence, which consists of remote verticillasters but is not leafy at apex (Figure 2). Furthermore, *M. pulegium* is distinguished from the other mint species by the calyx, which has unequal teeth (weakly two-lipped), while the corolla tube is gibbous beneath. The North American pennyroyal is *Hedeoma pulegioides* (L.) Pers., an annual plant growing in North America, which has a similar odor to *M. pulegium*.

Since Roman times, herbalists have recommended pennyroyal as an abortifacient herb. Recent data suggested that pulegone, the ketone, often the major constituent of pennyroyal oil, has hepatotoxic effects to animals and man.

Peppermint

Mentha × *piperita* L., a sterile hybrid of the species *M. aquatica* L. (Figure 2) and *M. spicata*, is probably the most important commercial aromatic herb in the world today from the standpoint of the size of the area cultivated for oil distillation. The peppermint leaves have a characteristic, sweetish, strong odor and an aromatic, warm, pungent taste, with a cooling aftertaste.

The essential oils of *M.* × *piperita* cultivated plants are characterized by the preponderance of menthone, isomenthone, and the different isomers of menthol. Peppermint oil finds wide application in the flavoring of chewing gums, sugar confectionery, ice creams, desserts, baked goods, tobacco, and alcoholic beverages. It is also frequently employed in the flavoring of pharmaceutical and oral preparations.

Spearmint

Under the vernacular name 'spearmint,' different *Mentha* species and hybrids producing carvone-rich essential oils are commerically exploited. In particular, two main 'types' of spearmint – Native and Scottish – are widely cultivated, mainly in the USA but also in China, Europe, and South Africa, for the commercial production of their essential oil. The native spearmint oil is obtained either from the species *M. spicata* L. (Figure 2) or from the sterile hybrid *M.* × *villoso-nervata* Opiz. (*M. longifolia* L. × *M. spicata*), whereas the Scottish spearmint oil is produced from the hybrid *M.* × *gentilis* L. nm. *cardiaca* Gray (*M. arvensis* L. × *M. spicata*).

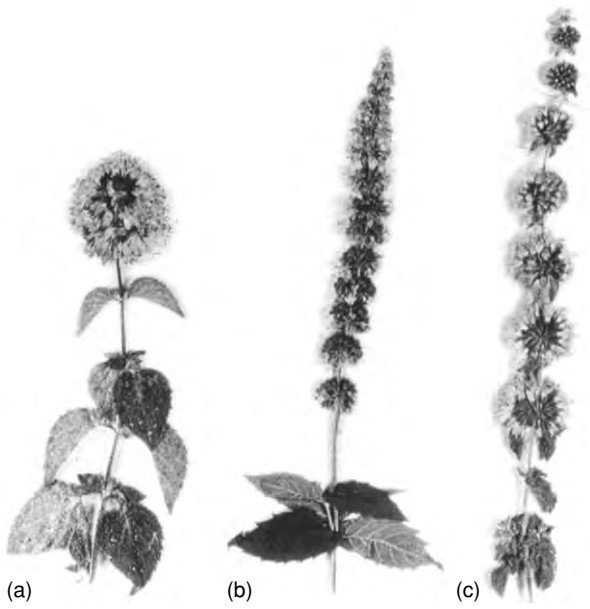

Figure 2 (a) *Mentha aquatica*; (b) *M. spicata*; (c) *M. pulegium*.

Spearmint plants are familiar garden herbs, and they are often used to flavor vegetables, soups, meat and fish sauces, and salads. The spearmint oil, characterized by the high participation of carvone, dihydrocarvone, and their related alcohols and esters, is mainly used in the flavoring of chewing gums, toothpastes, and other oral products.

Oregano

Oregano, one of the most popular herbs throughout the world, presents a serious problem to everyone trying to establish the identity of its botanical source. A vast number of species in over a dozen genera of different families have been referred to 'oregano' in the literature. Oregano is in fact a characteristic flavor produced by a number of plant species that yield essential oils with a more or less high content of carvacrol (noncrystallizable phenol). The flavor of oregano recently became very popular all over the world mainly because the fast food industry supports the ethnically based products. Dried leaves and flowering parts of different oregano plants, commonly known as 'the pizza herb,' are widely used to flavor food products, such as salads, vegetables dishes, fried potatoes, meats, sauces, sausages, and canned goods. Oregano is also employed as an ingredient in chilli powder and is used in chilli con carne and several other

Mexican dishes. Oregano oil sometimes replaces the dried herbs in the food flavoring. Several reports have mentioned its high antibacterial, fungicidal, insecticidal, and antioxidant activity. The species, which are widely used as oregano under different vernacular names, are described below.

Greek Oregano

Greek oregano consists of dried leaves and flowering parts of *Origanum vulgare* subsp. *hirtum* (Link) letswaart (syn. *O. heracleoticum* auct. non L.), and on commercial grounds, it is considered to be of the highest quality. It is a woody perennial up to 100 cm in height, and is found in the Balkan Peninsula and Turkey. It is distinguished from the other *Origanum* species by its dense spikes, clearly distinct from stems and branches, green calyces with five (sub)equal teeth and two-lipped white corollas (Figure 3). Furthermore, it is characterized by the conspicuously glandular-punctate (visible even to naked eye) leaves and calyces. It is mainly collected from the wild from Balkan countries and Turkey. The cultivation in gardens and open fields is nowadays very popular in the Mediterranean countries.

Figure 3 (see color plate 82) *Origanum vulgare*.

O. vulgare subsp. *hirtum* plants often yield an extremely high amount of essential oil (up to 8% dry weight basis), and their carvacrol content may reach the 95% of the oil produced. However, plants having a high thymol content (up to 85%) are not infrequent in the wild populations. In these cases, carvacrol, the compound responsible for characterizing a plant as being of the oregano type, is a minor constituent.

Spanish Oregano

Spanish oregano consists of leaves and flowers of *Coridothymus capitatus* (L.) Reichenb. fil. (*Thymus capitatus* Hoffmans & Link, *Satureja capitata* L.), a shrub 50–150 cm in height, with narrowly elliptical leaves, dorsally flattened calyces, and violet corollas (Figure 4). The flowers are arranged in dense heads. The plants are variable with respect to their essential oil composition, being either carvacrol or thymol-rich. Despite its name, Spanish oregano is common throughout the Mediterranean area.

Turkish Oregano

Origanum onites L. (*O. smyrnaeum* L., *Majorana onites* (L.) Bentham) is a perennial plant, up to 100 cm in height, of the east Mediterranean area. It is abundantly found in many of the Greek islands of the Aegean, extending to western and southern Turkey. Turkish oregano is distinguished from other *Origanum* species by the form of inflorescence (spikes arranged in false corymbs) and the one-lipped calyces. Hybrids between *O. onites* and *O. vulgare* subsp. *hirtum* are often found in the wild. Turkish oregano yields a smaller amount of essential oil (up to 4%) than Greek oregano, and its carvacrol content may reach the 77% of the total oil. It is mainly collected from the wild, but it is also cultivated in west Turkey.

Other species of the Labiatae, locally used as oregano or za'atar (the name used by the Arabs) condiments, are *Satureja thymbra* L., *Thymbra spicata* L., *Origanum compactum* Bentham, *O. elongatum* (Bonnet) Emberger & Maire and the 'Biblical hyssop,' *O. syriacum* L. (syn. *O. maru* L., *Majorana syriaca* (L.) Kost.); all of them are native in the Mediterranean region. Mexican oregano consists of dried leaves of *Lippia graveolens* Humb., Bonpl. & Kunth, a species belonging to the family Verbenaceae. Mexico is the main USA supplier.

Origanum dictamnus L. (Dittany of Crete), an endemic species of the Greek island Kriti (Figure 5) and well known since antiquity for its therapeutical

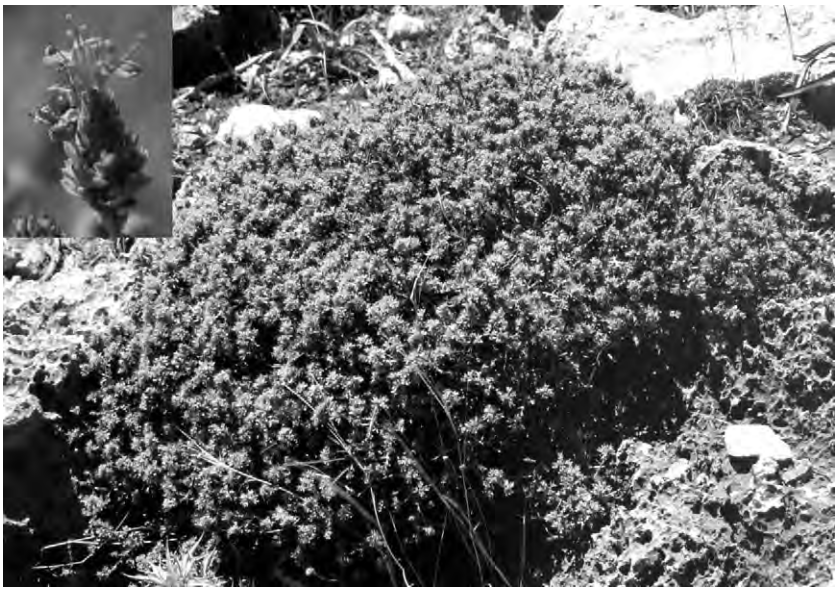

Figure 4 (see color plate 83) *Coridothymus capitatus*.

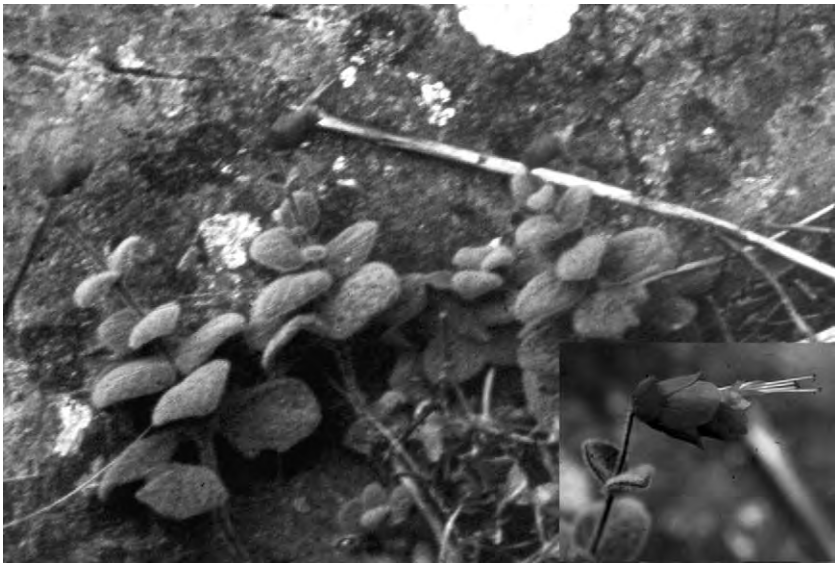

Figure 5 *Origanum dictamnus*.

properties, is employed in the flavoring of alcoholic beverages (Martini).

Rosemary

Rosemary (*Rosmarinus officinalis* L.) is an evergreen shrub, up to 2 m high, native to the Mediterranean region, and cultivated in several European countries and in the USA. It has linear leaves green on the upper surface, with numerous branched hairs making their lower surface whitish. The pale blue, rarely pink, or white flowers are borne in verticillasters produced in the axils of the leaves.

Dried rosemary leaves are aromatic and yield a slightly camphoraceous odor when crushed. They are used to flavour salads, vegetable dishes, soups, meat dishes, sausages, and sauces. Rosemary oil, widely employed in cosmetic products, sometimes replaces the dried leaves in the flavoring of food products. α-Pinene, 1,8-cineole, camphor, and borneol are usually the main rosemary oil constituents. Oils with a decreased amount of α-pinene and

camphor and increased amounts of 1,8-cineole and borneol are judged to be of a better quality.

Sage

The vernacular name 'sage' is ascribed to different aromatic species of the genus *Salvia*, which produce essential oils rich in 1,8-cineole, α- and β-thujone, or camphor. The dried sage leaves are highly aromatic and widely employed in the flavoring of sauces, pork and other meats, poultry stuffings, ground meats (hamburgers), baked fishes, soups, sausages, and canned foods. The essential oils have a fresh-herbaceous odor and are used in perfumery (industrial, soap, or cosmetic perfumes), in flavoring formulations for alcoholic beverages, liqueurs, canned meat, or spicy sauces; they also find application in pharmaceutical preparations.

Dalmatian Sage

Dalmatian sage consists of dried leaves of *Salvia officinalis* L., the most widely used sage plant. Its native occurrence is restricted to Italy and the western part of the Balkan Peninsula, but it is widely cultivated and naturalized in parts of southern and south central Europe. Cultivated as a culinary herb or as an ornament, it may be found all over Europe, where it was possibly introduced by the Romans in ancient times or by monks during the Middle Ages. It is a low (up to 60 cm) shrub, with oblong leaves, white-pubescent beneath, grey–green to silverous above. The violet–blue, pink, or white flowers are arranged in axillary verticillasters (Figure 6).

Salvia officinalis oils are mainly characterized by the predominance of α- and β-thujone (up to 65% of the total oil). However 1,8-cineole and camphor are often detected in considerable amounts (up to 22 and 38% of the total oil, respectively). In commercial grounds, oils with a combined thujyl ketone (α- and β-thujone) content more than 30% and camphor content less than 20% are most valued. Dalmatian sage oil is mainly produced along the Adriatic coast of the former Yugoslavia and Albania, whereas smaller quantities are distilled in Bulgaria, France, Turkey, and Germany.

Greek Sage

Greek sage is obtained from the foliage of *Salvia fruticosa* Miller (syn. *S. triloba* L. fil.). It is an east Mediterranean shrub, extending westwards to south Italy. Introduced by the ancient Greeks and Phoenicians, it was cultivated in the Iberian Peninsula, where nowadays it is naturalized. Greek sage is distinguished from Dalmatian sage by the yellowish green, often three-lobed leaves and the appressed white-tomentose stems.

Although there is a remarkable variation in wild-growing plants, Greek sage oils are generally characterized by high levels of 1,8-cineole (up to 66% of the total oil) and low levels of thujyl ketones and camphor. *S. fruticosa* has been renowned since ancient times for its pharmaceutical properties. Nowadays, the leaf decoction is used in traditional medicine for the treatment of several diseases. The essential oil is a folk remedy for toothache and intestinal complaints.

Spanish Sage

Salvia lavandulifolia Vahl, a west Mediterranean shrub up to 60 cm high, is employed as a flavoring agent under the common name 'Spanish sage.' It can be distinguished from the other sage species by its narrowly oblong to linear leaves. Spanish sage oil is mainly produced in Spain; it is characterized by the preponderance of 1,8-cineole and camphor (up to 59 and 37% of the total oil, respectively), whereas thujyl ketones are detected in negligible amounts (up to 1.3% of the total oil).

Figure 6 (see color plate 84) *Salvia officinalis*.

Cretan Sage

Salvia pomifera L. (Cretan sage) is an east Mediterranean shrub restricted to Greece and Turkey, and mainly distinguished by its membranous, often purple calyces. Cretan sage leaves are exploited on a local scale, often alternatively to Greek sage. However, its oils are always characterized by extremely high amounts of thujyl ketones (58–83% of the total oil), whereas the amounts of 1,8-cineole and camphor are negligible.

Salvia sclarea L. (Clary sage) is a short-lived perennial herb, widely distributed in Europe and South-west and Central Asia. Although it is called sage, its essential oils are quite different from the other sage species, being rich in linalyl acetate and/or linalool (up to 80% of the total oil). Clary sage oil is mainly produced in the former USSR, USA, Bulgaria, and France, whereas minor amounts are distilled in India, Switzerland, Morocco, and several other countries. It is widely used in perfumery but also in flavoring wines and other alcoholic beverages.

Savory

Plants of two species of *Satureja*, which produce essential oils rich in carvacrol, are employed mainly as culinary herbs under the common name savory: *S. hortenis* L. and *S. montana* L. *S. hortensis*, known as Summer savory, is an annual plant, up to 35 cm high, native to south Europe and Anatolia, and widely cultivated as a pot herb. The main area of production is France. It has linear leaves and white or lilac flowers arranged in verticillasters, borne in the axils of the upper leaves. *S. montana*, known as winter savory, is a native plant of south Europe. It belongs to a group of related species, growing wild in parts of the Mediterranean region. Among them, only *S. montana* is used on a larger-than-local scale. It is a small shrub, up to 60 cm high, with lanceolate leaves and white or pale pink flowers arranged in verticillasters, in the axils of the leaf-like bracts.

The value of the two savories is in the high carvacrol content, which gives a fresh, herbaceous, spicy odor with slightly sharp notes, reminiscent of oregano. The two herbs have a similar odor, though summer savory's odour is thought to be more rounded and harsh. They are used to flavor foods, such as sauces, soups, sausages, and canned meats. Savory oil sometimes replaces the dried leaves in food flavoring. The essential oils of *S. montana* wild growing plants are variable and, besides carvacrol, may have high amounts of *p*-cymene, thymol, linalool, borneol, or bornyl acetate.

Thyme

Under the name 'thyme,' plants of *Thymus* species, which produce essential oils rich in thymol, are employed for culinary or medicinal purposes. The species mostly used are *Th. vulgaris* L. (Figure 7) and *Th. zygis* L. and occasionally other species, like *Th. serpyllum* L. or *Th. pulegioides* L.

The herbs have a fragrant odor and a pungent taste, and are used in several food products, such as soups, meat, liver and pork sausages, fish, and poultry

Figure 7 *Thymus vulgaris*.

dressings. Thyme oil is widely employed in many pharmaceuticals and oral preparations. The essential oils produced by wild growing plants of most *Thymus* species are particularly variable. Several compounds have been found as main oil constituents of *Th. vulgaris* and *Th. zygis* plants grown in the wild, such as carvacrol, 1,8-cineole, geraniol, linalool, terpinen-4-ol, α-terpineol, or *trans*-sabinene hydrate.

Herbs of the Umbelliferae

L A Shelef, Wayne State University, Detroit, MI, USA

Background

Herbs of the family Umbelliferae are aromatic plants grown primarily for their use in flavoring of foods, liqueurs, and confectionery. The name Umbelliferae predates Linnaeus and the name Apiaceae was proposed by John Lindley in 1830 for the same family. Both Apiaceae and Umbelliferae are in current use.

The majority of the Umbelliferae plants are indigenous to the Mediterranean countries, where they grow naturally. Brought to northern Europe, they have adapted to climatic and growing conditions of many other countries where they are now cultivated. A point of interest in regard to members of the Umbelliferae plants is that some of them are sources of spices (the seeds) and herbs (leaves), as well as being consumed as vegetables (the bulbs of fennel and celery, for example). The characteristic odor and flavor of members of this family are associated with the major specific essential oil or oils in the edible portions, and particularly in the fruit or seed, in which the content is highest. Within a species, the content of the oil varies, depending on the plant variety, climatic and soil conditions, and storage or processing methods.

Most of the major volatile oils of the Umbelliferae seeds possess medicinal properties that were valued in the past. They have been considered mainly for their stimulant, carminative, pectoral, and palliative properties. Today, the volatile oils are prized less for their medicinal uses than for their flavor and aroma. While their concentration in the seeds is higher than in the leaves, the composition is often different, making the aroma of the herbs generally more delicate.

Production practices of spices and herbs vary widely and these affect the microbial content of the products. Aerobic plate counts of 10^6 microorganisms per gram at retail are common in many spices. Mold growth and formation of mycotoxins, the fungal metabolites, are also of concern in moist products. Cleaning processes and treatment with ethylene oxide eliminate a large portion of the microorganisms present, as well as insects and insect eggs. Propylene oxide is similar to ethylene oxide, although its penetrating ability is lower. While effective, fumigation with gases has been questioned because of toxicity. Irradiation treatment is also effective, and a dose of up to 30 kGy is allowed for dry spices and herbs. The treatment is allowed under Codex Alimentarius, and doses and labeling requirements vary from country to country. Specifications for acceptable contamination levels in products are provided by trade associations (e.g., American Spice Trade Association, European Herb Trade Association, British Herb Trade Association).

Essential oils of a large number of spices have been shown to possess antibacterial and antifungal properties. The ones found in Umbelliferae plants are anethole and, to a lesser extent, also eugenol.

Anethole, a major constituent of the essential oils of anise seed and fennel, has been reported to be effective against various foodborne microorganisms, including pathogens such as *Salmonella* spp. and *Staphylococcus aureus*. Essential oils and extracts of cumin and dill have been reported to be effective in preventing spoilage of wiener-type sausage.

Spices are also known for their antioxidant activity. While umbelliferous seeds such as caraway, celery, cumin, and fennel have some antioxidant properties, they are not as effective as spices of other families in preventing rancidity.

Seeds of the major members of the Umbelliferae family are discussed first in this article, after which the leaf types of the family are reviewed.

Umbelliferae Seeds

Seeds of the Umbelliferae family include anise, caraway, celery, coriander, cumin, dill, and fennel. Drying the seeds is essential for development of full aroma and for storage stability. In traditional methods, the plants are sun-dried after harvest. Commercially dried products are dehydrated under controlled conditions to a specified moisture content, uniform color and, when reconstituted, they retain the flavor and color. The proximate composition of umbelliferous seeds and their mineral content are shown in Table 1.

Grinding the seeds releases the natural flavors and permits control of flavor intensity and uniform distribution. It also improves the appearance of the food products and the economy in use of the seed. Spice-grinding techniques influence the flavor. Heat evolved during grinding causes flavor deterioration. In modern milling techniques such as cryomilling, the process is accomplished at very low temperatures, generally below −70 °C, by direct contact with liquid nitrogen refrigerant. In addition to the low temperature, the process protects the spice oils from oxidation by replacing the air in the mill. It also results in very fine grinding of the spices since the low temperatures render the seeds very brittle. Freeze-ground spices display better retention of aroma, flavor, and color. Moreover, the treatment lowers the microbial load.

Spices are stored in sealed containers under dry, cool conditions. Evaporation of aroma from the intact seed is slow, but once the seed is ground, evaporation is rapid, and oxidation and degradation take place. The shelf-life of the spice is shortened, and storage for no longer than 3 months is generally recommended.

Essential oils are the chief components of spices. The essential oil compounds and contents of the umbelliferous seeds are presented in Table 2. While each of the seeds is characterized by its essential oil composition, similarities in flavor are ascribed to the presence of identical chief compounds. For example, anethole is the chief component of anise seed and fennel, and these two spices are similar in flavor.

The volatile essential oils are extracted from the seeds by steam distillation. Using stainless-steel equipment, steam passes through the ground seeds and carries with it the volatiles. Extraction time varies, depending on the plant, from 6 to 12 h. After cooling, the condensate consists of a mixture of water and oil. The oil fraction is separated by gravity, filtered and dried. Oxidation of the unsaturated compounds (terpenes and sesquiterpenes) is avoided. Terpeneless and sesquinterpeneless extracts with improved storage stability are also produced.

Oleoresins are concentrated, viscous, resinous extracts of the flavor ingredients, obtained by extracting the volatile oils with organic solvents such as hexane and ethylene dichloride, using three to four volumes

Table 1 Proximate composition of umbelliferous seeds (per 100 g edible portion)

Table 2 Chief flavor components of umbelliferous seeds

Seed	*Oil content (%)*	*Chief oil, percentage of total*	*Other components*
Anise	2–3	Anethole, 80–90	Pinene, limonene, methyl chavicol, anisaldehyde, aniseketone
Caraway	3–6	D-carvone, 50–65	D-limonene
Celery	1.5–2.5	D-limonene, 60	Selinene, sedanolide, sedanonic anhydride
Coriander	0.1–0.5	D-linalool, 45–70	1,4-*p*-menthadien-7-al
Cumin	2–3	Cuminaldehyde, 35–50	Pinene, *p*-cymene, α-terpinene, cuminyl alcohol
Dill	2.6–3.7	Carvone, 43–63	D-limonene, carvacol, eugenol
Fennel	2–4	Anethole, 50–60	Fenchone, phellandrene, pinene, methyl chavicol, anisaldehyde, anisic acid

Data compiled from Lewis YS (1984) *Spices and Herbs for the Food Industry*, Orpington: Food Trade Press, and other sources.

of the solvent to one volume of the seeds. Steps in the process include grinding, extraction, and distillation. The solvent percolates down through the ground spice, carrying with it the volatile essential oils, the nonvolatile fatty oil (fixed oil), pigments, and resins. The major fatty acids in the fixed oil are oleic, linoleic, petroselinic (*cis*-6-octadecenoic), and palmitic, and their concentration depends on the seed. Heat and vacuum are used to remove the solvent.

Encapsulated oils are available, in addition to spice extracts and oleoresins. These consist of spray-dried emulsions of essential oils with a food-grade, modified, or soluble gum, which forms a protective capsule, preventing evaporation and oxidation. The dry product is the size of fine salt and is water-soluble. It contains about 20% essential oil or oleoresin and has applications in dry mixes such as dehydrated soups and sauces. The oils are released upon dissolution of the capsule.

Discussion of specific umbelliferous seeds follows. It covers historic background, habitat and cultivation, plant description, seed composition, and uses in foods and medicine.

Anise Seed (*Pimpinella anisum* L.)

Background Anise seed is reported to have been found in Egypt as early as 1500 BC. It was once considered an aphrodisiac and a cure for stomach disorders and shortness of breath. It was first used to flavor foods by the Romans in the Middle Ages. The name *Pimpinella* derives from *dipinella*, or twice-pinnate, referring to the shape of the leaves.

Habitat and cultivation Anise is native to Egypt, Greece, and Asia Minor; from there it spread in the Middle Ages to warm parts of Europe, and from there to India, South America, China, and the USA. Flowers appear after 3 months, and green fruit a month later. Yields of about 500–700 kg of seed per hectare are obtained.

Description The plant is an annual, about 50 cm high, with a branching stem, feathery leaves, yellow-white flower clusters, and green fruit (Figure 1). Harvested when the seeds mature, the plants are dried and the seeds are threshed and dried. The anise seed is ovoid in shape, 5 mm long, gray-brown, sweet, spicy, and aromatic.

Composition Upon distillation, anise seed yields 1.5–3.5% essential oil, approximately 90% of which is anethole, with the characteristic anise odor. It crystallizes on cooling to 15–20 °C. The crystallization temperature, which increases with anethole content, is used to evaluate the oil quality. The remaining

Figure 1 (see color plate 85) Herbs of the Umbelliferae: anise.Reproduced from Herbs/Herbs of the Umbelliferae, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

portion consists of 2% methyl chavicol and terpenes such as limonene, pinene, and others. In commercial use, 2.5 kg of the essential oil is equivalent to 100 kg of freshly ground anise seed in seasoning mixes.

Uses Anise seed is used for flavoring baked goods such as biscuits, cakes, sweet rolls and bread, soups, beverages and confectionery (e.g., licorice), and in preparation of cordials and liqueurs. Several Mediterranean alcoholic drinks are flavored with anise, which dominates them. Pastis in France (e.g., Pernod, Ricard, Berger) and anisette contain anise, as does ouza in Greece and arrak in the eastern Mediterranean countries. Meat products, especially Italian style, are flavored with anise seed, as are Indian foods, particularly vegetables and fish dishes from Bengal. The slightly roasted seed is commonly chewed after meals to sweeten the breath.

Medicinal activity The anise seed has aromatic, carminative, and stimulant properties. It is used in cough medicine, as a palliative, to relieve flatulence and colic, and in medicine designed to increase lactation. The oil is considered a good antiseptic.

Caraway (*Carum carvi* L.)

Background The word 'caraway' refers to its origin in the province Caria in Asia Minor. In ancient times, caraway seeds were used to mask the breath and to relieve stomach problems. Bread containing caraway seeds was eaten in ancient Rome.

Habitat and cultivation Caraway is indigenous to Europe, India, North Africa, and other countries. It is cultivated primarily in The Netherlands as well as in Morocco, Germany, Finland, Russia, Norway, Canada, and the USA. Fruit appear within 2 months after the flowers. The seed yield in The Netherlands is about 2200 kg ha^{-1}.

Description The plant is a biennial that grows to a height of 45–100 cm, bearing umbels of white flowers, which are followed by fruit. The plants are harvested when the fruit are still green. The fruit are allowed to ripen, then dried and threshed. The seeds, 6 mm long, are dark brown, slightly curved, ridged, and translucent. The aromatic odor evolves when the fruit is bruised, and the taste is pleasant. The wild seed is smaller than the cultivated one and has a stronger flavor.

Composition The seeds contain 3–6% volatile oil. Distilled oil is prepared from the Dutch, Norwegian, and Russian seeds. Carvone is the chief constituent, comprising 50–65% of the total volatile oil, which also contains the oxygenated oil, carvol. The spent seed after distillation contains protein and fat and is used for feed.

Uses The seeds are used in breads, rolls, and cakes, confections, cheese and soups, and to flavor cabbage, meat dishes, fish, salads, vegetables, and apples. The oil is used in alcoholic liqueurs, particularly in the German cordial kummel. It is also used in nonalcoholic beverages. In addition to the seeds, the tender leaves are used in soups, and the young roots, similar to parsnips, are eaten cooked.

Medicinal activity In the past, caraway was used as a carminative and for relief of indigestion.

Celery Seed (*Apium graveolens* L.)

Background The medicinal properties of celery seed are mentioned in Homer's *Odyssey* (eighth century BC). Its use to flavor foods is first recorded in France at the beginning of the seventeenth century.

Habitat and cultivation Celery is a biennial native to the Near East, southern Europe, and North Africa. It is cultivated for its seeds in India, France, the UK, The Netherlands, the USA, and other countries. Seed yields of around 620 kg ha^{-1} are considered good. World production is about 6000 t, half of which is produced in India.

Description The plant grows to a height of 50–100 cm, with coarsely toothed and segmented leaves and umbels of white flowers. The ovoid seeds are about 1–3 mm in length, brown and ridged. They are crushed and steam-distilled. The root, celeriac, has a pleasant, mild celery flavor and is popular as a vegetable in Europe.

Composition Celery seeds contain 2.5–3.0% volatile oil. Sedanolide (lactone of sedanolic acid) and sedanonic anhydride (1.3%) are responsible for the characteristic odor of the oil, which also contains D-limonene (60%) and selinene (10–20%).

Uses The herb seeds, volatile oil, and oleoresins are widely used in soups, sauces, pickles, eggs, salads, tomato products, and meats. Celery salt is a mixture of ground celery seed and sodium chloride, used as a seasoning in salads, fish and meat dishes, and other foods.

Medicinal activity Celery seeds are said to be carminative, stimulant, diuretic, tonic, and inducers of sleep.

Coriander (*Coriandrum sativum* L.)

Background Coriander was known as far back as 5000 BC and is mentioned in the Bible in Exodus 16:31. The use of the seeds at burials was recorded in 1550 BC. Its use by the Romans and by Hippocrates and other Greek physicians is documented. The Chinese have cultivated coriander since the fourth century, and its use in India and Europe dates back to early times. The name 'coriandrum' is derived from *koros*, a bug, referring to the disagreeable fetid smell of the leaves.

Habitat and cultivation Now indigenous to southern Europe, the plant was brought by the Romans from the east (Egypt). It is also cultivated in North Africa, Malta, India, Central America, Russia, and the USA. The yield of dry seed is 1200–2400 kg ha^{-1}. World production is estimated at 300 000 t annually, of which India produces more than 25%. At least a third of the crop is distilled for the oil. The deodorized fat (about 20% of the seed) is used as lubricant or for soap making. In India the seeds are subjected to mild toasting before use, to improve the flavor.

Description The plant is an annual, 30–100 cm high, branched, bright-green, with erect stems. The flowers are short-stalked umbels, 5–10 rays, pale mauve or white. The seeds are globular, beaked, finely ribbed, yellow-brown, 5 mm in diameter, with five longitudinal ridges. They mature 3 months after planting. The harvested plants initially have a disagreeable scent, which is lost after drying, and then become fragrant. There are two types of coriander, distinguished by the fruit diameter: 3–5 mm (*Coriandrum sativum* L. var. *vulgare*) and 1.5–3 mm (*C. vulgare* L. var. *microcarpum*).

Composition The seeds contain about 1% volatile oil. The alcohol D-linalool is responsible for the aroma of coriander, and a content of 60% or more is desirable. D-α-pinene, β-pinene, and α-terpinene, geraniol, borneol, decylaldehyde, and acetic acid are other constituents of the oil. The essential oil from the smaller fruits is superior in flavor and yield. Overall, coriander oil is more stable than other oils in the group.

Uses In the northern countries of Europe, coriander is added to bread, pastries, cheese, soups, vegetables, and stews. It is further used to flavor processed meat products such as liver sausage and bologna. In Peru, the spice is common in almost all dishes. It is frequently used in soups in Peru and Egypt, and it is an ingredient of curry powder.

Medicinal activity Coriander seeds are primarily used to disguise unpleasant-tasting medicine because of their aromatic taste and characteristic odor. The seed is a stimulant and carminative, and in the past it was considered an aphrodisiac. Extracts from coriander have been reported to improve glucose utilization, as shown by glucose tolerance tests.

Cumin (*Cuminum cyminum* L.)

Background Cumin is mentioned in the Bible in the books of Isaiah and Matthew, and in works of Hippocrates and Dioscorides. It was highly regarded as a condiment by the ancients, and is still used in medicine in India.

Habitat and cultivation Cumin is indigenous to Egypt, and is cultivated in the Mediterranean, India, China, Morocco, southern Russia, and other countries. It grows well on fertile, sandy loam soil free of weeds.

Description The cumin stem is slender and branched, 30–60 cm high. The deep-green leaves are divided into long narrow segments. The flowers are small, rose or white, in stalked umbels with only four to six rays, each about 8 mm long. The seeds are oblong, about 5 mm long, resembling caraway seeds, but lighter in color, bristly rather than smooth, and almost straight, with nine ridges overlapping as many oil channels (vittae). Odor and taste are similar to caraway but stronger, spicy, and curry-like.

Composition Cumin seeds contain 2–4% essential oil, consisting of 40–65% cuminaldehyde, and cymol or cymene and cyminol.

Uses Cumin is an ingredient of curry powder, and is essential in most Indian, Egyptian, and Turkish curries. It is also used in Mexican foods, in meat, poultry, and vegetables. In European countries such as Switzerland and The Netherlands, cumin is used to flavor cheese, while the Germans use it to flavor sauerkraut, bread and other baked products, and kummel liqueur.

Medicinal activity Cumin is considered a stimulant, antispasmodic, carminative, and a remedy for colic, but is not used because of the disagreeable flavor.

Dill (*Anethum graveolens* L.)

Background Dill is referred to in the Bible in Matthew by its original Greek name *Anethum*, and was used in the Middle Ages by magicians against witchcraft. The name is derived from the old Norse

word *dilla*, meaning to lull or soothe, referring to the carminative properties.

Habitat and cultivation Dill is a native of the Mediterranean and Russia. It is cultivated in many European countries, the USA and Canada, India, Pakistan, and Japan, and grows wild in Spain, Portugal, and Italy.

Description The plant, called dill weed, is 60–75 cm high, similar to but smaller than fennel, with feathery leaves on sheathing foot-stalks. The plant has generally one stalk, finely divided leaves, and flat umbels with yellow flowers and small, rolled-inward petals. The numerous flat seeds are approximately 5 mm in length, pungent and bitter. The whole plant is aromatic.

Composition The seeds contain 2.6–4% volatile oil, 40–60% of which is carvone. Additional constituents are dihydrocarvone, D-limonene, α-phellandrene, α-pinene, and dipentene.

Use Dill seed is used in pickles, pickled vegetables, sour cream- or mayonnaise-based sauces, cheese spreads, salad dressings and salads, a variety of vegetables, soups and fish sauces. Its use in seafood is popular in the Scandinavian countries. Some processed meat products, confections, and beverages are also seasoned with dill.

Medicinal activity In addition to the magical powers attributed to dill in ancient times, it was considered a palliative of stomach pains.

Fennel (*Foeniculum vulgare*)

Background The name 'foeniculum,' used by the Romans, is derived from the Latin word *foenum* for hay. This name led to another – *fanculum* – during the Middle Ages, and later to the popular name *fenkel*. The plant was assigned by Linnaeus to the genus *Anethum*, but was later placed by De Candolle in a new genus, *Foeniculum*. *Foeniculum vulgare* is the common or wild variety, *F. dulce* is the sweet (French) fennel, and *F. capillaceum* is the garden variety. Fennel was cultivated by the ancient Romans for its aromatic seeds, used as a vegetable and against witchcraft. It is mentioned in Spanish agriculture records dated 961 AD. Today, all parts of the fennel plant are edible – the seeds, leaves, stalks, and bulb.

Habitat and cultivation Fennel is indigenous to the Mediterranean and grows wild in most parts of temperate Europe, Egypt, India, Japan, China, the USA, and Argentina. It is a hardy perennial that grows particularly well on limestone soil. The yield of seeds is about 1200 kg ha^{-1}.

Description The plant grows to 1.2–1.5 m in height, with finely divided bright-green leaves and umbels of yellow flowers. The cultivated fennel (*F. capillaceum* or *F. officinale*) is taller than the wild variety, with larger stems, bearing fruit 6–12 mm long, double the size of the wild fennel. Several varieties of fennel seed are known, varying in size, volatile oil content, and taste. The most valued seed is elliptical, slightly curved, and pale gray-green in color, with a sweet, fragrant aroma similar to that of anise or licorice. In addition to the perennial varieties, *F. dulce* is an annual, native of Italy, about 30 cm high, with large, finely cut leaves and pale green-white stalks.

Composition Good varieties of fennel contain 4–6% volatile oil, of which the principal constituents are anethole (50–60%) and fenchone (19–22%). Fenchone is colorless, with a pungent camphoraceous odor and bitter taste. Small amounts of α-pinene, phellandrine, camphene, dipentene, methyl chavicole-hydroxyphenylacetone, and limonene are also present in the oil. While fennel grown in eastern European countries and Russia contains 4–5% volatile oil, French fennel yields only 2.1% oil, with lower levels of anethole and a sweet taste owing to absence of fenchone. Indian fennel contains only 0.72% volatile oil.

Uses Fennel seeds, as well as the leaves, are used with fish and seafood dishes. The seeds are used in soups, German and Italian breads, Polish bortsch, Italian sausage such as hot and sweet pepperoni, pickles, salads, poultry and meat dishes, and fruit pie fillings. The Spanish use the seed frequently in cooking and baking, and it is employed in flavoring cordials and liqueurs. Commercially, fennel seed or the extract is used to flavor medicine, soaps, and perfumes.

Medicinal activity Fennel oil has carminative properties, similar to those of dill and anise oil, and is considered beneficial in treating chest, spleen, and kidney diseases. The crushed seeds steeped in boiling water yield fennel water, which is helpful against flatulence. In India, toasted fennel seeds are chewed after meals.

Umbelliferae Leaf Types

Parsley is the most popular leaf-type herb of the Umbelliferae family. Similar, but less recognized

outside France, is chervil. The fresh leaves of parsley and chervil are most frequently used finely chopped on meat, fish, soups, and salads. Leaves of three of the herbs discussed in the first half of this article, namely coriander, dill, and fennel, also find many uses in the food industry and home food preparation. The composition of the fresh leaves is similar; they contain approximately 85% water, 3% protein, 1% fat, 10% carbohydrates, and 2% ash. The flavor substances in fresh leaves are generally present at lower concentrations than those found in seeds of the Umbelliferae plants. For example, dry dill seeds contain 2.6–4% volatile oil, whereas dill leaves or weed contain only 0.3–0.6% volatile oil. The composition of the oil differs as well.

Herb leaves are at their best when used fresh, and ideally should be used as soon as possible after picking. Their limited shelf-life can be extended by appropriate packaging and cold storage in the dark, since the organoleptic properties deteriorate when exposed to air and light. The leaves are preserved by drying to 5% moisture content or less. The composition of dehydrated chervil, coriander, dill, and parsley leaves is presented in Table 3. Drying conditions influence the flavor quality, and improved products are obtained by freeze-drying or lyophilization, as opposed to the conventional drying procedures, since exposure to heat impairs the flavor characteristics. In freeze-drying, the leaves are first frozen and placed in a vacuum, and the ice is sublimated. The freeze-dried leaves contain 1–3% moisture and have a fresh-weight replacement of 1:9. They are spongy and similar in volume and shape to the original material. The bulk density is about 0.3 g cm^{-3}. Stored at a cool temperature in airtight containers, the leaves are easily reconstituted when placed in cold water. Flavor and texture are excellent since maximum temperatures during final dehydration are less than 50 °C. Microwave freeze-drying of spice leaves has also been studied.

Properties of the leaves of chervil, coriander, dill, fennel, and parsley are discussed below.

Table 3 Proximate composition of selected umbelliferous dried leaves (per 100 g edible portion)

Nutrient	*Chervil*	*Coriander*	*Dill*	*Parsley*
Water (g)	7.2	7.3	7.3	9.0

Zinc (mg)	9		3	5

Data compiled from USDA (1977) *Composition of Foods*, USDA Agriculture Handbook 8–2. Washington, DC: US Department of Agriculture, and other sources.

Chervil (*Anthriscus cerefolium* L.)

Background The Greeks and Romans cultivated the plant during the Middle Ages. It was called *myrrhis* because of the similarity of the aroma to that of myrrh, a biblical spice. Used often in fried cooking, it is considered the gourmet's parsley.

Habitat and cultivation Chervil is an annual or biennial herb, native of western Asia and south-western parts of Russia, from which it reached the Mediterranean about 300 BC. It is cultivated in Europe, France, Italy, Spain, the UK, Russia, and the USA.

Description The plant grows to a height of 30–60 cm and has small, fine leaves and small white flowers (Figure 2). The flavor is similar to that of parsley with a hint of anise.

Figure 2 (see color plate 86) Herbs of the Umbelliferae: chervil. Reproduced from Herbs/Herbs of the Umbelliferae, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Uses Chervil is used frequently in French cooking in combination with parsley, tarragon, and chives, which make up the fines herbes. Alone, it is used like parsley, chopped fine and sprinkled on meat, fish, and soups, in salads and as a garnish. It is also used in baked products.

Coriander (*Coriandrum sativum* L.)

For background, habitat, and cultivation, see the section on coriander seeds, above.

Description Also called Chinese parsley or cilantro in Spanish, the plant leaves are quite similar in shape to the leaves of parsley but more jagged (Figure 3). The aroma is fetid. In contrast to the seeds, the leaves contain only about 0.1% volatile oil, in which aliphatic aldehydes such as decylaldehyde are present. These compounds give the leaves their disagreeable odor, which is so different from that of the seeds.

Uses The fresh young leaves are used like parsley to flavor salads and soups in the Middle East, India, China, Japan, Mexico, and South America. They are also used in chutney.

Figure 3 (see color plate 87) Herbs of the Umbelliferae: coriander. Reproduced from Herbs/Herbs of the Umbelliferae, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Dill (*Anethum graveolens* L.)

For background, habitat and cultivation, and description, see the section on dill seed, above.

Composition Distillation of oil from the plant yields about 0.3–0.6% of volatile oil. The carvone content is less than 20%, and the oil contains a high proportion of hydrocarbons. Phellandrene is responsible for the characteristic flavor.

Use The most important use of dill weed is in pickling cucumbers (dill pickles). The fresh leaves are used for flavoring salads, soups, sauces, and fish dishes, and in pastries. Dill butter is prepared by creaming butter with minced fresh or dried dill.

Fennel (*Foeniculum vulgare*)

For background, habitat and cultivation, and description, see the section on fennel seeds, above.

Uses The tender leaves are used for garnishes and to flavor salads, salad dressings, soups, and sauces. Stems of the cultivated fennel are also eaten in salads (Figure 4). The Italian fennel (*F. dulce*) is a popular vegetable in Italy. Cooked and served in cream sauce, it is reminiscent of celery in taste, although sweeter.

Medicinal activity The leaves of fennel were considered in ancient times to be aphrodisiac, to improve eyesight, stop hiccups, assist in losing weight, relieve stomach pains, and cure wheezing. Syrup prepared from fennel juice was given for chronic coughs. Boiled in water, the liquid is used to increase lactation.

Parsley (*Carum petroselinum, Apium petroselinum L., Petroselinum hortense (crispum)*)

Background The name 'petroselinum,' from which the name parsley is derived, is said to have been assigned by Dioscorides. Although Linnaeus assigned it in 1764 to the genus *Apium*, it is assigned today to the genus *Carum*. The herb was used in funeral rites by the Greeks, who held it sacred.

Habitat and cultivation Parsley is indigenous to the Mediterranean regions. It is cultivated in the Mediterranean countries, Europe, the USA, and Japan. The Germination period is 10–21 days and maturation occurs in 70 days.

Description Parsley is biennial or perennial, with dark-green stems growing to a height of about 60 cm. The plain-leaf parsley is by far the hardier, able to survive a severe winter. Several cultivated varieties exist, characterized by the plain leaf, the

Figure 4 (see color plate 88) Herbs of the Umbelliferae: fennel. Reproduced from Herbs/Herbs of the Umbelliferae, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

broad leaf (Hamburg), and the curled leaf (crispum). Of the latter, the ones with compact leaves are most valuable. The Hamburg variety is grown primarily for its enlarged root. The aroma of the leaves is slightly fragrant, and the taste is tangy and pleasant.

Composition The plant yields no more than 0.06% volatile oil, while the seed contains 3.5%. The main constituent of the volatile oil is apiole, and myristicin, D-pinene, and other aldehydes, ketones, and alcohols are also present. Total solids are 11–12%, of which sucrose is 0.2% and glucose is 0.1%.

Uses The most common uses of parsley are as flavoring to sauces, soups, omelets, stuffings, meat, and other dishes, or sprinkled finely chopped over salads and vegetables and in the preparation of parsley butter. Parsley, in combination with other herbs, is a component of the *bouquet garni* in French cooking. Dried leaves are also used for these purposes. The leaves are frequently used as garnish. The broad-leaf variety (Hamburg) is used for flavoring soups and stews, and the roots are also cooked and eaten like parsnips. Commercially, parsley is used in soup bases, seasoning mixes, salad dressings, and similar foods. Dehydrated parsley is available as flakes, as powder and minced.

Medicinal activity In the past, parsley was considered a remedy for a large number of disorders, including the ability to counteract poisons and for treatment of coronary conditions. Parsley, fresh and dehydrated, has carminative and diuretic properties. Parsley tea is prepared by steeping the dried leaves. The chopped leaves have been used externally as a remedy for bites and stings and as a treatment of cancerous tumors.

Herbs Used in Alcoholic Drinks

V B Veljković and M Z Stanković, University of Niš, Leskovac, Yugoslavia

Introduction

A wide variety of herbs, rich in specific flavoring compounds, mostly from their aromatic essential oils, are used in industries producing alcoholic drinks.

The herbs impart to an alcoholic beverage the characteristic recognized flavor (taste and aroma) and bouquet. These flavoring attributes have traditionally been one of the most significant qualitative factors in the use of alcoholic drinks. In addition, the essential oils from many aromatic herbs, so-called medicinal herbs, have many beneficial effects on metabolism, which are experienced after the controlled use of alcoholic drinks based on such herbs; for example, medicinal wines (*vina medicata*) have been used for a long time.

The commercially important alcoholic drinks based on herbs are as follows: beers, aromatized wines (vermouths and medicinal wines), liqueurs (bitter, fruit), and hard liquors (bitters, brandies, flavored distilled spirits, etc.).

Use of Herbs in the Alcoholic Drink Industry

In the alcoholic drink industry, both wild and cultivated herbs are used; a summary of the herbs used for this purpose, and known all over the world to a greater or lesser degree is presented in Table 1. Because of the need for larger quantities, the cultivation of some herbs is of great importance. Herbs are most often used dried or processed, and rarely fresh. Different parts of the herb are used: aerial parts, flowers, leaves, berries, roots, and seeds. The soluble essences (essential oils and extracts), obtained by processing either fresh or dried herbs or their parts, are also used in the flavoring of alcoholic drinks.

Herbs are used in alcoholic drink production either as flavorings, or as both fermentation substrate and flavoring agent. The flavor of a herb is dependent on its volatile and nonvolatile constituents; the former gives to the herb its distinctive odor, and the latter can affect some gustatory reaction sometimes coupled with a physiological effect.

Most herbs are used only for flavoring purposes. A base alcohol (beer, spirit, and wine) is combined with one or more herbs, known as the herbal formula, to obtain a special flavor. Herbal formulae usually contain more than one herb. One herb may be a major definitive constituent, while the others are added to develop the overall flavor of an alcoholic drink. For example, juniper berries are always used in gin production, but others, such as coriander seed, angelica root, or caraway seed, play a very important role, also as flavour ingredients, in some gin formulae. In a herbal formula, the selection of ingredients with respect to the major constituent is generally limited, and the proportions of constituents are normally constant and commonly not disclosed by manufacturers. The 'right' proportions are achieved through experimentation.

The herbs of appropriate quality are used for alcoholic drink production. The selection is largely based on organoleptic assessment. Color, overall appearance, odor, moisture content, quality, and content of essential oil or other specific characteristics are assessed for the purpose of selection and approval of quality of herbs or their parts. Although the specific flavor profile is within acceptable limits, quantitative variations in the flavor characteristics are often observed among different batches of the same herb material or even between different parts of the herb. Because of these variations, the herb material should contain the useful part of the herb, with a minimum content of the other parts of that or other herbs, and be of natural odor, color, and proper overall appearance, without any trace of decay or spoilage. The distinctive odor of the herb should be typical and 'clean,' with no trace of mustiness. The acceptable moisture content is usually in the range of 10–20%, mostly 12–14% on a dry-weight basis; it should not be too high, in order to reduce the risk of burning during storage, but too low a moisture content means that the herb material is old. The composition, color, and odor of the essential oil are important factors for the quality of an alcoholic drink, while its content is important for the economic production of the drink.

For the flavoring of alcoholic drinks, herbs are commonly used in the following basic ways:

- By maceration of the herb materials in a base alcohol (spirit, wine, etc.).
- By codistillation of the herb materials or their essential oils with a suitable high-quality spirit (usually grain or other neutral spirit).
- By mixing the essences of the herb materials with a spirit or wine.

Details of these processes differ among the various manufacturers, who usually do not disclose them. The maceration process is applied in the production of fruit brandies with aromatic herbs (usually with medicinal properties), bitters made with bittering herbs, and aromatized wines. Herbs rich in essential oils are macerated with a spirit containing 70% ethanol by volume, while the herbs rich in tannins are treated with a 50% spirit. The herb material is immersed in the chosen alcoholic base in a tank for a certain period of time and occasionally agitated. The liquid is drawn off, and the exhausted herb material is pressed to recover the residual liquid. The codistillation process is used in the production of hard liquors, such as gin. The herbs are placed in a still and covered with the base spirit of approved quality and alcoholic strength. The materials are charged loosely or held in

Table 1 Herbs used in alcoholic drinks

Common name	*Scientific name*	*Parts and essences used* [a]	*Description of the part used and the content of essential oil*	*Use in alcoholic drink*
Angelica	*Archangelica officinalis*	Root, essential oil, macerate	Fleshy tap root, 12–25 cm long; odor sweet and musk-like upon storing; taste sweet, becoming slightly bitter and astringent; oil < 1%	Brandies, gins, flavored spirits, liqueurs, vermouths
Anise	*Pimpinella anisum*	Seeds, essential oil, macerate Root	Gray-green to brown seeds, ovate, laterally compressed, pubescent, 3–5 mm long, 2–3 mm wide; odor anethole-like; taste sweet and aromatic; oil 1.5–4%	Brandies, flavored spirits, liqueurs, medicinal wines, vermouths
Arnica	*Arnica montana*	Root, macerate, percolate	Brown, hard, flexible, knotty root, 3–5 mm thick and 9 cm long; odor faint, aromatic; taste bitter and acrid; oil 0.1%	Bitters, flavored spirits, liqueurs
Balm	*Melissa officinalis*	Leaves	Green, rough cordate, serrated; odor of lemon; taste bitter; oil 0.1–0.3%	Liqueurs, flavored spirits, medicinal wines
Basil	*Ocimum basilicum*	Aerial parts	Low, sweet-scented bush; green, slightly toothed leaves; pink or white flowers; odor strong, pungent, sweet; taste peppery; oil 0.4–1.0%	Flavored spirits
Blessed thistle	*Cnicus benedictus*	Aerial parts	Medium height; dark green, deeply lobed, prickly; large, solitary, yellow heads of flowers; odor faint; taste bitter	Liqueurs, vermouths
Buffalo grass	*Hiërochloe odorata*	Aerial parts	Low, creeping range grass	Vodka
Burdock	*Arctium lappa*	Root	Fleshy, beet-like roots, up to 50 cm long, with brown cork; taste slightly bitter	Vermouths
Calamus	*Acorus calamus*	Root, essential oil, macerate, percolate	Brownish root, spongy texture, 12–25 mm thick, sometimes longer than 1 m; odor slightly sweet and aromatic; taste warm, pungent, rather bitter; oil 1.5–3.5%	Brandies (bitter), flavored spirits, liqueurs, medicinal wines, vermouths
Caraway	*Carum carvi*	Seeds, essential oil, macerate	Dark brown seeds with yellow ridges, crescent-shaped, 4–7 mm long, up to 1 mm broad; odor agreeable; taste pleasant, spicy, but sharp; oil 3–7%	Brandies, gins, flavored spirits, liqueurs, medicinal wines
Cardamom	*Eletaria cardamomum*	Seeds, essential oil	Pale to dark red-brown seeds, sickle-shaped, three-to four-sided, 3–5 mm long, 3 mm broad, hard; odor agreeable; taste strong, spicy, and aromatic; oil 5–9%	Brandies, flavored spirits, liqueurs, medicinal wines
Carnation	*Dianthus caryophyllus*	Flowers, essential oil, macerate	Deep pink, single or double flowers; odor clove-like; taste spicy	Brandy (bitter), flavored spirits, liqueurs, vermouths
Celery	*Apium graveolens*	Seeds, essential oil	Dark brown seeds, roundish-ovoid cremocarp; about 1–1.5 mm long, 1.5 mm wide, 0.5 mm thick; odor characteristic; taste strong and somewhat sharp; oil 2.5–3%	Liqueurs
Clammy sage	*Salvia sclarea*	Flowers, leaves, essential oil	Pale blue or lilac; large flowers; grayish-green, oblong, leaves; odour balsamic; taste aromatic and bitter; oil < 2%	Flavored spirits, liqueurs, vermouths
Common marigold	*Calendula officinalis*	Flowers	Light yellow to orange; odor slight and aromatic; taste salty and slightly bitter; oil in trace	Flavored spirits, liqueurs
Coriander	*Coriandrum sativum*	Seeds, essential oil, macerate	Tawny or reddish seeds, small, rounded (2–4 mm), ridged; odor mellow spicy; taste sweetly aromatic; oil 0.4–1.5%	Brandies, gin, flavored spirits, liqueurs, vermouths
Dandelion	*Taraxacum officinale*	Flowers Roots	Bright golden-yellow, tiny florets Cylindrical, tapering, 10–30 cm long, 1–2 cm wide; odor slight; taste somewhat bitter	Flavored spirits, liqueurs, medicinal wines, vermouths

Continued

Table 1 Continued

Common name	*Scientific name*	*Parts and essences used* [a]	*Description of the part used and the content of essential oil*	*Use in alcoholic drink*
Dill	*Anethum graveolens*	Seeds	Pale brown, oval, 3–5 mm long; odor and taste aromatic, pleasant and characteristic; oil < 4%	Flavored spirits, liqueurs
Elecampane	*Inula helenium*	Root, macerate, percolate	Grayish brown, fleshy root, 6 cm thick, up to 50 cm long; odor aromatic, pleasant; taste slightly bitter and pungent	Flavored spirits, liqueurs, medicinal wines, vermouths
European centaury	*Erythraea centaurium*	Flowering aerial parts	Stems, branched above, 20–30 cm in length; green-brown, oblong or elliptic leaves; rose pink, salver-shaped; odor distinct; taste bitter	Bitters, vermouths
Everlasting	*Helichrysum arenarium*	Flowers	Yellow, rarely orange, grape-like: odor faint, aromatic; taste bitter	Liqueurs
Fennel (wild)	*Foeniculum vulgare*	Seeds, essential oil, macerate	Green to yellow-brown, oblong cremocarps; odor anethole-like; taste sweet; becoming bitter; oil 3.5–6%	Flavored spirits, liqueurs, medicinal wines, vermouths
Fenugreek	*Trigonela foenum*	Seeds	Light to dark yellow-brown, rhomboidal; 2–3 mm thick, 3–6 mm long; odor specific; taste slightly bitter and mucilaginous	Vermouths
Galangal	*Alpinia officunarum*	Root, essential oil, macerate	Red brown on drying; hard, branching, nearly cylindrical root; odor pungent and spicy; taste pungent; oil 0.3–1%	Brandies, liqueurs, medicinal wines, vermouths
Garden thyme	*Thymus vulgaris*	Leaves, macerate	Yellow-green to brown-purple, narrow, ovate; odor thymol-like; taste strong, slightly sharp; oil 0.8–2.5%	Flavored spirits, liqueurs, medicinal wines, vermouths
Gentian	*Gentiana lutea*	Root, macerate	Nearly cylindrical, hard root, up to about 90 cm long, yellow-brown to brown; odor characteristic; taste sweet, becoming bitter	Gentian brandy, medicinal wines, vermouths
Germander	*Teucrium chamaedrys*	Aerial parts	Greenish; ovate, crenate leaves; pinkish-purple flowers; odor faintly aromatic; taste bitter and pungent; oil 0.06%	Liqueurs
German chamomile	*Matricaria chamomilla*	Flowers, essential oil, macerate	Yellow conical flower heads with white margins, odor aromatic; taste bitter; oil 0 ~ 5–1 ~ 5%	Liqueurs
Ginger	*Zingiber officinale*	Root, essential oil, macerate	Grey, striped; hand-like with irregular fingers; 8–12 cm long; odor aromatic and agreeable; taste strongly pungent; oil 1.5–3.3%	Liqueurs, medicinal wines, vermouths
		Aerial parts, flowers	Bine, dioecious; large, toothed leaves; small, yellowish green flowers	Vermouths
Hop	*Humulus lupulus*	Seeds, flowers	From the female plant; yellowish green, ovoid strobiles; odor aromatic; taste bitter; oil in seeds, 1–3%	Beers
Horehound	*Marrubium vulgare*	Aerial parts	Greenish; green-brown, crenate leaves; small, white flowers in dense clusters; odor faint, pleasant; taste bitter and pungent	Vermouths
Hyssop	*Hyssopus officinalis*	Aerial parts, essential oil	Fragrant, shrubby herb; dark green, slender leaves; spikes of blue-pink flowers; odor aromatic; taste bitter, minty; oil 0.3–1%	Liqueurs, medicinal wines, vermouths
Juniper	*Juniperus communis*	Fruits, essential oil	Blue-black, globular (5–8 mm) fruits; odor terpentine-like; taste aromatic, spicy and slightly of pine; oil 0.2–2%	Brandies, gin, geneva, Steinhger, borovička,
Lavender	*Lavandula officinalis*	Flowers, essential oil	Bluish-purple flowers; odor aromatic pleasant; taste aromatic, bitter; oil 0.9–3%	Liqueurs
Liquorice	*Glycyrrhiza glabra*	Root, macerate, percolate	Grayish brown root, brown on drying; odor characteristic; taste sweet	Brandies, liqueurs

Continued

Table 1 Continued

Common name	*Scientific name*	*Parts and essences used* [a]	*Description of the part used and the content of essential oil*	*Use in alcoholic drink*
Lovage	*Levisticum officinale*	Aerial parts, flowers, essential oil	Greenish; dark green-yellow, elliptic flowers; odor strong, pleasant taste, slightly spicy	Liqueurs
Lungwort	*Pulmonaria officinalis*	Aerial parts	Greenish; large spotted leaves; clusters of blue or purple flowers; taste astringent	Vermouths
Marjoram	*Origanum vulgare*	Aerial parts	Greenish; tough, woody stem; gray-green, ovate, crenate leaves; tiny mauve or pink flowers grouped in little round clusters; odor aromatic; taste sweet and spicy; oil > 0.1%	Vermouths
Motherwort	*Leonorus cardiaca*	Aerial parts	Very hairy, upright; deeply palmately lobed leaves with serrated margins; taste bitter	Flavored spirits, liqueurs
Orris	*Iris germanica*	Root, essential oil, tincture	Hard root, up to about 10 cm long, 2 cm thick, pale cream; odor violet-like; taste somewhat bitter; oil 0.1–0.2%	Brandies, liqueurs, vermouths
Pansy	*Viola tricolor*	Aerial parts, flowers	Dark green, spoon-shaped, crenate leaves; blue flowers with a short spur; odor slight; taste faintly bitter	Flavored spirits, liqueurs
Peppermint	*Mentha piperita*	Leaves, essential oil, macerate	Ovate-lanceolate, acute serrate leaves; odor strong, distinctive; taste pungent and cooling; oil 1.5–3.5%	Flavored spirits, liqueurs, medicinal wines, vermouths
Roman chamomile	*Anthemis nobilis*	Flowers	Yellow and white blossoms; with double, white florets; odor strong, aromatic; taste bitter; oil about 1%	Liqueurs, vermouths
Roman wormwood	*Artemisia pontica*	Aerial parts	Greenish; leaves twice- or triple-divided; yellow flower heads; odor and taste aromatic; oil about 1%	Liqueurs, vermouths
Rosemary	*Rosmarinus officinalis*	Leaves, essential oil, macerate	Leaves like coniferous needles; odor strong, distinct; taste pungent; oil 1.5–2%	Liqueurs, medicinal wines, vermouths
Saffron	*Crocus sativus*	Flowers, macerate, percolate, tincture	Bright orange-red stigmas; odor penetrating, distinct; taste aromatic, spicy, pungent; oil about 1%	Brandies, liqueurs, medicinal wines, vermouths
Sage	*Salvia officinalis*	Leaves	Grayish-green, oblong, hairy; odor aromatic; taste warm, pungent, slightly bitter; oil 0.5–2.5%	Flavored spirits, liqueurs, medicinal wines, vermouths
St John's wort	*Hyperycum perforatum*	Aerial parts, flowers	Pale green leaves with oil glands; bright yellow flowers; odor distinct; taste astringent; oil < 0.3%	Flavored spirits, liqueurs
Savory (summer)	*Satureja hortensis*	Aerial parts	Small, narrow, dark green leaves growing sparsely; white, tiny flowers; odor aromatic; taste slightly peppery; oil 2–3%	Flavored spirits, liqueurs, vermouths
Star anis	*Illicium verum*	Seeds	Shiny, light brown, hard, wrinkled; odor anise-like; taste spicy, sweet and pungent; oil 5–8%	Vermouths
Sweet clover	*Melilotus officinalis*	Aerial parts, essential oil	Long, stalked leaf divided into three narrow, ovate, toothed leaflets; small, yellow flowers; odor sweet, hay-like; taste aromatic	Liqueurs, vermouths
Sweet marjoram	*Majorana hortensis*	Aerial parts, essential oil	Branched; hairy leaves; small whitish or rose flowers; odor distinct, pleasant; taste aromatic, bitter; oil vermouths 0.5–1.3%	Flavored spirits, liqueurs,
Tarragon	*Artemisia dracunculus*	Leaves, macerate, percolate	Shrubby; dark, smooth, shiny leaves; odor aromatic; taste sweet and bitter; oil 0.5–2.8%	Flavored spirits, liqueurs, medicinal wines
Valerian	*Valeriana officinalis*	Roots, essential oil	Dark brown root, 2–4 cm long, 1–2 cm wide; odor pungent; taste bitter; oil 0.5–2%	Flavored spirits, liqueurs, vermouths

Continued

Table 1 Continued

Common name	*Scientific name*	*Parts and essences used* [a]	*Description of the part used and the content of essential oil*	*Use in alcoholic drink*
Wild thyme	*Thymus serpyllum*	Aerial parts, flowers	Low, spreading bush; very small, short-stalked, lanceolate obovate oblong leaves; pink-purple flowers; odor distinct; taste aromatic; oil < 1%	Flavored spirits, liqueurs
Woodruff	*Asperula odorata*	Aerial parts, flowers	Low-carpeting plant; slightly shiny leaves; small, white, star-shaped; odor cumarin-like	Brandies, vermouths, vodka
Wormwood	*Artemisia absinthium*	Aerial parts, macerate, percolate	Shrubby; silver-gray leaves; pale greenish-yellow flowers; odor pungent; taste aromatic, extremely bitter; oil < 0.9%	Bitters, flavored spirits, liqueurs, vermouths
Yarrow	*Achillea millefolium*	Aerial parts, macerate, percolate	Pinnate, finely divided leaves; small, white, or pinkish flower heads; odor fragrant; taste pleasant, bitter; oil 0.2–1.3%	Brandies, flavored spirits, liqueurs, vermouths

[a]The essences given are reported in the literature to be used for the flavoring of alcoholic drinks.

porous bags in the spirit, or placed in trays above the free surface of the spirit; the latter two methods have the advantage that the exhausted herbs can be easily removed from the still. The third method is commonly used in production of liqueurs and flavored spirits.

In a few cases, herbs contain not only specific flavoring compounds, but also a significant content of fermentable sugars (juniper berries, about 15–30%; gentian roots, about 25% on a dry-weight basis) which can be converted by strains of yeast into ethanol in an alcoholic fermentation process. For example, juniper berries can be used for flavoring grain spirits (gin, geneva), fruit spirits (fruit brandies; klekovača, from Yugoslavia), but also in the production of special alcoholic drinks which involves the alcoholic fermentation process, for example, Wacholderlüter (the base for Steinhäger), borovička, or brinjevac. The special flavor of the alcoholic drinks obtained in this way is mainly attributable to the flavoring compounds of the herb. Commonly, the herb materials are first comminuted and mixed with water in a specified ratio; sometimes, mineral salts (ammonium salts, phosphates) are also added. Then a certain amount of bakery or brewer's yeast is added. The fermentation conditions are usually regulated; in the fermentation of juniper berries, the temperature is about 25–30 °C, and pH is about 4. Owing to the presence of the aromatic compounds from the essential oil, which act as yeast inhibitors, fermentation is slow and can last up to a couple of weeks. The fermented mash is then distilled to obtain the alcoholic drink. The essential oil also distils and separates as a lighter phase. In the case of juniper berries, it is also possible at first to recover the essential oil by hydrodistillation, then to remove the residual plant material by filtration and finally to use the filtrate as the fermentation medium. By this procedure, the duration of fermentation process is significantly reduced (to about 1 day) and the yield of ethanol is increased.

It is clear that not only the herb materials but also every stage in herb processing and drink preparation affects, at least to some extent, the overall flavor of alcoholic drinks. A delicate balance between what is added and what is lost, transformed, or formed during herb processing and drink preparation is established.

Harvesting and Handling of Herbs

Harvesting

In order to retain their specific valuable properties, herbs have to be harvested at the correct time, which is characteristic for every herb. Table 2 lists the best moments for harvesting some commercially important herbs. The method of harvesting depends on the type and useful part of herb, and can be very primitive, usually by hand, or carried out using special machines, such as combine harvesters. Aerial parts are cut at ground level or somewhat above, and leaves are picked; they are often chopped before drying. Flower heads are picked out whole. Seed plants, after cutting, are left for a couple of hours or days in the field to dry or ripen, and the seeds are then shaken out or threshed for further drying, winnowing, or sifting. Roots are pulled out or turned out with a plough, freed of earth, tops, and rootlets, washed thoroughly and cut into smaller pieces for further drying.

Table 2 Harvesting and handling of herbs used in the alcoholic drink industry

Herb material	*Harvesting time*	*Drying*	*Packaging and storage*
Angelica root	End of autumn	In dark, well-aired places, or in dryers (35–45 °C)	Bags or bales; on shelves in dry, well-aired places
Anise seed	August and September when just beginning to turn brown	In shady or dark, well-aired places with frequent turning	Paper bags; in dry places
Arnica root	In autumn, after the leaves have died down	In shady or dark, well-aired places	Bags or bales; on shelves in dry, well-aired places
Balm leaves	Before flowering, without stems	Immediately after harvesting. In shady, well-aired places, or in dryers (40 °C)	Immediately after drying; hermetic packing; in dark, cool places
Basil aerial parts	During flowering in the early summer	In shady, well-aired places, or in dryers (35–45 °C)	Paper bags; in dry, air-conditioned places
Blessed thistle aerial parts and sowers	At the beginning of flowering in mid-August	Immediately after harvesting. In shady, well-aired places, or in dryers (40 °C)	Paper bags; in dry, air-conditioned places
Burdock root	In autumn, before becoming stiff	In dryers (35–45 °C)	Jute or paper bags; only stored for a few months
Calamus root	At the end of summer or during the autumn	In well-aired places, or in dryers (40 °C)	Bags; in dark, air-conditioned places
Caraway seeds	July to August	In the field until dry	Bags; in air-conditioned places
Cardamom seeds	The fruits are picked up whilst growing	In the sun	Bags; in air-conditioned places
Carnation flowers	May to August	In shady, well-aired places	Bags; in air-conditioned places
Celery seeds	August, in the early morning	Several hours in the field, or in dryers (35–40 °C)	Bags; in dry places
Clammy sage flowers and leaves	About 10 days after flowering	In shady, well-aired places; not recommended before distillation	Paper bags; in dry places
Common marigold flowers	During flowering, June to September	In the shade, or in dryers (40–50 °C) with good air circulation	Cartons; in dry places
Coriander seeds	August; after cutting, the herbs are left to complete ripening	In the shade. In dryers (35–45 °C) with good circulation	Jute bags; in dry, dark places
Dandelion flowers and roots	Immediately after flowering	In shady, well-aired places; often used fresh	Paper bags; when used fresh, the whole herb is transported
Dandelion roots	In autumn	In the open for several days, then in dryers (40–50 °C)	Paper bags
Dill seeds	When the fruits turn from green to brown	In the shade, or in dryers (35–45 °C) with good air circulation	In dry, dark places
Elecampane root	In autumn	In well-aired places, or in dryers (40 °C) with good air circulation	Bags or bales; in dry, well-aired places
European centaury aerial parts	During flowering (July–August)	In trays or other well-aired places, or in dryers (40–50 °C)	Paper or jute bags; in dry, well-aired places
Everlasting flowers	During flowering (June–September)	Immediately after harvest in well-aired places; in dryers (40 °C)	Jute or paper bags; on shelves in dry, cool and well-aired places
Fennel seeds	In summer	First in the shade, then in dryers (40 °C)	Well-closed cartons or paper bags
Fenugreek seeds	End of summer	In well-aired places	Well-packed; in dry places
Galangal root	In early spring	In the sun	Paper bags; in dark, cool places
Garden thyme leaves	During flowering (May–August)	In well-aired places, or in dryers (35 °C)	Paper bags; in dry places
Gentian root	In autumn	In the sun, or in dryers (80 °C)	Jute or paper bags; in dry, cool places
Germander aerial parts	April–July	In shady, well-aired places, or in dryers (35–45 °C)	Jute or paper bags; in dry, well-aired and cool places
German chamomile flowers	During flowering (April–June)	In shady, well-aired places, or in dryers (40 °C)	Cartons, metal boxes or waterproof paper bags; separated from other herbs; in dry, air-conditioned places
Ginger root	About 10 months after planting	In the sun for a day	In dry, dark, and cool places
Hop seeds	In the summer (July–September), when matured	In the shade; in dryers (60 °C)	Textile bags; on shelves in dry, well-aired places

Continued

Table 2 Continued

Herb material	*Harvesting time*	*Drying*	*Packaging and storage*
Horehound aerial parts	During flowering in the summer (June–August)	In shady, well-aired places	Paper, well-closed bags
Juniper berries	August–October	In the sun with frequent turning; in dryers (maximum 40 °C)	Jute bags; in dry, well-aired places
Lavender flowers	During flowering (from mid-June to mid-July)	In dry, well-aired places, or in dryers (40–45 °C)	Bags or bales
Liquorice roots	In the third or fourth year (September–October)	Stacked, in the field; in dryers (50 °C) after thorough cleaning	Stacks covered with hay; the clean roots are packed in bags
Lovage aerial parts and flowers	During flowering	In shady, well-aired places	Bags or bales
Lungwort aerial parts	During flowering (March–April)	In shady, well-aired places	Paper bags
Marjoram aerial parts	During flowering (July to mid-August)	Immediately after harvest; in well-aired places; in dryers (40 °C)	Bags or bales
Motherwort aerial parts	During flowering (June–August)	In well-aired places; in dryers (50–60 °C)	Bales; on shelves in dark, cool and well-aired places
Orris root	Second or third year, in July or August	In the sun for 5 or 6 days; complete drying in well-aired places	Textile bags
Pansy aerial parts and flowers	During flowering (in summer)	In shady, well-aired places	Paper bags or bales
Peppermint leaves	During flowering (in summer)	Left in the field to fade and lose 50% of water (may be used to distil); further drying in shady, well-aired places	Cartons or paper bags
Roman chamomile aerial parts	During flowering (April–June)	In shady, well-aired places; in dryers (40 °C)	Cartons, metal boxes or waterproof paper bags; separated from other herbs; in dry, air-conditioned places
Roman wormwood aerial parts	During flowering (July–September)	In shady, well-aired places; in dryers (40–45 °C)	Bags or bales; in dry, well-aired places
Rosemary leaves	May–October	In shady, well-aired places; in dryers (35–45 °C)	Jute or paper bags; in dry, air-conditioned places
Saffron flowers	During flowering	In shady, well-aired places	Paper bags
Savory aerial parts	During flowering (April–July)	In shady, well-aired places; in dryers (35 °C)	Paper bags
Star anis seeds	When fully ripened	In shady or dark, well-aired places with frequent turning	Paper bags; in dry places
Sweet clover aerial parts	During flowering (June–July)	In shady, well-aired places; in dryers (40 °C)	Paper bags
Sweet marjoram aerial parts	Immediately before flowering (June–September)	In shady, well-aired places; in dryers (40 °C)	Bags
Tarragon leaves	July–September	In well-aired places; must be green	Jute bales; in dry, dark places
Valerian roots	In early spring or in autumn	In well-aired places; in dryers (35–40 °C)	Jute bales or bags; in dry, well-aired places
Wild thyme aerial parts and flowers	During flowering (May–July)	In shady, well-aired places; in dryers (35–40 °C)	Bags or bales; on shelves in dry, well-aired places
Woodruff aerial parts and flowers	During flowering (May–August)	In the shade, with frequent turning	Well-closed containers
Wormwood aerial parts	During flowering (July–August)	In shady, well-aired places; in dryers (40–45 °C)	Bags or bales; in dry, well-aired places
Yarrow aerial parts and flowers	During flowering (June–August)	In dry, shady, well-aired places; in dryers (40–45 °C)	Cartons; in dry, cool, well-aired places

Drying

Fresh herbs are perishable to varying degrees and can be stored for only a limited period of time without spoiling. Spoilage and deterioration in quality of herbs are recognized by changes in color, flavor, and overall appearance. With proper handling procedures, spoilage can be prevented, and shelf-life can be significantly extended.

Drying is a simple and most common method of preserving herbs; dried herbs can be used all year round. Herbs or their parts should be dried immediately after harvesting to decrease the risk of spoilage and the loss of volatile oils. Dried herbs are also relatively immune to microbial spoilage.

Drying a herb or its parts involves removing an amount of water from the herb material by evaporation in the open or in a heated air flow. The principle of drying is the same for all herbs, although specific drying conditions may be required, as can be seen in Table 2.

The oldest method of drying herbs, usually used in the case of wild aromatic herbs, is drying in the open. The herb materials are spread thinly in suitable shady or dark and well-aired places (on the floor, on shelves, in the attic, or in trays). The herb materials should not be turned over too often, to avoid their disintegration. If the herbs are spread too thickly, the danger of burning increases. The duration and efficiency of drying depend on weather conditions. Drying can require a couple of weeks and, if the weather is rainy, the herbs can be spoiled by decay.

Dehydration in a heated air stream offers obvious advantages over drying in the open, notably regulated drying conditions, shorter duration of the process (several hours or even minutes), fewer flavor and color changes as well as a decreased danger of spoilage. When cultivated, herbs are normally dried in heated air driers, such as tray, screen-conveyor, or rotary dryers, to insure efficient drying of large quantities of the herb materials at economic capacity. The drying conditions are regulated by the air temperature, relative humidity, and flow rate. With warm air (40–80 °C), the duration of drying is usually a couple of hours. Drying in hot air (200 °C or even higher) requires a few minutes (2–5 min).

Dried herb materials can be ground, crumbled, rubbed, or treated by any other suitable method for further processing, packaging, or storing.

Packaging and Storing

There is always a risk of spoiling and the loss of volatile compounds during long-term storage, especially under unfavorable conditions. Generally, herbs, leaves, and flowers are sensitive, while roots and seeds endure prolonged storage quite well. Deterioration in quality is accelerated by moisture, light, oxygen, and elevated temperature. Dried herb materials are best kept in a dark, dry and well-aired room at a low temperature. In many cases, the dried herb materials can be stored satisfactorily in paper, linen, or cotton bags placed in well-closed containers or bins. Properly dried and packed herb materials (Table 2) can be kept at room temperature for months, or even a couple of years. Sometimes, storage appears to favor development of the aromatic principles, probably owing to the action of the specific enzymes.

Production of Essences

The processing of herb materials is usually carried out using traditional methods, notably hydrodistillation and solvent extraction, the main goal being to recover their essences: essential oils and extracts. These essences are very suitable for direct application in alcoholic drink preparation as they insure higher consistency in quality of the alcoholic drink. In addition, they are more easily stored, with less danger of spoiling during long-term storage, although their flavor properties seldom compare favorably with those of the herb materials from which they were recovered. In the case of essential oils, this distortion is caused by chemical interchanges resulting in artifacts, the evaporation of the low-boiling components, the dissolution of certain water-soluble components in the still liquors, and the degradation of nonvolatile cellular matter during hydrodistillation.

For complete isolation of valuable essences, the herb material must be properly prepared by comminution to some extent, which depends on the nature of the herb material. Flowers are usually distilled uncomminuted, leaves are ground, seeds must be thoroughly crushed, while roots and arid stalks should be cut into smaller pieces. For this purpose, standard equipment can be used, e.g., roller mills for crushing seeds, cutters for chopping roots, and similar comminuting machines. When comminuted, the herb materials should be immediately processed to hinder the loss of volatile flavorings.

The essential oils are mainly recovered from the herb materials by hydrodistillation. The herb material is put into a still and heated with direct steam (steam distillation); it can also be immersed in warm water (water distillation) or placed on the perforated plate above the bottom of the still partially filled with water (steam and water distillation), and then heated by any of the usual methods. Water distillation is well suited for finely powdered materials and flowers; water and steam distillation is favorable for herb and leaves; and steam distillation is most successful for seeds and roots. The resulting vapor mixture

passes through a condenser, and the condensate is collected in a Florentine flask where the essential oil is separated from the water; this water can be returned to the still or, in some cases, used as fragrant water (*aquae aromaticae*). The duration of a batch distillation depends on the procedure applied, the kind of herb materials, and the extent to which the herb material is comminuted. Steam distillation requires a shorter time for completion than steam and water or water distillation. The essential oils from aerial parts or leaves are usually recovered after 1.5–2 h, from seeds after 4–6 h, and from roots after 6–8 h. In general, the distillation of comminuted herb material requires half the time for complete recovery, as compared with uncomminuted material, and gives higher yields of oil. Different methods of distillation result in essential oils of different composition. The yield of essential oil depends upon several factors, including the age of the herb material, its geographical origin, weather conditions, and the method of distillation. On distillation at atmospheric pressure, thermolabile components can be decomposed and, in such cases, the application of reduced pressure is suggested; in some cases, distillation at an increased pressure is preferred. It is possible to apply solvent extraction first and then to submit the extract thus obtained to steam distillation at reduced pressure, as in the case of orris root.

Traditional extraction processes involve the use of high-proof alcohols, and these are widely employed for dried herbs, leaves, and roots. The extracts obtained have the 'true,' natural odor of the herbal materials. The methods commonly applied are maceration, percolation, and digestion. The extracts obtained are sometimes concentrated by distilling off the alcohol under vacuum. The products, so-called resinoids, are usually dark, viscous, almost solid, and can be used in the flavoring of alcoholic drinks.

Extraction with dense carbon diooxide (CO_2) has also been applied in the removal of essences from some herbs. Dense CO_2 has many advantages over conventional organic solvents. It is without color, odor, or taste, easily removable from the extract, chemically inert, and nonflammable. In the subcritical state, liquid CO_2 behaves as a selective, nonpolar solvent, which under normal operating conditions (0–10 °C, 50–80 bar) dissolves virtually all the useful flavor components. CO_2-extracted juniper berry oil has already been used in the flavoring of gin. The essential oil of ginger roots has also been obtained by liquid CO_2 extraction. Due to the higher pressure and temperature applied, supercritical CO_2 has a higher solvent power than the liquid CO_2. Extraction with supercritical CO_2 is carried out at relatively low temperature (usually 40–60 °C) and high pressure (200–500 bar). It is important that the dissolving power and selectivity can be controlled by selection of adequate pressure/temperature combination. Many aromatic herbs have been extracted with supercritical CO_2, such as coriander seeds, rosemary, sage, and peppermint leaves.

HISTAMINE

R K Bush, University of Wisconsin-Madison Medical School, Madison, WI, USA
S L Taylor, University of Nebraska, Lincoln, NE, USA

Background

Histamine or β-aminoethylimidazole is formed by enzymatic decarboxylation of histidine, an amino acid that occurs naturally in many tissues in the human body, in the tissue of other animals and plants, and in foods (Figure 1). Once formed, histamine may be metabolized (1) by methylation of the ring by histamine-*N*-methyltransferase to 1-methylhistamine or (2) by oxidative deamination by diaminoxidase (histaminase) to imidazoleacetic acid. Methylhistamine can be deaminated by monoamine oxidase to form methyl imidazoleacetic acid. Imidazoleacetic acid is conjugated with ribose to imidazoleacetic acid riboside. These latter two products are readily excreted in the urine. Many tissues have the capacity to metabolize histamine by one or both pathways.

Distribution

Histamine is present in many human tissues, including skin, intestinal mucosa, heart, lung, and nerve endings in the brain. The usual body storage sites for histamine include mast cells and basophils (Figure 2). Since most of the histamine is stored in the secretory granules of mast cells and basophils, only small amounts (0.2–0.4 mmol) are found in the circulation. A variety of stimuli, both immunological and non-immunological, may trigger the release of histamine from the mast cell or basophil. During tissue stresses of growth or repair, histidine decarboxylase activity is increased; histamine synthesis is also increased, which suggests that histamine may be important in healing processes. The newly formed histamine is rapidly metabolized rather than being stored. Histamine is metabolized by the pathways described above.

Pharmacological Effects

The biological effects of histamine are mediated through three types of receptors, H_1, H_2, and H_3 (Table 1). Histamine binds to these receptors, eliciting a variety of biological and physiological responses. These receptors have different signal transduction mechanisms. The H_1 receptors are coupled to phosphoinositide breakdown and to calcium metabolism, whereas H_2 receptors are linked to adenylate cyclase. Stimulation of the H_1 receptor causes

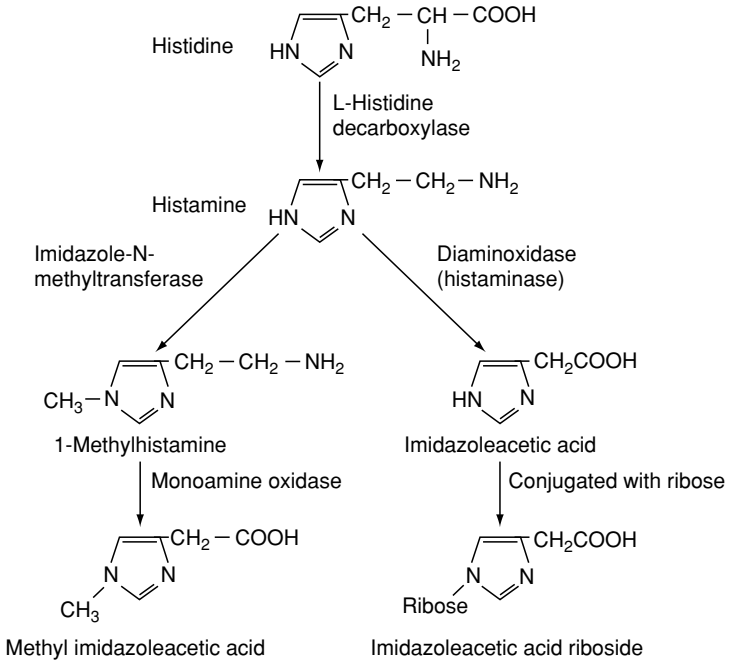

Figure 1 Pathway of synthesis and metabolism of histamine in human cells. The conversion of L-histidine to histamine is catalyzed by L-histidine decarboxylase, which is also found in certain bacteria. The degradation of histamine occurs via two routes; the blockade of one shunts the metabolism to the other. Adapted from Marquardt DT (1983) Histamine. *Clinical Reviews in Allergy* 1: 343–351, with permission.

Table 1 Characteristics of histamine receptor subtypes

	H_1 receptor	*H_2 receptor*	*H_3 receptor*
Effects of stimulation	Bronchial smooth muscle constriction Increased vascular permeability Gut smooth muscle constriction Vasodilation Pruritus Increased cyclic guanosine monophosphate levels	Increased gastric acid secretion Increased pepsin secretion Decreased IgE-mediated basophil histamine release Increased cyclic adenosine monophosphate levels Decreased lymphocyte-mediated cytotoxicity	Regulate synthesis and release of histamine from histaminergic nerves Inhibits endogenous norepinephrine release from sympathetic nerves
Stimulus–response coupling	Linked to phosphoinositide breakdown Increased calcium mobilization	Linked to adenylate cyclase	?
Antagonists	Chlorpheniramine, diphenhydramine, loratidine, cetirizine, fexofenadine	Cimetidine, ranitidine, famotidine, nizatadine	Thioperamide, clobenpropit

bronchial smooth muscle constriction in the airways of the lung (bronchospasm) and increased vascular permeability in the skin, which may be manifested as swelling or hives and produces itching by affecting nerve endings. Stimulation of H_2 receptors in the stomach results in increased acid secretion, which can produce indigestion or peptic ulcer disease. The H_3 receptor stimulus–response coupling is presently unknown. The H_3 receptors were initially described in presynaptic nerve endings and on nerve bodies of histaminergic neurons in the brain, where they function as autoreceptors to regulate the synthesis and release of histamine. H_3 receptors have also been located in the airways and gastrointestinal tract.

These histamine receptors and their responses can be antagonized by specific compounds. For the H_1 receptor, classical antihistamines such as diphenhydramine and chlorpheniramine act as competitive antagonists for the receptor. The H_2 receptor is antagonized by the compounds, cimetidine and ranitidine, whereas the H_3 receptor can be antagonized by thioperamide.

Role in Allergic Reactions

Allergic reactions are among the most commonly recognized effects of histamine. Specific immunoglobulin E (IgE) antibodies (the class associated with allergic reactions), which may be directed at various allergens, including inhalants such as pollens, molds and animal dander, foods, drugs, or insect venoms, are bound to the surface of mast cells and basophils (Figure 2). When the allergen cross-links two IgE molecules attached to the mast cell or basophil surface, histamine release occurs. Histamine then interacts with tissue histamine receptors (predominantly H_1), which can produce local reactions such as

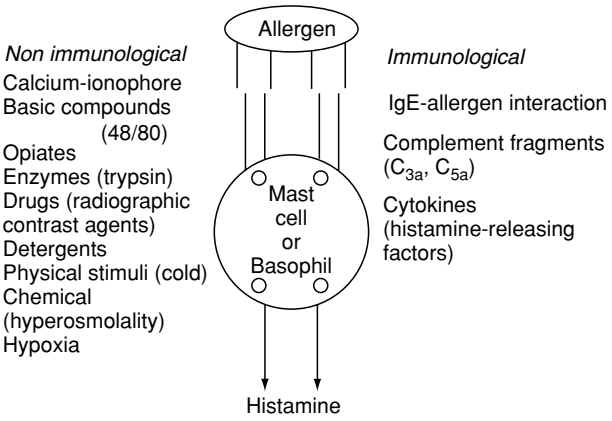

Figure 2 Human mast cell or basophil stimulated to release preformed histamine by a variety of immunological and nonimmunological mechanisms.

sneezing, nasal and ocular pruritus (itching), rhinorrhea (nasal discharge), and nasal congestion. In asthmatics, histamine release may cause cough, wheezing, and dyspnea (shortage of breath) owing to bronchial smooth muscle constriction. More generalized systemic symptoms can occur as a result of the ingestion of foods and drugs, insect stings, or parenteral administration of various medications. These reactions, whether immunological or nonimmunological in nature, result in a release of histamine leading to a prompt and sharp rise in plasma histamine levels. The severity of the reactions is proportional to the magnitude of this rise. Mild reactions are associated with low histamine levels, approximately 1 mmol. Elevation beyond this level can produce generalized reactions with urticaria (itchy skin rash), gastrointestinal disturbance, cardiac arrhythmias, and hypotension (low blood pressure). At levels in excess of

12 mmol, life-threatening responses such as severe hypotension, bronchoconstriction, and ventricular fibrillation can occur. (*See* **Food Intolerance**: Types; Food Allergies.)

Cardiovascular Effects

Histamine causes vasodilation and increased vascular permeability. This can result in flushing and decreased peripheral vascular resistance with subsequent lowering of the blood pressure. Extravasation of fluid results in angioneurotic edema (swelling of the skin on the eyes, lips and extremities). These effects are primarily mediated through H_1 receptor stimulation. Stimulation of the H_1 and H_2 cardiac receptors can lead to a variety of rhythm disturbances.

Bronchial Smooth Muscle Effects

Stimulation of the H_1 receptors in bronchial smooth muscles causes constriction, producing narrowing of the airways. This results in breathing difficulties and wheezing. Stimulation of H_2 receptors may lead to relaxation of airway smooth muscle, although this effect is minimal.

Effect on Gastric Secretion

Gastric mucosal mast cells release histamine, which causes an increase in gastric acid secretion by gastric parietal cells through H_2 receptors. Histamine interacts with acetylcholaine and gastrin to control acid output in the stomach. H_2 receptor antagonists (cimetidine, ranitidine) are widely used to treat peptic ulcer disease because of their ability to decrease acid secretion.

Central Nervous System Effects

Two major sources of histamine in the brain are mast cells and histaminergic neurons. Mast cells are located near blood vessels and may affect local blood flow. Histaminergic neurons (nerve cells whose principal neurotransmitter is histamine) are limited in number, but their axons branch into long ascending fiber networks that ultimately innervate much of the brain. Their role is not clear, but the central effects of histamine include antidiuresis (fluid retention) through the release of vasopressin, induction of adrenocorticotrophic-releasing hormone and prolactin secretion, increase in blood pressure and heart rate, temperature regulation, and control of arousal mechanisms. The sedative affects of the first generation antihistamines (e.g., chlorpheniramine, diphenhydramine), which block H_1 receptors functions are well known. In contrast, second-generation H_1 blockers (loratidine, fexofenadine, cetirizine) that do not readily cross the blood–brain are less likely to induce sedation.

Effect on the Immune System

Histamine may have a more general effect on the immune system than its role in allergic reactions. Stimulation of H_2 receptors suppresses lymphocyte proliferation, T-cell-mediated cytotoxicity, lymphokine production, natural killer cell cytotoxicity, and antibody production by B-lymphocytes. Histamine in certain dose ranges is chemotactic for eosinophils, which are the principal effector cells in killing of parasites such as schistosomes. Parasites that invade body tissues generate profound IgE antibody responses. Interaction of parasite antigens with specific IgE antibodies on the surface of mast cells causes histamine release and the subsequent attraction of eosinophils to the area. Eosinophils can degranulate, releasing their granular proteins, which are potent toxins to parasitic organisms. (*See* **Immunology of Food.**)

Role of Cellular Proliferation

Another physiological role for histamine appears to be in wound healing, since proliferating tissues synthesize histamine at a higher rate than normal tissue. The contribution to wound healing is still not completely understood, however.

Histamine Poisoning

Histamine is present in measurable quantities in certain foods, including cheese, meat, wine, yeast products, and some vegetables such as spinach and tomatoes (Table 2). The ingestion of large quantities of histamine can result in clinical symptoms indistinguishable from those of an allergic reaction. These include flushing, throbbing or severe headaches, palpitations of the heart, abdominal cramps, and diarrhea. Dizziness, burning of the mouth or throat, nausea, hives, and angioneurotic edema can occur. Cough, wheezing, and severe respiratory distress may appear in patients who have an underlying allergic background, particularly in those with asthma. Symptoms generally begin 30–60 min after ingestion of foods containing high concentrations of histamine. (*See* **Migraine and Diet.**)

Measurement of Histamine in Food

A number of analytical methods for measuring the histamine content of foods have been developed including fluorometric methods, thin-layer chromatography, oxygen-sensor-based methods, and biologic methods. In addition, a number of commercially available enzyme-linked immunoassay test kits are marketed in the United States and Europe.

Table 2 Foods with high histamine content

Food	*Histamine content ($\mu g\ g^{-1}$)*
Fish	
Tuna, mackerel, bonito, mahi-mahi, bluefish	ND–9000
Sardine, herring, anchovy	ND–2000
Cheeses	
Swiss	ND–2500
Roquerfort and blue	Trace–4090
Cheddar	ND–1080
Gouda	Trace–200
Mozzarella	ND–50
Wines	
American red	0.2–15.5
American white	0.2–11.4
European red	ND–30
European white	ND–20
Dry sausages	Trace–650
Sauerkraut	< 5.0–200
Soya sauce	ND–2740

Scombroid Fish Poisoning

Scombroid fish poisoning results from eating spoiled fish of the Scombridae and Scomberessocidae families, and produces headache, itching, diarrhea, flushing, and palpatations immediately afer ingestion. These fishes include tuna, mackerel, skipjack, and bonito. However, nonscombroid fishes, such as mahi-mahi, blue fish, amberjack, marlin, herrings, sardines, and anchovies, have also been implicated in scombroid-toxin-like illness. Scombroid fish poisoning is the most common cause of ichthyotoxicosis worldwide. In addition to ingestion of fish, histamine poisoning can occur occasionally through ingestion of cheese such as Swiss, Cheddar and Gouda. (*See* **Fish**: Spoilage of Seafood.)

There has been some debate as to whether histamine is the sole cause of scombroid poisoning, but histamine is the most likely causative agent of scombroid fish poisoning. As clinical proof of the role of histamine, a definitive study involved three patients who were exposed to marlin, and later developed the classical symptoms of scombroid fish poisoning. Urinary excretion of histamine and its metabolite, *N*-methylhistamine, was measured. Urine samples collected 1–4 h after ingestion of fish show that the histamine and the *N*-methylhistamine levels were respectively nine to 20 times and 15–20 times more than the normal mean, a likely indication of exposure to high histamine levels. During the subsequent 24 h, the levels fell to four to 15 times and four to 11 times the normal values, respectively, and had returned to normal by 14 days. There was no evidence of mast cell activation as measured by the principal urinary metabolite of prostaglandin D_2. In addition, ingestion of a high concentration of histamine has been demonstrated to produce symptoms of scombroid poisoning. These symptoms are generally self-limiting, lasting a few hours, and can be quickly treated with systemic antihistamine administration. Elevated histamine levels in fish tissue have been associated with poor refrigeration, which results in bacterial spoilage and histamine formation. Bacteria possessing histidine decarboxylase can contaminate the gastrointestinal tract, skin, and gills of fish. In the case of cheese, the entry point to contamination by the histamine-producing bacteria is raw milk. Refrigeration of raw milk and fish, good hygiene during food preparation, and careful control of fermentations will therefore avoid the problem. Cooking, however, will not destroy histamine.

HIV DISEASE AND NUTRITION

C Baldwin, Chelsea and Westminster Hospital, London, UK

Introduction

The acquired immunodeficiency syndrome (AIDS) is a disorder characterized by progressive and profound immunodeficiency that renders the infected individual highly susceptible to life-threatening opportunistic infections and tumors. It is caused by infection with the human immunodeficiency virus (HIV). The first cases of AIDS were reported in June 1981. At the end of December 1999 the World Health Organization reported that there were 47 million cases of HIV infection worldwide, of which more than 40 000 were in the UK. AIDS is the now the fourth leading cause of mortality.

In the early days of HIV infection survival was limited by the occurrence of lethal opportunistic infections such as *Pneumocystis carinii* pneumonia and *Mycobacterium avium* complex and the lack of antiretroviral therapies. As understanding of the natural history of the disease improved and effective prophylaxis against the common opportunistic infections became available, the associated morbidity and mortality improved. Initial treatment approaches were limited to the use of nucleoside analog monotherapy, such as with zidovudine (AZT), which provided only transient clinical and immunological benefits. Over 1995 and 1996, availability of a new diagnostic test, viral load measurement, and new drug classes such as protease inhibitors and nonnucleoside reverse transcriptase inhibitors heralded a new approach to HIV management. The era of highly active antiretroviral therapy (HAART), in which suppression of plasma viral replication to below viral load assay limits (currently < 50 HIV RNA copies ml^{-1}) is achieved in a substantial proportion of individuals, has changed the clinical management, prognosis, and survival of people with HIV. The immunologic benefits gained through virus control with 'cocktails' consisting of three or more drugs have led to dramatic reductions in the incidence of the major opportunistic infections and mortality. As the clinical management of HIV infection has altered, so has its nutritional management, although the indications for nutritional support remain less clearly defined. However, concern that many therapy combinations or individual components of therapy may lead to metabolic perturbations in individuals with HIV has led to a new era of nutritional evaluation and investigation in persons with HIV. This article reviews what is known about the nutritional status of people with HIV infection, the nutritional problems specific to this infection and its treatments, and the objectives of nutritional support.

Nutritional Status of People with HIV Infection

Before the introduction of HAART, profound weight loss and wasting were amongst the most common observations in people with HIV infection. In 1987 the Centers for Disease Control (CDC) included HIV wasting ($> 10\%$ loss of baseline body weight + pathogen-negative diarrhea or persistent night sweats), which could not be explained by the presence of concurrent infection, in the list of AIDS-defining illnesses. Two-thirds of men with AIDS were reported to weigh less than 90% of their usual body weight. Since 1995 effective combination therapy has been associated with significant weight gain in the majority of people. Indeed, some patients report gaining excessive amounts of weight on therapy. This may be due to a modest reduction in resting energy expenditure (REE) and improvement in gut function and nutrient absorption, and additionally, the resolution or prevention of minor infections which may contribute to bouts of weight loss. Weight loss and wasting are less common in people receiving HAART but still occur in some people who have an excellent antiviral/immunological response, in some cases as a result of side-effects of therapy. Additionally, not all patients respond or respond durably to HAART.

Weight loss in HIV infection is often multifactorial in its causation, even within individual patients. The management of weight loss is dependent on an understanding of the underlying pathophysiology.

Two major mechanisms dominate the pattern of tissue loss in HIV-related weight loss:

1. Protein-energy malnutrition (PEM) is a condition synonymous with starvation, resulting when the body's needs for protein, energy, or both cannot be met by diet. In HIV infection this could result from inadequate intake or nutrient malabsorption.
2. Cachexia is a clinical syndrome characterized by a mixture of metabolic abnormalities that lead to weight loss through accelerated wasting of host tissue mass, and failure of adequate nutrient intake, absorption, and utilization. This is

different from malnutrition in that there is a marked and rapid depletion of muscle rather than fat.

The major difference between PEM and cachexia is that the nutritional effects of starvation can be reversed by the provision of appropriate feeding whilst the nutritional changes associated with cachexia cannot.

Malnutrition is associated with important clinical consequences independent of the underlying disease. Chronic undernutrition leads to deficiencies in work capacity, immune function, wound healing, organ function, mental state, and growth in children. When secondary malnutrition occurs as a result of disease it is associated with additional problems: reduced quality of life, disease complications, poor clinical outcomes, and increased costs of management. In a study of men with AIDS wasting (mean weight loss 15%), the extent of muscle wasting was highly predictive of the strength and functional capacity of the leg muscles, demonstrating the important relationship between loss of lean body mass and functional capacity. Additionally, in people with HIV infection, weight loss has profound prognostic implications, predicting shortened survival, increased risk of hospitalization, and increased risk of being diagnosed with an opportunistic infection. The effects of weight loss are independent of immune function (as measured by CD4 lymphocyte counts). Recently published observations have quantified the impact of weight loss in HIV infection, demonstrating that a weight loss trend over a 4-month period of even as little as 0–3% was predictive of increased subsequent mortality. Weight loss of more than 5% was associated with a relative risk of 1.88 ($P < 0.001$) of developing an opportunistic infection in the follow-up period.

Characteristics of Malnutrition

Early studies of weight loss and body composition conducted in a group of men with AIDS-related weight loss, compared with an HIV-negative control group, demonstrated that weight loss in this group was associated with a profound depletion of body cell mass that was greater than that expected for the body weight reduction, whereas fat mass was largely preserved. These studies were performed before the first antiretroviral drugs became available and therefore represent untreated HIV infection.

A 1993 study examined patterns of weight change in 30 individuals with HIV over a period of 9–49 months. Two typical patterns of weight change were described – acute and chronic weight loss. Acute weight loss (Figure 1) was usually rapid, occurring at a rate of 4 kg per month or greater, and was associated with opportunistic infections, mainly nongastrointestinal. Recovery to usual or preillness weight was common. Chronic weight loss (Figure 2), in contrast, occurred at a slower rate of less than 4 kg per month, was progressive, and was associated mainly with gastrointestinal disease. These observations have a number of important implications for the nutritional management of people with HIV. First, they demonstrated that HIV infection was not associated with unremitting weight loss. Treatment of the underlying infection leads to the ability to regain weight, often back to preillness weight, and therefore HIV does not prevent an appropriate anabolic response. Second, weight loss may precede specific signs and symptoms of infection and, therefore, is of significant diagnostic value. This potential diagnostic role prompted the recommendation that weight

change be recorded in all patients and be represented graphically in patient notes. Third, weight gain achieved following recovery from weight loss episodes usually occurs without the use of invasive nutritional support and, therefore, could be seen to represent the natural history of weight change in HIV infection.

Body Composition and Effective Antiviral Therapy

Advances in the management of HIV infection have had a significant impact on the incidence of weight loss and wasting but nutritional status has not returned to normal. In 1998 the first reports appeared of altered body composition in people with HIV infection. A syndrome of fat redistribution and associated metabolic abnormalities has been described which has become known as lipodystrophy. The syndrome(s) consists of accumulations of fat (lipohypertrophy) in the abdominal area (intraabdominal in men, breast enlargement in women), posterior neck ('buffalo hump'), and fat loss (lipoatrophy) in the face (particularly the temporalis, nasolabial, and buccal fat pad), arms and legs (leading to vein prominence). Metabolic changes, including hypercholesterolemia, hypertriglyceridemia, hyperglycemia, and insulin resistance, are also reported in association with the syndrome. There is so far no accepted definition for the syndrome of fat redistribution or any accepted set of standardized diagnostic criteria. However, the clinical presentation is characteristic and highly stigmatizing. Reports of the prevalence of the fat redistribution syndrome vary widely, depending in part on definition, from as low as 2% up to 84%. Initially the syndrome was thought to be associated solely with protease inhibitors, but more recently it has been reported in people receiving all classes of antiretroviral therapy. Several authors have proposed mechanisms to explain the development of the syndrome but the causes remain unknown. Identified risk factors include duration of antiretroviral therapy, older age, and white race. The use of protease inhibitors may accelerate time to syndrome onset.

An accurate assessment of body composition in people with fat redistribution is difficult. Bioelectric impedance analysis will not accurately measure body composition in this syndrome as it is unable to detect regional distribution or assess any changes that may occur. Dual X-ray absorptiometry (DEXA) scanning can determine regional fat compartments and may be useful in assessing people with fat redistribution, although the absence of data on normal body composition as well as regional body composition may limit its usefulness in diagnosing the syndrome. Computer-assisted tomography and magnetic resonance imaging can quantify body fat and therefore may be of most use in assessing body composition in this syndrome, although they are not always practical.

Deficiencies of Individual Nutrients

A number of studies have attempted to measure vitamin and mineral levels in HIV-positive subjects compared with a control group. Overall, results suggest that specific nutrient deficiencies are common in HIV infection and especially in the advanced stages of disease. The actual extent of overt and marginal deficiency and their significance is unclear. More information is needed on factors that might influence nutrient status measures, such as nutrient intake, drug–nutrient interactions, the influence of disease, and the presence or absence of infection; improvements in methods of nutrient assessment are also needed.

There is extensive literature on the relationship of nutrient deficiencies to immune function. Nutritional deficiencies can impair immunity and so influence a person's susceptibility to infections. It has been suggested that dietary manipulations might diminish or reverse the immune defects caused by HIV infection and enhance resistance to opportunistic infections. At present there is insufficient evidence to support the use of particular nutrient supplements to modulate immune function. The use of vitamin and mineral supplements containing 100% of the recommended daily allowance for all micronutrients has been proposed in the USA by the Task Force on Nutrition Support in AIDS to insure sufficiency. Although some authors have suggested supplementary levels of some vitamins and minerals in people with HIV in an attempt to achieve normal plasma levels, the benefits of this approach in the short and long term are unclear.

There is no evidence that megadoses of any vitamin or mineral will alter the course of disease or improve the nutritional status of people with HIV.

The Mechanisms of Malnutrition in HIV Infection

There are a number of factors that may lead to the development of malnutrition in HIV infection: altered food intake, malabsorption of nutrients, and changes in metabolism.

Reduced Food Intake

Food intake in an HIV-positive person may be affected by many physical and emotional factors. Anorexia is an accepted response to infection. Loss of appetite is a problem in people with HIV infection and may result from the associated opportunistic

infections, malignancies, gastrointestinal symptoms, side-effects of medication, emotional issues, or a combination of these.

Nutrient Malabsorption

Malabsorption is common in HIV infection and may result from intestinal pathogens and the side-effects of medication.

Metabolic Alterations

Hypermetabolism in association with febrile illness is a familiar concept. A number of investigators have measured REE in asymptomatic HIV infection and demonstrated an increase of around 10%. The presence of opportunistic infections is associated with greater increases in REE of up to 34%. There is still much to be learned about the mechanisms of metabolic regulation that accompany weight loss and wasting in HIV. It is not understood why an increase in metabolic rate is not accompanied by an increase in food intake. Cytokines such as tumor necrosis factor (TNF) and interferons are responsible for many aspects but there is now evidence that they are not alone responsible for the wasting process.

If a person is to be in energy balance, then energy intake must be equal to REE plus energy used in activity (total energy expenditure (TEE)). A study published in 1995 examined the relative contributions of changes in energy expenditure and intake to the pathogenesis of HIV-related weight loss and has provided important information on the underlying causes of weight loss in HIV infection. It examined energy balance in a group of 21 HIV-infected individuals. TEE, REE, activity levels, and food intake were measured during episodes of weight loss, weight gain, and during periods of weight stability. It confirmed that REE is raised in individuals with HIV infection and that during periods of opportunistic infection REE is elevated even further. During periods of weight loss TEE was not elevated but reduced to be almost equal to REE, accounted for by a reduction in activity levels, and was raised during periods of weight gain, therefore TEE could not account for the changes in energy balance necessary to cause weight changes. Measurement of energy intake confirmed that reduced energy intake is the prime determinant of weight change in HIV-associated weight loss. It has been suggested that it is possible to predict the composition of tissue loss during periods of starvation and that there is an inverse relationship between the amount of body fat and the ratio of fat-free mass (FFM) to total tissue lost during food restriction. In the study mentioned above, the amount of FFM lost during periods of weight loss was 58% of the total, which is similar to that predicted using Forbes' equation and is consistent with undernutrition as the underlying mechanism of weight loss in this group of people with HIV.

These findings suggest that an adequate supply of nutrients could prevent weight loss or promote weight gain in people with HIV-related weight loss but simple deficiency of nutrients is not the only possible cause of weight loss. Several other aspects of altered metabolism have been described in people with HIV infection, termed metabolic dysregulation, which may account for relatively greater losses of lean body mass relative to fat in some people (a predominantly cachectic mechanism). First, reduced *de novo* lipogenesis is a classic response to starvation in healthy subjects. In AIDS wasting, *de novo* lipogenesis is increased in the majority of subjects. Second, AIDS wasting is associated with hypertriglyceridemia and low serum cholesterol levels compared with HIV-negative controls, which may be indicative of futile cycling of free fatty acids and triacylglycerols. Futile cycling is thought to be mediated by TNF and is said to occur when free fatty acids are released from fat and returned to the liver, where they are reesterified in triacylglycerols and secreted as very-low-density lipoproteins (VLDL), to return to the fat cell for breakdown and restorage as triacylglycerols. Third, AIDS wasting is associated with serum testosterone levels in the lowest quartile of the normal range. Low testosterone concentrations are observed in about 50% of men with wasting and are usually associated with advanced disease, weight loss, and hypogonadism, suggesting that the low concentrations are stress- or starvation-induced.

The above aspects of metabolic dysregulation do not occur uniformly amongst people with HIV-related weight loss and considerable heterogeneity has been noted in this population. It has been suggested that people with AIDS wasting fall into different pathogenetic subsets and that it may be possible to categorize people into those who have lost weight as a result of 'starvation' and who may therefore respond to provision of nutrients and differentiate them from the subset of patients who are cachectic and may not be able to respond appropriately to nutrition.

Nutritional Problems for People with HIV

People who are HIV-positive are vulnerable to a wide range of pathogens. A person's ability to continue to eat normally may be altered by the disease itself or by the treatment (Table 1). The nutritional problems for people with HIV fall into three main categories:

1. Wasting and weight loss resulting from symptoms that have an impact on food intake, such as dysphagia, taste changes, pain, nausea and vomiting, and shortness of breath
2. Restrictions on food intake imposed by antiretroviral treatments
3. The side-effects of antiretroviral therapy, such as nausea, vomiting and diarrhea and dsylipidemias, impaired glucose tolerance, and body shape changes

Dietetic management can be effective in managing weight loss resulting from a range of symptoms. Drug regimens may demand one of the following adaptations:

1. Eating at the same time as taking the drug
2. Avoiding food for an hour or two after taking the drug
3. Eating or avoiding certain types of food in order to insure maximum absorption of medication

Dietary advice to accommodate antiretroviral therapy is highly individualized and tailored to specific circumstances and to specific combinations of drugs and therefore will not be covered in any detail here.

The metabolic and body shape changes associated with HIV represent a new challenge in the management of HIV infection. The aim of the management of fat redistribution is to replace lost fat and to reduce accumulated fat deposits. So far, management has tended to concentrate on changes to drug therapy which involve switching away from drugs implicated in the causation of the syndrome. A range of interventions have been tried and modest benefits have been reported, which may in part relate to the relaxation of dietary restrictions associated with some medications and to improved well-being. The use of recombinant human growth hormone has been shown to have some positive benefits, predominantly on reducing accumulations of abdominal and dorsocervical fat, in a few small studies. Diet and exercise remain unevaluated as possible management strategies for the fat redistribution syndrome.

The clinical significance of the metabolic complications associated with the fat redistribution syndrome are not known. A small number of reports

Table 1 Common manifestations of acquired immunodeficiency syndrome (AIDS) and potential nutritional problems

AIDS-related infections and cancers	*Potential nutritional problems*
Opportunistic infections	
Fungal	
Candida	
Oral	Sore mouth, altered taste perception, anorexia, reduced saliva production
Esophageal	Dysphagia
Cryptococcus	
Meningitis	Pyrexia, nausea, and vomiting
Protozoan	
Toxoplasmosis	Pyrexia, ethargy, confusion
Pneumocystis carinii pneumonia (PCP)	Pyrexia, dyspnea, anorexia and weight loss, tiredness and lethargy
Bacterial	
Mycobacterium avium intracellulare (MAI)	Pyrexia, anorexia and weight loss, diarrhea and malabsorption
Viral	
Cytomegalovirus (CMV)	Pyrexia, diarrhea, and malabsorption
Herpes simplex (oral)	Dysphagia
Human immunodeficiency virus (HIV)	Pyrexia, diarrhea, and weight loss
Parasitic	
Cryptosporidium	Diarrhea and malabsorption, anorexia, weight loss, nausea and vomiting, pyrexia
Microsporidia	
Cyclospora	
Isospora	
Cancers	
Kaposi's sarcoma (gastrointestinal)	Dysphagia, sore mouth, anorexia, abdominal discomfort and obstruction, diarrhea, and malabsorption
Non-Hodgkin's lymphoma	Anorexia, weight loss, dysphagia, diarrhea
Other	
AIDS enteropathy	Diarrhea and malabsorption, weight loss
AIDS encephalitis	Confusion, dementia, lethargy
Side-effects of HAART	Nausea, diarrhea, dyslipidemias
Coinfections	e.g. hepatitis B and C, alcoholic liver disease

HAART, highly active antiretroviral therapy.

have been published of myocardial infarction in people on HAART. Additionally, fatal pancreatitis with hypertriglyceridemia has been reported. The extent to which lipid disturbances and hyperglycemia are associated with an increased risk of vascular disease and increased survival is unknown and is the subject of a 15 000-patient global study. Results are not expected for another 2 years. Currently, management of isolated hyperlipidemia is through conventional dietary advice and lipid-lowering agents. As some statins (human menopausal gonadotropin coreductase inhibitors) may interact with protease inhibitors, advice should be sought before introducing these agents.

The effective treatment of the fat redistribution syndrome will be most successful only once the mechanisms are understood. However, approaches which in small, mostly cohort studies have yielded benefit in some patients include exercise, growth hormone, antiretroviral therapy modification, and metformin. No uniformly effective management has been established. The use of supplements such as acetyl-L-carnitine, coenzyme Q-10 (ubiquinone), and riboflavin to support mitochondrial function in adipocytes has been widely suggested but not evaluated.

Objectives of Nutritional Support

The objectives of nutritional support in people with HIV infection vary widely depending on the stage of the disease and the presence or absence of symptoms which have an impact on nutritional intake.

Asymptomatic HIV Infection

When a person is diagnosed with HIV infection but is symptom-free, he or she often considers dietary change within a framework of lifestyle changes to maintain health. Dietary information is available in a variety of media, from the advice of friends and family, to magazine articles, television programs, and the internet. The rationale for making dietary changes in people with asymptomatic infection is based on avoiding nutrient deficiencies, which may have an impact on immune function and maintaining an ideal body weight. Advice is aimed at promoting a regular balanced intake of a variety of foods. There is no evidence for increased or decreased requirements of any nutrient compared with the HIV-negative population.

Prior to the introduction of HAART, healthy-eating guidelines designed to promote a reduced intake of fat and sugar and an increase in fiber were considered inappropriate in people with HIV. Since the introduction of HAART and the associated survival advantages and potential cardiovascular side-effects, it may be pertinent to provide dietary advice in line with healthy-eating guidelines. There is no evidence base for such a recommendation, however.

People with HIV infection are at greater risk of contracting food- and waterborne infections since they are immunosuppressed and often suffer from coexisting disease or infections. It is generally recommended that people with HIV are given advice on food hygiene and water safety. Some local policies specify that this happens once a defined level of immunosuppression is reached. Cryptosporidiosis is a waterborne protozoa which can cause chronic diarrhea in immunosuppressed individuals. There have been reports of outbreaks of cryptosporidial infection in people with HIV infection where tap water has been implicated as the cause. The UK Department of Health recommends that people with HIV with a low CD4 lymphocyte count should boil all water (including still, bottled water) used for drinking, brushing teeth, and washing fruit and salad vegetables. This practice has not been adopted throughout the UK and will vary with local policies.

Unproven diet therapies There is currently no cure for HIV/AIDS. Faced with this, many people seek to take control of their own treatment and this often involves the use of diet therapies, which claim to prevent the progression of the disease, or to cure it. There can be tremendous psychological benefit from following a particular treatment, and people should not be discouraged from following a regime of their choice, but helped to evaluate and adjust their eating habits in order to meet nutritional goals. It is important that eating remains an enjoyable experience and that people do not subject their food choice to unnecessarily rigid rules that may detract from enjoyment.

The following considerations are helpful in evaluating dietary options:

- The diet should not contain substances in amounts that may be physically harmful.
- It should not completely replace health care that is generally accepted as effective.
- It should allow for an adequate energy and protein intake along with a variety of foods.
- It should not incur unnecessary expense or hardship.

Symptomatic HIV Infection

Many of the manifestations of HIV infection affect a person's ability to eat normally and maintain body weight, and therefore nutritional support is indicated.

The management of a person with weight loss should involve a number of steps: first, diagnosis and treatment of any underlying opportunistic infections, second, control of any symptoms that may have an impact on food intake; and third, dietary advice.

In the first instance dietary advice should be to maximize food intake by making alterations in the type and timing of meals, including well-chosen snacks between meals, and possibly modifying existing foods to increase their energy and protein content. This approach is a basic tool of dietetics that has received little research attention. A small uncontrolled study in 34 people with HIV demonstrated that dietary advice was associated with significant improvements in nutrient intake, weight, and anthropometric indices. A recent randomized controlled study of dietary counseling with or without oral nutritional supplements showed that nutritional counseling can achieve a substantial increase in nutrient intake in 50% of malnourished people with HIV which after 6 weeks was not associated with changes in weight and nutritional status.

A second line of dietary intervention is the use of specialized proprietary food supplements in combination with a balanced food intake. These usually take the form of prepacked drinks that are nutrient-dense and nutritionally complete. Since the appearance of these products 12–15 years ago, they have acquired the reputation of being able to promote weight gain in a person who is losing weight. A systematic review of energy-dense supplements in illness-related malnutrition has demonstrated significant benefits to weight and nutritional status but the effects on morbidity and mortality are less clear. A small number of studies have looked at the use of oral nutritional supplements in people with HIV and demonstrated short-term benefits to nutritional intake, weight, and nutritional status. More studies are needed to clarify the role of nutritional intervention in HIV-related weight loss and particularly the effects on morbidity, mortality, and clinical outcome.

If adequate nutrition cannot be achieved orally, then enteral or parenteral nutrition should be considered. The major indication for nutritional support in HIV is the failure to maintain body weight. The main goals of nutritional support are to improve survival morbidity by reducing the complication rate associated with secondary infections and to improve quality of life. There are a small number of studies that have looked at the efficacy of nutritional support in HIV. In general they have concentrated on the safety and on the ability to replenish lean body mass. Reports of rates of infection vary considerably with enteral and parenteral feeding but the general conclusions are that nutritional support can be provided with safety in people with HIV infection but should be undertaken with caution because of the serious risk of infection. A small number of studies have looked at the ability to replenish lean body mass using enteral and parenteral nutrition. The results suggest that nutritional support can effectively maintain body composition and reverse the depletion of fat and lean tissue in patients with weight loss in the absence of concurrent infection or when provided in conjunction with effective treatment of an infection. In the stressed catabolic patient with systemic infection, malnutrition is not restored towards normal with nutritional support and weight gains tend to be mainly fat and not lean body mass. It is important to note that in some studies the provision of artificial feeding led to prolonged survival with improved functional capacity and resumption of employment – benefits which should not be overlooked when considering the initiation of nutritional support.

The provision of nutritional support in the terminal stages of disease is a controversial issue. One study demonstrated benefits to quality of life associated with the provision of parenteral feeding in the terminal stages of illness. Recently, studies of the effects on survival of enteral and parenteral feeding have underscored the importance of starting feeding before it is too late.

The area currently receiving the most interest in relation to nutrition and HIV infection is the use of growth hormone and anabolic steroids for their ability to replenish lean body mass. Testosterone and testosterone analogs and recombinant human growth hormone have been demonstrated to replenish lean body mass effectively in people with 5–15% weight loss. Benefits have been demonstrated with and without supervised exercise programs. This is a relatively new area of nutrition and the potential role of anabolic therapies in conjunction with the provision of nutritional support raises many questions:

- Does increasing lean body mass change the prognosis?
- Is long-term anabolic steroid use safe?
- Which patients are likely to benefit – those with mild or advanced disease?
- Should steroids be used intermittently or continuously?
- Which anabolic drug is most effective?

Advances in the understanding of the pathophysiology of weight loss wasting have led to a greater understanding of the role of nutrition in HIV infection. The primary determinant of weight loss is frequently reduced food intake but this cannot alone explain all aspects of HIV-associated wasting and

the observed responses to nutritional support. Maintenance of an adequate food intake is an essential part of treatment but more information is needed on its combination with appropriate anabolic therapies to maintain normal body composition and functioning.

Improvements in the drug therapy of HIV management have had significant impacts on morbidity and mortality but the emergence of the fat redistribution syndrome as a side-effect of therapy represents a new challenge to the clinical and nutritional management of HIV infection.

HOMOGENIZATION

R A Wilbey, The University of Reading, Reading, UK

Introduction

An emulsion is a stable mixture of two normally immiscible phases as a continuous and a disperse phase. Particles of the disperse phase should be small, ideally 1 μm or less, when Brownian motion becomes a significant factor. The stability of an emulsion also increases with its viscosity. These conditions are the reverse of those needed for efficient separation, the movement of particles above 1 μm following Stokes' law. There are many examples of emulsions in foods, e.g., milk, cream, ice cream, butter, margarine, mayonnaise and salad dressings, sauces, cake batters, and some beverages. (*See* **Colloids and Emulsions**.)

The first treatment of milk to give a finer, more stable, emulsion that would remain homogeneous on standing has been attributed to Auguste Gaulin, whose first patent was granted in 1899. High-pressure homogenization is the most widely used method for stabilizing milk and milk products. It has also been widely used in other sectors of the food industry and in the preparation of nonfood emulsions of low to medium viscosity.

The term 'homogenization' has since been applied to similar emulsification processes, so that the terms 'emulsification' and 'homogenization' may often be treated as synonyms rather than homogenization being regarded as a specialized method of emulsification. A wide range of equipment has been developed for the homogenization of foodstuffs. The simplest of these methods is the high-shear mixer, which has been adapted for both batch and in-line processing. The colloid mill has been widely used for the homogenization of more viscous foodstuffs such as sauces and mayonnaises. Emulsification may also be the result of shear forces acting during other food-preparation processes, such as the cooling of margarine in scraped-surface heat exchangers, the working of butter and in the use of pin mills and disk mills.

The formation of a stable homogeneous foodstuff will depend on both the nature of the foodstuff and the process. There is often an optimum viscosity of the continuous phase for a given homogenizing technique, while lower viscosities in the disperse phase will aid homogenization. The presence of surface-active components may play a critical role in the formation and maintenance of an emulsion. The quantity of disperse phase will also affect the particle size distribution in the emulsion. This article will concentrate on the processes rather than the food components.

High-shear Mixers

Batch Mixers

High-shear mixers are commonly used for the batch mixing of food ingredients and the formation of emulsions. Most high-shear mixers rely on the development of a shear gradient between the rapidly rotating rotor and a static surface or stator. For low-viscosity liquids, the rotor is normally a simple turbine blade, and the stator is perforated. Figure 1 illustrates a mixer with a vertical-slotted disintegrating head that may also be used for breaking up fibrous tissue; a larger number of small square or round holes would normally be used in the stator screen for emulsification alone.

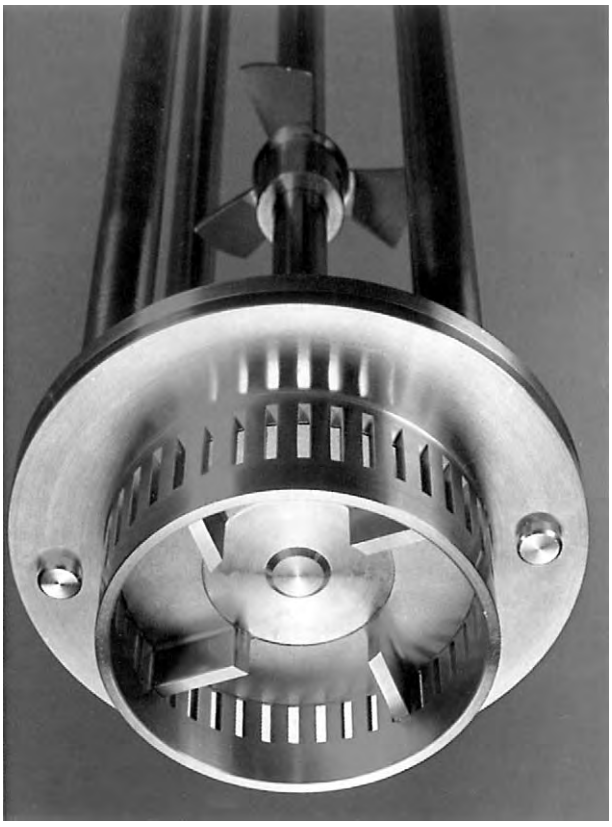

Figure 1 Batch high-shear mixer (courtesy of Silverson Machines Ltd).

The mixer is normally coupled directly to an electric motor, wound to run at 2850 r.p.m. for small mixers or at 1425 r.p.m. for large models, giving rotor tip speeds of approximately 100–150 m s^{-1} for pilot-scale applications. The flow of liquid from the turbine is principally radial, the flow being obstructed by the stator. Some liquid will pass between the rotor tip and the stator: the smaller the clearance, the greater the shear forces that will be developed. The bulk of the liquid, however, will be forced through the perforations in the rotor: the smaller the perforations, the greater the shear exerted on the mixture to be emulsified.

With batch mixing, the mixer may be left running until the desired homogenization/emulsification has been achieved. This method is limited by the viscosity of the foodstuff as adequate flow within the batch mixing vessel is essential, and more viscous foods and large batch sizes are better homogenized by other techniques.

In-line Mixers

In-line mixers for homogenization use the same basic principles as the batch mixers. In the simplest system,

the liquid passes from the turbine through the screen into an outer chamber and is discharged into the pipeline without any recirculation (Figure 2). The turbine has a weak pumping action. For some foods, there may not be sufficient shear in one pass through the homogenizing head so that either two or more mixers need to be placed in series, or the mix recirculated back to the feed tank until a sufficient degree of emulsification has been achieved.

Where recirculation needs to be carried out, this may be incorporated into the design of the mixer by allowing recirculation of part of the discharge from the shear head back to the inlet. The degree of recirculation depends upon the mixer design; the type shown in Figure 3 uses a high degree of recirculation to ensure a homogeneous discharge.

Colloid Mill

The colloid mill derives its emulsifying action from the high shear on the foodstuff as it flows between the rotor and stator, as illustrated in Figure 4. The rotor may be coupled directly to a motor or driven via a variable-speed gearbox. Typical rotor tip speeds are 20–50 ms^{-1}.

Normally, the gap between the rotor and stator are adjustable, typically between 100 and 200 μm, to enable a range of shear rates and throughputs to be achieved. The shear on the product will follow the general relationship:

$$\text{Shear stress } T = \mu \frac{v}{h}$$

where μ = viscosity, v = peripheral velocity, and h = clearance.

Greater disruption may be achieved by using toothed surfaces on the rotor and stator, e.g., for peanut butter, though where a grinding action is needed, a larger clearance may be used. The colloid mill may be used as an in-line emulsifier and is particularly effective with viscous foodstuffs, though the minimum particle size of the disperse phase (1–2 μm) will not reach the submicron sizes that may be achieved with the high-pressure homogenizer.

The High-pressure Homogenizer

The high-pressure homogenizer may be regarded as comprising two parts: a high-pressure pump and one or more homogenizing valves.

The High-pressure Pump

Pressure is used as the driving force for the homogenization process, the liquid mixture to be homogenized being raised to the homogenization pressure by a positive displacement pump. In all but the smallest pumps, there are at least three, sometimes five or

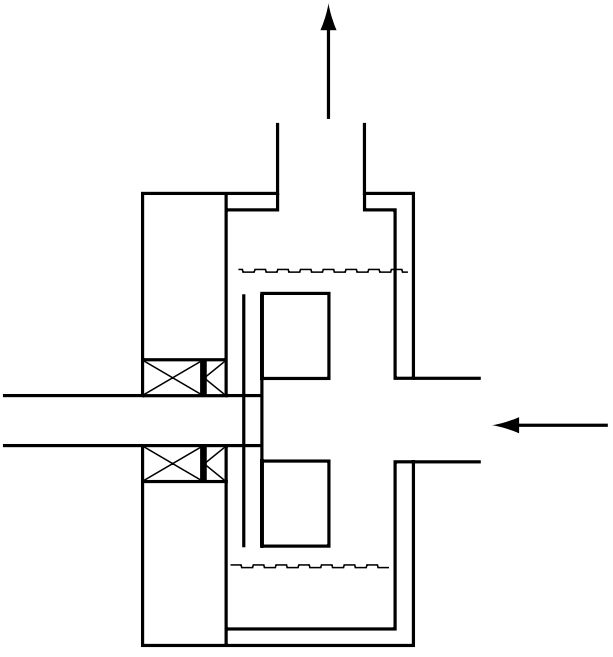

Figure 2 Schematic section through an in-line high-shear mixer.

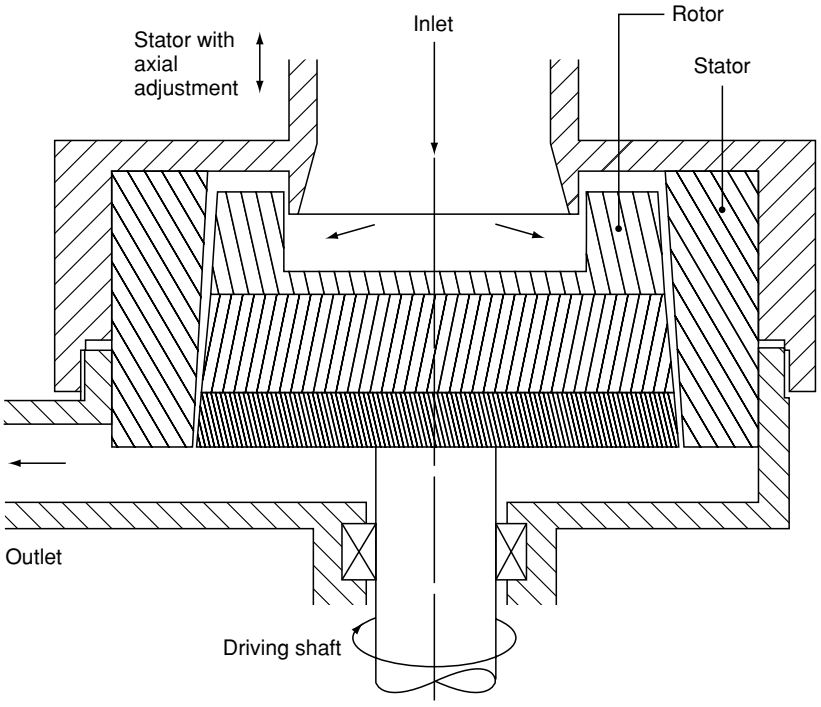

Figure 4 Schematic section through a colloid mill (courtesy of Fryma Ltd, Hemel Hempstead, UK).

seven, pistons. The pistons must be arranged so that they operate consecutively to maintain as even a feed pressure as possible. Both the pistons and the pump block are typically of stainless steel construction, but the piston seal rings are of a soft composite material and can be a source of cleaning problems. The layout of the high-pressure pump is illustrated in Figure 5.

The mixture to be homogenized is fed into the pump block under a slight positive pressure. A gravity feed is sufficient to ensure that the inlet valves are flooded, but continuous operation may be better served by feeding at a small positive pressure (e.g., up to 0.1 MPa) from a centrifugal pump via a preheater.

Two types of valve have been used in the pump block, either ball valves or poppet valves, as illustrated in Figure 6. The upper, discharge, valves are usually spring-loaded to ensure rapid closing.

Ball valves have a smaller contact area with the valve face, and they exert a greater pressure at the point of contact. This is an advantage for viscous liquids and when small particulates may be present in the feed stock, since valve leakage is the limiting factor in the high-pressure homogenization of liquids containing suspended particles. Poppet valves need to be fitted more carefully to the larger valve face, but, when properly maintained, they have a better performance with low-viscosity liquids such as milk.

A third, mushroom, design of valve has been introduced recently, designed as an optimum compromise between the ball and poppet designs. Both inlet and discharge valves are spring-loaded to ensure good seating.

The mixture is discharged from the pumping chambers of each piston into a high-pressure manifold. The pressure in this manifold is normally monitored by a pressure gauge, which must be of hygienic construction, with a diaphragm between the product and the sensor mechanism, plus a means of cleaning the space around the diaphragm. The only exit for product from this high-pressure manifold is through the homogenizing valve.

The Homogenizing Valve

Many designs of homogenizing valve have been invented, but for most valves, the same basic principles apply. The mixture, which must already be a homogeneous mix and itself a coarse emulsion, flows from the high-pressure manifold into the fixed valve seat. The internal diameter of the valve seat is smaller than the manifold, so the velocity of the liquid is increased. To escape from the valve seat, the liquid must flow radially across the face of the valve. The gap between the valve face and the seat is controlled so that a constant pressure drop across the valve is maintained. The opposing force (operating pressure times the valve area) may be provided by a heavy duty spring, a torsion bar, hydraulic pressure or by direct contact with a screw threaded lever. The basic design

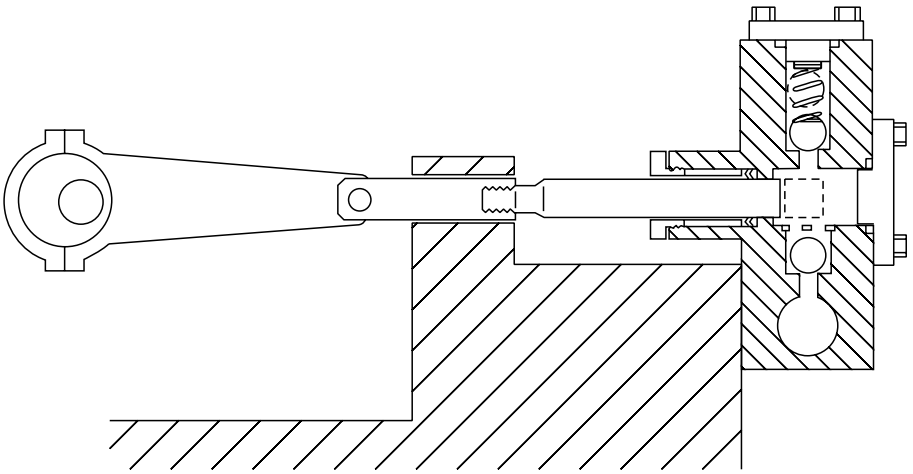

Figure 5 Schematic section of a high-pressure pump.

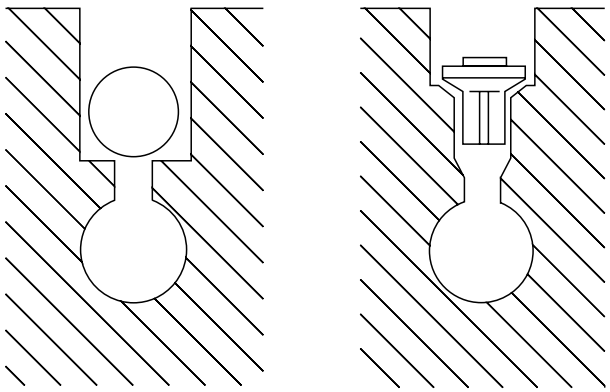

Figure 6 Types of valve: (a) ball; (b) poppet.

is illustrated in Figure 7. Pneumatic actuators have been used in some machines with capacities of less than $10\,000\,l\,h^{-1}$, thus reducing the variance in homogenization pressure. For most dairy products, the homogenization pressure is in the range of 2.5–30 MPa with throughputs of up to $\approx 50\,000\,l\,h^{-1}$ for milk. Machines are available that will produce a feed pressure of more than 100 MPa, though these are restricted to lower throughputs by the power required to drive them.

The gap between the valve and its seat is many times greater than the diameter of the droplets created in the emulsion, e.g., in a normal large-scale dairy application, the gap would be greater than 100 μm, the size of the gap tending to increase with the throughput of the machine. Even so, the cross-sectional area of the flow path within the valve is much smaller than that in the high-pressure manifold, so the velocity of the liquid will rise as it enters the valve. This acceleration can result in distortion of the particles of the disperse phase (often called the wire-drawing effect), which will reduce their stability. Within the valve, there will be a number of effects on the liquid that may contribute to the disruption of the fat globules:

1. Shear effects will result from the high velocity gradients between the liquid and the surfaces of the homogenizing valve. This effect, in combination with the wire-drawing effect, will lead to disruption of globules.
2. Turbulence also results from the high velocity of the liquid in the valve, causing eddy currents within the flow. High-velocity impacts between particles can lead to disruption, and so increases in velocity are associated with decreased fat globule size in the case of oil-in-water emulsions.
3. High-frequency vibrations (> 10 kHz) have been observed in some valves that may be of mechanical origin or a result of turbulence or cavitation. When homogenizing at high temperature, the drop in pressure as the liquid accelerates within the valve may result in the pressure momentarily falling below the saturation vapor pressure of an aqueous continuous phase, leading to the formation of steam bubbles. Collapse of these bubbles as the pressure increases again sets up high-pressure shock waves. Opinions vary about the contribution of cavitation and other sources of vibration to the overall disruptive effect during homogenization.
4. Impact can contribute to the homogenizing effect in some designs of homogenizing valve, where an impact ring is placed perpendicular to the flow of liquid from the valve. With valve exit velocities of 200–300 m s^{-1}, there can be a significant disruptive effect as the jet of emulsion impinges on the ring.

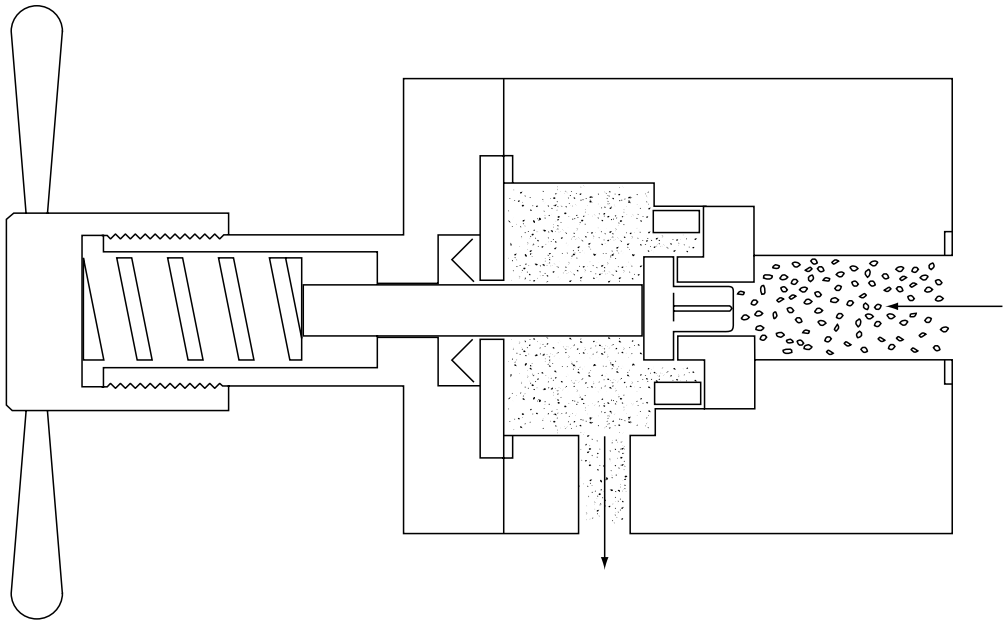

Figure 7 Schematic section through a homogenizing valve assembly.

Homogenizing valves have been produced from very tough corrosion-resisting alloys such as stellite. A better resistance to erosion may now be achieved using tungsten carbide and ceramic valves, though these are more difficult to produce and are more fragile. A very wide range of homogenizing valve designs using both single and multiple homogenizing surfaces have been produced, with the aim of increasing homogenization efficiency and thus reducing the energy costs. Various claims for up to 30% energy savings or a 40% reduction in homogenization pressure for an equivalent size reduction with these new designs have been made, in comparison with the traditional Gaulin valve design.

Practical Considerations in the Use of High-pressure Homogenizers

Since homogenizers operate at high pressures, problems can be encountered with the seals. The pistons are normally lubricated with potable water to minimize wear of the rear seals, though in aseptic machines, the pistons are also surrounded by a steam seal to avoid product contamination. With nonaseptic machines, the homogenization step is normally carried out prior to the heat treatment to minimize hygiene risks. Icecream mix may be homogenized at the heat treatment temperature (66–80 °C). In general, the efficiency of a high-pressure homogenizer increases with temperature, but temperature is normally limited by the product.

Constant homogenizing pressure is necessary for efficient reproducible emulsification. Rapidly fluctuating pressure may be due to a faulty gauge, but the most common cause is poor seating of the valves. Seating problems can result from wear, from incorrect placement of valves in the seatings, or from dirt or foreign bodies on the seats. The presence of air in the feed can also cause problems, and deaeration may be needed in some processes prior to homogenization.

With many dairy emulsions, the fine particles produced by homogenization tend to flocculate. These flocculated globules behave as large particles and separate from the emulsion. The introduction of a second homogenization stage or a multistage valve can overcome this problem. The pressure drop across the second stage valve should be relatively small, typically 3–5 MPa, to break up the aggregates. With two-stage homogenization, it is common practice to set the second-stage pressure first then to set up the first stage, remembering that the gauge will indicate the total pressure. The introduction of a second pressure gauge between the first- and second-stage valves aids control of the process. Where very find dispersions are desired, multiple high-pressure homogenization has been used.

Other Emulsifying Systems

Ultrasonic homogenization uses a transducer or a mechanical wedge to generate high-frequency vibrations at over 10 kHz, typically 18–50 kHz, so that the output is barely audible. These give rise to shock waves plus possibly cavitation in the mixture.

Efficiency declines with increasing frequency, the upper limit being about 50 kHz. It has been suggested that the efficiency of the process is increased by introducing or creating microbubbles or particles that resonate with the frequencies generated in the apparatus. The transducer method has been used on a small scale for producing emulsions and for disrupting cells, whereas the wedge method has been used for emulsification in food products

Emulsification may also be achieved by mixing high-speed streams of the two phases, the resultant mixture then being forced through a small orifice to create a high-velocity impinging jet. This method, known as microfluidization, is essentially a modification of the high-pressure homogenizer principle but can be employed for very small sample sizes.

As with other methods, there can be considerable heat production.

HONEY

L W Doner, US Department of Agriculture, Wyndmoor, PA, USA

Background

Honey serves to assure the survival of honeybee colonies and, consequently, the pollination and survival of many plants. It was one of man's earliest foods, as honeybees were producing it long before man appeared on the earth. Honey remained the primary sweetener for humans until the late nineteenth century, when its consumption was exceeded by sugar cane-, sugar beet-, and later corn-derived sugars. Honey remains the only sweetener that can be stored and used precisely as it is produced by nature. It is an exceedingly complex substance that is produced by honeybees from floral nectar and, less frequently, honeydew. Honeydew consists of syrups deposited on plants by other insects, such as aphids. Whereas nectar from the many floral sources generally contains just the sugars fructose, glucose, and sucrose, honey contains these and many other more complex sugars. The additional sugars arise largely as a result of honeybees adding several enzymes during the nectar-to-honey ripening process. The presence of active enzymes and the acidity of honey result in its composition being in a constant state of change.

Comprehensive surveys of average honey composition have established that the major components are fructose (38.4%), glucose (30.3%), and water (17.2%). In addition to the two major sugars are an array of more than 20 higher sugars, which are formed by linking the fructose and glucose in various combinations. Honey is therefore primarily a carbohydrate material, and sugars comprise over 95% of its solids content. The principal physical characteristics of honey are due to its sugars, but subtle differences in minor constituents from nectar are responsible for the flavor differences of honey from different floral sources. These constituents include flavoring and aroma compounds, pigments, acids, and minerals. These substances are concentrated during the ripening process, where most of the water from nectar is removed. In order to assure the integrity of honey markets, methods have been developed to detect the addition of inexpensive sugar mixtures as adulterants.

Honey Production and Processing

To summarize, foraging honeybees ingest nectar and honeydew and store it in their honey sac. Pollen is also collected, and this provides the protein portion of the honeybee diet. Pollen, however, is not integral to the production of honey. The honey sac weighs 40–70 mg when full and can account for more than 90% of the weight of the bee. Enzymes are secreted and mixed with the sac contents. Upon returning to the hive, the contents are passed on to the house bees, who carry out the ripening process. This consists of alternately expelling and ingesting the honey sac fluid for 15–20 min. When the nectar has lost about half of its moisture, small droplets of this semiripened honey are deposited in the comb cells. In 1–3 days, numerous enzyme-mediated changes will have occurred and honey density attained. The cells are then capped over with wax and the honey stored as food. Compositional changes continue during ripening, the most prominent result being the production of an increasingly complex array of sugars. This is largely a result of continuing enzyme activity. An enzymatic process is also employed to produce hydrogen peroxide, in order to stabilize the honey against microbial growth.

The primary objectives of commercial honey processing include maintaining the desired physical state, be it liquid or finely granulated, and keeping it free of fermentation. Methods for accomplishing the objectives are well established and have been used for many years. Beekeepers remove the hive units (supers) from the colony and then remove the wax cappings by mechanical slicing. The honey is then centrifugally extracted from the wax comb. Raw honey contains pollen, some wax, sugar-tolerant yeasts, and often some crystals of glucose monohydrate. Flavor and aroma are optimal just after processing, but further treatment is required before large-scale marketing. The process of pressure filtration is used to produce liquid honey, after controlled heating to destroy yeasts and to dissolve sugar crystals. The application of heat to honey requires careful control so that the color, flavor, and aroma of honey are not impaired. Honey is sold in the liquid form, in a finely granulated form known as honey spread or finely granulated honey, and as comb honey. The requirements for the stability of these forms are increasingly stringent, as honey has become a world commodity available in markets throughout the year.

World honey production has increased steadily and, in the year 2000, was estimated to be about 1.2 million tonnes. About 25% of this production is the object of international trade. The three largest honey-exporting countries are China, Argentina, and Mexico, and the largest importers are Germany, Japan, and the USA. The USA is the leading consumer of honey, and honey consumption in Asia has increased substantially in recent years, especially in Japan and China.

General Composition

Honey samples vary in composition, and this variability reflects contributions of the plant source of nectar, beekeeping practices, and climate and environmental conditions. Honeys representing many floral sources in the USA have been analyzed, and the average compositions are listed in Table 1. Many honeys from other countries have been analyzed and generally found to provide similar values. There is wide variability among all the honey components. Among the major components, however, fructose levels exceed those of glucose, the only exceptions being dandelion and blue curls honeys.

Moisture

Moisture content is one of the most important characteristics of honey, as it influences the keeping quality, granulation, and body. The natural moisture of honey in the comb is that remaining from the nectar after it is ripened by the bees. The amount of moisture is a function of factors involved in ripening, such as environmental conditions, original moisture content of the nectar, and strength of the honeybee colony. Normal ripened honey has a moisture content below 18.6%, and when the moisture content exceeds that level, honeys are liable to ferment. This can occur if the count of ubiquitous osmophilic yeasts is sufficiently high. After extraction of the honey from the comb, its moisture content may change, depending on the conditions of storage. Low moisture levels can result in the crystallization of glucose, a process termed granulation. Few

Table 1 Average composition of honey[a]

Property	*Average*	*Range*
Moisture	17.2	12.2–22.9
Fructose	38.4	30.9–44.3
Glucose	30.3	22.9–40.7
Sucrose	1.3	0.2–7.6
'Maltose'[a]	7.3	2.7–16.0
Higher sugars	1.4	0.1–3.8
Ash	0.17	0.02–1.03
Nitrogen	0.04	0.0–0.13
pH	3.91	3.4–6.1

[a]Data for 490 samples; all values in percentages except for pH; 'maltose' includes all reducing disaccharides.

beekeepers measure the moisture content of honey, instead relying on guesswork and leaving this measurement to processors.

Several methods are available to measure honey moisture, including direct drying, viscosity measurement, refractometry, and use of the Karl Fischer titration method. The last method is the most accurate, but the hand refractometer is sufficiently accurate and more convenient to use. This instrument must be used with appropriate sugar solutions as standards.

Sugars

The simple sugars fructose and glucose account for over 85% of its solids, so honey is essentially a highly concentrated sugar solution in water. Another 10% of the honey solids includes at least 25 other more complex sugars (Table 2), giving it the most complex sugar profile of any natural product. Some of these sugars are present in very low levels, and they are formed by linking fructose and glucose in many different combinations.

Until the middle of the twentieth century, the only sugars thought to be present in honey were the nectar sugars fructose, glucose, and sucrose, and small amounts of an ill-defined, highly complex carbohydrate. After the ill-defined material was shown to consist of many individual sugars, researchers provided some explanations as to how they could arise from the nectar raw material. It was revealed that while the acids of honey may be responsible for generating some of the sugars, most are generated as a result of the action of enzymes contributed by the honeybees during the ripening process. The enzymatic formation of these sugars is discussed in the following section on the honey enzymes.

A variety of methods have been required to characterize the many honey sugars. Traditional colorimetric methods continue to be useful for determining levels of reducing and nonreducing sugars in honey, but these methods do little to reveal the high degree of complexity. Enzymatic methods can also be used, such as glucose oxidase for measuring glucose levels. Beginning in about 1950, various chromatographic methods have been shown to be extremely useful. Charcoal-celite chromatography continues to be applied for separating the honey sugars into mono-, di-, and higher saccharide fractions. These fractions are then further resolved using paper-, charcoal-celite column-, thin-layer-, high-performance liquid-, capillary gas-liquid-, and high-performance anion exchange chromatography. The latter two chromatographic modes have been especially useful in separating closely related sugars. After their purification, physical methods such as infrared and nuclear magnetic resonance spectroscopy have been applied to identifying the sugars listed in Table 2 as components of honey. Some of these are present at extremely low levels, providing additional challenges to the analyst. (*See* **Fructose**; **Glucose:** Properties and Analysis; **Sucrose:** Properties and Determination.)

Enzymes

Enzymes that have been identified as honey components are listed in Table 3, along with the number of samples analyzed. These are mostly added by the honeybee, although some traces of plant enzymes may be present. Honeybees add these enzymes in order to accomplish the nectar-to-honey ripening process, and they are largely responsible for providing the compositional complexity of honey. The processes involved in the conversion of the three nectar sugars into at least 25 additional sugars of greater complexity are far from being totally understood. It is becoming increasingly clear, however, that enzyme-catalyzed reactions are responsible for the formation of many of these sugars.

Table 2 Sugars that have been identified as honey constituents

Monosaccharides	*Disaccharides*	*Trisaccharides*	*Higher saccharides*
Fructose	Sucrose	Melezitose	Isomaltotetraose
Glucose	Maltose	Maltotriose	Isomaltopentaose
	Maltulose	Isomaltotriose	
	Isomaltose	3-α-Isomaltosyl glucose	
	Nigerose	1-Kestose	
	Turanose	Panose	
	Kojibiose	Isopanose	
	Laminaribiose	Erlose	
	α,β-Trehalose	Theanderose	
	Gentiobiose	Centose	
	Palatinose	Laminaritriose	
	Cellobiose

Table 3 Enzymes that have been identified as honey constituents

Enzyme	*Number of samples*
α-Glucosidase	1468
β-Glucosidase	11
Glucose oxidase	124
Catalase	38
Acid phosphatase	25
α-Amylase	1746
β-Amylase	1746

From Doner LW (1991) The enzymes of honey. In: Fox PF (ed.) *Food Enzymology*, pp. 143–161. London: Elsevier Applied Science.

The enzyme α-glucosidase is probably the most significant honey enzyme, since it is responsible for many of the important changes that occur during riping. It is often referred to as invertase or sucrase in the honey literature. α-Glucosidase converts the nectar disaccharide sucrose into its constituent monosaccharides, fructose and glucose, a process known as inversion. This reaction is vital because sucrose crystallizes easily and also because its inversion allows the preparation of the super-saturated glucose/fructose mixture found in honey. α-Glucosidase catalyzes additional reactions, leading to the formation of several addition sugars. Researchers have found that incubation of the enzyme with fructose, glucose, and sucrose results in sugars not from hydrolysis reactions but from transglucosylation reactions. By this process, higher sugars are produced from simpler sugars. Sugars from Table 2 that have been identified are kojibiose, nigerose, maltose, isomaltose, turanose, α, β-trehalose, and erlose. The trisaccharide erlose was first discovered as a honey component, and is formed by the reaction of glucose with the glucose moiety of the disaccharide sucrose.

When the most recently discovered honey enzyme, β-glucosidase, has been incubated with fructose, glucose, and sucrose, other honey sugars have resulted. These were the glucose–glucose disaccharides, laminaribiose and gentiobiose. Thus, at least nine of the honey sugars are produced by the action of α- and β-glucosidase on the nectar sugars. The mode of formation of most of the honey trisaccharides remains to be elucidated.

Another honey enzyme contributed by the honeybee, glucose oxidase, is largely responsible for the antibacterial property of honey. This activity was termed inhibine until it was identified to be hydrogen peroxide. This antibacterial agent is produced by the action of glucose oxidase on its glucose substrate. In addition to hydrogen peroxide, gluconic acid is produced by the enzyme. The acidity of this sugar acid is largely responsible for the low pH of honey. In conjunction with the high solids content and resulting low water activity, it helps to stabilize honey against fermentation.

The honey enzymes catalase and acid phosphatase have not been studied in great detail. Catalase was discovered in honey in 1910 and is responsible for converting hydrogen peroxide into water and oxygen. The role of this enzyme appears to be in controlling the levels of hydrogen peroxide in honey, since there is an inverse relationship between the levels of enzyme and substrate.

Acid phosphatase was first reported in 1938 when incubation of β-glycerophosphate with diluted honey was found to result in formation of phosphoric acid and glycerol. The source of this enzyme is unclear. One study suggested that it is only present in slightly fermented honey samples and that yeast is the probable source. A more recent study suggested a plant source for acid phosphatases, since activities were found in pollen and nectar.

Diastase enzyme is added to nectar by bees during ripening, and is a mixture of α- and β-amylase. These enzymes are known to degrade starch, but since nectars are not known to contain starch, their role during ripening is unknown. The activity of honey diastase is known to be reduced upon heating and is easily measured. As a result, its measurement has been used for many years to estimate the extent of heating to which a honey has been exposed. This information is used in countries where such heating is believed to reduce or deplete certain ill-defined health-promoting properties. A problem with this approach is that diastase levels in fresh honeys vary considerably, and extended storage can significantly deplete its level. (*See* **Enzymes:** Functions and Characteristics.)

Minerals

The mineral content of honey is reflected in its total ash content (Table 1). In general, dark honeys have a higher mineral content than light honeys. Like other honey components, ash content is highly variable, ranging from 0.02% to over 1%. The levels of individual minerals that comprise the ash are also variable, but potassium accounts for about one-third of the total amount. Its level exceeds by about 10-fold that of the other major minerals in honey, sodium, calcium, and magnesium. Less abundant elements found in honey are iron, manganese, copper, chlorine, phosphorus, sulfur, and silicon. Sensitive instrumental methods such as atomic absorption or plasma emission spectroscopic analysis can be used to accurately determine levels of even the most trace minerals.

Acids

The great sweetness of honey largely masks flavor contributions of the acids, which generally account

for about 0.5% of the solids. The acids account for the low average pH (3.99) value, which is in part responsible for the excellent stability of honey. Several acids have been found in honey, gluconic acid being present in considerable excess over the others. It arises from glucose through the action of the enzyme glucose oxidase, added by the honeybee. The combined effect of its acidity and the hydrogen peroxide concurrently produced assist in preserving nectar and honey from spoilage. Less prominent acids reported to be in honey are formic, acetic, butyric, lactic, oxalic, succinic, tartaric, maleic, pyruvic, pyroglutamic, α-ketoglutaric, glycollic, citric, malic, 2- or 3-phosphoglyceric acids, and glucose 6-phosphate. (*See* **Acids:** Properties and Determination.)

Proteins and Amino Acids

Protein and amino acid levels in honey are reflected in nitrogen content, which is low, 0.04% on the average, but variable, ranging up to 0.1%. About 40–80% of the total nitrogen in honey is in protein, and most of the remainder resides in the free amino acids. About 20 different nonenzymatic proteins have been identified in honey, many of which are common to all honeys. Some appear to originate in the honeybee, and others in the plant source of nectar. Except for the honey enzymes, little is known about many of the proteins in honey. Their presence results in honeys having a lower surface tension than they would have otherwise, and this encourages the formation of fine air bubbles and a marked tendency to foam. (*See* **Protein:** Food Sources.)

The quantity of free amino acids in honey is small and of no nutritional significance. Honeys have been found to contain between 11 and 21 free amino acids. Proline accounts for about half of the total, most of which originates from the honeybee, rather than from nectar or pollen. Aside from proline, the amino acids glutamic acid, alanine, phenylalanine, tyrosine, leucine, and isoleucine are present in the highest levels. Amino acids react with some of the honey sugars to produce yellow or brown materials, and age-related darkening of honey is probably a result of these reactions.

Flavor, Aroma, and Color

The dominant flavor of honey is sweetness, arising from the blend of the major sugars fructose and glucose, and the wide array of other sugars. Sweetness is common to all honeys, regardless of the floral source of the nectar. Other components common to all honeys, such as gluconic acid and proline, also make contributions to the general flavor of honey. The uniqueness of a given honey is due to contributions of compounds from the wide variety of floral nectar sources. Honey assumes many of the subtle flavor and aroma characteristics of these sources, and there are perhaps as many variations in flavor and aroma as there are nectar sources. Flavors are sufficiently distinctive that experienced honey tasters can identify dozens of different floral sources. Typical flavors range from the most delicate and desirable to those that are harsh and objectionable. (*See* **Flavor (Flavour) Compounds:** Structures and Characteristics.)

As many as 129 components have been separated from extracts of honey, and many of these are volatile organic compounds. Each of these is present in very low levels. About two-thirds have been identified, and many of these probably contribute to honey flavor and aroma, and perhaps color. Low-molecular-weight aldehydes, ketones, alcohols, and esters, make up the bulk of the compounds. One compound present in all honeys is hydroxymethylfurfural. This is produced from decomposition of sugars, especially fructose, in the presence of acid. The high fructose level and low pH of honey combine to favor its formation, which is accelerated when honey is heated. Synthetic honey flavors contain a large proportion of phenylacetic esters, as most of these compounds have a honey taste and aroma. A closely related compound, phenylethyl alcohol, is present in several natural honeys. The flavor and delicate bouquet of honey are vulnerable to heat and improper storage, which can level the subtle distinctions among unique floral sources. Honey is heated during commercial processing in order to delay granulation and avoid fermentation, but careful attention must be given to the time and amount of heat, or valuable flavor and aroma compounds can be lost.

Generally, lighter colors are associated with the milder, more pleasantly flavored honeys. Honey cannot be judged solely on the basis of color, as some of the most distinctively and strongly flavored honeys, such as basswood, are very light, whereas very mild and pleasant honeys such as tulip poplar can be quite dark. Color limits are often specified in trading of honey, however, because flavor is so subjective. Several systems are used for the objective measurement of honey color, and some are designated as official in various countries. Seven classifications are used for international trade; water white, extra white, white, extra light amber, light amber, amber, and dark amber.

Quality Assurance

Much of what has been learned about the composition and properties of honey has resulted from research aimed at verifying its authenticity. Being of

limited supply and relatively expensive, for many years, honey has been a target for adulteration with inexpensive, highly refined sweeteners. High profits are realized when mixtures of these sweeteners and honey are illegally labeled and marketed as pure honeys. Sweeteners that have been mixed with honey over the years have included corn syrup, which contains mostly glucose, and hydrolyzed cane and beet sugars, which contain both fructose and glucose. High fructose corn syrup was the most recent sweetener used to adulterate honey, and it also contains fructose and glucose. Corn syrup is easy to detect, because glucose levels in adulterated mixtures are higher than those normally found in honey. The other three sweeteners are difficult to detect, because adulterated mixtures contain fructose and glucose within the range normally found in honeys.

Methods to detect adulteration of honey have been required to guarantee the integrity of honey markets, therefore assuring an adequate supply of honeybee colonies for crop pollination. In 1977, shortly after the advent of high fructose corn syrup, a method was developed to detect its presence or the presence of sugar cane-derived sweeteners in honey. The test was based on differences in the ratios $^{13}C/^{12}C$ between honey plants and corn and sugar cane plants. The tropical grasses sugar cane and corn employ a different photosynthesis process to fix carbon dioxide, and this results in higher ratios of $^{13}C/^{12}C$ than are found in honeys. These ratios can be precisely measured using isotope ratio mass spectrometry. The application of these tests by government agencies largely discouraged widespread adulteration of honey with sweeteners from corn and sugar cane. Adulteration strategies have shifted to the addition of hydrolyzed beet sugar syrups, which have $^{13}C/^{12}C$ values in the same range as honey. Some progress is being made in its detection, as some oligosaccharides are present in the adulterants that are not present in honey, and these can be detected using sophisticated chromatographic approaches.

Uses of Honey

Most of the honey produced is used directly as a table sweetener or spread. The most significant indirect uses are in baking, cereal, confectionary, and meads. Honey is primarily a high-energy carbohydrate food, possessing distinct flavors that cannot be found elsewhere. The honey sugars are largely the easily digestible simple sugars, similar to those in many fruits. The protein and enzymes of honey, though used as indicators of heating history and hence table quality in some countries, are not present in sufficient quantities to be considered nutritionally significant. Several of the essential vitamins are present in honey, but in insignificant levels. The mineral content of honey is variable, but in the darker honeys, the level can be quite high. Honey is also included in many over-the-counter pharmaceutical preparations, providing flavor and textural properties valued by consumers.

HORMONES

Contents

Adrenal Hormones

L N Parker, University of California, Long Beach, CA, USA

Background and History

Hormones secreted by both parts of the adrenal gland, the cortex and medulla, affect metabolism of proteins, carbohydrates, fat, minerals, and water. The human adrenal glands are paired structures located at the superior pole of each kidney. They are compound glands, composed of an outer cortex and an inner medulla. The cortex secretes three classes of steroid hormones. In humans, the main examples of these hormones are cortisol, a glucocorticoid; dehydroepiandrosterone (DHEA), an androgen; and aldosterone, a mineralocorticoid.

The adrenal medulla secretes nonsteroidal hormones with a catechol nucleus, among them epinephrine (adrenaline), norepinephrine (noradrenaline), and dopamine. Norepinephrine and epinephrine are primarily involved in the biological alarm mechanism of the sympathoadrenal system. The embryological development of the adrenal cortex and medulla are different, as are their control mechanisms and functions, and in some nonhuman vertebrates, including fish, are located apart from each other.

The adrenal glands were described in the sixteenth century by Eustachius, although their functions remained unknown for approximately three centuries. In the nineteenth century, histological studies revealed three zones in the adrenal cortex, and an inner medullary zone which stained differently from the cortex in the fetal and adult adrenal gland. The functions of the adrenal glands were then gradually elucidated. In 1855, Thomas Addison described a group of patients with anemia, pigmented skin, gastrointestinal symptoms, and marked weakness, who were found at autopsy to have atrophied adrenal glands. Their condition of adrenal failure still bears his name, Addison's disease. At approximately the same time, the physiologists Claude Bernard and Charles Brown-Séquard popularized the concept of internal secretions by glands, and showed by adrenalectomies in animals that the adrenal glands are essential for life.

The next clues about the role of the adrenal glands were discovered beginning at the turn of the twentieth century, when a substance with vasopressor activity was isolated from the adrenal medulla, purified and named adrenaline, or epinephrine. In retrospect, epinephrine thereby became the first hormone with a known chemical structure. Shortly thereafter, it was hypothesized that the adrenal glands controlled salt balance as well as blood pressure when it was found that sodium salts could prolong the life of adrenalectomized animals. A generation later, by the use of lipid, rather than aqueous extracts, steroid hormones were sequentially discovered and purified after it was observed that crude lipid extracts of adrenal glands could keep adrenalectomized animals alive indefinitely. The first adrenal steroid hormone synthesized was deoxycorticosterone (DOC), a weak mineralocorticoid, in 1937. The first glucocorticoid synthesized was cortisone in 1949, and by 1955 the main mineralocorticoid in humans, aldosterone, had been characterized and synthesized. Experiments soon demonstrated adrenocortical control by the pituitary gland, and in turn hypothalamic control of adrenocorticotropin (ACTH) was demonstrated conclusively by the characterization and synthesis of corticotropin-releasing hormone (CRH) in 1981. More recent research has focused on many aspects of adrenal gland function, such as hormone synthesis, hormone receptors, and mechanisms of intracellular action. Clinical research has shown the clinical usefulness of epinephrine and related substances in the treatment of asthma, glucocorticoids in the treatment of inflammatory and other conditions, and mineralocorticoids and related substances in the management of autonomic insufficiency.

Structure of the Adrenal Glands and Hormones Secreted

Adrenal Cortex

The location of the human adrenal glands and the structures surrounding them are shown in Figure 1. The weight range of each adrenal gland is approximately 3.5–5 g, and the cortex comprises about 90% of the gland volume. Chronically increased ACTH secretion causes adrenal weight to increase. The adrenal glands, normally adjacent to the kidneys, are surrounded by fat, and can be separated from the kidney in obesity. Occasionally, accessory adrenal tissue is found in the connective tissue near the main glands, most commonly in locations such as in the retroperitoneal celiac plexus, in the hilum of the spleen, near the ovaries or broad ligament, in the scrotum or in the liver. Embryologically, the adrenal cortex is derived from mesenchymal cells adjacent to the urogenital ridge. The fetal adrenal can be recognized by 2 months of gestation, at which time it is invaded by neuroectodermal cells which will form the medulla. By the second trimester, there is a thin outer definitive zone, which will later form the adult adrenal cortex, but the inner fetal zone comprises most of the adrenal mass. After birth, the fetal zone, which secretes mostly DHEA sulfate (DHEAS), rapidly involutes by 2 months of age, and disappears by 1 year.

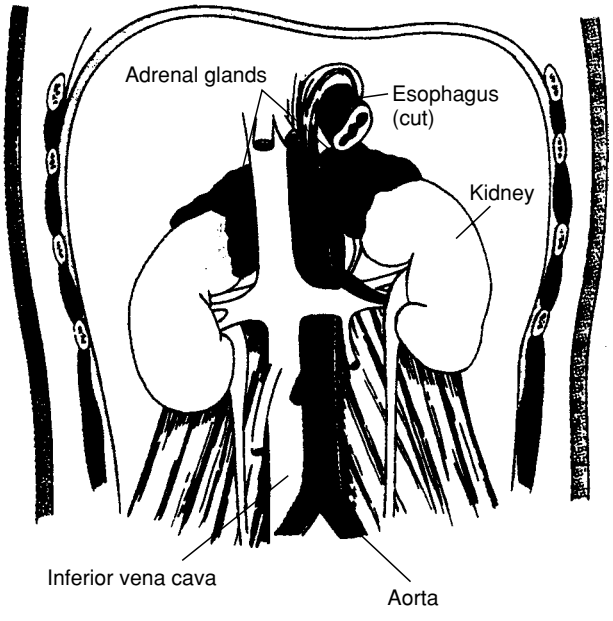

Figure 1 Location and surrounding structures of the human adrenal glands. Reproduced from Gaudin A and Jones K (1989) *Human Anatomy and Physiology*. San Diego: Harcourt Brace Jovanovich, with permission.

By 1 year of age, three zones can be identified by light microscopy in the definitive adrenal cortex, as shown in Figure 2. The outer zone, the zona glomerulosa, is relatively thin, and consists of cells which secrete aldosterone. The middle zone, the zona fasciculata, is usually the thickest layer of the adrenal cortex, and has a columnar structure. Its cells are relatively clear, since they are large and have a high lipid content. The inner zone, the zona reticularis, surrounds the medulla. Its cells are relatively dark-staining and compact in appearance, and often contain lipofuscin pigment granules. Both the zona fasciculata and the zona reticularis produce cortisol and androgens, but in the human, the zona reticularis has sulfotransferase activity, and produces DHEAS. Chronically increased ACTH concentrations result in lipid depletion from the zona fasciculata and an increase in the width of the zona reticularis.

Adrenal Medulla

The adrenal medulla is part of the sympathetic nervous system, which arises from cells of the neural crest during embryonic development. Storage granules which stain brown with chromic acid due to oxidation of catecholamines to melanin give the cells which contain them the name chromaffin or pheochrome cells. These cells are also found on both sides of the aorta, and comprise the paraganglia. The largest collection of these cells is found near the inferior mesenteric artery, where the cells fuse to form a fetal structure called the organ of Zuckerkandl, which undergoes involution within the first year of life. The remainder of the chromaffin cells in the paraganglia and adrenal medulla persist during adult life and secrete norepinephrine, epinephrine, and dopamine. In the adrenal medulla, the cells are arranged in an irregular network with a rich blood supply, and are in contact with sympathetic ganglia. The cells of the adrenal medulla are innervated by preganglionic

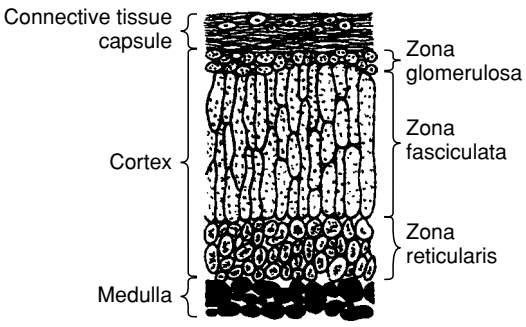

Figure 2 Histology of the human adrenal gland. Reproduced from Gaudin A and Jones K (1989) *Human Anatomy and Physiology*, San Diega: Harcourt Brace Jovanovich, with permission.

fibers of the sympathetic nervous system. Most of the blood supply of the adrenal glands enters through the cortex and drains into the medulla, except for some vessels which supply the medulla directly.

Physiological Effects of Adrenal Gland Hormones

Adrenal Cortex

As in the case of other steroid hormones, glucocorticoids exert their effects on target cells by interacting with soluble cytosolic receptor proteins, after mostly passive diffusion into cells. The glucocorticoid receptor is a single-chain polypeptide with a molecular weight of 94 kDa which binds glucocorticoids with a high affinity. After binding glucocorticoids at the COOH-terminus, the DNA-binding region in midmolecule binds to the nucleus. The glucocorticoid receptor is a member of a family of DNA-binding proteins which act as regulators of gene transcription, including receptors for all types of steroid hormones, the thyroid hormone receptor, and the retinoic acid receptor. The hormone-binding domain of these receptors is well conserved, but the most distinctive feature is the highly conserved central DNA-binding domain. This is the zinc-finger domain, a series of finger-like loop structures of amino acids anchored at the base by a zinc ion chelated between two pairs of cysteine and histidine residues (Figure 3), which interact with coils of the DNA double helix. Glucocorticoid receptor complexes interact with specific glucocorticoid response elements, usually located near the promoter region of target genes.

Glucocorticoids are named for their effect of increasing hepatic glucose production by several mechanisms. They increase activity of hepatic gluconeogenic enzymes such as glucose-6-phosphatase and phosphoenolpyruvate carboxykinase, in the latter case by gene transcription. Glucocorticoids also activate glycogen synthase and inactivate the glycogen-mobilizing enzyme glycogen phosphorylase, with a net increase in hepatic glycogen synthesis. Finally, glucocorticoids decrease peripheral glucose utilization in part by decreasing adipocyte glucose transporter mRNA levels.

With respect to protein and fat metabolism, glucocorticoids stimulate catabolism of nonhepatic proteins with a resultant release of glucogenic amino acids, largely from skeletal muscle, and an increased uptake into liver for gluconeogenesis. In adipose tissue, glucocorticoids stimulate lipolysis and subsequent release of glycerol and free fatty acids, while enhancing the rate of fat oxidation. Pharmacological amounts of glucocorticoids cause osteopenia on a chronic basis, by inhibiting osteoblast function, thereby decreasing new bone formation, and by decreasing intestinal calcium absorption.

Cortisol is a major stress hormone and is secreted in so many different forms of stress that an increase in cortisol secretion is often considered to be part of the definition of a stressful stimulus. It has been speculated that cortisol functions to aid survival in stress by improving the metabolic milieu by means of the energy-producing and biosynthetic pathways described above. The inflammatory process is common in stress caused by illness or injury, and cortisol may also help to minimize damage to the body resulting from excessive inflammation by stimulating mechanisms such as lysosomal membrane stabilization, which prevents release of proteolytic enzymes, and reduction in capillary permeability to avoid leakage of plasma and blood cells into an inflamed area. Among the mechanisms by which cortisol performs these functions is the inhibition of the action of histamine, and the synthesis of prostaglandins. Cortisol inhibits the accumulation of neutrophils at sites of inflammation. Cortisol also has numerous other effects, such as maintenance of normal cardiac output and renal blood flow, and modification of immunological responses. One mechanism for the modification of immunological responses is the promotion of lymphocyte apoptosis.

Adrenal androgens such as DHEAS circulate at high concentrations in young adults, and in the case of DHEAS, the concentration is much greater than that of cortisol. However, their functions are not as clearly elucidated. There is evidence that these steroids have a hepatic receptor, and that they may prevent osteoporosis, facilitate the birth process by

causing cervical softening, modify immunological processes, mediate female libido, and serve as precursors for the more potent sex steroids. In animal studies these steroids have been shown to protect against obesity, diabetes, and certain types of infections and tumors. There is DHEAS in the human brain, and it has been shown to be synthesized in rat brain, but its function in the nervous system of either species is not known.

Aldosterone and other mineralocorticoids maintain normal sodium and potassium concentrations and intravascular volume by regulating electrolyte transport across epithelial surfaces. The specific renal type I mineralocorticoid receptor is unrelated to the glucocorticoid receptor at the amino-terminus, but partially homologous at the steroid-binding COOH-terminus, and highly homologous at the DNA-binding zinc-finger domain. Cortisol displaces aldosterone from this receptor, but *in vivo* is converted locally to cortisone by the microsomal 11-β hydroxysteroid dehydrogenase enzyme, and cortisone has relatively little affinity for the mineralocorticoid receptor. After binding to the mineralocorticoid receptor, mineralocorticoids induce protein synthesis and subsequent activation of a sodium pump, which transports sodium across cell membranes. In the kidney, sodium is absorbed, and potassium and hydrogen ions are secreted. Under the influence of aldosterone, sodium is therefore conserved, and potassium and hydrogen ions are excreted into the urine. Aldosterone has similar effects in sweat glands, salivary glands, and in the intestinal lumen.

Adrenal Medulla

Catecholamines exert their effects via two classes of receptors, α and β. Adrenergic receptors interact with catecholamines on the extracellular side of the plasma membrane, and with G proteins within the cell membrane. Adrenergic receptors are part of a large family of membrane-associated proteins which includes muscarinic acetylcholine receptors. Regions of these proteins show considerable homology with each other, especially the membrane-spanning domains. As with other receptors which are coupled to G proteins, there are seven hydrophobic membrane-spanning domains connected by three extracellular and cytoplasmic loops. Stimulation of the α class of receptors by norepinephrine results in a variety of actions, such as vasoconstriction and blood pressure elevation, pupillary dilatation, and bladder sphincter contraction. Epinephrine also stimulates α receptors. However, in addition, epinephrine also stimulates the β types of receptors, which result in actions such as vasodilatation, acceleration of the heart rate, bronchodilatation, glycogenolysis, and lipolysis. These actions are part of the physiological response to stressful stimuli, and complement those of cortisol. Dopamine is a weak agonist of both the α and β classes of receptors, but in addition, there are several classes of dopaminergic receptors in the central nervous system and peripheral tissues.

In liver, catecholamines promote glucose output by activating glycogenolysis, accelerating gluconeogenesis, and inhibiting glycogen synthesis. Stimulation of adrenergic receptors by catecholamines increases activity of adrenyl cyclase and conversion of glycogen phosphorylase from the inactive to the active form, while there is a simultaneous increase of amino acid uptake by the liver, which increases substrate availability for gluconeogenesis. In adipose tissue, catecholamines also stimulate lipolysis by increasing activity of hormone-sensitive lipase, and the cleavage of triglycerides into fatty acids and glycerol for increased gluconeogenesis and energy availability.

Synthesis and Control of Adrenal Gland Hormones

Adrenal Cortex

The adrenal cortex produces cortisol in response to ACTH secreted by the pituitary gland. The secretion of ACTH occurs in response to decreased circulating concentrations of cortisol, as part of a negative-feedback system, and in response to stressors of many types, including surgery, hemorrhage, thermal injury, and hypoglycemia. In addition, there is a circadian rhythm of pulsatile ACTH and cortisol secretion which in humans results in increased secretion towards the end of the sleep period, and therefore higher levels of circulating cortisol in the morning. ACTH is a 39-amino-acid peptide derived from a larger molecule, 241-amino-acid proopiomelanocortin (POMC). The first 24 amino acids of ACTH are constant and bioactive in many species. POMC secretion is under the control of neurotransmitters and hypothalamic CRH, as shown in Figure 4. POMC undergoes extensive posttranslational processing, producing many peptides, including ACTH, as shown in Figure 5. There is evidence from animal experiments that non-ACTH POMC peptides may synergize with ACTH in control of corticosteroid secretion. Concentrations of CRH, a 41-amino-acid peptide, are high in the hypophysical portal system.

The mechanism of action of ACTH involves many steps, including initial binding to an adrenal cell surface receptor, which ACTH upregulates, thereby increasing the steroidogenic response to ACTH stimulation. ACTH binding activates adenyl cyclase

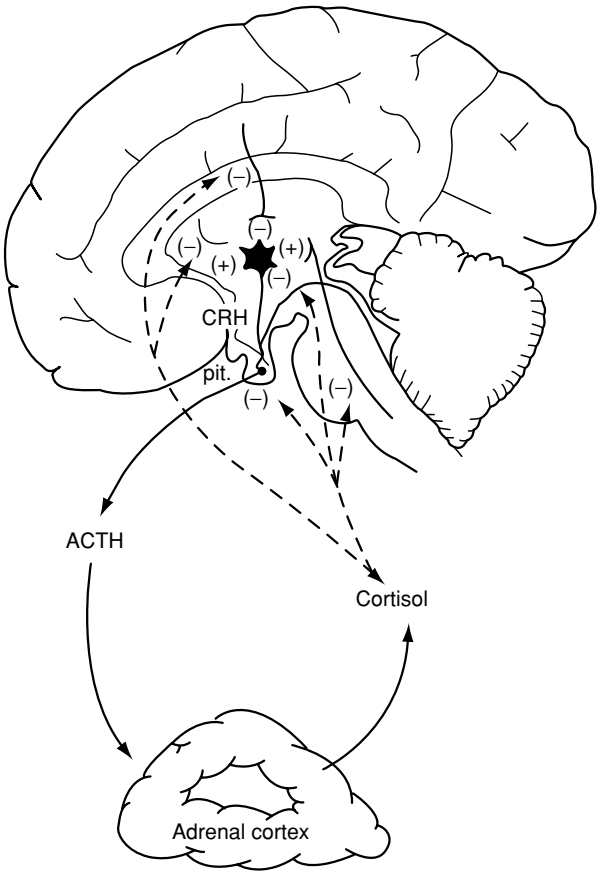

Figure 4 Cortisol feedback loop in the hypothalamic–pituitary–adrenal system. CRH, corticotropin-releasing hormone; pit, pituitary gland; ACTH, adrenocorticotropic hormone. which increases cyclic 3′,5′-monophosphate (cAMP) concentrations, which in turn activate cAMP-dependent protein kinase and phosphorylation of a number of proteins in the presence of extracellular calcium. There is an increase in activity of cholesterol ester hydrolase, which produces free cholesterol for the rate-limiting conversion of cholesterol to pregnenolone. Intracellular delivery of cholesterol to the inner mitochondrial membrane is facilitated by the 30-kDa steroidogenic acute regulatory protein, induced by cAMP. The conversion of cholesterol to pregnenolone then proceeds via the mitochondrial side-chain cleavage enzyme. Plasma lipoproteins also provide cholesterol for steroidogenesis.

As shown in Figure 6, pregnenolone can be converted to mineralocorticoids, glucocorticoids, or androgens. Many of the microsomal enzymatic steps are controlled by ACTH by regulation of the rate of steroidogenic enzyme synthesis. In contrast to the situation in the human, there is little activity of the enzyme 17β-hydroxylase (Figure 6) in rodents, and therefore the main glucocorticoid is corticosterone in this species.

Cortisol and ACTH secretion are closely related, and linked by a negative-feedback loop, as described above. Adrenal androgens, such as DHEA, are also secreted in response to acute ACTH stimulation, but their control is more complex since in some situations they are not secreted in parallel with cortisol. These situations include adrenarche, puberty, aging, polycystic ovarian syndrome, stress, serious illness, anorexia nervosa, and starvation. Adrenarche is the process of adrenal gland maturation which occurs before puberty at approximately age 7, and which involves increased secretion of DHEA and DHEAS along with unchanged secretion of cortisol. In contrast, during aging, while basal levels of cortisol are unchanged, levels of DHEAS peak in young adulthood in both sexes, and then decline markedly, as shown in Figure 7. The decrease in concentrations of adrenal androgens in stress, serious illness, anorexia nervosa, and starvation is somewhat similar to the situation in aging, except that it is reversible with recovery. The reason for the dissociation between cortisol and adrenal androgen secretion is not clear, but may involve regulation by a non-ACTH POMC-related peptide.

Aldosterone is produced only by the zona glomerulosa, because it is the only zone with aldosterone synthase activity. The zona glomerulosa does not have 17β-hydroxylase activity, and does not produce cortisol. Although ACTH causes acute stimulation of aldosterone secretion, there are other more important control mechanisms in addition to ACTH. Angiotensin II is the major regulator of aldosterone secretion. Secretion of angiotensin II is controlled by renin, as shown in Figure 8. Renin release is regulated primarily by the sodium concentration of fluid in contact with the renal juxtaglomerular cells, and renal perfusion, as sensed by renal baroreceptors. Increased renin release is stimulated by decreased sodium concentration or renal arteriolar blood pressure. Renin mediates the conversion of hepatic renin substrate (angiotensinogen) to the 10-amino-acid peptide, angiotensin I, which in turn is converted to the 8-amino-acid peptide angiotensin II, a potent vasopressor, by the converting enzyme in lung and other tissues. The 7-amino-acid peptide angiotensin III is also bioactive in stimulation of aldosterone secretion.

Angiotensins II and III bind to high-affinity zona glomerulosa cell surface receptors and stimulate aldosterone production from cholesterol by a calcium-dependent mechanism involving activation of protein

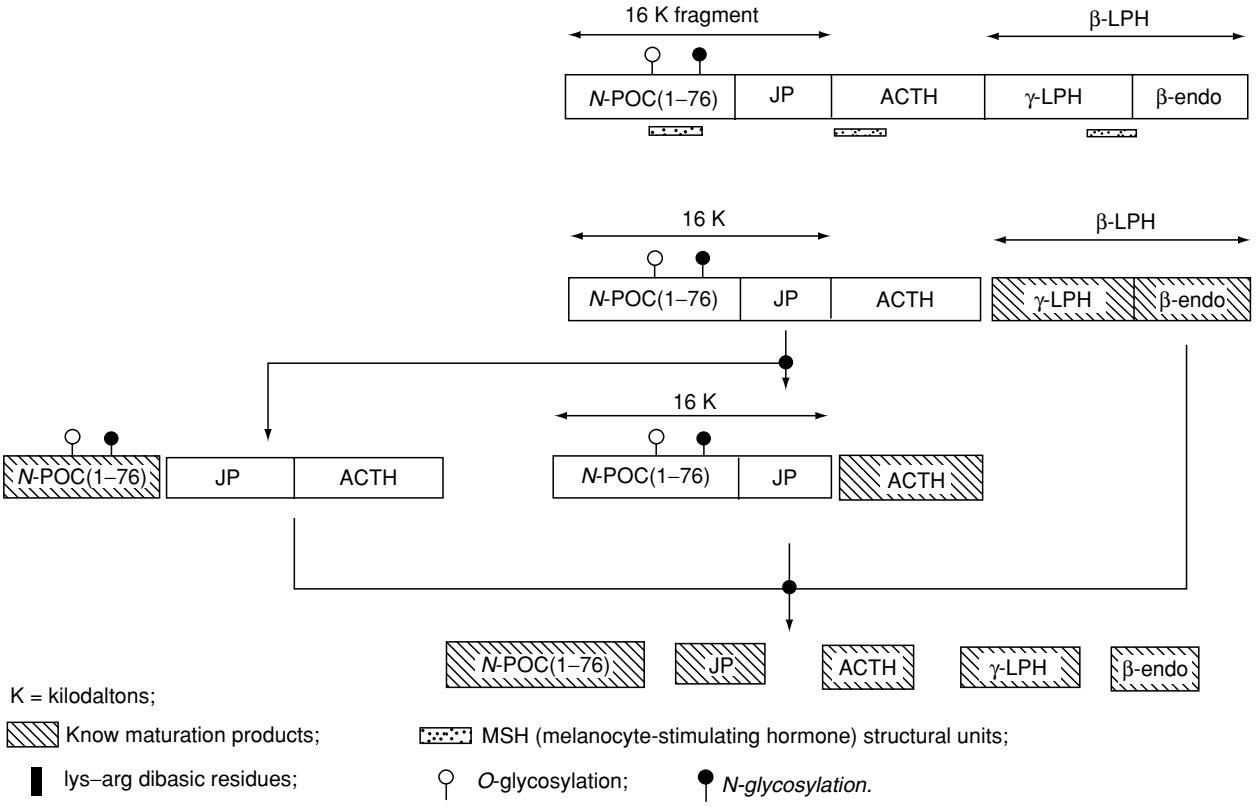

Figure 5 Structure and processing of proopiomelanocortin (POMC; POC). ACTH, adrenocorticotropic hormone; LPH, lipotropin; endo, endorphin; JP, joining peptide. Reproduced from Seidah N et al. kinase C, rather than adenylate cyclase. In addition, aldosterone synthesis may be modified by lipoxygenase pathway metabolites of arachidonic acid. Potassium ion also influences aldosterone secretion by a direct effect on zona glomerulosa cells, and forms the basis for a feedback mechanism to regulate the concentration of extracellular potassium ions. Concentrations of potassium ion have the opposite effect on renin concentrations, but the direct effect on aldosterone secretion is predominant. In addition, as in the case of cortisol and adrenal androgen secretion, there is evidence that an influence on aldosterone secretion may be exerted by non-ACTH POMC-related peptides.

Adrenal Medulla

Control of the adrenal medulla is exerted by the sympathetic nervous system. Whereas preganglionic fibers of the parasympathetic branch of the autonomic nervous system emerge from cranial and sacral spinal nerves, those of the sympathetic nervous system emerge from the thoracic and lumbar spinal nerves and innervate many organs, including the adrenal medulla. Preganglionic nerve impulses are transmitted to postganglionic fibers by liberation of acetylcholine at nerve terminals. This results in secretion of catecholamines by the peripheral sympathetic nervous system and by the adrenal medulla. Norepinephrine is the major secretory product of the peripheral nervous system, and is primarily a neurotransmitter, not a circulating hormone. In the human adrenal medulla, the ratio of epinephrine to norepinephrine secretion is approximately 4:1, and concentrations of epinephrine, a circulating hormone, are sufficient to stimulate adrenergic receptors.

Catecholamine biosynthetic pathways are shown in Figure 9. The rate-limiting step in catecholamine biosynthesis is the initial conversion of tyrosine to dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase (TH), an enzyme which is inhibited by DOPA, dopamine, and norepinephrine. Tyrosine itself is derived from the diet, or converted in the liver from phenylalanine by phenylalanine hydroxylase. The decarboxylation of DOPA to dopamine is catalyzed by aromatic-L-amino acid decarboxylase (AADC). Unlike the other enzymes of catecholamine biosynthesis, AADC is not only found in sympathetic nerve

endings and the adrenal medulla, but also in nonneuronal tissues, including the kidney, and catalyzes the decarboxylation of other aromatic amino acids in addition to DOPA, including 5-hydroxytryptophan, which is converted to serotonin.

Dopamine β-hydroxylase (DBH) catalyzes the hydroxylation of dopamine to form norepinephrine. The enzyme is found in sympathetic nerve endings, and also in adrenal medullary chromaffin granules, which release DBH along with norepinephrine when stimulated. The major difference between the catecholaminergic pathways of the adrenal medulla and the peripheral nervous system is the presence of the enzyme phenylethanolamine-*N*-methyl transferase (PNMT) in the medulla. This enzyme, also found in small amounts in the brain, catalyzes the conversion of norepinephrine to epinephrine, using *S*-adenosylmethionine as a methyl donor. PNMT is inducible by high concentrations of cortisol which are present in the capillary sinusoidal circulation from the adrenal cortex to the medulla.

A large percentage of synaptically released catecholamines are inactivated by reuptake into storage granules. Metabolism of circulating catecholamines occurs via two main pathways, mediated by the enzymes catechol-*O*-methyltransferase (COMT) and by monoamine oxidase (MAO), as shown in Figure 10. The end product of norepinephrine and epinephrine metabolism, after transformation by both enzymes, is 3-methoxy-4-hydroxymandelic acid (vanillylmandelic acid). Catecholamines in the liver and gut are also inactivated by sulfate or glucuronide conjugation of the phenolic hydroxyl group.

The hypothalamus is the main regulator of sympathetic nervous system function. Impulses from the posterior and lateral hypothalamus result in generalized discharge of the sympathetic nervous system, including the adrenal medulla, although they can also be activated separately. The sympathoadrenal system is characterized by speed and integration, in that catechol-mediated events can take place within seconds, and can coordinate vascular, metabolic, and hormonal components. As discussed above, these responses occur to a variety of noxious, threatening, or stressful stimuli. In addition, the sympathetic nervous system is instrumental in maintaining an appropriate circulating volume and cardiac output during changes of posture from supine to upright. These feedback systems are mediated by sensors in the carotid sinuses, aorta, and medulla, which detect changes in circulatory volume and blood pressure. Although of different embryological origins, and operating via different regulatory mechanisms, the hypothalamic–pituitary–adrenocortical system and the sympathoadrenal system complement each other in the maintenance of homeostasis and a stable metabolic milieu in response to many forms of stress.

Thyroid Hormones

J Vanderpas, Faculté Médecine, FUNDP, Namur, Belgium

Iodinated Thyroid Hormones

Thyroid Follicles and their Development

The thyroid gland displays a peculiar, highly organized architecture characterized by the presence of spheroidal structures – follicles – that are composed of a single layer of epithelial cells (thyroid follicular cells) surrounding a closed cavity (follicular lumen) filled with colloid, a concentrated solution of thyroglobulin (Tg). The follicle has been defined as the morphologic and functional unit of the thyroid. Notably, during intrauterine life, the onset of thyroid function (around 10 weeks in humans) coincides with the appearance of differentiated follicles. It is the follicular organization, together with the polarity of the follicular cells, that allows the several biochemical steps required for thyroid hormone biosynthesis: (1) secretion of a peculiar protein with iodinated amino acids in the follicular lumen as exocrine cells; (2) reabsorption of this peculiar protein, with hydrolysis of its iodinated amino acids; (3) release of iodothyronines into blood by endocrine secretion.

The follicle cell divides the follicular lumen (where hormone synthesis begins) and the blood stream, from where iodine has to be uploaded and where hormones will be released at the end of the process.

The surface of a polarized thyroid follicular cell is divided into two functionally distinct, but physically contiguous regions: an apical and a basolateral domain. Junctional complexes between cells separate these two domains and prevent the mixing of asymmetrically distributed proteins (**Figure 1**). The apical domain displays a differentiated tissue-specific organization characterized by the presence of apical microvilli and pseudopods, and by the localization of thyroperoxidase (TPO). Na^+/I^- symporter (NIS), epidermal growth factor, and thyroid-stimulating hormone (TSH) receptors are located in the basal domain. Thyroid hormone synthesis requires basal-to-apical transport of iodide and Tg. Conversely, hormone secretion is based on apical-to-basal transport of Tg and hormones; in addition, a bidirectional ion transport system controls follicular size.

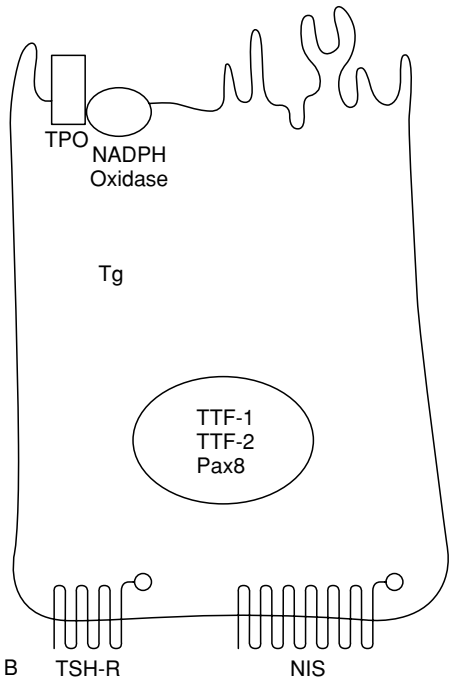

Figure 1 Schematic structural representation of thyroid follicular cell with its polarized architecture. TSH-R, thyroid-stimulating hormone receptor; NIS, Na/I symporter; Tg, thyroglobulin; TPO, thyroperoxidase; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate; TTF-1.

The thyroid primordium of the human embryo is first visible at 20 embryonic days, as a midline enodermal thickening in the floor of the primitive pharynx. It migrates caudally to form a transient thyroglossal duct, and reaches its final position at 35 embryonic days. Tg is detectable at 60 embryonic days, and this step corresponds to the occurrence of fetal thyroid hormone biosynthesis. The early stages of folliculogenesis are independent of thyrotropin. At midgestation (18–20 weeks), the hypothalamopituitary–thyroid axis begins to develop, and thyrotropin is absolutely necessary for thyroid growth and function.

Biosynthesis of Thyroid Hormones

Figure 2 summarizes the process of thyroid hormone synthesis, which includes active concentration of

iodine, incorporation of iodine in thyroglobulin, and breaking down thyroglobulin to release tetraiodothyronine (T_4) and triiodothyronine (T_3).

NIS An active transport mechanism allows thyroid cells to concentrate iodide (I^-) some 20- to 40-fold its level in extracellular space. This transport system is sensitive to other inhibiting anions (thiocyanate, perchlorate). It is found in other tissues (salivary glands, mammary gland). In the thyroid, it is restriced to the basolateral cell membrane. The key protein in the transport mechanism is the human Na/I symporter (hNIS). Its synthesis is stimulated by TSH. It is a 12-loop protein, of 65 kDa. It has homology with the Na/glucose transporter.

hTg Human Tg (hTg) is a 660-kDa protein. It contains 66 tyrosils, and half of them – in maximal conditions – are able to incorporate iodine in a covalent binding, resulting in mono- or diiodotyrosine (MIT, DIT) residues. Some iodothyrosine residues fuse, to form T_4 with its four iodine atoms and T_3 with its three iodine atoms. In normal physiological conditions, Tg contains five residues each of MIT and DIT, 2.5 of T_4 and 0.7 of T_3. These proportions depend on iodine supply, and on Tg accumulation in follicles. Its synthesis and release of thyroid hormones is under thyrotropin control. Iodine by itself, independently of thyrotropin, has an autoregulatory function on Tg synthesis and metabolism.

hTPO Human hTPO is a 103-kDa protein localized in the apical membrane of the follicular cell. It contains heme and, in the presence of hydrogen peroxide, it iodinates tyrosil residues of hTg present in the lumen of the follicles. The iodination process of proteins is not specific to thyroid cells: macrophages and leukocytes iodinate bacteria proteins through a similar process, involving myeloperoxidase in place of hTPO. However, the further step of coupling and thyroid hormone synthesis is quite specific to the thyroid. The same hTPO enzyme is responsible for the coupling of DIT and MIT in T_3 and T_4. It is proposed that the loops of hTg polypeptide make some DIT and MIT residues close, and the TPO enzyme and hydrogen peroxide interact to produce free radicals which form a diphenyl ether across the $OH^\bullet$ free radicals.

hThOX Reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is essential to produce hydrogen peroxide at the apical membrane of the follicular cells. It has recently been identified as a specific thyroid oxidase, with NADPH and calcium as substrates. It has a cytochrome moiety.

The sites of tyrosine iodination, as well as the sites of iodotyrosine coupling on Tg molecule are not stochastic, but are hierarchically defined. The number of iodinated tyrosine residues depends closely on the iodine supply and on thyrotropin stimulation. Figure 3 depicts the general scheme of preferential sites of iodination and coupling. The thyroid stores its hormones as colloid in the follicular lumen, still part of the Tg peptide structure. This process guarantees a stable storage of both iodine and iodinated thyroid hormones in variable-iodine-supply conditions. A normal human adult thyroid accumulates 10–20 mg iodine, which represents a storage for at least 3 months (required daily administration of iodine: $\pm$ 100 µg). This storage depot allows the thyroid to dole out thyroid hormones as the body needs it, and to mobilize it rapidly when called for. Such

mobilization is accomplished by bringing stored Tg back from the follicular lumen into the cell, passing it through endosomal and lysosomal digestive systems, and delivering free hormone to the basal membrane for secretion into the circulation. About 70% of Tg's iodine is in the form of the inactive precursors MIT and DIT, which the thyrocyte deiodinates and then recycles the iodine. The most important enzymes for Tg degradation are the lysosomal proteases. The best characterized are the aspartic endopeptidase cathepsin D and the cysteine endopeptidases cathepsin B and L. Peptides produced by the individual enzymes purified from human thyroids were isolated and the sites of cleavage identified by analogy to the cDNA sequence of hTg. Figure 3 summarizes, also, the major cleavage sites for each enzyme. Cathepsin L (dotted broken arrows in Figure 3) attacked near hydrophobic residues, particularly leucine, and its major cleavage sites were within the C-terminal 400 residues of Tg. Cathepsin D (solid arrow in Figure 3) preferentially cleaved peptide bonds between hydrophobic residues, particularly aromatic ones, similar to its activity in other tissues. Cathepsin B (dashed broken arrows) had its principal cleavage sites in both the N-terminal and C-terminal regions. The presence of major hormonogenic sites at Tg's extreme N- and C-termini may favor selective release of thyroid hormone during proteolysis. The endopeptidases cleave Tg into large peptides that must then be further degraded by exopeptidases. The several exopeptidases identified in the thyroid include dipeptidylpeptidases I and II, lysosomal dipeptidase I, and the carbaxyl exopeptidase *N*-acetyl-L-pbenolalanyl-L-tyrosine hydrolase. Also, cathepsin B has exopeptidase activity, in addition to its role as an endopeptidase. The combination of cathepsin B and lysosomal dipeptidase I is sufficient to release T_4 from its most important site at residue 5.

The thyroid stimulated by TSH shows prompt and vigorous engulfment of material from the lumen to form colloid droplets, which are then internalized into the thyrocyte and passed through its lysosomal-degradative pathway. However, under more usual physiologic conditions, colloid resorption takes place by micropinocytosis, and endocytotic vesicles are formed and pass successively through an endosomal compartment and then into lysosomes. The initial event in micropinocytosis appears to involve the entrance of Tg into coated pits, probably without the intervention of receptors; the amount processed depends on the availability of endocytotic vesicles and the amount of Tg in the lumen.

Tg's structure, specifically, the completion of its carbohydrate side chains, is important for its trafficking at the apical membrane. Immature Tg molecules are deficient in both iodine and glycosylation, so they have exposed *N*-acetylglucosamine residues. These residues are recognized by membrane receptors that apparently direct these immature molecules back to the Golgi for glycosylation and subsequent iodination. These observations suggest that Tg molecules are sorted in the endosomes, perhaps by iodine content, with immature molecules being recycled and mature ones readied for degradation and hormone release.

Some proteolytic processing may take place in endosomes before Tg enters lysosomes. Lysosomal enzymes are also present in endosomes, where the acidic pH would favor their activity. Some proteolytic processing may occur even before endocytosis. For example, cathepsin B activity has been detected at the cell surface of cultured thyrocytes. In the same experimental model, activation of cysteine proteases permitted T_4 release at extralysosomal sites, as well as in the lysosomes, although T_3 release appeared to be restricted to lysosomes.

Specific cleavages in the peptide chain of Tg are also associated with its iodination. Such breaks occurred in the presence of protease inhibitors, thus suggesting that proteolytic enzymes were not involved. However, other specific proteolytic cleavages may also occur as early events in Tg degradation. Limited digestion with trypsin has identified several susceptible regions in the Tg molecule, most notably a region after residue 500 and another one around residue 1800.

T_4 emerges from the lysosomal-degradative pathway, probably as the free hormone or perhaps in small peptides. Most is secreted into the circulation. A specific transport mechanism across the basal membrane has not been identified. While still in the thyroid, some T_4 is converted to T_3 by type 1 selenium-dependent 5′-iodothyronine deiodinase. This enzyme is the same as that in other tissues, such as the liver and kidney, produces T_3, the active form of the hormone, from circulating T_4.

About 70% of Tg's iodine is in MIT and DIT. Although small amounts of MIT and DIT are secreted into the circulation, most is deiodinated within the thyroid and its iodide is returned to the general pool for recycling. This mechanism is important for iodine conservation, as shown by the functional iodine deficiency of patients who have the rare defect that blocks this step. The iodotyrosine deiodinase responsible for this activity is an NADPH-dependent flavoprotein (it is not a selenium-containing enzyme, and it should not be confound with iodothyronine deiodinase). Its partial purification showed a molecular weight of about 42 000, and it consisted of two possibly identical subunits.

Circulating Thyroid Hormone and Free Thyroid Hormone Metabolism

Iodothyronines produced by the thyroid are highly hydrophobic, and need to be bound to specific proteins for transport through the general blood circulation to their target tissues. In blood, thyroid hormones are not covalently bound to specific thyroid hormone-binding proteins (thyroid hormone-binding globulin (TBG) and transthyretin (TTR), previously known as prealbumin). They are also transported aspecifically by albumin. Table 1 shows the properties of the major human thyroid hormone-binding proteins.

Free fraction of thyroid hormones describes the percentage of total hormone that is unbound. About one molecule of T_4 in 4000 and one molecule of T_3 in 400 is free; the remaining molecules are bound to the specific and aspecific proteins. By contrast to corticoid-binding proteins, none of the thyroid hormone-binding proteins has a role in the delivery of thyroid hormones to target tissues. Only free hormones are delivered to target tissues: so, clinical thyroid status is closely dependent on free thyroid hormone concentration, and the general equilibrium is as follows:

$$\text{Free } T_4 + \text{TBG} \Leftrightarrow [\text{TBG}\ldots T_4]$$

The normal free T_4 concentration and TBG concentration are such that about half of TBG sites available to thyroid hormone binding is occupied by T_4. This involves that within a certain range; free hormone concentration is linearly associated with total hormone concentration. So, TBG stabilizes the tissue distribution of T_4.

Modern immunoassays measure the serum free T_4 and free T_3 concentrations, which are directly related to clinical thyroid status.

Table 2 presents the kinetic parameters of circulating total and free thyroid hormones in a 70-kg adult human.

Table 1 Properties of the major human thyroid hormone-binding proteins

Property	*Thyroxine-binding globulin*	*Transthyretin*	*Albumin*
Molecular weight (kDa)	54	55	66
Peptide structure	Glycoprotein	Peptide tetramer	Single chain
Concentration (mol l^{-1})	3×10^{-7}	2×10^{-6}	6×10^{-4}
Half-life (days)	5	2	15
% of tetraiodothyronine carried	75	10–15	10–15

Nuclear T_3 receptor binding *in vitro*	10^{-9}	10^{-10}	No data

T_4, tetraiodothyronine; T_3, triiodothyronine.

Within some tissues (mainly, liver and kidney), circulating T_4 is deiodinated in circulating T_3 by a selenium-dependent type 1 iodothyronine deiodinase. In normal iodine supply conditions, half of circulating T_3 derives directly from thyroid (breakdown of Tg), and half from liver conversion of T_4 to T_3. The same deiodinase is also able to convert T_4 to reverse T_3 (metabolically inactive). In some physiological conditions such as the neonatal period (cord blood) or during illness, the preferential liver conversion of T_4 to reverse T_3 explains the paradoxical serum profile of low T_3 syndrome without hypothyroidism. The exact mechanism of preferential conversion of T_4 to reverse T_3 in place of T_3 is still unexplained.

Thyroid Hormone Action at the Cellular Level

Free thyroid hormones T_4 and T_3 diffuse through the cell membrane of their target tissues. Up to now, no specific membrane receptors have been identified, and it is considered that this delivery to cells is through a passive diffusion mechanism.

Within the cell, iodothyronine deiodinases act to convert intracellular T_4 to intracellular T_3 or reverse T_3 (Figure 4).

The differential intracellular conversion of T_4 to T_3 in peripheral tissues (thyroid; muscle, including the heart; liver; kidney; adipose tissue, etc.) and in central tissues (central nervous system, including pituitary gland) is explained by the divergent distribution of selenium-containing iodothyronine deiodinases. Type 1 is present mainly in peripheral tissues, while type 2 is present mainly in the central nervous system. Type 2 deiodinase has a much lower affinity constant for T_4 than type 1 deiodinase (1 nmol l^{-1} versus 23 µmol l^{-1}). This explains why, within the central nervous system, in normal physiological conditions, 80% of

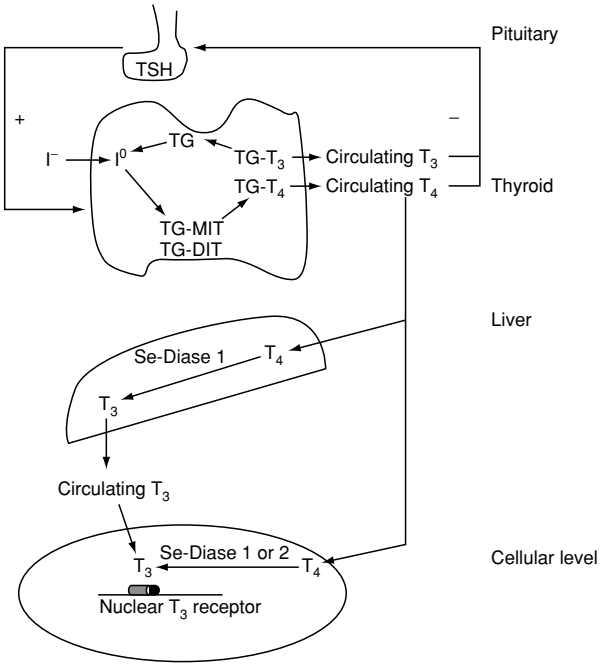

Figure 4 Some metabolic steps in iodine metabolism. Pituitary thyrotropin (TSH) stimulates thyroid I^- uptake, and enzymatic organification of iodine (I^0) by thyroperoxidase (TPO) in a mono- and diiodotyrosine (MIT and DIT), which are further coupled by the same enzyme thyroperoxidase (TPO) in tri- and tetraiodothyronine (T_3 and T_4). Part of T_4 is further deiodinated to T_3 in the liver by selenium-containing enzymes selenium-dependent iodothyronine deiodinases 1 and 2 (Se-Diase 1 and 2). At the cellular level, the active hormone is T_3, which binds to a specific nuclear T_3 receptor. T_3 comes directly from circulating serum T_3 or from the intracellular conversion of T_4 to T_3.

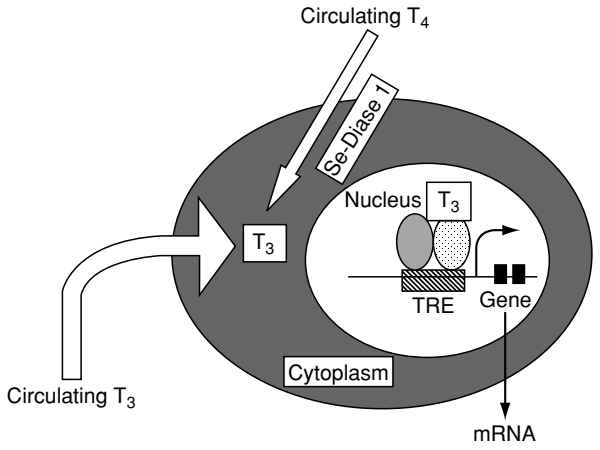

Figure 5 Simplified model of thyroid hormone action on nuclear thyroid hormone receptor. T_4, tetraiiodothyronine; T_3, triiodothyronine; Se-Diase 1; selenium-dependent iodothyronine deiodinase 1; TRE, T_3 response element.

intracellular T_3 derives from local deiodination of T_4, while, in peripheral tissues, this percentage is less than 50%. Moreover, in case of incipient biochemical hypothyroidism, when serum T_4 is already decreased but serum T_3 is still normal, there is increased type 2 deiodinase activity and increased thyroid type 1 deiodinase activity, while there is decreased type 1 deiodinase activity in other peripheral tissues (liver, mucle, heart, kidney). These mechanisms involve central hypothyroidism reflected by increased serum TSH, while peripheral tissues are still euthyroid (there is no evidence of hypothyroidism in peripheral tissues). The advantage of such a complex feedback mechanism is to stimulate maximally the thyroid by TSH in case of incipient biochemical hypothyroidism.

At the nuclear level (Figure 5), thyroid hormone acts through a T_3 response element (TRE). Most thyroid hormone activity described up to now is mediated via these high-affinity nuclear receptors – even if some extranuclear actions of thyroid hormones are also described. The principal differentiation effects of thyroid hormones (brain development, bone maturation) and the metabolic effects of thyroid hormones (uncoupling protein, fatty acid metabolism, malic enzyme activity) are mediated via these receptors. The binding of thyroid hormone T_3 to its receptor involves an induction (positively regulated genes) or a repression (negatively regulated genes) of specific messenger RNAs and the translation of these mRNAs in specific proteins. Examples of positively regulated genes include β-adrenergic receptor, fatty acid synthetase, malic enzyme, growth hormone, uncoupling protein, and type 1 iodothyronine deiodinase (except in thyroid). Examples of negatively regulated genes are TSH, prolactin, type 2 iodothyronine deiodinase, and type 1 iodothyronine deiodinase in thyroid.

The translated protein may also act indirectly, for example, thyroid hormones influence growth via insulin-like growth factor 1 (IGF-1). Nevertheless, this action is not present in hypophysectomized rats. So, the thyroid hormone action on liver IGF-1 is indirect:

$$T_3 \Uparrow \rightarrow \text{Pituitary and circulating growth hormone} \Uparrow \rightarrow \text{Liver and circulating IGF-1} \Uparrow$$

The TRE belongs to the family of *erb*-related receptors (including receptors for estrogen, progesterone, glucocorticoid, mineralocorticoid, androgen, vitamin D, retinoic acid). The receptor binds to the DNA via zinc-fingers. It forms a dimer which is stabilized when bound to T_3 (homodimer) or to 9-*cis*-retinoic acid (heterodimer).

A congenital mutation in TRE is a – rare – cause of resistance to thyroid hormones (200 cases have been

described in the world) characterized by elevated serum free T_4 and elevated serum TSH. Individuals with this syndrome do not in general exhibit signs of hypothyroidism, presumably because the resistant state is compensated for by increased levels of thyroid hormones. In some cases, the syndrome may include attention-deficit hyperactivity disorder, reduced intellectual development, delayed skeletal maturation, tachycardia, and deafness.

Calcitonin

Thyroid also synthesizes calcitonin. The parafollicular or C cells are distributed among follicular cells. These cells derive from the neural crest (by opposition to the endodermal origin of follicular cells). In human adults, these cells represent less than 1% of the follicular cells. Parafollicular cells are also secreting other hormones like gastrin and somatostatin. During ontogeny, around embryonic day 24 in humans, C cells of neural crest origin colonize a vestigial organ – the ultimobranchal organ, derived from the fourth pharyngeal pouch. This ultimobranchial organ, with its embryonic C cells, migrates toward the thyroid, where its cells diffuse among the follicules.

Calcitonin is derived from a 136 amino acid precursor peptide which, after cleavage, leaves an active protein of 32 amino acids.

Calcitonin inhibits bone resorption, peculiarly during growth. For example, it decreases serum calcium after administration of pharmacologic doses. In adults, however, the effect of calcitonin on calcium homeostasis is marginal. Moreover, children born without thyroid (thyroid aplasia) and adequately treated with substitutive T_4 hormonetherapy do not present alterations of calcium homeostasis nor osteoporosis. So, if there is no doubt that calcitonin exerts an effect at pharmacological doses, its role in normal human physiology, even during growth, remains largely unknown.

Gut Hormones

L M Morgan, University of Surrey, Guildford, UK

Introduction

The gut is the body's largest endocrine organ, both in terms of the number of endocrine cells and number of hormones. The very word 'hormone' was first used by Bayliss and Starling in 1902 to describe the action of the gastrointestinal (GI) hormone secretin. However, the firm establishment of the gut's endocrine status was not achieved until 1970 when the primary structure of the three classical endocrine gut hormones secretin, gastrin, and cholecystokinin (CCK) was finally determined. Since the 1970s there has been a rapid explosion in our knowledge of the variety and complexity of bioactive peptides found in the gut, made possible by new investigative technologies, especially those of molecular biology. The gut has been shown to contain not only endocrine hormones but a huge variety of neuropeptides, and many gut peptides which were formerly believed to be classical hormones have since been shown to be widespread neurotransmitters. This has led to a much broader understanding of the diversity of physiological roles for gut peptides. These roles extend far beyond the absorption and digestion of food in the gut itself to the coordination and regulation of many bodily functions outside the gut. This article reviews the major hormones of the GI tract, their characteristics, physiological effects, and the regulation of their secretion by nutrients and other stimuli. It focuses on those aspects of gut hormone physiology that are concerned with the digestion and metabolism of nutrients and the role of gut hormones in the regulation of appetite and food intake itself.

Distribution and Synthesis

GI hormones were first identified within gut endocrine cells, which are scattered throughout the mucosal epithelium lining the gastric glands, intestinal crypts, and villi. Typically these cells are pyramidal and lie on the basement membrane. Some cells extend to the lumen of the gut by means of tufts of microvilli and some connect to one another via cytoplasmic processes. In addition, the neuronal cells of the gut which form the submucosal and myenteric plexi also produce a wide variety of gut peptides. The peptide-secreting cells share many features, and they were probably derived from a common precursor cell that differentiated to

produce each endocrine or neurocrine cell line, a hypothesis which accounts for the widespread distribution of gut peptides outside the gut itself, in neural tissue and the central nervous system. With the exception of secretin, gastric inhibitory polypeptide (GIP), and peptide YY (PYY), most of the gut-regulatory peptides are indeed also present in brain tissue. Many of the gut peptides thus act as paracrine or neurocrine transmitters rather than as endocrine hormones. This enables many functions of the digestive tract, e.g., secretory or motor functions, to be regulated by interaction between the endocrine and nervous systems. In addition, gut neuropeptides are involved in many centrally mediated functions, such as the perception of appetite and regulation of food intake.

The GI hormones are low-molecular-weight single-chain polypeptides, of chain length generally fewer than 50 amino acids. Most are synthesized by a prohormone mechanism in a manner similar to insulin. However, unlike insulin, GI hormone genes often express several different bioactive peptides. After the initial translation product of the gene is formed, a series of modifications, collectively called posttranslational processing, can result in a number of peptide products of varying chain lengths and biological activities.

Characterization

The major gut hormones of known structure are listed in Table 1, together with the primary attributes by which they have been characterized. Each year

Table 1 Distribution and biological actions of the major gastrointestinal (GI) hormones

Hormone/peptide	*Site of distribution in GI tract*	*Major biological effects*
Secretin family		
Secretin	Endocrine cells, duodenum, and jejunum	Stimulation of pancreatic exocrine secretion
Gastric-inhibitory polypeptide	Endocrine cells, duodenum, and jejunum	Stimulation of insulin secretion
Glucagon-like peptides (GLP-1, GLP-2, glicentin, oxyntomodulin)	Endocrine cells throughout GI tract. Highest concentrations in terminal ileum and colon	Stimulation of insulin secretion and satiety. Inhibition of gastric acid secretion. Trophic effect on gut mucosa
Vasoactive intestinal peptide	Nerve fibers throughout GI tract	Modulation of gut motility. Stimulation of intestinal secretion. Regulation of blood flow
Gastrin family		
Gastrin	Endocrine cells, antrum, and duodenum	Stimulation of gastric acid secretion. Trophic actions on gut mucosa
Cholecystokinin	Endocrine cells, duodenum, and jejunum Nerve fibers, pancreas, and colon	Stimulation of pancreatic secretion, gallbladder contraction, satiety. Inhibition of gastric emptying
Pancreatic polypeptide family		
Pancreatic polypeptide	Endocrine cells, pancreas	Inhibition of pancreatic exocrine, gastric acid secretion
Peptide YY	Endocrine cells throughout GI tract. Highest concentrations in terminal ileum and colon	Inhibition of gastric acid secretion, gastric emptying, intestinal motility
Neuropeptide Y	Nerve fibers throughout GI tract. Pancreas	Inhibition of intestinal and insulin secretion
Tachykinin family		
Substance P	Nerve fibers throughout GI tract	Smooth-muscle contraction regulation of blood flow
Neurokinin A (neuromedin L)	Nerve fibers throughout GI tract	
Neurokinin B (neuromedin K)	Nerve fibers throughout GI tract	
Bombesin-like peptides		
Gastrin-releasing peptide	Nerve fibers throughout GI tract	Smooth muscle contraction. Trophic actions on gut mucosa. Stimulation of gastrin
Neuromedin B	Nerve fibers throughout GI tract	
Somatostatin	Endocrine cells, nerve fibers throughout GI tract, especially stomach, colon, pancreas	Inhibition of many gut peptides, especially gastrin and insulin; gastric, pancreatic, and biliary secretion
Neurotensin	Nerve and endocrine cells throughout GI tract, especially ileum and jejunum	Inhibition of gastric motility and secretion Stimulation of pancreatic exocrine secretion
Motilin	Endocrine cells throughout small intestine, especially duodenum, jejunum	Regulation of interdigestive gut motility. Inhibition of gastric motor activity
Galanin	Nerve fibers throughout GI tract, pancreas	Inhibition of gastric emptying, gut motility, insulin, and other gut peptide secretion

several new bioactive peptides are added to the growing list of GI hormones, and currently the number of regulatory peptides isolated from the GI tract is well in excess of 50. Many of the GI hormones show a large degree of structural homology, and can be divided up into distinct families on the basis of similarities in their amino acid sequence. There is often considerable overlap in the biological activities of hormones in the same group, for example most members of the secretion family have the ability to potentiate insulin secretion. Gut peptides which do not fit into family groups are termed 'orphan' peptides. The ability of GI hormone genes to express multiple phenotypes has led to great molecular heterogeneity and complexity of their hormone products. For example, secretin was originally believed only to exist as a 27-amino-acid peptide. However, by 1990, three additional secretins with full bioactivity had been identified, two of similar size to secretin-27 and formed by variable trimming of secretin-27's carboxyl terminal, and one large bioactive molecule, secretin-71, produced by trimming out the mid-sequence of the prohormone, preprosecretin. Prohormones can also contain more than one active sequence. Within the secretin family, a group of closely related glucagon-like peptides is derived from a single preproglucagon gene. Posttranslational processing is cell-specific; thus in the pancreas glucagon is the hormonal gene product, whilst in the gut, glicentin and oxyntomodulin (extended versions of glucagon) are produced, together with two additional bioactive peptides, glucagon-like peptides 1 and 2.

Some of the neurally distributed gut peptides were first isolated from brain tissue. Somatostatin was originally isolated and characterized from the hypothalamus before its discovery in gastric mucosal cells and the pancreas. The enkephalins, members of the tachykinin family, were first isolated from brain tissue, where they are often detectable in higher concentrations than in tissues within the GI tract.

The gut hormones occurred very early on in evolutionary terms and various members of the gut hormone families are extensively distributed throughout the animal kingdom. Some of the mammalian gut hormones have amphibian counterparts. The bombesin-like peptides, of which gastrin-releasing peptide (GRP) is the chief mammalian example, were originally isolated in amphibian skin. In addition, neurotensin, CCK and the tachykinin, substance P, have their amphibian skin counterparts – xenopsin, caerulein, and physalaemin respectively. Substance P and CCK-like peptides have been found in invertebrate neurons and a CCK-like peptide has even been isolated in hydra, one of the simplest present-day multicellular organisms.

Physiological Effects

Gut peptides can be separated into three functional categories: endocrine, paracrine, and neurocrine, reflecting their cellular location and mode of delivery to target cells (Table 2). Endocrine peptides reach their targets via the general circulation, paracrine by diffusion or via the local circulation, and neural peptides by synaptic transmission.

Essential first steps in identifying the physiological function of a gut peptide are to determine its cellular location, pharmacological properties, and the regulation of its secretion. This is hindered by two features of the neurendocrine system of the gut. The first is the wide dispersion and comingling of peptide-containing cells which make it difficult to excise one endocrine or neural system without interfering with another. The second feature, characteristic of neurons, is the existence of different peptides within the cell along with nonpeptide neurotransmitters, leading to the possibilities of very complex interactions. Nevertheless, the physiological roles of gut hormones in several major functions of the GI tract and the interaction between endocrine and nervous systems have been elucidated and are described below.

Control of Gastric, Pancreatic, and Biliary Secretion

There are three major endogenous stimulators of gastric acid secretion: gastrin, acetylcholine, and histamine; it is probable that all three are interdependent under physiological conditions in humans. The major action of gastrin is to release acid from parietal cells in the fundus and body of the stomach, although it also exerts indirect effects on acid secretion via the stimulation of histamine release from ECL cells. Regulation of gastrin secretion is under the control of both humoral and local factors and also the

autonomic nervous system, illustrating the complex interaction between endocrine, neurocrine, and paracrine systems. Gastrin release is stimulated directly by the ingestion of food, especially protein, and by the neuropeptide GRP, which is itself released by cholinergic stimulation. Gastrin secretion is inhibited by acid, and by somatostatin, acting in a paracrine manner. The ingestion of fat, once the fat has passed though the stomach and into the small intestine, inhibits gastric acid secretion via the stimulation of GI hormones GIP, glucagon-like polypeptide-1 (GLP-1), and CCK. It seems likely that their modes of action vary and include both direct inhibitory effects on parietal cells, as in the case of CCK, and indirect effects on acid secretion via gastrin and somatostatin.

Pancreatic exocrine secretion contains two major components. The first is an aqueous solution containing a high concentration of bicarbonate whose function is to neutralize acid entering the duodenum from the stomach. The second is a solution of enzymes which aid the absorption and digestion of carbohydrate, fat, and protein. Secretin and cholecystokinin are traditionally thought to be responsible for pancreatic exocrine secretion, but other gut peptides, notably vasoactive intestinal peptide (VIP), neurotensin, and pancreatic polypeptide, may also influence secretion. Secretin is responsible for most of the water and bicarbonate secretion. CCK acts synergistically with secretin to augment pancreatic bicarbonate output, and interactions between neurotensin and secretin also appear to be important. During digestion, pancreatic exocrine secretion is partly controlled by efferent vagal fibers, mediated by VIP. Pancreatic polypeptide inhibits pancreatic secretion and may be involved with the damping-down of pancreatic exocrine secretion following a meal.

CCK has been considered a major hormone controlling gallbladder emptying, and release of pancreatic enzymes. However, the lack of reliable assays to measure circulating levels of CCK has caused difficulty in ascribing a physiological, as opposed to pharmacological, role for the hormone. Recent studies using CCK-A (the predominant CCK receptor found in the pancreas and gallbladder) receptor antagonists have confirmed the role of CCK as the primary stimulator of gallbladder contraction, although the effects of CCK receptor antagonists on pancreatic secretion are less clear, probably reflecting multiple pathways of control for pancreatic exocrine secretion.

Gastric Emptying and Gut Motility

Between the striated muscles of the esophagus and the external anal sphincter, which are dependent upon efferent nerves for proper functioning, lie the smooth muscles which form the bulk of the GI tract. They are capable of executing their function without extrinsic innervation, and sympathetic and parasympathetic nerves act only in a modulatory capacity. The intrinsic nerves of the gut form two major networks or plexi: the myenteric plexus which lies between the longditudinal and circular muscles of the gut, and the submucous plexus, which lies between the mucosa and circular muscle layer. Control of gut motility involves many neuronally located gut peptides. Receptors for many peptides have been located on gut smooth muscle cells, including motilin, the opioid peptides, the tachykinins, VIP, and neuropeptide Y.

Regulation of the rate of gastric emptying depends on many factors, including the physical state and size of the meal and its macronutrient content. Three endocrine gut hormones have been implicated in the control of gastric emptying. Secretion of CCK is responsible for the delay in gastric emptying when fat is added to a meal; the presence of fat in the duodenum is a powerful stimulus for CCK release. GLP-1, secreted in response to the presence of all three macronutrients in the upper small intestine, also delays gastric emptying and regulates the influx of nutrients into the upper part of the gut. Peptide YY, which is colocalized and often cosecreted with GLP-1, inhibits gastric emptying and also small intestinal motility. It has been termed the 'ileal brake' and its actions following a meal are thought to enable sufficient time to occur for the meal's absorption. Following the ingestion of food, waves of alternate contraction and relaxation descend from the gut, facilitating the passage of food and aiding its absorption. VIP causes smooth muscle relaxation and its distribution is consistent with the role of a transmitter in the descending inhibitory nerves. Opioid peptides increase the contractile activity of the gut and their net effect is to slow the transit of food. The tachykinins also have potent exitatory and spasmogenic effects on smooth muscle and appear to be involved in regulation of the peristaltic reflex.

When fasting is prolonged, interdigestive myoelectric complexes occur. These are waves of contraction beginning in the stomach which move slowly down the small intestine, whose function is to clear out the intestine between feeds and keep the intraluminal bacterial population low. Motilin is primarily involved in the regulation of this interdigestive activity.

Potentiation of Insulin Secretion and other Metabolic Effects

One of the more important metabolic actions of gut hormones is their ability to modulate insulin secretion. Orally administered glucose leads to far higher circulating insulin levels than the same amount of

glucose administered intravenously. This ability of the gut to stimulate insulin secretion has been termed the enteroinsular axis. Gut peptides potentiate insulin secretin via both neural and endocrine pathways but, in humans, the endocrine role of the gut hormones (collectively termed incretins) is considered to be quantitatively the more important. Although most members of the secretion family of gut hormones have the ability to stimulate insulin in pharmacological doses, only GIP and GLP-1 are both secreted in response to glucose ingestion and stimulate insulin secretion at physiological levels. Together they account for the entire endocrine arm of the enteroinsular axis.

GIP and GLP-1 are both potent stimulators of glucose-induced insulin secretion. On a molar basis, GLP-1 is the stronger stimulator, but as it circulates at lower concentrations than GIP, the contribution of the two hormones to the enteroinsular axis are approximately equivalent. These hormones only stimulate insulin secretion in the presence of hyperglycemia. This can be looked upon as providing a safeguard against inappropriate insulin secretion, as both hormones are also stimulated by oral fat, when insulin secretion would be undesirable unless its hypoglycemic properties were counteracted by simultaneous ingestion of carbohydrate.

The neural arm of the enteroinsular axis is more poorly defined. Both CCK- and VIP-containing neurons have been implicated as neurotransmitters stimulating insulin secretion. The smaller forms of CCK (CCK-4 and CCK-8) also appear to be biologically active, although their precise role in insulin stimulation is not yet fully known.

Consistent with the anabolic role that gut hormones play in carbohydrate metabolism, by stimulating insulin secretion, is a parallel anabolic role in lipid metabolism. GIP has been shown to have an anabolic effect on lipid metabolism, stimulating lipoprotein lipase and enhancing postprandial triglyceride clearance from the plasma. GIP and GLP-1 have also been shown to stimulate *de novo* fatty acid synthesis in adipose tissue. These two GI hormones, which potentiate the secretion of insulin, also exhibit insulin-like actions systemically and provide a direct link between the absorption and subsequent metabolic fate of ingested nutrients.

Appetite Regulation

The regulation of hunger and satiety is a complex process, involving the interaction of both physiological and psychological factors. There is good experimental evidence for the involvement of several of the gut hormones in the short-term regulation of appetite, although the precise mechanisms whereby they exert their effects in human appetite control are less clear. CCK and GLP-1 have been found to mediate satiety in both animal and human studies. The inhibitory effects of CCK on food intake are stimulated by fat ingestion, and appear to be mediated by a local gastrointestinal action, although CCK is partially dependent upon an intact vagal nerve supply in order to exert its satiety effects. Peripheral administration of GLP-1 has been shown to suppress appetite in most, if not all human studies; circulating GLP-1 can theoretically pass the blood–brain barrier to act centrally. Neuropeptide Y is distributed in the central nervous system as well as within the gut. It acts in the brain upon appetite centers in the hypothalamus to stimulate food intake, and it may also be implicated in the regulation of leptin, the peptide secreted from adipose tissue which is involved with the longer-term mediation of satiety.

Regulation of Secretion

Ingestion and absorption of food are the major stimuli to gut hormone secretion, especially the endocrine gut hormones. The major nutrient stimuli for these hormones are listed in Table 3. The type of nutrient that stimulates the secretion of an individual gut hormone usually relates to its physiological role. GIP and GLP-1, for example, the potentiators of insulin secretion, are stimulated by carbohydrate, which in itself stimulates insulin secretion by raising circulating glucose levels. Fat ingestion is a major stimulus to secretin and CCK whose primary function is concerned with stimulating pancreatic and biliary secretion, thus aiding the digestion of fat. GIP secretion is also stimulated by fat absorption, consistent with the role of GIP in aiding the clearance of circulating lipids after a meal, and aiding their uptake into adipose tissue. The secretory response of a gut hormone to nutrients is a very precise one. For example, carbohydrate-induced GIP secretion is stimulated specifically by the absorption of actively transported sugars such as glucose and galactose. The mere presence of nutrients in the gut lumen is insufficient to stimulate GIP secretion, and sugars such as fructose, whose absorption does not require active transport mechanism, do not stimulate GIP secretion. In contrast, GLP-1 secretion is not dependent upon the absorption of nutrients, a property which is consistent with its role as a regulator of gastric emptying and the smooth delivery of nutrients to the upper part of the gut. Chronic dietary changes can also affect gut hormone secretion; a high-fat diet, for example, has been shown to increase GIP secretion in response to both carbohydrate and fat ingestion.

Table 3 Nutritional and other regulation of endocrine gastraintestinal hormone secretion

Hormone/peptide	*Major nutritional stimulants*	*Other modulators of secretion*
Secretin	Fat. Exit of meal from stomach causing duodenal acidification	Stimulation: bile salts Inhibition: somatostatin
Gastric-inhibitory peptide (GIP)	Fat, carbohydrate. Absorption from upper small intestine	Inhibition: insulin
Glucagon-like peptides	Carbohydrate, fat. Presence of food in upper small intestine	Stimulation: gastrin-releasing peptide (GRP) Inhibition: somatostatin
Gastrin	Amino acids and protein in stomach lumen; meal-induced gastric distension	Stimulation: GRP, acetylcholine, norepinephrine (noradrenaline) Inhibition: acid (pH < 3), GIP, secretin, GLP-1, somatostatin
Chdecystokinin	Fat (hydrolysis of triglyceride), phenylalanine and tryptophan	Stimulation: GRP Inhibition: trypsin, bile salts, somatostatin
Pancreatic polypeptide	Ingestion of meal, especially carbohydrate	Stimulation: GRP, motilin, vagal stimulation Inhibition: somatostatin
Peptide YY	Ingestion of meal, especially fat	Inhibition: GLP-1
Somatostatin	Ingestion of meal, especially fat and protein. Meal-induced lowering of gastric pH	Stimulation: GIP, CCK, secretin Inhibition: opioid peptides
Neurotensin	Fat ingestion	Stimulation: GRP Inhibition: somatostatin
Motilin	Stimulated by both oral and intravenous fat (inhibited by glucose, amino acids)	Stimulation: duodenal acidification Inhibition: secretin, GRP, somatostatin

GLP-1, glucagon-like peptide 1.

Interactions between the various gut hormones play an important part in the regulation of gut hormone secretion, particularly in an inhibitory capacity (Table 3). Thus somatostatin is a physiological paracrine inhibitor of gastrin secretion and probably plays an endocrine role in the regulation of other gut hormones, e.g., secretin and neurotensin. GRP is so named because of its role in the stimulation of gastric secretion. GRP infusion will also cause increased plasma concentrations of many other GI hormones, although the physiological relevance of this is unclear.

Less is known about the regulation of gut neuropeptide secretion. These peptides are synthesized by intramural neurons and released from nerve terminals by physiologically appropriate stimuli (e.g., chemical or mechanically induced reflexes). Vagal stimulation has been implicated in the release of several gut neurotransmitter peptides, e.g., VIP and GRP, but its regulatory role has yet to be fully defined.

Pancreatic Hormones

N H McClenaghan and P R Flatt, University of Ulster, Coleraine, UK

Pancreatic Secretions

The pancreas is a secretory gland playing a key role in the metabolism of carbohydrates, proteins, and lipids. Cells of the exocrine pancreas (acini) secrete pancreatic juice into the duodenum, which contains enzymes for the digestion of major food

components. The endocrine pancreas synthesizes and secretes peptide hormones into the blood, thereby controlling nutrient homeostasis by determining the metabolic fate of absorbed glucose, amino acids, and fatty acids, and their mobilization in times of need from body stores. The following sections focus specifically on the endocrine pancreas, and the synthesis, secretion, and action of pancreatic hormones.

Organization of the Endocrine Pancreas

The endocrine function of the pancreas resides within the islet of Langerhans, which constitute 1–3% of total pancreatic mass. The normal adult pancreas contains about 1×10^6 pancreatic islets scattered throughout the body of this elongated organ. Islets are spherical structures less than the size of a pinhead, each comprising a cluster of 2000–6000 individual islet cells surrounded by a connective tissue capsule. The diameter of the islet ranges from 20 to 300 μm, depending on cellular composition.

Pancreatic Islet Cells

Pancreatic islets consist of four major types of secretory cell producing insulin (β cells), glucagon (α_2 cells), somatostatin (α_1 cells; also referred to as δ cells) and pancreatic polypeptide (PP cells) (Table 1). These are sometimes also referred to as B, A, and D cells, respectively. The products of several other minor secretory cell types located in the islets remain unknown. Islets also contain small amounts of additional peptides colocalized with classical islet hormones or present in nerve fibers. These agents have various effects on insulin secretion, as indicated in Table 1.

Each islet is composed of 60–70% β cells located primarily as a central core surrounded by an outer mantle of α_2 cells (5–25%), α_1 cells (5–10%) and PP cells (15–20%). The proportion of α_2 and PP cells varies considerably, depending on islet embryonic origin and location in the pancreas. Islets distributed the tail and body of the pancreas are generally rich in α_2 cells and contain relatively few PP cells, whereas the converse applies for islets located the ventral head region of the pancreas.

Table 1 Hormones, peptides colocalized in hormone-producing cells and neurotransmitters in islets of Langerhans

	Cell type	*Effect on insulin secretion*
Hormones		
Insulin	β cells	↓
Glucagon	α_2 cells	↑

Islet Vasculature

Islets are well vascularized and receive a considerable flow of blood from afferent arterioles arising from the splenic and pancreaticoduodenal arteries. Within the islet, the afferent vessels appear to perforate the cellular mantle, supplying a dense network of capillaries that traverse the β cell core, before draining into a small number of venules that ultimately feed into the pancreatic vein. The vasculature of individual islets is believed to constitute a tiny intraislet 'portal' system, with blood flowing progressively past β, α_2, and α_1 cells. This arrangement provides effective delivery to islet cells of bloodborne stimuli, such as glucose, and ensures rapid circulation of the secreted islet hormones to peripheral sites of action. There is also recent evidence that elevation of blood glucose specifically increases islet blood flow, via a cholinergic mechanism.

Islet Innervation

Islets receive an abundant supply of cholinergic, adrenergic, and peptidergic (nonadrenergic, noncholinergic (NANC)) nerves that innervate islet cells and the surrounding capillaries. In addition to the classical neurotransmitters – acetylcholine and noradrenaline – the islets contain a number of neuropeptides that exert stimulatory or inhibitory effects on islet cell secretions (Tables 1 and 2). Parasympathetic innervation is activated by feeding, whereas sympathetic nerves are activated in situations of need such as starvation or fright.

Islet Cell Interactions

Glucagon stimulates the secretion of insulin and somatostatin, whereas both insulin and somatostatin

are general inhibitors of islet hormone secretions (Table 2). This provides the basis for the possible involvement cellular interactions in the integration of islet secretory function (Figure 1). Such interactions may be restricted to adjacent cells within the islet, termed paracrine interactions, or may be more widely mediated through the intraislet portal system, which delivers insulin from β cells downstream to α_2 cells, followed by onward passage of both insulin and secreted glucagon to the somatostatin-containing α_1 cells.

Hormone Biosynthesis and Secretion

Biosynthesis and secretion of islet hormones occur through a similar sequence, involving the production of a precursor polypeptide in the rough endoplasmic reticulum followed by posttranslational enzymatic conversion to the active hormone. The active hormone is stored in secretory granules before ultimate release from the stimulated cell by a regulated process termed 'exocytosis.' This involves movement, aided by microtubules and microfilaments of the granule to

the periphery, followed by fusion of the granule membrane with the plasma membrane and liberation of the granule contents into the blood.

More specific details of events concerning biosynthesis and secretion are best known for insulin. In the β cell, transcription of messenger ribonucleic acid (mRNA) gives rise to production of preproinsulin, an 11.5-kDa polypeptide. This is rapidly cleaved within 1 min by proteolytic enzymes to proinsulin (86 amino acid residues, 9 kDa) which is transported by microvesicles to the Golgi apparatus. Proinsulin is then packaged into secretory granules, where it is converted by proteases to equimolar amounts of insulin (51 residues, 6 kDa) and proinsulin C-peptide. A number of second messengers are involved in coupling stimulus recognition to the secretion of insulin by exocytosis. These include cytoplasmic calcium ion concentration ($[Ca^{2+}]_i$), cyclic adenosine monophosphate (cAMP), diacylglycerol (DAG), and inositol 1,4,5-trisphosphate (IP_3).

In pancreatic α_2 cells, the initial product of the proglucagon is a 160-residue polypeptide (18 kDa) that contains the amino acid sequences of several biologically active peptides in addition to glucagon. Posttranslational processing of proglucagon yields glucagon (29 residues, 3.5 kDa) as the main product, plus a proglucagon fragment and, possibly, small amounts of glicentin-related pancreatic peptide (GRPP). In pancreatic α_1 cells, preprosomatostatin (116 residues) is similarly processed to prosomatostatin (92 residues) before conversion to the active, 14-amino-acid form of somatostatin (SRIF-14, 1.5 kDa). In PP cells, pancreatic polypeptide (36 residues, 4.3 kDa) also appears to be produced from a larger, 95-amino-acid, prohormone form. In the intestine, the posttranslational processing of proglucagon and prosomatostatin differs, yielding as major products glucagon-like peptide-1[7-36]-amide (GLP-1[7-36]-amide) and the 28-amino-acid form of somatostatin (SRIF-28), respectively.

Regulation of Secretion

A wide range of nutrients, hormones, and neurotransmitters are capable of influencing the secretion of insulin, glucagon, somatostatin, and pancreatic polypeptide (Tables 1 and 2). In the case of insulin, the major physiological regulator of β cell function is the prevailing plasma glucose concentration. Other metabolizable nutrients can mimic the stimulatory action of glucose, but these other agents basically act as modulators of the glucose response.

Insulin acting locally within the islet is an influential inhibitor of glucagon secretion. Glucose inhibition of glucagon secretion is thus attributable in large part to concomitant stimulation of the β cell with the release of insulin. γ-Aminobutyric acid (GABA), cosecreted with insulin from the β cell, has also been suggested to contribute to inhibition of α_2 cells. The paradoxical ability of amino acids and food-activated elements of the enteroinsular axis to stimulate glucagon as well as insulin secretion is often considered to offer protection from hypoglycemia that might result from the marked stimulation of insulin release. An alternative interpretation is that the stimulation of glucagon release serves to promote insulin secretion by paracrine interaction within the islet. Other situations associated with secretion of glucagon include hypoglycemia, starvation, and stress. In these circumstances, glucagon serves to mobilize nutrient fuels from body stores to meet immediate energy requirements.

Nutrient Regulation of Insulin Secretion

Although many factors influence the secretion of pancreatic hormones, the regulation of insulin secretion is particularly critical for normal metabolism and maintenance of good health. β cell dysregulation leading to deficient insulin secretion results in impaired glucose tolerance, hyperglycemia and type 2 diabetes (also known as noninsulin-dependent diabetes mellitus). Hypersecretion of insulin may result in life-threatening hypoglycemia, as observed in certain individuals with an islet cell tumor (insulinoma).

Nutrients exert direct and indirect effects on insulin secretion. Thus, in addition to the direct stimulatory actions of glucose, amino acids, and fatty acids on the β cell, the ingestion of food and absorption of nutrients trigger neural and hormonal elements of the enteroinsular axis (Figure 2). Activation of the parasympathetic nerve innervating the islets liberates acetylcholine from nerve terminals close to β cells. Stimulation of intestinal endocrine cells leads to the secretion of GLP-1[7–36]-amide, gastric-inhibitory polypeptide (GIP) and cholecystokinin (CCK). These agents are powerful insulin secretagogs at raised glucose concentrations, and they markedly augment the direct stimulatory actions of glucose and other nutrients.

The mechanisms through which nutrients and enteroinsular stimuli trigger insulin secretion from β cells involve elevation of $[Ca^{2+}]_i$ and sensitization of the exocytotic process to normal stimulatory action of $[Ca^{2+}]_i$ (Figure 3). Metabolizable nutrients, including glucose, certain amino acids, and fatty acids, act by virtue of the ability of the β cell to metabolize these substances with the generation of adenosine triphosphate (ATP). ATP generation results in closure of ATP-sensitive potassium channels (K_{ATP}) channels in

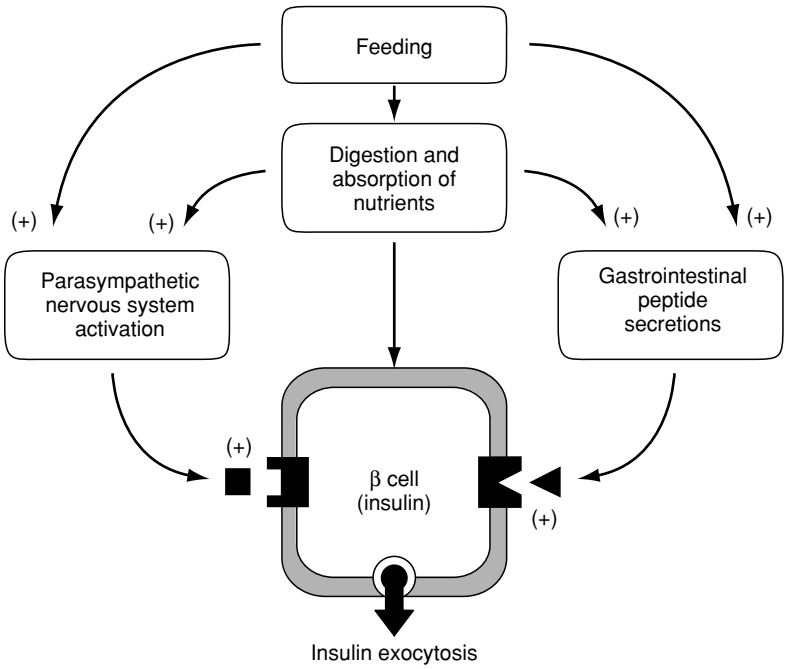

Figure 2 Major neural and hormonal pathways regulating the insulin secretory response to feeding.

the plasma membrane, leading to membrane depolarization. This results in the opening of voltage-dependent calcium channels (VDCCs) allowing Ca^{2+} to enter the β cell down its concentration gradient. The subsequent increase of $[Ca^{2+}]_i$ triggers secretion of insulin by exocytosis. Elevation of $[Ca^{2+}]_i$ helps to restore the membrane potential through opening of Ca^{2+}-sensitive K^+ channels in the plasma membrane. Conditions of elevated $[Ca^{2+}]_i$ increase the sensitivity of the β cell to the stimulatory actions of phospholipase C and adenylate cyclase. Acetylcholine, CCK, GLP-1[7-36]-amide and GIP are particularly potent activators of these enzymes. Generation of IP_3 inhibits Ca^{2+} sequestration by the endoplasmic reticulum, whereas protein kinase C (PKC) and cAMP sensitize the secretory process to the stimulatory action of Ca^{2+}. cAMP also activates protein kinase (PK) responsible for phosphorylation of functionally important proteins.

Physiological Actions

Within the islet, insulin is the principal hormone that appears to directly modulate the secretory activity of other islet cell types. Outside the islet, insulin is the anabolic hormone and driving force behind the regulation of carbohydrate, protein and lipid metabolism (Figure 4). Glucagon is the main catabolic counter-regulatory hormone, but the net effect of glucagon is more dependent on the insulin:glucagon molar ratio rather than the absolute level of glucagon *per se*. The minute-to-minute control of insulin and glucagon secretion from the islets is therefore of paramount importance in the overall regulation of nutrient homeostasis.

Insulin and glucagon exert major effects on the metabolism of carbohydrate, protein and lipid (Table 3). The principal actions of insulin are to lower circulating concentrations of glucose, amino acids and fatty acids, to increase fat storage in adipose tissue, and to promote the formation of muscle protein. Insulin achieves this by stimulating glucose and amino acid uptake and by alteration of the activities of enzymes in liver, muscle, and adipose tissue. These enzymes mediate the effects of insulin on glycogenesis, glycogenolysis, gluconeogenesis, glycolysis, lipogenesis, lipolysis, ketogenesis, and both the synthesis and degradation of protein. The actions of insulin on these metabolic pathways are generally opposed by the action of glucagon. Secretion of this counter-regulatory hormone in conjunction with a decrease in the insulin:glucagon molar ratio serves to generate a catabolic response in times of need, involving mobilization of nutrients from various tissue stores.

Somatostatin and PP secreted from the islets are less significant in physiological terms than the other two pancreatic hormones. Somatostatin and PP are also found in endocrine cells of the intestine, and they are both released into the circulation following feeding.

↑, stimulatory effect; ↓, inhibitory effect; –, no effect.

Somatostatin is a potent inhibitor of secretion from endocrine (pancreas, intestine, pituitary) and exocrine cells, partly acting through paracrine effects, thus contributing to the fine tuning of insulin and glucagon secretion. Somatostatin also inhibits the following aspects of gastrointestinal function, largely as a result of inhibition of gut hormone secretions: gastric acid secretion; secretion of bile and pancreatic juice; gall bladder contraction; intestinal motility; intestinal absorption; splanchnic blood flow.

PP has been shown to exert various actions at pharmacological concentrations. These include the following: inhibiting exocrine and endocrine pancreatic secretions; gall bladder relaxation; increasing gastrointestinal motility; inducing satiety. However, there is presently little convincing evidence for a physiological role of PP.

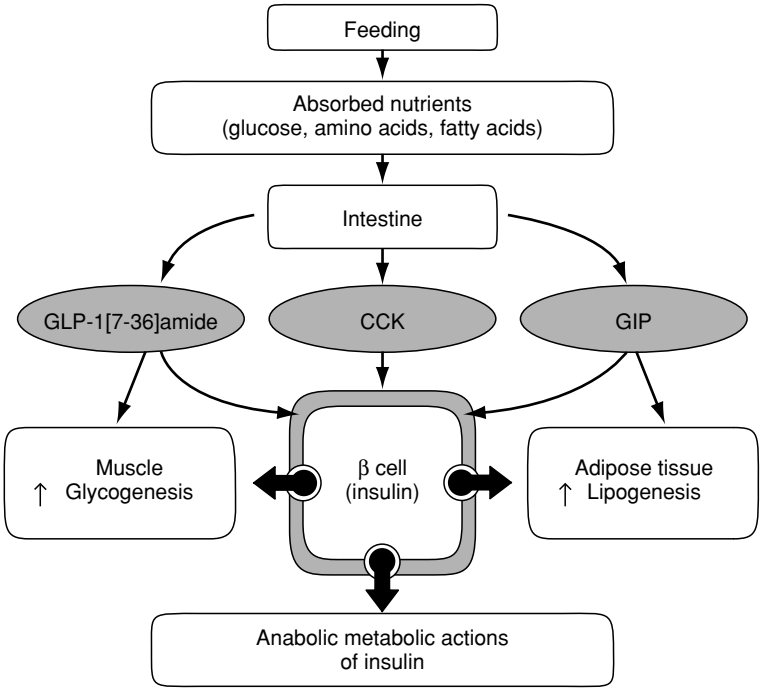

Figure 4 Insulin-mediated anabolic responses to feeding. CCK, cholecystokinin; GIP, gastric inhibitory polypeptide; GLP-1[7-36]-amide, glucagon-like peptide-1[7-36]-amide.

Mechanisms of Action

Insulin and the other pancreatic hormones are secreted into the interstitial fluid; they cross the endothelial barrier and enter the circulation. Effects at the target cells are initiated by the action and binding of the hormone to specific cell surface receptors (Figure 5). The binding of the hormone to these receptors initiates a sequence of postreceptor events ultimately culminating in the various biological actions of the hormone. Rapid events on the secretion of other hormones are mediated by changes of $[Ca^{2+}]_i$ and the activities of adenylate cyclase and phospholipase C (see above). Stimulation of glucose uptake by muscle and adipose tissue results from insulin-induced translocation of glucose transporter proteins (GLUT4) from cytoplasmic vesicles to the plasma membrane. Classical metabolic effects of insulin and glucagon at target cells are achieved by activation and suppression of enzyme activity (so redirecting cell metabolism) or by altering the rate of synthesis of enzymes at the level of transcription and translation.

Insulin binding to the external α-subunit of the glycoprotein insulin receptor leads to a conformational change in the receptor that stimulates tyrosine kinase activity. The activated the β-subunit autophosphorylates at tyrosine sites in addition to phosphorylating intracellular proteins (Figure 5). Indeed it is the tyrosine kinase activity that is essential for insulin signaling. The best characterized postreceptor signal transduction pathway centers around insulin-receptor substrate 1 (IRS-1). Rapid tyrosine phosphorylation following insulin stimulation results in noncovalent binding between phosphorylated sites and specific domains on intracellular protein targets. This ultimately results in the various important biological effects of insulin on target tissues (Figure 5). Following initiation of postreceptor events, the insulin–receptor complex is internalized by the target cell, and whereas receptors are recycled to the cell surface, insulin is degraded intracellularly. Elevated insulin levels, for example in obesity or type 2 diabetes, results in insulin receptor 'downregulation' through decreasing numbers on the cell surface and also by reducing tyrosine kinase activity of the receptor.

Endocrine Pancreas in Diabetes

The two major forms of diabetes, type 1 insulin-dependent diabetes mellitus and type 2 diabetes, are associated with marked changes in the structure of the endocrine pancreas. In long-standing type 1 diabetes, the insulin deficiency is the result of total autoimmune destruction of β cells, while the mass of α_2, α_1 and PP cells remains virtually unchanged. However, in type 2 diabetes, the β cell mass is marginally decreased in association with increases in the α_2 cell

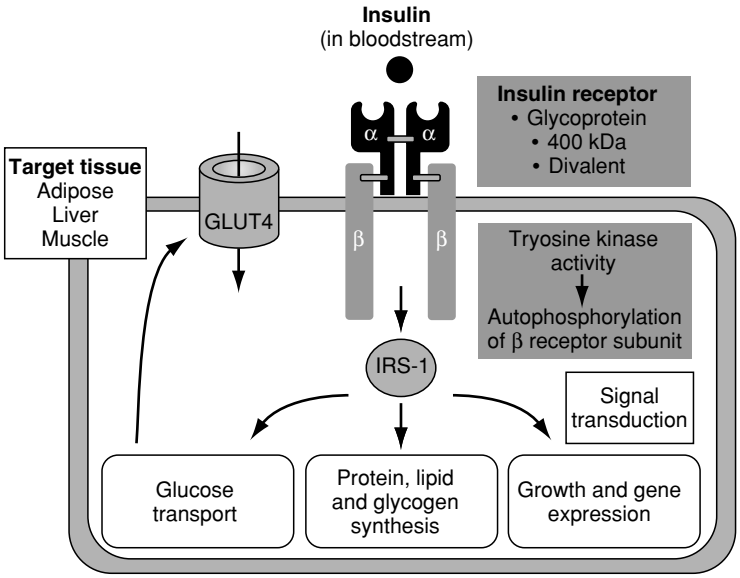

Figure 5 Insulin signalling in target cells. α, α-subunit of insulin receptor; β, β-subunit of insulin receptor; GLUT4, glucose transport protein; IRS-1, insulin receptor substrate-1.

mass and α_2:β cell ratio. Hyperglucagonemia and inappropriate α_2 cell function, both owing to a lack of inhibition of glucagon secretion by insulin, contribute to glucose intolerance and associated metabolic disarray generally observed in diabetes.

Type 2 diabetes is classically associated with defective β cell function, normal or moderately raised insulin concentrations, and insulin resistance. Insulin secretory responses to glucose and other stimuli are impaired in magnitude and kinetics. The β cells in type 2 diabetics are also known to release excessive amounts of proinsulin rather than insulin. Since proinsulin cross-reacts with most antisera used to measure insulin, actual concentrations of insulin in type 2 diabetes are likely to be much lower than previously estimated. Proinsulin and derived fragments exhibit only 10–50% of the biological activity of insulin, and therefore may contribute to the condition of insulin resistance.

Pituitary Hormones

M Wallis, The University of Sussex, Falmer, Brighton, UK

The Pituitary Gland

In humans the pituitary gland (**Figure 1**) is a small organ about the size of a pea which occupies a bony pocket in the skull (the sella turcica), situated below

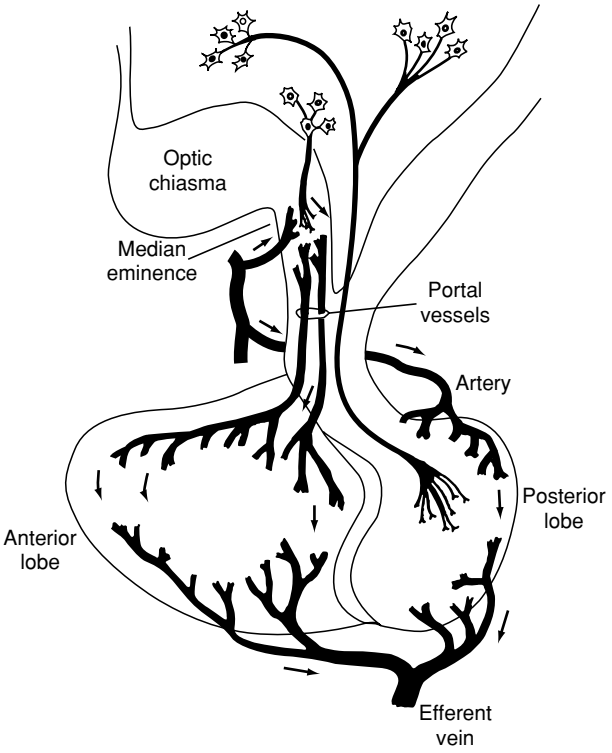

Figure 1 The pituitary gland. Factors secreted at nerve terminals in the median eminence of the hypothalamus are carried via the hypophysial portal vessels to the anterior lobe of the pituitary gland where they regulate the secretion of the various pituitary hormones. Precursors of oxytocin and vasopressin are synthesized in neurons in the hypothalamus and transported via axons (with concomitant processing to the active peptides) to the posterior lobe of the pituitary gland. Modified from Wallis M (1988) The molecular basis of growth hormone deficiency. *Molecular Aspects of Medicine* 10: 429–509.

the midbrain. It is attached to the floor of the third ventricle of the brain (the hypothalamus) by a stalk and this close association between the brain and the pituitary is of general importance to the functioning of the latter. The gland comprises two main parts, with different embryological origins – the neurohypophysis and the adenohypophysis. The neurohypophysis (posterior lobe) originates as a downgrowth from the floor of the brain, the connection with the brain being retained as a major component of the pituitary stalk. The bulk of the neurohypophysis is made up of the swollen nerve terminals of nerve cells which have their cell bodies in the hypothalamus (particularly the supraoptic and paraventricular nuclei), and whose axons pass through the stalk to the neurohypophysis. The adenohypophysis is ectodermal in origin, being formed during development from a pouch (Rathke's pouch) derived from an ingrowing of the cells that will form the roof of the mouth. The adenohypophysis comprises several regions, including the anterior lobe (the source of most adenohypophysial hormones) and the intermediate lobe. The anterior lobe contains about six different hormone-secreting cell types, secreting 6–10 different hormones (Table 1); the main function of several of these is to control the activity of other endocrine glands. Pituitary growth hormone has a particularly important role in regulating the nutritional balance of the organism, and this hormone is emphasized in the second half of this article.

Neurohypophysial Hormones

The neurohypophysis in mammals secretes two peptide hormones, oxytocin and vasopressin (antidiuretic hormone, ADH). Each of these is a nonapeptide, including a disulfide bridge and an amidated C-terminus. Oxytocin and vasopressin are very similar, differing only at two positions. Peptides with slightly different structures but substantially different biological actions are found in lower vertebrates; some invertebrates possess related peptides.

In mammals oxytocin functions mainly to regulate contraction of smooth muscle, especially in mammary gland (leading to milk ejection) and uterus (stimulating uterine contraction in parturition). Several lines of evidence, including recent studies with transgenic (knockout) mice, suggest that the effects on the uterus may be of relatively little physiological importance, although the hormone is widely used clinically to induce birth. The significance of the effects on milk ejection is clearly established – if secretion of oxytocin is prevented (for example, by anesthetizing a suckling animal) the young are unable to obtain milk from the mammary gland. The mechanism of action of oxytocin involves binding to a G-protein-linked receptor on the target cells, followed by activation of intracellular signalling systems leading to elevation of Ca^{2+} levels and myosin light chain phosphorylation.

The main physiological action of vasopressin in mammals is regulation of water resorption by the kidney. A small elevation of blood osmotic pressure leads to increased vasopressin secretion and increased water retention at the kidney. Again, the hormone binds to a specific G-protein-linked receptor on its target cells, followed by activation of intracellular signaling systems, including elevation of cyclic adenosine monophosphate (AMP) levels, leading to insertion of water channels into the luminal membrane of cells of the loop of Henle in the kidney. Vasopressin has various other effects, including actions on blood pressure, hepatic metabolism, and adrenocorticotropic hormone (ACTH) secretion; at least some of these are mediated by a different type of receptor from that found in the kidney.

Table 1 The hormones of the mammalian pituitary gland

Hormone	*Abbreviation*	*Chemical nature*	*Main actions*
Posterior lobe			
Oxytocin		Peptide (9 residues)	Stimulates milk ejection, uterus contraction
Vasopressin (antidiuretic hormone)	VP (ADH)	Peptide (9 residues)	Antidiuretic, raises blood pressure
Intermediate lobe			
α-Melanotropin (α-melanocyte-stimulating hormone)	α-MSH	Peptide (13 residues)	Causes skin darkening, especially in amphibia; functions as neuropeptide in the brain
Anterior lobe			
β-Melanotropin (β-melanocyte-stimulating hormone)	β-MSH	Peptide (18–22 residues)	Causes skin darkening, especially in amphibia
Corticotropin (adrenocorticotropic hormone)	ACTH	Peptide (39 residues)	Stimulates corticosteroidogenesis and growth of adrenal cortex
Lipotropin	LPH	Peptide/protein (~91 residues)	Weakly lipotropic (may be primarily a precursor of β-MSH and β-endorphin)
β-Endorphin		Peptide (31 residues)	Analgesia?
Growth hormone (somatotropin)	GH	Protein (~190 residues)	Promotes growth, many anabolic actions, stimulates insulin-like growth factor 1 production
Prolactin	PRL	Protein (~200 residues)	Lactogenic activity (many other actions, particularly in lower vertebrates)
Thyrotropin (thyroid-stimulating hormone)	TSH	Glycoprotein (2 subunits)	Stimulates thyroid hormone production
Follicle-stimulating hormone	FSH	Glycoprotein (2 subunits)	Stimulates maturation of the Graafian follicle in female, spermatogenesis in male
Luteinizing hormone (interstitial cell-stimulating hormone)	LH	Glycoprotein (2 subunits)	Stimulates maturation and release of ovum and early development of corpus luteum in female, steroid production by gonads in male

Note that some doubt remains as to whether β-MSH, LPH, and β-endorphin are physiologically significant hormones.

Oxytocin and vasopressin are synthesized as precursors in the cell bodies of (different) neurons in the hypothalamus. They are packaged into granules, which pass down the axons of these neurons, through the pituitary stalk, to the swollen axonal endings in the neurohypophysis, where they are stored. Conversion of precursors to active peptides occurs during formation and transport of secretory vesicles, catalyzed by prohormone-converting enzymes included within the vesicles. Also formed by processing of these precursors are neurophysins, which act as binding proteins for oxytocin and vasopressin prior to release. Secretion of the hormones from the nerve endings occurs by exocytosis in response to nerve signals coming down the axons of the same cells. For oxytocin a neural loop links sensory receptors in the mammary gland (detecting suckling) via a number of synapses, to the cell bodies of the neurons that synthesize the hormone. This in turn triggers firing of these neurons, so that an electrical signal passes down their axons and causes depolarization of the plasma membrane of the swollen nerve endings in the neurohypophysis. The entry of Ca^{2+} which follows this provides the signal for exocytosis. The released oxytocin passes via the blood stream to the mammary gland, where it induces milk ejection within a few seconds of the initial suckling stimulus. Similar neural loops regulate secretion of vasopressin, initiated at receptors in the brain that detect changes in osmotic pressure, or in the atrium and carotid sinus that detect changes in blood volume or pressure.

Adenohypophysial Hormones

The hormones of the adenohypophysis are all peptide or protein in nature, and fall into three main families: (1) corticotropin (ACTH), melanocyte-stimulating hormone (MSH) and related peptides (the melanocortin family); (2) growth hormone (GH) and prolactin; (3) thyrotropin or thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH) and luteinizing hormone (LH) – the glycoprotein hormone family.

The Melanocortin Family

ACTH is a peptide of 39 residues concerned mainly with regulation of the adrenal cortex, including production and secretion of corticosteroids. It binds to a G-protein-linked receptor in the membrane of target cells in the adrenal cortex, and acts at various points on the pathway leading to steroid synthesis partly via action of cyclic AMP as a second messenger. MSHs

are peptides of 13–22 amino acids, produced characteristically in the intermediate lobe of the pituitary, which regulate skin color in some species by stimulating synthesis and altering distribution of pigment in cells called melanocytes. The actions of MSHs are particularly marked in amphibia. Although they occur in the pituitary gland of many mammals their physiological role there is not clear, although in at least some species they probably do have a role in controlling skin pigmentation. MSHs have been described in the human pituitary, but there is some evidence that in the adult at least they are artifacts of extraction procedures and of little physiological importance. ACTH and MSHs show similarity in amino acid sequences, and it is now known that they are formed from a common biosynthetic precursor, proopiomelanocortin (POMC), together with a larger peptide β-lipotropin and the opioid peptide β-endorphin. Despite this, ACTH and α-MSH are secreted from different cell types (corticotrophs and melanotrophs), reflecting different processing pathways in different cells.

Although MSHs and the other POMC-derived peptides were originally characterized in the pituitary, it is now clear that they are also expressed in the brain, and that as neuropeptides they may play an important role in energy homeostasis and the regulation of obesity. Recent studies indicate that the peptide hormone leptin, produced by adipose cells, acts at least partly by stimulating production of α-MSH in hypothalamic neurons. Binding of α-MSH to specific receptors (MC4 receptors) in hypothalamus and cortex leads to reduced feed intake and increased energy expenditure. Animals with defective MC4 receptors become obese, but the importance of this mechanism for human obesity has not yet been established.

The Growth Hormone/Prolactin Family

GH and prolactin are both medium-sized proteins comprising a single polypeptide chain of 190–200 amino acids. They are structurally similar, and are related to the placental lactogens found in humans, ruminants, and rodents. GH plays a major role in regulating somatic growth and is discussed further below. Prolactin has a number of different actions in mammals, the most important being concerned with regulation of lactation and mammary growth. Prolactin acts with other hormones, including insulin, insulin-like growth factors, corticosteroids, thyroid hormone, and GH (depending on the species) to stimulate growth of the mammary gland and synthesis and secretion of milk components including proteins (caseins, α-lactalbumin, etc.), sugar, and fat. It acts partly at the gene level to stimulate production of specific proteins via a membrane-bound receptor, Jak kinase and STAT proteins, a mechanism similar to that of GH (see below). In ruminants milk production appears to be stimulated more effectively by GH than prolactin, and the use of GH to enhance agricultural milk production is being actively pursued. Whether GH and/or prolactin can influence the nutritional content of milk, as well as total production, is not clear.

The Glycoprotein Hormone Family

The third family of pituitary hormones includes the glycoprotein hormones: the two gonadotropins, FSH and LH, and TSH. These are structurally related to the chorionic gonadotropin (hCG) produced in the human placenta. They are complex proteins, including in each case two subunits (α and β), each of which is about 100 amino acids long and carries one or more carbohydrate moieties. The α-subunit is common to FSH, LH, and TSH (and also hCG), while the β-subunits are different, and provide the hormonal specificities. A three-dimensional (3D) structure has been reported for hCG which shows a number of interesting features, including a 'disulfide knot' in each subunit and a very close association between α- and β-subunits, 'sealed' by a peptide strand and disulfide bridge which act as a kind of 'seat belt.' In the female, FSH and LH control the estrus cycle (menstrual cycle in primates): FSH stimulates growth of the Graafian follicle and production of estrogen by granulosa cells, while LH stimulates maturation of the ovum, ovulation, and development of the corpus luteum. In the male, LH stimulates the steroid-producing interstitial cells to produce androgens, while FSH stimulates spermatogenesis. The actions of both LH and FSH involve binding to G-protein-linked receptors and are mediated in part by cyclic AMP. The actions of TSH are concerned almost exclusively with regulation of the thyroid gland, including stimulation of growth of the gland and production of thyroxine and triiodothyronine.

Regulation of Secretion of Adenohypophysial Hormones

The secretion and synthesis of the hormones of the pituitary gland are largely under the control of the hypothalamus. For the neurohypophysis, as discussed above, such regulation involves nerve signals operating via the axons of the hypothalamic neurons within which vasopressin and oxytocin are synthesized and transported to the neurohypophysis.

Hypothalamic regulation of synthesis and secretion of adenohypophysial hormones in mammals involves primarily blood-borne neuroendocrine factors rather than nerve signals. A capillary plexus in the

hypothalamus allows the blood to pick up neuroendocrine secretions; the capillaries then combine to form the hypothalamic–hypophysial portal vessels which pass down the pituitary stalk and form a second capillary network in the adenohypophysis. This system allows efficient transfer of neuroendocrine factors from the hypothalamus to the adenohypophysis (Figure 1). These factors are mostly peptides, though the catecholamine dopamine is also an important regulator. Most stimulate secretion of one or more adenohypophysial hormones, but some are inhibitors. They are listed in Table 2.

ACTH secretion is stimulated by the hypothalamic peptide corticotropin-releasing hormone (CRH), which synergizes with vasopressin and possibly other factors. α-MSH secretion from the intermediate lobe may be partly under neural control, but is also regulated by hypothalamic peptides and inhibited by dopamine. Secretion of TSH is stimulated by the tripeptide TSH-releasing hormone (TRH). Secretion of FSH and LH is stimulated by the decapeptide LH-releasing hormone (LHRH: gonadotropin-releasing hormone (GnRH)); FSH and LH are synthesized in and secreted from the same cell type (gonadotroph). Prolactin secretion is largely under inhibitory control, by hypothalamic dopamine and possibly other factors. TRH and a number of other peptides can stimulate prolactin secretion, but their physiological significance is not clear. GH secretion is stimulated by the 44-residue peptide GH-releasing hormone (GHRH), and inhibited by the 14-residue peptide somatostatin. Both appear to be physiologically important, though stimulatory control predominates. Recently another peptide (ghrelin) that stimulates GH secretion has been characterized (see below).

Many other factors can influence anterior pituitary secretion, by modulating the actions of the hypothalamic regulators and/or in some cases by direct action at the pituitary. Thus, the secretion of FSH and LH may be modified by hormones produced by the gonads, including gonadal steroids and peptide hormones such as inhibin. Such modulation probably underlies differential release of LH and FSH from a single cell type. Hormones produced from other endocrine organs can also affect secretion of the pituitary hormones regulating those organs. Thus thyroid hormones modulate TSH secretion, and corticosteroids affect ACTH secretion. Secretion of GH is modulated by insulin-like growth factors (IGFs).

At the physiological level, factors controlling the release of hypothalamic peptides are obviously important in the overall control of pituitary hormone secretion. These factors include neural signals (including sensory inputs and signals deriving from endogenous rhythms) and hormonal/metabolic factors, such as glucose or amino acid levels, steroid hormone levels, etc. The hypothalamus provides a mechanism by which the neural and hormonal regulatory systems can be integrated, providing a combined input to the pituitary gland which in turn controls many of the endocrine glands of the body.

Growth Hormone

Each of the pituitary hormones has direct or indirect effects on nutrition. Thus, ACTH and TSH stimulate production of hormones involved in metabolic regulation. Prolactin, by stimulating lactation, affects both the nutrition of the offspring and the nutritional balance of the mother in whom much of the metabolic effort may be diverted towards milk production. However, the pituitary hormone that is most directly involved in regulating the nutritional balance of the organism is GH.

Structure

GH is a protein hormone of about 22 kDa molecular weight. Amino acid sequences of GHs from many

Table 2 The hypothalamic hormones that regulate the adenohypophysis

Hormone	*Abbreviation*	*Chemical nature*	*Main actions*
TSH-releasing hormone	TRH	Peptide (3 residues)	Stimulates release of TSH and possibly prolactin
LH-releasing hormone	LHRH	Peptide (10 residues)	Stimulates release of LH and FSH
Somatostatin (GH release-inhibiting hormone)	SRIF	Peptide (14 residues)	Inhibits release of GH (and many other secreted peptides)
Dopamine	DA	Catecholamine	Inhibits release of prolactin and MSH
GH-releasing hormone	GHRH	Peptide (44 residues)	Stimulates release of GH
Corticotropin-releasing hormone	CRH	Peptide (41 residues)	Stimulates release of corticotropin

TSH, Thyroid-stimulating hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; MSH, melanocyte-stimulating hormone.

Note that these are the hypothalamic factors that have now been well characterized. Other factors have been proposed, but either they have not been fully characterized or their physiological significance is in doubt. These include oxytocin-related peptides that may be involved in regulating MSH secretion, a factor that may specifically stimulate FSH secretion, an inhibitor of adenocorticotropic hormone secretion, and factors involved in stimulation of prolactin release.

species are available, and the three-dimensional structures of pig and human GHs have been determined, using X-ray diffraction. The structure comprises a four-helix bundle with an unusual ('up-up-down-down') topology. A similar topology has now been seen in a variety of cytokines and growth factors, indicating that GH is a member of a large protein superfamily (the cytokine family). The receptors for members of this family are also related. There is considerable sequence variation between GHs from different mammals. Most notably, human GH is very different from GHs of nonprimate mammals. Variation in biological properties is also seen – in particular, nonprimate GHs are not active in humans, and human GH, unlike most nonprimate GHs, possesses lactogenic (prolactin-like) activity. The species specificity has meant that it has been necessary for therapeutic purposes to prepare human GH on a large scale in order to treat human hypopituitary dwarfism (see below).

Biological Actions

GH stimulates somatic growth in most vertebrates. Removal of the pituitary gland leads to marked slowing of growth in young animals, and the effect can be reversed by GH treatment. Humans with deficient GH production suffer from retarded growth, leading to dwarfism, which can often be treated by exogenous GH. On the other hand, excess GH, due usually to an adenohypophysial tumor, leads to gigantism (if the tumor develops early in life, before the epiphyses of the long bones fuse) or acromegaly (if the tumor develops later, when only certain bones, characteristically those of the face, hands and feet, can still grow). GH is not the only factor affecting growth, of course. All animals have a genetic program that determines their normal adult size range, presumably optimized by evolutionary pressure to fit a particular niche. The role of GH is presumably to regulate growth of the organism within this optimum range, relative to environmental factors, particularly nutrition. Thus, if food is in short supply, normal growth is slowed, and if the short supply is followed by surplus, growth may be increased to above normal levels (catch-up growth). The final size that an adult mammal achieves will be a compromise between the optimal size that the genetic program determines, and what can be achieved given the environmental circumstances, particularly with regard to nutrition. For an animal to grow in an unregulated fashion towards a predetermined size (defined mainly in terms of bone length) could lead to decreased fitness, due to decreased muscle mass or bone strength. The link between the effects of nutrition and GH on growth is emphasized by the observation that responses to GH in experimental animals may be influenced markedly by the plane of nutrition.

The biological actions of GH are complex, and not well understood. The overall effect of the hormone is to promote growth, and it has direct or indirect effects on many aspects of protein, carbohydrate, and lipid metabolism, as well as effects on division and differentiation of some cell types. Whether all of these effects should be seen as directly related to stimulation of growth, or whether some of the actions of the hormone should be considered quite separately from the growth-promoting effects, is not clear. Some of the actions of GH are mediated by somatomedins/IGFs (**Figure 2**). These are single-chain polypeptides that show structural similarity to insulin. Two main IGFs have been characterized – IGF-1 and IGF-2. IGF-1 is most markedly GH-dependent. IGFs occur in the circulation largely in association with specific binding proteins, of which there are at least six types. These binding proteins extend the half-life and modulate the activity of IGFs; at least one of them is itself GH-dependent.

Circulating levels of IGF-1 are low in hypophysectomized rats or GH-deficient animals or people, and are increased following administration of GH. Unlike GH, IGF-1 stimulates cartilage growth directly, which is a prerequisite for growth of bone. For some time it was considered that circulating IGF-1 (produced mainly in the liver) was the main mediator of the actions of GH on cartilage and bone growth, but it is now clear that GH stimulates IGF-1 production in many tissues, including cartilage, and that the growth factor probably acts locally to stimulate tissue growth, possible synergizing with GH itself.

In addition to its actions on cartilage and bone growth, mediated largely by IGFs, GH also has anabolic effects on various other tissues. For example it stimulates protein synthesis in muscle and liver, including both a general enhancement of the protein synthetic machinery, and induction of gene expression for specific proteins, including IGFs and their binding proteins. GH also has effects on carbohydrate and lipid metabolism. The effects on carbohydrate metabolism include short-term insulin-like effects and longer-term antiinsulin (diabetogenic) effects. Actions on lipid metabolism include stimulation of lipid mobilization and uptake, and decrease in lipid synthesis. Overall the metabolic effect of the hormone is to promote lipid utilization and decrease carbohydrate utilization. The extent to which these metabolic actions are mediated by IGFs is not clear.

Mechanism of Action of Growth Hormone

Understanding of the mechanism by which GH acts has increased substantially over the past decade. As

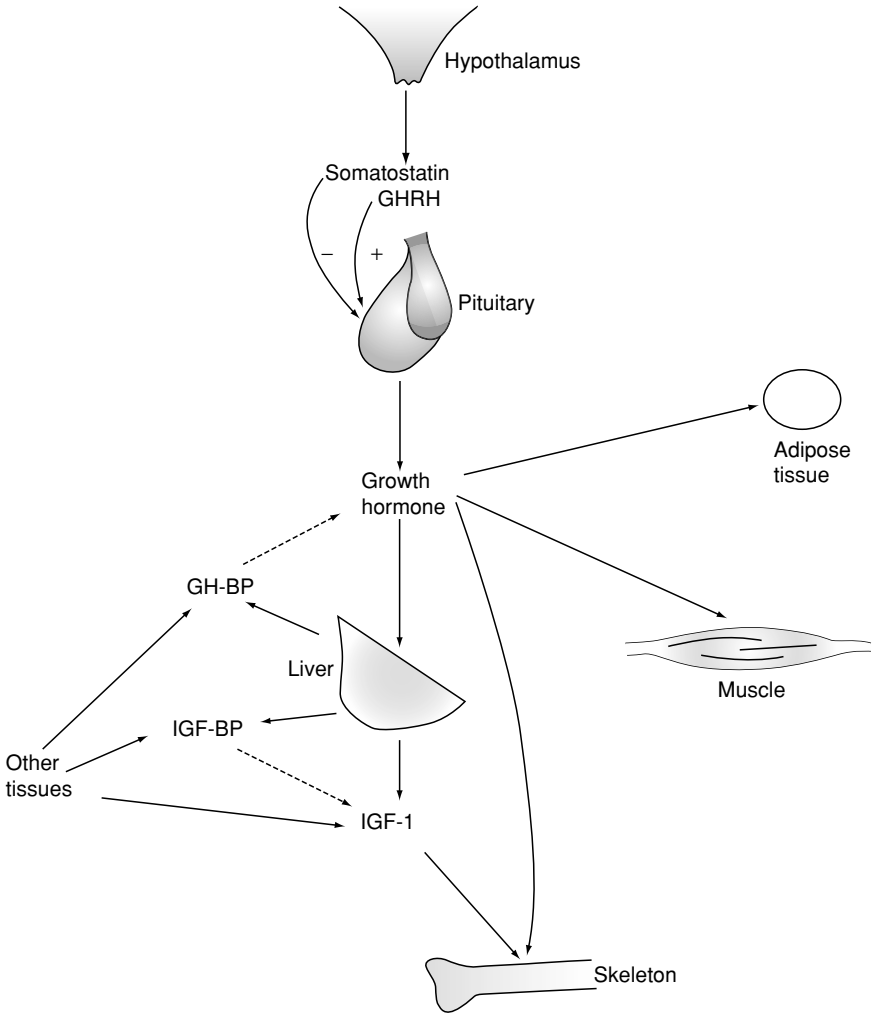

Figure 2 The hypothalamic–pituitary–somatic axis. Circulating insulin-like growth factor 1 (IGF-1) derives both from the liver and other tissues; at least some of the actions of IGF-1 involve local rather than humoral effects. The half-life and actions of growth hormone (GH) and IGH-1 are modulated by corresponding binding proteins (BP). GHRH, growth hormone-releasing hormone. Modified from Wallis M (1988) The molecular basis of growth hormone deficiency. *Molecular Aspects of Medicine* 10: 429–509.

with other polypeptide hormones the interaction with the target cell is via a membrane-bound receptor. When the GH receptor was first cloned and characterized in 1987 it proved to be of a type not previously observed. Since then, receptors of a similar type have been identified for a number of other polypeptide signaling molecules (members of the cytokine receptor family), including prolactin, erythropoietin, and various growth factors and lymphokines. All of these receptors comprise a single membrane-spanning domain, with substantial extracellular (ligand-binding) and intracellular domains. For GH there is evidence that the hormone binds to two receptor molecules, effectively dimerizing or cross-linking the receptor. The most striking demonstration of this has come from X-ray crystallographic studies, which revealed the detailed 3D structure of GH bound to two molecules of the extracellular domain of the receptor. Cross-linking of two extracellular domains brings together the corresponding intracellular domains, and it is thought that interaction between these allows the signal to be transmitted to the interior of the target cell. Thus far there is evidence for only one GH receptor gene in any one mammalian species, but there is generation of receptor heterogeneity by allelic variation, alternative splicing during pre-mRNA processing and/or posttranslational modification. The significance of such receptor heterogeneity is not yet clear, but a notable feature of it is the presence of a soluble form of the extracellular domain in the normal circulation – this acts as a GH-binding protein and may modulate the activity of the hormone and/or prolong its half-life.

The GH receptor is neither a G-protein-linked receptor, nor does it include a protein kinase. However, a major aspect of its mechanism of action is that on activation, following hormone binding and dimerization, it binds and activates a soluble cytosolic protein kinase Jak2. This leads to phosphorylation of the receptor itself and of a number of intracellular effector proteins, including members of the Stat (signal transduction and activation of transcription) protein family, particularly Stat5. Phosphorylated Stat5 moves to the nucleus where it acts as a transcription factor, stimulating the transcription of key GH-dependent genes, including the gene for IGF-1. Activation of Jak2 also leads to stimulation of various other intracellular signal transduction mechanisms, including the MAP kinase pathway.

Regulation of GH Secretion and Synthesis

The secretion of GH is regulated by stimulatory and inhibitory peptides produced in the hypothalamus, including GHRH and somatostatin. Stimulatory control generally predominates. Recently another peptide that stimulates GH release, ghrelin, has been identified in the stomach. Its physiological role is not yet clear, but it also stimulates appetite and may provide a link between GH secretion and food intake. The actions of these peptides are modulated by factors acting directly at the pituitary level, including IGFs, thyroid hormones, and glucocorticoids. Secretion of the hypothalamic peptides is in turn regulated by neural and metabolic factors. GHRH, and hence GH secretion, is stimulated by hypoglycemia, high levels of amino acids such as arginine or leucine (which may result from a high protein meal), and lowered free fatty acid levels. GH levels are lowered in obese subjects, and recent studies suggest that the 'fat hormone' leptin may play some role in modulating GH secretion. GH secretion is normally pulsatile in animals and humans, which complicates the determination of 'normal' levels.

Growth Hormone Deficiency

In humans GH deficiency gives rise to stunted growth/dwarfism and can have a number of causes, some of which are hereditary. Hereditary GH deficiency can be due to: (1) deletion of the gene that codes for GH; (2) mutations that prevent normal development of GH-producing cells (somatotrophs) and GH synthesis; (3) defective GH receptors (so that although normal levels of the hormone are produced they fail to produce normal responses in the target cells); and (4) other reasons, not fully understood. Most cases of GH deficiency in humans are not hereditary in origin, however; they often appear to be due to damage to the link between hypothalamus and pituitary, so that the normal control of GH secretion by GHRH is disrupted. Such disruption can be due to birth trauma, blows to the head in infancy, or other causes. In such cases the pituitary can often respond to GHRH administered exogenously, and this is being explored as a therapeutic approach to treat human hypopituitary dwarfism.

Children suffering from stunted growth due to clearly established GH-deficiency can be treated using human GH, and this has become a standard therapy. Provided GH treatment is started sufficiently early, growth can be restored to near normal, and heights within the normal range can be achieved. For about 20 years the GH used for such therapy was extracted from human pituitary glands obtained postmortem, and in many countries extensive schemes were established for collection of such material. In the mid-1980s, however, concern arose about the contamination of some human GH preparations with infective agents, particularly the prions causing Creutzfeldt–Jakob disease (CJD), and use of GH derived from human pituitaries was largely stopped. Fortunately at that time the possibility arose of using human GH prepared by genetic engineering techniques, and this is now widely employed.

The possibility of using GH to treat forms of short stature other than those due to clear-cut GH deficiency has been considered for some time. The availability of GH produced by recombinant DNA methods in potentially unlimited quantities makes wider usage more feasible, and this is being explored actively. As well as extending treatment to children whose short stature is due to primary causes other than GH deficiency, the use of recombinant DNA-derived GH to treat adults with GH deficiency is being considered, as is its use for promoting anabolism in muscle-wasting conditions such as acquired immunodeficiency syndrome (AIDS), cachexia, and even old age.

Growth Hormone Excess

Oversecretion of GH, usually due to a pituitary tumor, leads to excessive growth. Where this occurs before puberty it can lead to giantism, though this is rare. Where it occurs after puberty (when further growth of the long bones is not possible) it can lead to acromegaly, in which those bones which can still grow in response to GH do so, leading to enlarged hands and feet and distorted facial features. The very high circulating levels of GH and IGF-1 seen in acromegalic patients also lead to thickening of the skin, enlargement of some soft tissues, and often

disorders of the cardiovascular, muscular, and endocrine systems. Diabetes mellitus is relatively common in acromegaly, and shows clinical features rather different from normal, presumably because GH itself has diabetogenic properties.

Acromegaly can be treated by surgical removal of the pituitary tumor, radiation therapy, administration of a drug (e.g., bromocriptine or a somatostatin analog) that inhibits GH secretion and tumor growth and/or use of a GH receptor antagonist (pegvisomant). Very rarely acromegaly is caused by a GHRH-secreting tumor elsewhere in the body, such as the pancreas.

Growth Hormone and Malnutrition; Catch-up Growth

The role of GH in malnutrition and starvation is complex and poorly understood. In humans, GH levels increase on fasting, in both normal and obese subjects, and fall again on refeeding. Paradoxically, IGF-1 levels fall in response to starvation, despite the high GH levels. Such a dissociation of GH and IGF-1 levels is particularly marked in protein-calorie malnutrition (kwashiorkor), where IGF levels may be in the hypopituitary level despite elevated GH levels, but it is also seen in conditions such as anorexia. The mechanism by which the dissociation of GH and IGF-1 levels arises is poorly understood, as is its significance for the control of nutritional balance during malnutrition, but it may effectively allow a dissociation of the actions of the hormone on growth promotion (much reduced during periods of malnutrition) from those on metabolism (still required since the hormone promotes utilization of fat). GH responses to starvation in the rat differ from those seen in humans – both GH and IGF-1 levels fall; responses in ruminants and pig are similar to those in humans.

In children, if nutrition improves after a period of malnutrition, the phenomenon of catch-up growth can occur, in which growth increases to an above normal rate, allowing some or all of the lost ground to be restored. Involvement of the GH/IGF axis in this phenomenon is likely, but the mechanism is unclear.

Nutritional Control of IGF Levels

Although GH clearly plays an essential part in the control of circulating and local IGF-1 levels, it is by no means the only factor. Insulin and thyroxine are important, and nutritional level also regulates both the level and activity of IGF-1. Indeed, IGF-1 levels in the circulation are remarkably sensitive to nutrients, and can provide a marker for nutritional status and effectiveness of treatment. Nutritional influence on IGF-1 levels may be mediated to some extent by insulin or thyroid hormones (but not GH, given the divorce between GH and IGF-1 levels in malnutrition, referred to above), but it is clear that to some extent they are direct. Actions on GH receptor levels, which are lowered on fasting, may be involved in severe dietary restriction, but in less severe protein restriction postreceptor mechanisms appear to predominate. Nutritional level also affects the activity of circulating IGF-1: (1) by altering the balance of the IGF-binding proteins that modulate the half-life, tissue availability, and receptor-binding of IGF-1; (2) by regulating formation of inhibitors of IGF-1; and (3) by altering type 1 IGF receptor levels. The involvement of so many factors in regulating IGF levels and activity probably plays an important part in integrating their various influences on growth.

Growth Hormone and Animal Biotechnology

GH can stimulate growth, meat production, and lactation in farm animals and the availability of large quantities of the hormone produced by recombinant DNA methodology has stimulated work designed to assess and apply the hormone in animal agriculture. Recombinant DNA-derived bovine GH (frequently referred to as bovine somatotropin, BST) has been subjected to extensive trials as an agent for promoting milk production, and is now being used commercially for this purpose in some countries. The ability of GH to promote meat production in various farm animals has been studied extensively. Not only is muscle growth stimulated, but fat content is much reduced, so that a potentially healthier product results. Possible applications of GH in fish farming have also been studied.

The potential for the use of recombinant DNA-derived GH in agriculture is great, but such usage remains controversial because of concerns about food safety, animal welfare, and economic impact. Indirect ways of modulating GH levels and actions in farm animals may prove more acceptable than direct administration of the hormone. Such indirect approaches include immunological modulation, modification of endogeneous hypothalamic activity, and use of the transgenic approach to introduce additional genes for GH into animals. The transgenic approach, coupled with cloning, is particularly powerful, though again welfare and other considerations may limit its usefulness.

Steroid Hormones

A W Norman, University of California-Riverside, Riverside, CA, USA

Introduction

Steroid hormones are well known both physiologically and clinically as regulators of diverse biological responses, including profound effects on cellular metabolism, development, and physiology. The steroid hormones are the estrogens (female sex steroids), androgens (male sex steroids), progestins, mineralocorticoids, glucocorticoids, and vitamin D with its daughter metabolites.

All these different steroid hormones are synthesized from the common precursor, cholesterol, and structurally differ only in the pattern of chemical bonds within the rings and modifications on the side chain. The exquisite specificity of physiological effects that these steroid hormones evoke is mediated by high-affinity intracellular receptor proteins that are exclusively localized in the specific target tissues for each steroid hormone. Specific interaction of the hormone–receptor complex with DNA sequences of the hormone-responsive gene(s) results in the tissue-specific expression of proteins which either directly or indirectly generate the biological responses attributable to the steroid hormones. The application of cellular and molecular biological techniques has allowed greater understanding of the way in which such small molecules exert diverse biological effects with exquisite specificity.

Historical Perspective

The first steroid hormone that was discovered, estrone, was isolated in 1929, before the characterization of the ring structure of the steroid nucleus. Studies by Professor A. Windaus in Göttingen, Germany, in the 1930s led to the chemical characterization and structural determination of cholesterol, using classical organic chemistry manipulations. Methodological advances such as radioisotopes, chromatography, mass spectrophotometry, and nuclear magnetic resonance spectroscopy have all facilitated the elucidation of structures of the other steroid hormones.

Chemistry

In mammalian systems, there are six families of steroid hormones that can be classified on both a structural and a biological (hormonal) basis. These are

the: (1) mineralocorticoids, which instruct the renal tubule to retain sodium; (2) glucocorticoids, which exert manifold effects on carbohydrate metabolism; (3) progestins, which are essential for reproduction; (4) estrogens, which induce female secondary sexual characteristics; (5) androgens, which induce male secondary sexual characteristics; and (6) the vitamin-D hormone, 1,25-dihydroxyvitamin D_3 (1,25-$(OH)_2D_3$), which is important for regulation of calcium and phosphorus homeostasis, bone growth, and development. Also, the bile acids are structurally related to cholesterol and thus constitute a seventh member of the steroid family. All of these steroids are biologically derived from cholesterol.

All steroids are derived from a cyclopentanoperhydrophenanthrene backbone that comprises three C_6 cyclohexane rings designated as A, B, and C, fused to a fourth C_5 cyclopentane ring, notated as the D ring. Within the family of steroid hormones, each member is distinguished by chemical alterations such as isomerization, aromatization, dehydrogenation, and fission in the ring structure, and modifications such as hydroxylations in the side chains of the cholesterol backbone that are catalyzed by specific enzymes present in the endocrine glands. The chemical formulae of these steroid hormones are depicted in Figure 1.

Biosynthesis of Steroids

Figure 2 summarizes in general terms the metabolic pathways leading from cholesterol to the six major steroid hormones (Table 1). The principal tissues of synthesis of the five classical steroid hormones (estrogens, androgens, progestins, glucocorticoids, and mineralocorticoids) are the adrenal cortex, ovaries, and testes. Also, during pregnancy, the fetal–placental unit can serve as a source of estrogen and some other hormones. The sites of synthesis of the sixth class of steroid hormones, the prohormone vitamin D_3 and its metabolites, are the skin, liver, and kidney. The bile acids, which are the seventh important structural class of mammalian steroids, have no known hormonal activity; they are principally synthesized in the liver and are secreted from the gallbladder to participate in digestion and absorption where they function as a detergent to solubilize fats.

Figure 3 describes the relationship between the stimulatory peptide hormone and the six classes of steroid hormones. The biosynthesis of each steroid hormone by its endocrine gland is stimulated by a specific cognate peptide hormone. Thus, for example, the biosynthesis of cortisol in the adrenal cortex is only stimulated by its tropic (stimulatory) peptide hormone adrenocorticotropic hormone (ACTH). ACTH is only secreted by the anterior pituitary gland.

Biosynthesis of Progestins

As evident from Figure 2, the common pathway leading to the production of six classes of steroid hormones primarily involves conversion of cholesterol (which possesses 27 carbon atoms) into pregnenolone and then progesterone (which possesses 21 carbon atoms). Progesterone is synthesized by the corpus luteum of the ovary and placenta and constitutes the chief progestational steroid in humans.

Biosynthesis of Glucocorticoids and Mineralocorticoids

The glucocorticoids and mineralocorticoids are 21-carbon corticosteroids produced by the adrenal cortex (Figure 1). The principal glucocorticoid in males is cortisol, while aldosterone is the main mineralocorticoid.

Biosynthesis of Androgens and Estrogens

The androgens, which possess 19 carbon atoms, are produced in the testes in males, and in the ovaries and placenta in females. Under some circumstances the adrenal cortex can also produce physiologically significant androgens such as androsterone, 4-androstene-3,17-dione, and dehydroepiandrosterone. The major naturally occurring steroids with androgenic activity (in decreasing order of relative potency) are 5α-dihydrotestosterone (5α-DHT; 150–200%), testosterone (100%), androstanediol (65%), androst-4-ene-3,17-dione (25%), androsterone (10%), and dehydroepiandrosterone (10%). The hormonally active form of testosterone in males is 5α-DHT, which is chiefly produced in the prostate gland, although skin, testis, and submaxillary glands also can produce small quantities.

The estrogens, which possess 18 carbon atoms, are produced in the ovarian follicle, corpus luteum, and fetal–placental unit. In both males and females, the adrenal cortex can generate small quantities of estrone from androst-4-ene-3,17-dione. The major naturally occurring steroids with estrogenic activity are estra-3,17β-diol, estra-3,16α, 17β-triol, and estrone.

Biosynthesis of Vitamin D Metabolites

Chemically, the vitamin D steroids are secosteroids because of the breakage of the B-ring, leaving the A-, C-, and D-rings intact (Figure 1). The parent vitamin D is produced in the skin from 7-dehydrocholesterol as a consequence of ultraviolet or sunlight action, which breaks the 9,10 carbon–carbon bond. The sites of synthesis of the vitamin D metabolites are the liver and kidney. The hormonally active forms of vitamin D are $1,25(OH)_2D_3$ and 24,25-dihydroxyvitamin

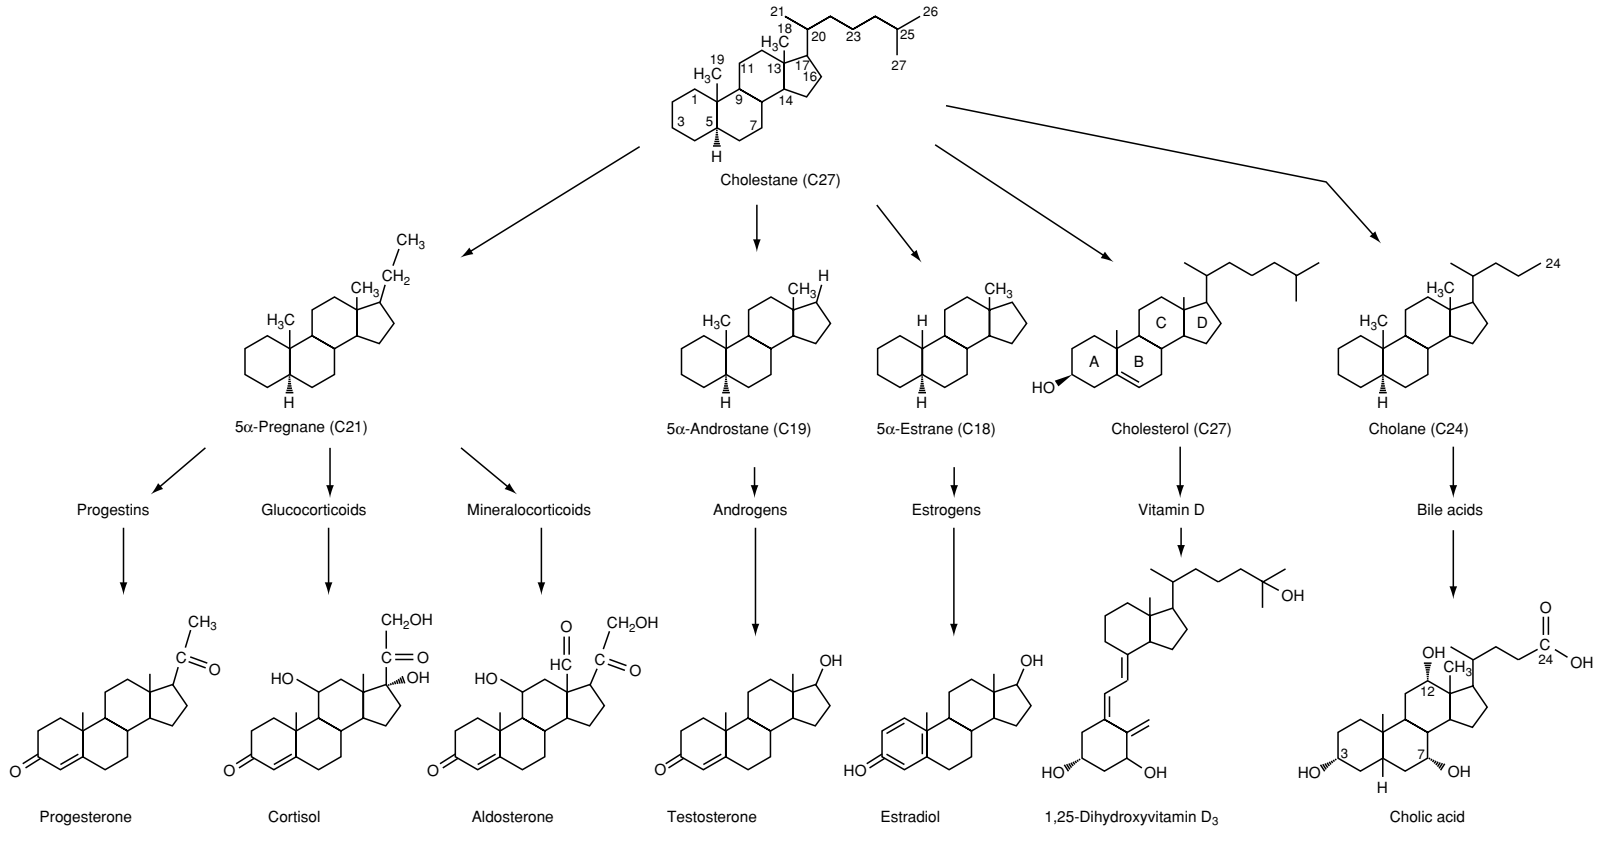

Figure 1 Family tree of the seven principal classes of steroids (bottom row); all of the steroids except cholic acids are steroid hormones. All of the steroids are structurally derived from cholestane (top row), which is closely related to cholesterol.

D_3 (24,25$(OH)_2D_3$), which are instrumental in generating a wide array of cellular responses. These aspects are detailed elsewhere in this volume.

Enzymes involved in Steroid Metabolism

Table 1 summarizes some general properties of the key enzymes involved with conversion of cholesterol into the six key steroid hormones. The various classes of enzymes that participate in the biosynthesis of different steroids include: (1) lyases, which cleave the carbon–carbon bonds bearing vicinal hydroxyl groups in the cholesterol side chain; (2) dehydrogenases and isomerases which convert the 5-ene-3β hydroxysteroid to 4-ene-3-oxosteroid; (3) aromatase enzyme (present in the microsomes of placenta and ovaries), which mediates the aromatization of the A-ring with a phenolic 3-hydroxyl group in the estrogens (Figure 1); and (4) hydroxylases, which play a key role either in the sequential hydroxylation of C22, C20, C17 of the cholesterol side chain or in the stereospecific hydroxylation of the ring structure to yield the different steroids (Figure 1). Thus, for example, the three hydroxylases 17α-, 21-, and 11β-hydroxylase are required for cortisol synthesis, and the 1α and 24-hydroxylases are involved in the production of bioactive vitamin-D metabolites.

All these apparently different hydroxylation reactions are mediated by a family of enzymes called

Table 1 Key enzymes concerned with production of steroid hormones

Enzyme reaction[1]	*Enzyme*		*Reaction(s) mediated*	*Subcellular location*[2]	*Gene location*
	Long name	*Short name*			
①	P450 side-chain cleavage; formerly known as desmolase	(P450scc)	20R-hydroxylation; 22R-hydroxylation; scission of C20–C22 carbon bond	M	15
②	3β-Steroid dehydrogenase-Δ^5, Δ^4-isomerase	(Isom)	Oxidizes 3β-OH to oxo group; isomerizes Δ^5 ene to Δ^4 ene	ER	
③	21-Hydroxylase	(P450c21)	21-hydroxylation	ER	6p
④ ⑤ ⑥	11β-Hydroxylase	(P450c11)[3]	④ 11β-hydroxylation; ⑤ 18-hydroxylation; ⑥ oxidation of C18 hydroxyl to an aldehyde	M	8q

DHEA, dehydroepiandrosterone; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate.

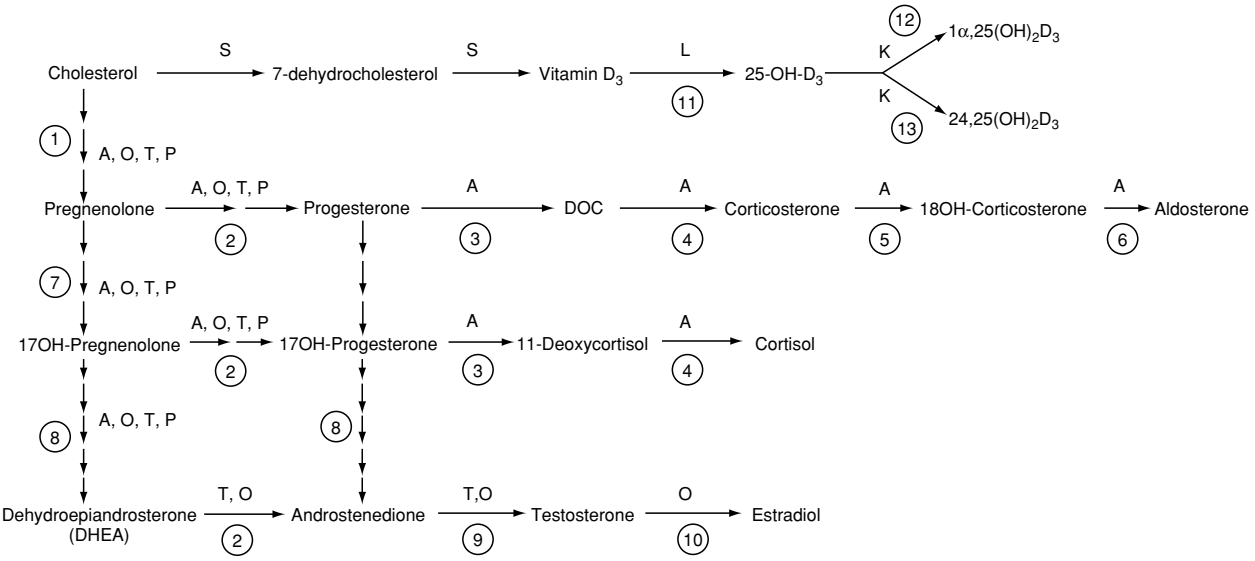

Figure 2 Principal pathways of human steroid hormone synthesis. The details of the enzyme reactions (circled numbers) are summarized in Table 1. Reactions ①, ②, ⑦, and ⑧ are found universally in the adrenals, ovary, testes, and placenta. Reactions ⑨ and ⑩ are found principally in the testes and ovaries. Reactions ⑪ → ⑬ describe the pathway of production from cholesterol of the prohormone vitamin D and its hormonal metabolite products 1,25-dihydroxyvitamin D_3 ($1\alpha,25(OH)_2D_3$) and 24,25-dihydroxyvitamin D_3 ($24,25(OH)_2D_3$). Reaction ⑪ is P450c25 present in the mitochondrial and/or endoplasmic reticulum of the liver. Reactions ⑫ and ⑬: P450c1α and P450c24 are present in the mitochondria of the kidney proximal tubule. Tissue codes: A, adrenals; O, ovaries; T, testes; P, placenta; S, skin; L, liver; K, kidney; DHEA, dehydroepiandrosterone; DOC, deoxycorticosterone.

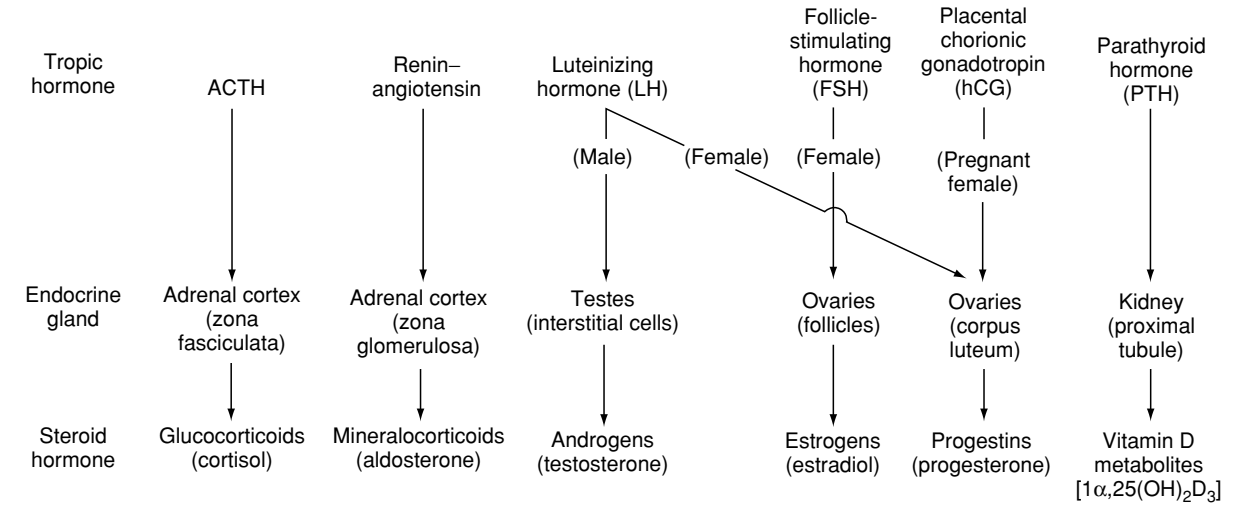

Figure 3 Relationship between stimulatory peptide hormones and the production of steroid hormones. For each of the six classes of steroid hormones, the specific stimulatory or tropic peptide hormone is indicated as well as specification of the organ or cell upon which it acts. Also, in males, follicle-stimulating hormone is known to act upon the Sertoli cells of the seminiferous tubules to increase the production not of a steroid hormone but of several sperm proteins, androgen-binding protein, and inhibin, a peptide hormone. ACTH, adrenocorticotropic hormone.

cytochrome P450 hydroxylases which have a cytochrome moiety at the catalytic center. The cytochrome P450 enzymes are present in either the mitrochondrial or microsomal fraction of cells present in the liver, adrenal cortex, ovary, testis, kidney, placenta, lungs, and intestinal mucosa. The mitochondrial cytochrome P450s are comprised of a flavoprotein dehydrogenase, which accepts electrons from the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH), and the nonheme

iron protein adrenodoxin, which accepts electrons from flavoprotein and transfers them to the cytochrome P450 protein. The microsomal hydroxylase system lacks the adrenodoxin component. Cytochrome P450 hydroxylases (also known as mixed-function oxidases) catalyze oxidation-reduction reactions in which one atom of the substrate (O_2) ends up on the steroid as a part of the hydroxyl and the other oxygen atom as part of water (H_2O); the necessary reducing equivalents are derived from NADPH.

Transport

All steroid hormones, which are quite water-insoluble, circulate in blood, bound to plasma proteins called steroid hormone-binding globulins. The androgens and estrogens are both transported by a plasma β-globulin, which is a hepatic glycoprotein with a molecular weight of 94 000. This carrier protein has a high affinity (K_d 1.5×10^{-10} mol l^{-1}) for testosterone, 5α-DHT, and estradiol but not for progesterone or cortisol. The glucocorticoids are systemically transported via the corticosteroid-binding protein (CSBP) or transcortin, which is also a hepatic protein. Similarly, the vitamin D sterols are bound to the vitamin D-binding protein (DBP), and α-globulin. The primary role of all these different sterol-binding proteins is to provide a reservoir of bound hormone which can effectively dampen oscillations in the 'free' concentrations of hormones.

Catabolism and Excretion of Steroid Hormones

The catabolic pathways that result in the inactivation of the steroid hormones occur mainly in the liver. Conjugation of the hydrophobic steroids either with sulfate or glucuronides renders the hormone more hydrophilic for easy excretion in the urine. The excreted species are usually polyhydroxyl forms with the particular glucuronide or sulfate: these conjugations are mediated by sulfokinase and glucuronyl transferase enzymes.

Functions of Steroid Hormones

Steroid hormones secreted by the endocrine glands exert profound influences on cell growth, development, and physiology, chiefly by controlling the synthesis of particular proteins. All steroid hormones modulate cellular responses by either inducing or repressing the transcription of specific proteins at the genetic level.

A general result of glucocorticoid action is a direct effect of increased glucogen, especially in the liver, and increases in the levels of circulating glucose. Prolonged high levels of glucocorticoids can lead to the death of susceptible cells which accounts for muscle wasting and immunodeficiency. As a powerful antiinflammatory agent, glucocorticoids may act on many cells to induce the synthesis of the protein(s) lipomodulin. Lipomodulin acts as an inhibitor of phospholipase A_2 and thereby prevents the release of prostaglandins, prostacyclins, and leukotrienes, some of which mediate processes of inflammation and pain.

Mineralocorticoids such as aldosterone promote sodium reabsorption by the kidney tubules, usually followed by changes in water balance; in terms of function they mesh with the vasopressin system and atrial natriuretic factor which also control water absorption and excretion by the kidney and also participate in the regulation of blood pressure.

The biological responses of androgens are divisible into four categories: (1) growth-promoting or androgenic effect on the male reproductive tract; (2) stimulating or anabolic effect on body weight (skeletal growth, skeletal muscle growth, subcutaneous fat distribution, growth of prostate and seminal vesicle); (3) development of male secondary sexual characteristics (growth of external genitalia, enlargement of larynx and thickening of vocal cords, hair growth distribution); and (4) actions in the central nervous system and brain (differentiation of brain cortex, hypothalamus, initiation of puberty).

The dominant effect of estrogens occurs in the female reproductive tract. Significant biological activity of estrogens also occurs in the hypothalamus, brain, and mammary tissue. Estrogens primarily initiate the transcription of specific proteins in the uterus, and affect uterine cell proliferation and differentiation. A classical developmental role of estrogen in the liver of the adult hen is in the induction of vitellogenin, which is transported to the ovary and cleaved to yield egg proteins, phosvitin, and lipovitellin.

The biological activity of progesterone is restricted to the female reproductive tract and mammary tissue. Some of the effects mediated by progesterone include thermogenesis in women, regulation of egg movement through the fallopian tubes, preparation of uterus to receive the blastocyst, alteration of electrical activity in the brain, control of uterine contraction (at parturition), and generation of the secretory system of breast during pregnancy.

The steroid hormone $1,25(OH)_2D_3$ is principally involved in the regulation of mineral (calcium and phosphorus) metabolism, bone growth, and differentiation. A detailed account of the manifold effects of vitamin D is given in a subsequent article. (*See* **Cholecalciferol**: Properties and Determination; Physiology.)

Mechanism of Action of Steroid Hormones

The receptors for all the steroid hormones, $1\alpha,25(OH)_2D_3$, thyroid hormone, and retinoic acid, are all proteins which exist exclusively in the cell nucleus or are partitioned between the cytoplasm and nucleus. Each of these receptor proteins functions as DNA-binding proteins, where they regulate the expression of genes related to the biological response of the hormone in question.

Figure 4 presents a generic model of a typical steroid receptor. The protein consists of a single polypeptide chain divided into six domains. Starting at the N-terminus, the domains are respectively (1, 2) the A/B or variable (sequence and length) domain; (3) the C or DNA-binding domain which contains two zinc fingers; (4) the D or variable hinge region; (5) the E or ligand-binding domain; and (6) the F or variable domain.

Figure 5 illustrates the striking structural homology between all the domains of the steroid superfamily. All these proteins are related evolutionarily. The ancestor of these proteins may be the oncogene product v-*erb* A.

The steroid receptors are labile soluble proteins with molecular weight ranging between 50 and 94 kDa. The molecular cloning of steroid receptors has greatly facilitated the delineation of the various functional domains of these receptor proteins (Figures 4 and 5). All members of steroid receptors bear a short DNA-binding domain comprising about 70 amino acids containing many conserved cysteine residues. Eight of the cysteines are organized into two so-called zinc fingers, each containing four cysteine residues tetrahedrally coordinating a zinc ion. Based on the amino acid sequence within the DNA-binding region of steroid receptors, they can be classified into two subfamilies: (1) glucocorticoid receptor is the prototype of the smaller subfamily which includes progesterone, androgens, and mineralocorticoid receptors; (2) the estrogen receptor is the prototype of the larger subfamily which includes the vitamin D receptors, thyroid hormone receptors, and receptors for retinoic acid. Steroid receptors exhibit a large C-terminal domain, responsible for binding hormone, known as hormone-binding domain (HBD). The amino-terminal region contains hypervariable amino acids and certain transactivation sequences. Recent studies have shown that functional properties of steroid receptors are modulated by phosphorylation, dimerization, and association with other proteins such as heat shock proteins (HSPs).

A model of the steroid hormone mode of action is provided in Figure 6. In step 1, the hormone (H) dissociates from the plasma transport protein. In step 2, the hormone enters the target cell by diffusing through the outer cell membrane. Then, depending upon the subcellular localization of the unoccupied receptor, the hormone will either interact with the receptor in the cytoplasmic compartment (glucocorticoid and aldosterone receptors) or continue through

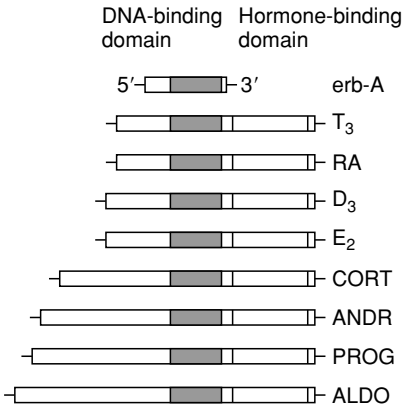

Figure 5 Steroid receptor gene superfamily. T_3, triidothyronine; RA, retinoic acid; D_3, 1,25-dihydroxyvitamin D_3, E_2, estradiol; CORT, cortisol; ANDR, androgen; PROG, progesterone; ALDO, aldosterone. The N-terminal domain (open rectangle to the left of the DNA-binding domain) represents the sequences of least homology among the receptors.

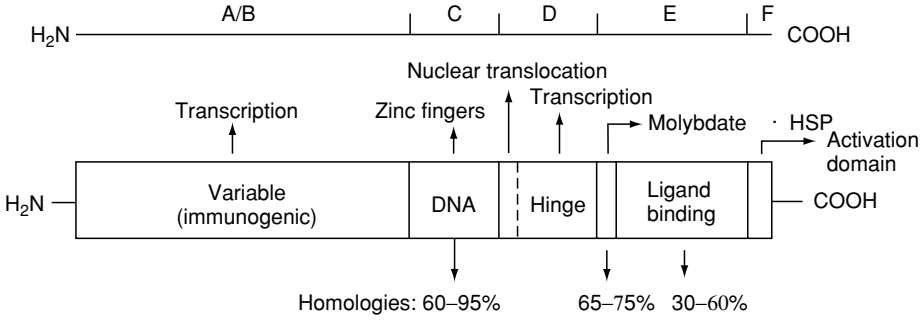

Figure 4 Model of a typical steroid hormone receptor illustrating the six functional domains A → F. HSP, heat shock protein.

the cytoplasm and cross the perinuclear membrane to interact with a receptor in the nucleus (thyroid, estrogen, progesterone, retinoic acid, and $1,25(OH)_2D_3$ receptors).

The unoccupied form of the steroid receptor is believed to exist in the cell as a conjugate with a dimer of the 90-kDa HSP; in Figure 6 the HSP dimer is indicated by a pair of ovals. It has been suggested that the HSP's function is to occlude the DNA-binding domain of the receptor which prevents the unoccupied receptor from binding to DNA.

In steps 3 and 4, the receptor becomes transformed or activated as a consequence of release of the 90-kDa HSP and binding of its cognate ligand, so that the DNA-binding domain is now exposed. In step 5, the cytoplasmic activated receptor translocates to the nucleus, probably through a nucleopore. Then in step 6, the activated receptor, or more likely a homodimer of the receptor, seeks out the correct sequence of DNA that will allow it to form a high-affinity complex between the receptor and the hormone response elements (HRE) of the promoters of a selected set of genes and also any required transcription factors.

As a consequence of the activated receptor binding to the promoters, either induction or repression of that gene will occur, leading to more or less of the mRNA coded for by that gene.

The newly transcribed mRNAs are translocated to the cytoplasm where they become incorporated into polysomes and undergo translation (step 7). In the final step, step 8, the increased or decreased amount of new proteins generates more or less of the biological response(s) dictated by that hormone in that target cell. For any given hormone, a wide array of biological responses can be modulated depending upon the phenotype of the target cell that possesses the cognate receptor. In any given target cell phenotype, only a small subset of genes will have their DNA chromatin in an active or open configuration. Thus, while a hormone may modulate as many as 300 genes in a given organism, in a specific target cell perhaps only a few genes will be available for regulation.

Summary

Steroid hormones impact profoundly on cellular metabolism, development, and physiology. The

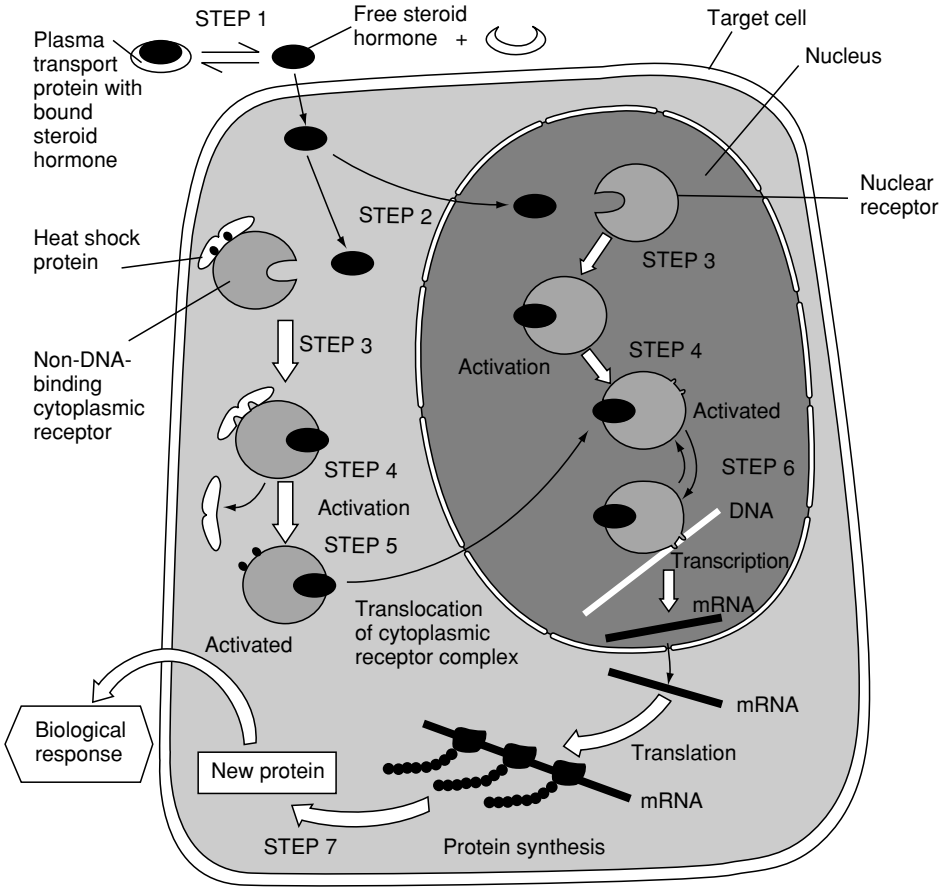

Figure 6 Model of steroid hormone mode of action. A detailed description is given in the text.

repertoire of cellular responses elicited by the various steroid hormones is mediated by specific intracellular receptor proteins localized in target tissues. Cloning of the receptor genes has allowed detailed structure–function analysis of these physiologically important molecules. Greater insight and appreciation of the complex molecular details of steroid hormone action should be possible with the application of modern cellular and molecular biological techniques.

HORSE MEAT

E Rossier, Formerly of CEREOPA, Paris, France

Introduction

The custom of eating horse meat is probably as old as the world itself and, without venturing into prehistoric times, the majority of the nations of Antiquity (Persians, Greeks, Romans, Chinese, Cossacks, etc.) all ate horse meat.

Paradoxically, in European countries Christianity has strived to abolish the eating of horse meat since the seventh century AD. This ban was based on religious beliefs and was only dispelled after 1870. The eating of horse meat then developed quickly thanks to the vigorous action of several well-known personalities in scientific and, in particular, medical circles.

This article explains the situation of the world market as well as the nutritional and hygienic qualities of horse meat.

The World Horse Meat Market

Horse meat is produced in several countries, although the level of production is often marginal when compared to other types of meat.

The USA is the major producer. The other principal countries are Mexico, Argentina, Canada, China, Mongolia, Ethiopia, Chile, and Brazil, as well as several European countries – Poland, Yugoslavia, France, and Italy. The Commonwealth of Independent States (former Soviet Union) is also a large producer although few data are available.

The majority of these countries are exporters of carcass meat, semicarcass meat, quartered or boned meat, or else of live animals destined for slaughter in the importing country. In practice, a few countries dominate trading, the USA being the lead producer, followed by Argentina and Canada.

There are also a few main importing countries and in these consumption exceeds production which has diminished as a result of mechanization of agriculture and transport. This is particularly so in France, Japan, Italy, Belgium, and the Netherlands. The other markets are much more limited: Switzerland, Austria, Sweden, Norway, and Denmark.

The internal production of horse meat is adequate for domestic consumption in Mongolia, China, Mexico, Ethiopia, and the Commonwealth of Independent States.

In many countries there is a considerable horse population, but little information is available regarding the final use to which the animals are put, except in the production of dog and cat food.

Except for the countries mentioned above, Italy, France, Japan, Belgium, the Netherlands, Spain, Switzerland, and Sweden are the principal consumers (**Table 1**). Only small proportions of these

populations eat the meat. This attitude might change significantly if the meat were promoted with a specific image in view of the qualities mentioned below.

There are several restraints on consumption of this type of meat, in particular cultural or religious prohibitions, the 'noble animal' symbolism of horses, and the often specific distribution channels of horse butchers, although more widespread distribution is gradually taking over.

Butcher Qualities

Carcass Characteristics

As horses were not intended to produce meat for consumption, unlike other species, the meat that has been eaten has come mainly from grazing animals, working horses and, more recently, sport and racing horses.

The growth in production of young meat, especially from the Trait breed, is new in several European countries and Japan. The horse is in fact a good meat producer. Carcass yields are high (real yield is equal to weight of warm carcass divided by live empty weight), bordering on 70% for young stallions born from the Trait breed and comparable with those for cattle meat.

The carcass contains a very high proportion of muscle (70%) and little fat (10–14%). The distribution of adipose tissue is not the same as in cattle, as horse carcasses contain more subcutaneous and internal adipose deposits. On the other hand, there is a smaller proportion of intermuscular fat. Horse carcasses therefore look more 'glazed,' but studies on the relative growth of different tissues, organs, and body regions have confirmed that the horse is a lean animal. (*See* **Meat**: Structure.)

Changes to the Meat after Slaughter

The physiological principles of postmortem change are identical for the horse as for other species. However, horse meat differs from cattle meat in its speed of maturation. Rigor mortis sets in rapidly (in several hours), and the pH quickly drops to 5 or 6, which limits microbial proliferation and allows autolysis of the muscle. (*See* **Meat**: Slaughter.)

Horse meat contains a large amount of glycogen and adenosine triphosphate (ATP) and therefore retains a degree of plasticity and elasticity for a long time.

Maturation occurs quickly in horse muscle. Most of the maturation is achieved 4–5 days after slaughter, allowing the meat to be eaten very fresh. As for preservation, several factors combine to give horse meat an excellent sanitary quality, including short storage period for maturation, and low pH. But the large proportion of glycogen, lactic acid, and nonprotein nitrogen encourages microbial development. The meat must therefore be sold quickly and stored at low temperature before being eaten.

Organoleptic Qualities

Tenderness

This criterion largely overshadows other quality parameters since the consumer's satisfaction when tasting the meat depends on this. (*See* **Sensory Evaluation**: Texture.)

It is the insoluble protein constituents of the meat which more or less determine its tenderness: the collagen of connective tissue and its degree of polymerization, myofibril proteins, and muscular fibers.

It seems that, with horses as with other species, there are important variations between animals, age, and different muscles of the same carcass.

These variations in toughness result from large differences in the level of collagen present and its fluctuation with the age of the animal. The collagen content is at its maximum at 18 months. The solubility of collagen, which is linked to its aging and hardening, seems to reduce rapidly until 24 months and then stabilizes thereafter. Thus insoluble collagen reduces the tenderness. Horse meat is generally considered to be very tender, however, and this quality of tenderness is one of the consumer's main reasons for purchase.

Color

It is important to consider the color of horse meat, in particular minced horse meat, which constitutes a high proportion of the value of horse carcass. The color is linked to the myoglobin content in the muscles. (*See* **Sensory Evaluation**: Appearance.)

Adult horse meat is very rich in myoglobin and iron and looks very red. This is a quality sought after by consumers in some countries (France), whereas others (Italy) prefer lighter-colored meats. The level of pigment varies according to the particular muscles and the age of the animal. The content of heme iron is still very low at 6 months, giving a very clear, 'brassy' meat. A strong color hardly appears before 18 months.

Nutritional Qualities

The structures – particularly of the muscular fibers – of horse meat are classical and identical to those of other species. On the other hand, the chemical composition of horse muscle is highly characteristic and conveys particularly interesting nutritional qualities.

Average Composition of Horse Meat

At the beginning of the twentieth century the average composition of horse meat was published as follows: water, 74.27%; nitrogenous substances, 21.71%; fats, 2.55%; nonnitrogenous substances, 0.46%; mineral materials, 1.01%. More recent writers give very similar figures, shown in Table 2. Globally, water content is higher in horse meat than in other species; a very low lipid content in horse meat also leads to a low energy value. The high level of water in horse meat can be a handicap for certain processes and can present technological problems for the salted horse meat trades.

Carbohydrates

Horse meat is rich in carbohydrates, especially glycogen. It is one of its main characteristics. It contains from 0.5 to 3 times more than cattle meat. This high level of glycogen gives horse meat a sweeter flavor than beef. (*See* **Carbohydrates**: Classification and Properties.)

Lipids

The main dietary quality of this meat is its low level of lipids. However, this meat is interesting not only in its low lipid content and its distribution of lipids throughout the carcass at different adipose deposits, but also in the structure of these fats. They are mainly comprised of triglycerides with a high proportion of unsaturated and polyunsaturated fatty acids: palmitoleic acid ($C_{16:1}$), oleic acid ($C_{18:1}$), linoleic acid ($C_{18:3}$) and arachidonic acid (C_{20}). (*See* **Fatty Acids**: Properties; **Fats**: Classification.)

Proteins

The proteins are the major constituents after water. They can be divided into extracellular proteins, e.g., collagen, and intracellular proteins. Horse meat is interesting not only in its proportion of proteins but also in the distribution of different amino acids. The few studies on the amino acid content of horse meat show a strong percentage of essential amino acids such as lysine, leucine, and isoleucine. (*See* **Amino Acids**: Properties and Occurrence; **Protein**: Chemistry.)

Minerals and Vitamins

Principal minerals As shown in Table 3, horse meat possesses a low sodium content (21 mg per 100 g on average) and is therefore suitable for those on low-sodium diets; this meat has a strong image of being 'good for the health.' The red color of the adult meat can darken and turn brown rather quickly as a result of oxidation, which makes the meat difficult to present and market. Refer to individual minerals.

Trace elements There are heavy metals such as cadmium, zinc, and lead in horse meat. Practically all heavy metals are present but in very small quantities, with no risk of toxicity. (*See* **Heavy Metal Toxicology**.)

Vitamins The few reported findings in the literature suggest the presence of few fat-soluble vitamins and

Sulfur	10

more water-soluble vitamins in horse meat. (*See* **Vitamins**: Overview.)

Hygienic Qualities

Horse meat is reputed for its hygienic qualities as it is consumed very fresh. It is even common for minced horse meat to be eaten raw.

Parasitic and Microbial Contaminations

Horse meat is naturally not very contaminated. Although it is claimed to be safe, it must be fresh to be eaten raw or lightly cooked. In fact, its richness in glycogen can encourage the growth of microorganisms. Contamination often occurs at the surface and can easily spread, especially as the meat is often minced. A strict code of hygiene is necessary. (*See* **Contamination of Food**.)

Parasitic infections are rare but must be given special attention. Lesions of the digestive tract must be watched for as well as similar signs of the effects of parasites in both living and dead animals. (*See* **Parasites**: Occurrence and Detection.)

Bacteria such as *Salmonella* are the main agents of contamination of horse meat. They are easily destroyed by cooking heat, but as the meat is often consumed either without being fully cooked through or even raw, they can survive in the food. A very strict code of hygiene is therefore required when working with horse meat in the slaughterhouse and in the butcher's shop.

The transmission of the parasitic disease trichinosis through the consumption of horse meat was unknown until roughly 1975. The disease can be spread amongst carnivores (e.g., dogs, cats, foxes) rodents (e.g., badgers, rats) and omnivores (e.g., pigs, boars, bears, humans), and infestation in horses is quite unusual.

Processing

Horse meat lends itself to butchering and salting processes, either for typical horse meat products (e.g., sausages, saveloy, andouilles, smoked hams) or else in conjunction with other meats. This process has been developed in Belgium, Italy, and France as well as in Japan, where hams are reconstituted, often mixed with other meats. Also in Japan, horse meat is frequently incorporated into corned beef. (*See* **Meat**: Preservation.)

Conclusion

Horse meat shows many advantages in terms of processing and storage, and organoleptic, nutritional, and hygienic qualities.

Some of the special characteristics of this meat are carried over from generation to generation: it is the meat to treat anemia; it is meat suitable for tuberculosis diets; it is the meat for energy; these are special characteristics familiar to nutritional biochemists.

These characteristics, in the current context of competition between meats and other available sources of proteins, and as a result of changes in eating habits in recent years, make horse meat, at the very least, a most interesting meat with the following advantages: high butcher yields; high levels of glycogen and good-quality proteins (essential amino acids); low contents of salt and lipids; tenderness associated with collagen characteristics and their distribution; a characteristic sort of fatty tissue with a predominance of unsaturated fatty acids; safe in terms of residues or contamination provided that the conditions of slaughter, transport, storage, and distribution are satisfactory in order to reduce as much as possible the dangers of microbial infection.

Ultimately, horse meat not only possesses obvious dietary qualities for people in good health and particularly for children, but also is very suitable for those on special diets or everyday diets, e.g., diabetics, obese subjects, those with gout, hypercholesterolemia, hypertriglyceridemia, gastrectomy or kidney insufficiency, and those following a residue-free diet or a low-sodium diet.

HUNGER

J Blundell and A Gillett, The University of Leeds, Leeds, UK

Hunger and the Regulation of Appetite

Hunger refers to a drive or state of motivation that impels animals to search for food. In humans, hunger represents a subjective experience or feeling that is associated with the desire to obtain and eat food. This is how the word 'hunger' is used in everyday social discourse, and scientific methods have been applied to understand the mechanisms underlying this common subjective experience. From a functional point of view, hunger achieves a purpose: that nagging feeling, the presence of which serves to stimulate thoughts about food and eating, is useful and reminds us that the body needs food. In this way, hunger can be seen to possess a clear biological function.

Measurement of Hunger

How do we describe the experience of hunger as it occurs in everyday life? More than 25 years ago, a serious attempt was made to investigate this issue by giving people a questionnaire that asked about physical sensations in a number of bodily areas, moods, urges to eat, and preoccupation with thoughts of food. The questionnaire was completed before and after eating. It was found that the observation 'I feel hungry,' is typically based on the perception of bodily feelings, which at times may be very strong. Gastric sensations, a hollow feeling, or stomach rumbling, are frequent indicators of hunger, although people also report sensations in the mouth, throat, and head. These accompany more diffuse feelings of restlessness and excitability as well as an urge to eat. In one celebrated project, known as the Minnesota experiment, a group of volunteers were placed on a semistarvation diet for 6 months, and their experience of hunger was extreme. Nearly two-thirds reported feeling hungry all the time, and a similar proportion experienced physical discomfort due to hunger. Subjects experienced a marked increase in what was referred to as 'hunger pain.' For some, this pain, vaguely localized in the abdomen, was of mild discomfort. For others, it was intensely painful.

Eating changes both the pattern of physical sensations and the accompanying emotional feelings, with unpleasant and aversive sensations being replaced by pleasant sensations. For example, an aching stomach becomes relaxed, and the feeling of excitement and irritability is replaced by one of contentment.

Despite a great deal of individual variability in the perception of these sensations, hunger can be associated with clear symptoms; it is partly through reference to these that people can make judgements about the intensity of their hunger experience. The measurement of hunger, desire to eat, or urge to eat is most commonly conducted using fixed-point or visual-analog scales. Respectively, these require the subject to choose a number from a scale or a point on a line that corresponds to their current state of hunger. Careful presentation of these scales to people who understand what is being asked of them will yield meaningful information. More importantly, quantifying the subjective experience of hunger makes it a state, which is amenable to scientific investigation. Consequently, hunger can be described qualitatively in terms of the sensations with which it is associated, and it can also be measured quantitatively. This means that the significance of hunger can be understood through its structure and by its intensity. In recent years, the visual analog scale technique has been incorporated into the screen of a small handheld computer. This device, called the Electronic Appetite Rating System (EARS) provides a convenient and user-friendly way of monitoring hunger during the course of a day.

Hunger, Eating Patterns and the Satiating Power of Food

If hunger is the feeling that reminds us to seek food, then the consumption of food is the action that diminishes hunger and keeps it suppressed for a certain period of time, perhaps until the next meal or snack. The capacity of food to reduce the experience of hunger is called the satiating power or satiating efficiency. This power is achieved by certain properties of the food itself engaging with various physiological and biochemical mechanisms within the body that are concerned with the processing of food once it has been ingested. The satiating power of food therefore results from a variety of biological processes and is an important factor in the control of hunger. Some foods have a greater capacity to maintain suppression over hunger than other foods. (*See* **Satiety and Appetite**: Food, Nutrition, and Appetite.)

How is hunger related to the overall control of human appetite and food consumption? The feeling of hunger is an important component in determining what we eat, how much we eat, and when we eat. However, it must be seen in a context of social and physiological variables. On the one hand, eating patterns are maintained by certain enduring habits, attitudes, and opinions about the value and suitability of foods and overall liking for them. These factors, derived from the cultural ethos, largely determine the range of foods that will be consumed, and sometimes the timing of consumption. The intensity of hunger experienced may also be determined, in part, by the culturally approved appropriateness of this feeling.

On the other hand, normal hunger is more importantly associated with the events surrounding meals – so-called periprandial circumstances – and the periods between meals. Thus, hunger can be considered to arise from an interaction between the physiological requirements of the body for food (or particular nutrients) and the capacity of food to satisfy these requirements. Hunger will therefore be successively stimulated and suppressed, giving rise to a diurnal rhythm. This rhythm, and the relationship between hunger and eating, may be modulated by certain social factors (e.g., distressing psychological events) or interrupted by some disease states.

Hunger and the Satiety Cascade

When food consumption reduces hunger and inhibits further eating, two processes are involved. For technical precision and conceptual clarity, it is useful to describe the distinction between satiation and satiety. Both terms may be assigned workable operational definitions (i.e., definitions that depend upon measurable events). Satiation can be regarded as the process that develops during the course of eating and eventually brings a period of eating to an end. Accordingly, satiation can be defined by the measured size of the eating episode (volume or weight of food, or value of the energy content). Hunger declines as satiation develops and usually reaches its lowest point at the end of a meal. Satiety is defined as the state of inhibition over further eating that follows the end of an eating episode and arises from the consequences of food ingestion. The intensity of satiety can be measured by the duration of time elapsing until eating is recommenced, or by the amount consumed at the next meal. The strength of satiety is also measured by the duration of the suppression of hunger. As satiety weakens, so hunger is restored. Figure 1 indicates the changes that occur in the rating of hunger during a meal (as satiation develops) and following a meal (as satiety evolves). It can be seen that the measurement of hunger is an important index of the degree of satiation and satiety.

In the view of some researchers, satiation and satiety can be referred to as intrameal satiety and intermeal satiety, respectively. What mechanisms are responsible for these processes? It is clear that the mechanisms involved in reducing hunger and in maintaining the suppression over hunger range from those that occur when food is initially sensed, to the

effects of metabolites on bodily tissues following digestion and absorption (across the wall of the intestine and into the bloodstream). By definition, satiety is not an instantaneous event but occurs over a considerable time period; it is therefore useful to distinguish different phases of satiety, which can be associated with different mechanisms. This concept is illustrated in Figure 2.

Four mediating processes are identified: sensory, cognitive, postingestive, and postabsorptive. These maintain inhibition over hunger (and eating) during the early and late phases of satiety. Sensory effects are generated through the smell, taste, temperature, and texture of food, and it is likely that these factors inhibit eating in the very short term. Cognitive effects represent the beliefs held about the properties of foods, and these factors may help to inhibit hunger in the short term. The category identified as postingestive processes includes a number of possible actions, including gastric distension and rate of gastric emptying, the release of hormones such as cholecystokinin, and the stimulation of physicochemically specific receptors along the gastrointestinal tract. The postabsorptive phase of satiety includes those mechanisms arising from the action of metabolites after absorption across the intestine and into the blood system. This category embraces the action of chemicals such as glucose and amino acids, which may act directly on the brain after crossing the blood–brain barrier or may influence the brain indirectly via neural inputs following stimulation of peripheral chemoreceptors. The most important suppression and subsequent control of hunger is brought about by postingestive and postabsorptive mediating processes.

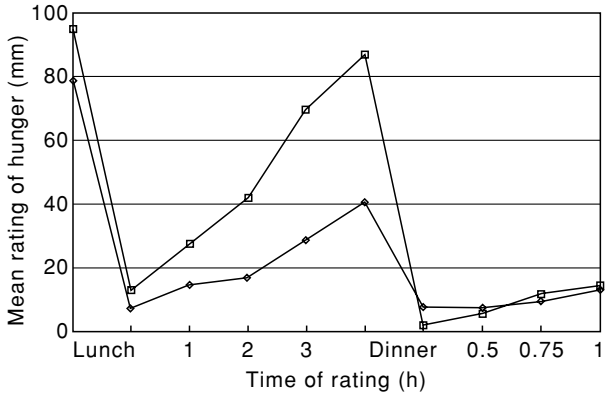

Figure 1 Profiles of the ratings of the subjective experience in two groups of subjects, one of which ate a large lunch (◇) and the other a lunch 50% smaller (□). Each meal suppressed hunger, but the intensity of hunger recovered more rapidly following the small meal. Four hours after the first meal, subjects were given another meal to eat (dinner), and hunger was again suppressed. Hunger ratings reflect the amount of food consumed and the timing of meals.

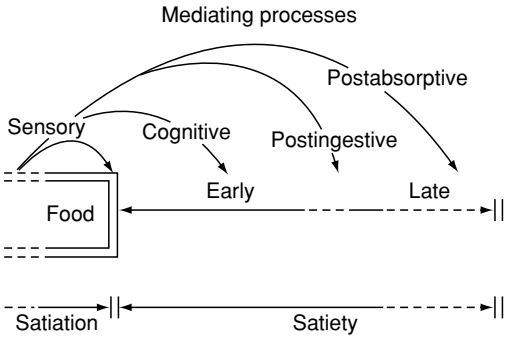

Figure 2 Satiety cascade. This diagram represents the mediating processes, arising from food consumption, that influence the feeling of hunger and determine the satiating efficiency of the food.

Conditioned Hunger

It should be kept in mind that the psychobiological system for appetite control has the capacity to learn, i.e., to form associations between the sensory and postabsorptive characteristics of foods. This means that it will be useful to distinguish between the unconditioned effects of foods, i.e., those in which the natural biological consequences of food processing in the gut are reflected in satiety, and the conditioned effects that come into play owing to the links developed between sensory aspects of food – particularly those that are tasted – and later metabolic effects generated by the same food. The sensory characteristics (or cues) therefore come to predict the impact that the food will later exert. Consequently, these cues can suppress hunger according to their relationship with subsequent physiological events. However, the potency of this mechanism depends upon the stability and reliability of the relationship between tastes (sensory cures) and physiological effects (metabolic consequences) of food. When there is distortion or random variation between sensory characteristics and nutritional properties, the conditioned control of hunger is weakened or lost. Therefore, learned hunger will not be an important factor when the food supply contains many foods with identical tastes but differing metabolic properties.

Is Hunger the Cause of Eating?

In searching for an answer to this question, we can begin by considering whether hunger is a necessary or a sufficient condition for eating to occur. Since hunger may be present, but a person may volitionally prevent

themselves from eating (e.g., someone undertaking a fast for moral or political conviction), hunger is not a sufficient condition. Occasions can also be imagined where a person would eat, if food was particularly tempting, where no hunger was being experienced.

Therefore, it appears that hunger is neither a sufficient nor a necessary condition for eating, i.e., the relationship between hunger and eating is not based on biological inevitability. However, under many circumstances, there is a synchronous relationship between the pattern of food intake and the rhythmic oscillation of hunger. Moreover, the results of many studies confirm the strong relationship between the intensity of experienced hunger sensations and the amount of food consumed. For example, when hunger and eating have been monitored continually, it has been reported that 'the correlation using hunger ratings and intake during the same hour of the day was $r = < 0.5$ ($P < 0.02$). That is, hunger ratings at the start of each hour were correlated with reported intake in the hour following each hunger rating.' In addition, significant correlations have been found between hunger ratings prior to a lunch and subsequent intake of fat, protein, and energy, indicating that these measures of subjective hunger provide a valid index of actual food intake. The correlations found in almost all studies indicate that, in many circumstances, the measured intensity of hunger reliably predicts the amount of food that will be consumed. This fact has led to the proposal that there is a causal connection between hunger and the size of a following meal. Table 1 shows measured correlations between hunger, food intake, and related subjective experiences.

These observations provide the basis for a working conceptualization. The correlations are sufficiently strong and reliable to allow us to act as if hunger is a cause of eating. In actuality, it is probably the case that common physiological mechanisms induce changes both in hunger and in the eating response. Therefore, we can consider an appetite control system in which hunger, eating, and physiological mechanisms (of the satiety cascade) are coupled together. However, the coupling is not perfect, and there will be circumstances where, for example, a physiological treatment will change eating but not hunger. In other words, uncoupling can occur. However, when this happens, e.g., under certain conditions of fasting or in disordered eating, the mechanisms responsible can provide useful information about the role of hunger in the overall control of appetite. It should be noted that, although a number of individuals often deny that sensations of hunger are related to when eating occurs, under scientifically controlled conditions, there is usually a strong relationship between hunger and eating. (*See* **Sensory Evaluation**: Sensory Characteristics of Human Foods.)

Table 1 Intercorrelations between ratings of hunger, other subjective sensations, and measure of food intake observed in experimental studies in lean and obese subjects (all correlation coefficients shown are statistically significant)

	Food intake (kcal)	*Hunger*	*Desire to eat*	*Fullness*
Lean subjects				
Hunger	0.75			
Desire to eat	0.77	0.96		
Fullness	−0.69	−0.93	−0.97	
Prospective consumption	0.80	0.97	0.95	−0.91
Obese subjects				
Hunger	0.65			
Desire to eat	0.68	0.96		
Fullness	−0.54	−0.75	−0.77	
Prospective consumption	0.66	0.88	0.89	−0.78

Disorders of Hunger

The clinical eating disorders, anorexia nervosa and bulimia nervosa, are commonly believed to encompass major disturbances of hunger. Yet the role that hunger may play is not entirely clear. Contrary to the literal meaning of the term, 'anorexia' is not experienced as a loss of appetite. Rather, clinicians recognize that anorexics may endure intense bouts of hunger during their self-imposed restricted eating. For some, their strength in resisting intense episodes of hunger provides a feeling of self-mastery and control that is absent in most other areas of their lives. Anorexics therefore overcome their feelings of hunger. However, there is some evidence to suggest that in conditions of total starvation, hunger may become temporarily diminished. However, once eating is recommenced, hunger may return rapidly and with extreme intensity. (*See* **Anorexia Nervosa**.)

Like anorexia, bulimia finds its literal meaning in an altered state of hunger – 'ox hunger.' But again, the term is imprecise. Close analysis of the physiological states, which characteristically provide an eating binge, show hunger to be lower than it is prior to a normal meal. In addition, while the urge to eat may be strong during a binge, the large amount of food consumed implies some defect in satiation rather than in hunger. Research that has monitored hunger in eating disordered patients during a simple meal describes both great individual variability in the hunger experience and examples of extreme disorganization. In some cases, hunger appears quite dissociated from the circumstance of eating. It is likely that a stable

eating pattern is necessary in order to normalize the experience of hunger, and this may take a long time to establish. (*See* **Bulimia Nervosa**.)

Obesity is another condition in which hunger is often assumed to be impaired. In seeking a cause for excess weight, overeating has been regarded as being caused by high levels of hunger. Although it is now accepted that, on average, obese individuals have a higher energy intake than lean people, this cannot necessarily be assigned to higher levels of hunger. It appears that the experience of hunger is similar in lean and in most obese subjects. Studies suggest that in general, there is no gross fault in the obese food-intake regulation system. Any 'fault' is likely to be subtle. An indication of this comes from the response to a reduced-energy diet. Obese people, in common with those of normal weight, respond to a reduction in their energy intake by increased feelings of hunger. Alternatively, anorectic drugs or nutrients that suppress hunger appear to do so similarly in obese and lean people. Attempts to lose weight by dieting may fail because of an inability to manage hunger. However, it should be recognized that for some very obese people, the sensation of hunger occurs in an eccentric fashion and is not related to periods of eating. Some people can report strong feelings of hunger and fullness simultaneously, (*See* **Obesity**: Etiology and Diagnosis.)

Hunger and Health

The analysis of the phenomenon of hunger, the influencing mechanisms, and its relationship to the regulation of food intake indicate that hunger is a potent factor in the maintenance of general health. In societies where food is plentiful, the relatively mild experiences of hunger play a biological useful role in the orderly regulation of eating patterns. When food is scarce, the power of hunger can drive people to desperate deeds. In certain disease states, a very intense hunger or its absence can indicate the severity of the underlying pathology. In other extreme circumstances, hunger is forced out of synchrony with physiological mechanisms, eating behavior, or both. This labile or disregulated hunger reflects the pathology of the appetite system. The drive to eat, identified as hunger, is therefore a significant marker of health. If the mechanisms underlying this drive are compromised, hunger can become difficult to control. (*See* **Malnutrition**: The Problem of Malnutrition.)

HYPERLIPIDEMIA (HYPERLIPIDAEMIA)

J P D Reckless and J M Lawrence, University of Bath, Combe Park, Bath, UK

Lipids

Lipids are a heterogeneous group of substances that play key roles in normal physiology. Two groups are important – that where a main component includes one or more fatty acids (such as triglycerides and phospholipids) and that where the main component is a steroid nucleus (such as cholesterol and steroid hormones). Both groups are relatively insoluble in water. The lipoprotein transport system carries these hydrophobic compounds through the aqueous medium of blood plasma to their site of use, in a carefully regulated process. Lipoproteins consist of a package of triglycerides, cholesterol (free and esterified), phospholipids, and apolipoproteins, with a hydrophilic shell and a hydrophobic core (Figure 1). The sites of synthesis are the gut and liver. The main lipoproteins are high (HDL), low (LDL), and very low (VLDL) density lipoproteins, and chylomicron7s. Each has a different group of surface apolipoproteins, pivotal in determining the site, mechanism, and speed of lipoprotein metabolism. The precise molecular composition in each lipoprotein class varies considerably.

Hyperlipidemia means high levels of fats in the blood, which may be physiological postprandially. Pathological hyperlipidemia results from disordered metabolism of the lipoproteins with either excess production, altered clearance, or both. It is most commonly multifactorial, involving both environmental and intrinsic factors. Many genetic disorders are now well recognized, causing various degrees of hyperlipidemia or dyslipidemia (altered composition). Genetic studies have helped the understanding of lipoprotein metabolism.

This review discusses normal lipoprotein metabolism, focusing on hyperlipidemia. As treating hyperlipidemia has significant benefits in terms of long-term health, having an understanding of normal and abnormal lipoprotein metabolism is becoming increasingly important.

The Intestine

Most dietary fats are triglycerides. These are hydrolyzed to mono- and diacylglycerols, nonesterified fatty acids (NEFA) and glycerol by pancreatic or gut lipases, and absorbed as mixed micelles in the small intestine. In the intestinal cells, triglycerides are reformed and interact with apolipoprotein B-48 (apoB48) to form chylomicrons. ApoB48 is the structural protein for chylomicrons. Each chylomicron has one molecule of apoB48 and carries very large numbers of triglyceride molecules. Precise numbers vary widely, as does the chylomicron size, depending on the diet (diameter 100–1000 nm). Chylomicrons also accommodate any dietary cholesterol absorbed

(usually less than 0.5 g per day). They are released into the intestinal lymphatics and subsequently into the circulation via the thoracic duct.

Chylomicron Metabolism

In the systemic circulation, chylomicrons receive apolipoproteins additional to apoB48, particularly apolipoprotein C (apoC) and apolipoprotein E (apoE), from HDL (Figure 2). One apoC, apoC-II, activates the enzyme lipoprotein lipase (LPL) and facilitates ligand/enzyme binding between LPL and chylomicrons. LPL is found widely on capillary endothelial tissues of many organs including adipose tissue and skeletal and cardiac muscle. The activated enzyme hydrolyzes chylomicron-triglyceride, and NEFA are released for uptake into tissues to be stored or used as energy. As triglyceride is removed, the relative concentration of cholesterol rises, and the lipoprotein becomes smaller and denser. Excess surface components of phospholipids, free cholesterol, and apolipoproteins (but not the apoB48) are transferred to HDL. The efficiency of this process depends on the activity of LPL and also the VLDL triglyceride level in the circulation, as VLDL competes with chylomicrons for LPL. The chylomicron remnant is removed by liver receptor uptake, dependent on multiple copies of apoE on the remnant surface. This receptor is structurally related to the LDL receptor (*see* Low Density Lipoprotein) as a member of the LDL-supergene family and is named the LDL receptor-related protein (LRP). The affinity of the binding depends on the apoE phenotype. Chylomicron remnant removal effectively delivers dietary cholesterol and residual triglyceride to the liver.

Very Low Density Lipoproteins (VLDL)

VLDL are the other major triglyceride-rich lipoproteins (Figure 3). They carry endogenous, hepatically

synthesized triglycerides, largely derived from dietary carbohydrate or from plasma NEFA, and are of a large size (30–60 nm diameter). Each VLDL particle has a single molecule of a larger apoB form, apoB100, with other apolipoproteins (apoE and apoCs) being acquired in plasma from HDL. Like apoB48, apoB100 has a structural role, but also a functional role as a ligand for catabolism. The same gene codes for apoB in both gut and liver, but in the gut, there is post-translational editing of messenger RNA, resulting in a stop codon at position 2153. A truncated (48%) apoB48 is then formed as the structural apolipoprotein, whereas in VLDL, the whole 100% of apoB is synthesized to provide also the functional ligand component.

VLDL size is dependent on the triglyceride content, with large buoyant triglyceride-enriched VLDL being formed at times of triglyceride excess. These large VLDL may be a poorer substrate for the usual path of metabolism involving apoCII-dependent activation of LPL and apoCII-LPL binding similar to that seen with chylomicrons, and thus have a longer residency time in the blood. As triglyceride is hydrolyzed, VLDL particles shrink with loss of surface components to HDL and subsequent catabolism to LDL via IDL. This process is less efficient in the presence of high triglyceride levels and large buoyant VLDL. A longer plasma residency time allows a greater exchange of triglyceride from VLDL into LDL and HDL with reverse exchange of cholesterol ester, mediated by cholesterol ester transfer protein (CETP). This produces cholesterol-enriched VLDL remnants that are less readily metabolized to LDL and can be removed by alternative, but potentially atherogenic, pathways. Additionally, this process produces triglyceride-enriched LDL that shrink as some triglyceride is hydrolyzed in the liver by another endothelial enzyme, hepatic lipase, producing small, dense LDL_3 (see below).

Intermediate Density Lipoproteins (IDL)

Intermediate density lipoproteins are formed as an intermediate step in the normal metabolism of VLDL. They are catabolized rapidly, and the concentration in the plasma is therefore usually very low. IDL are either taken up directly by the liver through binding of surface apoE on IDL to apoE or apoB100/apoE receptors, or are converted to LDL. The exact mechanism of this is unclear but involves the loss of

apoE and the C-apolipoproteins and further triglyceride hydrolysis by hepatic lipase.

Low Density Lipoproteins (LDL)

LDL are effectively responsible for delivery to tissues of cholesterol used for cell membrane synthesis and repair, and for processes such as synthesis of steroid hormones and vitamin D (Figure 4). Entry into cells occurs either in a concentration-dependent nonspecific manner or, more importantly, by a very closely regulated receptor-mediated pathway. LDL bind to specific LDL apoB100/apoE receptors on cell membranes, and LDL–receptor complexes are internalized and undergo lysosomal degradation. The cholesterol ester is hydrolyzed to free cholesterol, while most of the LDL receptors are recycled. The highest concentration of receptors is found in the liver.

In order to maintain cellular function, the cell content of cholesterol is very tightly regulated. High intracellular levels of free cholesterol lead to:

1. Suppression of endogenous cell cholesterol synthesis by inhibition of the rate limiting enzyme 3-hydroxy, 3-methylglutaryl coenzyme-A reductase (HMG CoA-reductase).
2. Suppression of apoB-100/apoE receptor synthesis.
3. Increased activity of acyl-coenzyme A cholesterol acyl-transferase (ACAT), leading to increased cholesterol esterification.

LDL particles are not homogeneous and can be divided on the basis of size and density into LDL_1, LDL_2, and LDL_3. LDL_1, the largest and least dense, is a better substrate for the LDL receptor and is also less easily oxidized. Individuals with higher levels of LDL_1 relative to LDL_3 are said to have a type A phenotype, and those with the converse are said to have a type B phenotype. Excess LDL_3 is associated with an excess risk of coronary heart disease (*see* Hyperlipidemia and the Origin of Clinical Atheroma below).

High Density Lipoproteins (HDL)

HDL are the smallest, most dense of the lipoproteins, and are involved as cholesterol acceptors in reverse cholesterol transport from the peripheral tissues to the liver where the cholesterol is either excreted into the bile or assembled into other lipoproteins (Figure 5). HDL are synthesized in both the liver and gut. Initially secreted as disk-shaped protein and phospholipid bilayers, they mature by acquiring lipid and protein components from intracellular and extracellular fluids and from other lipoproteins to form spherical particles of 5–15 nm diameter. The predominant and structural apolipoproteins of HDL are apolipoproteins A-I and A-II, with significant amounts of apoCs and apoE, but with no apoB. HDL particles are divided by size and density into smaller and denser HDL_3 and larger and less dense HDL_2. HDL_2 particles tend to contain apo A-I only and HDL_3 particles tend to contain both apoAI and apoAII. The presence of larger, less dense HDL_2 correlates with more efficient reverse cholesterol transport.

The mechanism of reverse cholesterol transport is gradually being elucidated. Evidence suggests that cells replete with cholesterol express HDL-binding sites on the plasma membrane. Intracellular signaling promotes hydrolysis of stored cholesterol esters, movement of free cholesterol to the cell surface, and transfer down a concentration gradient to HDL. Surface cholesterol is esterified by lecithin cholesterol acyl transferase (LCAT), an HDL-associated enzyme. The resulting hydrophobic cholesterol ester enters the HDL core, leaving the surface cholesterol depleted and thus maintaining the concentration gradient with the cell membrane. Cholesterol esters are transferred from HDL by CETP to VLDL, IDL, and LDL. Cholesterol esters are delivered to the liver substantially by receptor-mediated LDL uptake, and some directly delivered from HDL. Synthesis of HDL depends on transfer of surface components from VLDL catabolism. When there is hypertriglyceridemia, the number and size of VLDL particles rise. As larger VLDL particles tend to be catabolized more slowly, the availability of surface components for HDL is reduced, hence partly explaining the frequent inverse relationship between the concentrations of VLDL and HDL.

Consequences of Hyperlipidemia

While severe hypertriglyceridemia can lead to pancreatitis, the major consequence of hyperlipidemia is accelerated atherogenesis with premature coronary heart disease (CHD), stroke, and peripheral vascular disease. The major risk factors for early CHD are hypertension, cigarette smoking, hyperlipidemia, and diabetes mellitus, risk increasing markedly when multiple risk factors are present.

Hyperlipidemia and the Origins of Clinical Atheroma

Atheroma occurs in large elastic and muscular arteries such as the aorta, coronary, femoral, and carotid

arteries, and especially at predisposed sites such as bifurcations where there is flow disturbance. Plaques form on the basis of fatty streaks that may be present very early in life. Damage to the endothelial lining from high blood pressure, local injury, or poor oxygen supply results in increased permeability, enabling lipoproteins to pass more easily into the subendothelial space. LDL and triglyceride-rich lipoprotein remnants are atherogenic. The influx into the arterial wall depends on both the concentration and the size of the LDL particles in plasma. The higher the concentration of LDL in the plasma, the greater is the degree of influx, and smaller denser LDL_3 particles cross the endothelium more easily. LDL in the arterial wall undergoes a number of changes including oxidation with LDL_3 particles being more susceptible. The oxidized LDL particles are engulfed by scavenger macrophages. These macrophages are formed from monocytes that have traversed the damaged endothelial wall and are immobilized in response to a number of chemical signals. In response to altered LDL, the macrophages express acetylated LDL receptors and take up LDL to become lipid rich foam cells. These undergo apoptosis producing a lipid-rich extracellular medium. Smooth muscle cells migrate from the arterial media in response to this process. These proliferate and produce a connective tissue matrix rich in collagen, elastin, and proteoglycans forming the plaque cap, as part of a damage-healing process.

Plaques may be asymptomatic. In contrast, they may result in a significant reduction in blood flow, producing symptoms such as angina or claudication. A plaque that has a thin cap and a large lipid core may be unstable and susceptible to rupture. In such plaques, the excess macrophage component produces metalloproteinases that break down the collagen matrix (synthesized by smooth muscle cells), making cap thinning and plaque rupture (especially at the shoulder of the cap) more likely. Should this happen, acute occlusion of a vessel may occur, causing syndromes such as acute myocardial infarction.

Classification of Hyperlipidemia

Hyperlipidemia normally refers to high concentrations of the blood lipids, cholesterol, and triglycerides. These high levels reflect underlying changes in lipoproteins, and could be caused by overproduction, reduced catabolism or both. Thus, high levels of triglycerides reflect elevated concentrations of the triglyceride-rich lipoproteins, chylomicrons and VLDL, and their remnants. An increase in cholesterol concentration usually reflects an increase in LDL, with or without an accompanying increase in VLDL. Occasionally, raised total cholesterol may be due to a very high HDL alone.

Hyperlipidemia may be secondary to other medical disorders or therapy, or it may be primary. Primary hyperlipidemia may be caused by a single gene defect or, more commonly, by a polygenic background influenced by environmental factors.

Originally, primary (inherited) disorders were classified on the physicochemical characteristics of lipoproteins defined in the laboratory using ultracentrifugation or electrophoresis (Table 1). Treatment of a patient's hyperlipidemia often results in changes in the lipoprotein pattern and laboratory characteristics, so that such a classification has limited value. It is more useful to define the disease or metabolic defect, and as this is becoming increasingly possible, efforts to do this should always be made. Secondary causes of hyperlipidemia are listed in Table 2. Obesity, diabetes, and excess alcohol commonly act on a genetic background to produce hyperlipidemia.

Hypercholesterolemia

Common or Polygenic Hypercholesterolemia

In the population as a whole, cholesterol levels approach a normal distribution. Epidemiological

Table 1 Classification of hyperlipidemia (Fredrickson's classification, as modified by the World Health Organization)

Type of hyperlipidemia	*Cholesterol*	*Triglyceride*	*Lipoprotein raised*
I		Raised	Chylomicrons
IIa	Raised	Normal	LDL
IIb	Raised	Raised	LDL plus VLDL
III	Raised	Raised	IDL
IV	Normal or raised	Raised	VLDL
V	Raised	Markedly raised	Chylomicrons plus VLDL

Table 2 Commoner secondary causes of hyperlipidemia

Cause	*Example*
Metabolic and nutritional	Obesity Alcohol
Endocrine	Diabetes mellitus Hypothyroidism Pregnancy
Drugs	β-blockers Thiazides Estrogens
Renal disease	Chronic renal failure Nephrotic syndrome
Liver disease	Biliary obstruction

studies have shown that the risk of coronary artery disease rises with the cholesterol level. Several large-scale intervention studies have demonstrated that lowering cholesterol reduces CHD risk in both primary and secondary (after the event) prevention.

In addition to common or polygenic hypercholesterolemia, a number of well-defined inherited syndromes are well recognized resulting in hypercholesterolemia and an increased CHD risk.

Familial Hypercholesterolemia (FH)

Familial hypercholesterolemia is the commonest disease in Western populations to be caused by a single dominant gene defect. It is characterized by a raised cholesterol from birth, subsequent development of cutaneous and tendon xanthomata, and premature vascular disease (Figure 6). The gene coding the LDL receptor is found on chromosome 19. Over 150 different LDL receptor mutations have been characterized, affecting receptor synthesis and function. Heterozygous FH (1 mutant and 1 normal gene) affects 0.2% of the population, the homozygous condition occurring at a rate of 1:1 000 000. A true homozygote will have two copies of the same defect, but compound heterozygosity (with two different defects) is more common.

Homozygous FH is characterized by extreme hypercholesterolemia (cholesterol is approximately four times normal) with cutaneous and tendon xanthomata and corneal arcus beginning in childhood. Significant atheromatous involvement of the aortic root with coronary ostial stenosis is present by puberty, and death from coronary heart disease usually occurs prior to the age of 20 in untreated individuals.

Figure 6 Xanthomata in the extensor tendons of the hands in familial hypercholesterolemia. Reproduced from Hyperlipidaemia, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

Tendon xanthomata are also pathognomonic of heterozygous FH occurring in some adults. LDL cholesterol is typically twice normal. Untreated, it leads to CHD in 50% of males by the age of 50 years, and 50% will have died by the age of 60. Fifty per cent of females will have clinical CHD by age 60 when 15% will have died.

The diagnosis of homozygous FH is usually straightforward. Heterozygous FH should be considered in any patient with hypercholesterolemia and personal or family premature CHD. Tendon xanthomata in any family member almost certainly establish the diagnosis, as does high LDL in children.

FH is also caused by abnormalities in apoB such as in familial defective apolipoprotein B-100 where a glutamine-for-arginine substitution in the amino acid 3500 codon in apoB produces an abnormal truncated apoB with impaired binding to the LDL receptor. Like classical FH, it is also an autosomal dominant, affecting about one in 600 of the population.

Familial Combined Hyperlipidemia (FCH)

FCH was first described in 1973 in families of hyperlipidemic patients surviving a myocardial infarction. Less clearly defined than FH, it affects perhaps 1–2% of the population. It is heterogeneous, the etiology remaining uncertain without a single gene defect having been found. Diagnosis requires multiple affected family members and is complicated by variation in time of lipid levels that on occasion may be normal. Cholesterol, triglycerides, or both may be raised with type IIa, IIb, or IV phenotypes.

FCH predisposes to premature atherosclerosis and may be present in 10% of patients with CHD before age 60. Elevated apoB levels are frequently found that may have a central role in atherogenesis in FCH, and apoB concentrations can be a better predictor of CHD than LDL cholesterol. LDL and VLDL each contain one apoB100 molecule, so when apoB is raised, there are increased plasma particle numbers. As LDL numbers increase, the apoB:LDL cholesterol ratio rises, as each particle is relatively cholesterol-poor. LDL particles in FCH are smaller, denser, and more atherogenic (see hyperlipidemia and the origins of clinical atheroma). LDL_3 synthesis is enhanced by the presence of hypertriglyceridemia.

In FCH, no mutations have been found in the apoB structural locus on chromosome 2, but an apoB-raising allele of uncertain location may occur in

some FCH patients. Families heterozygous for LPL or apoC-II deficiency (*see* Severe hypertriglyceridemia below) may exhibit a phenotype similar to FCH. Further work is needed to characterize the FCH genetic background. Hyperapobetalipoproteinemia is a related condition characterized by raised apoB with normal LDL associated with premature CHD.

Hypertriglyceridemia

Hypertriglyceridemia results from overproduction of triglyceride-rich lipoproteins and/or a catabolic defect, due to either a primary lipoprotein disorder or secondary to associated diseases.

Severe hypertriglyceridemia

Severe hypertriglyceridemia (triglycerides > 11 mmol l^{-1}) usually results from secondary factors (e.g., uncontrolled diabetes mellitus, obesity with insulin resistance, and excess alcohol) acting upon a less severe hyperlipidemia. Usually, treatment of the underlying problem will partly correct the hypertriglyceridemia. Inherited abnormalities of lipoprotein metabolism, producing severe hypertriglyceridemia, cause accumulation of chylomicrons with or without VLDL. This gives a pancreatitic, and rarely a CHD, risk.

Lipoprotein lipase deficiency A recessively inherited condition affecting one per million population, this deficiency is caused by mutations in the LPL gene on chromosome 22 resulting in defective function and chylomicron accumulation. Recurrent pancreatitis usually occurs in early adulthood. Eruptive xanthomata are characteristic, and hepatosplenomegaly and lipemia retinalis may occur, with triglycerides ≥ 100 mmol l^{-1}.

Apolipoprotein C-II deficiency ApoC-II activates LPL, and deficiency therefore presents similarly to LPL deficiency, although it is rarer.

Moderate hypertriglyceridemia

Moderate hypertriglyceridemia is often polygenic exacerbated by secondary causes. It is seen frequently with type 2 diabetes and obesity and is an independent CHD risk factor, particularly when associated with a low HDL cholesterol. High triglycerides result in reduced synthesis of HDL, more of which will be HDL_3, increased plasma levels of LDL_3, and a consequent increased risk of atheroma.

The Insulin Resistance Syndrome (see Table 3) This term was coined in 1988 to describe a cluster of abnormalities that frequently occur together in type 2 diabetes. These people are often hypertensive and obese with associated insulin resistance and hyperinsulinemia. A consequence of insulin resistance is increased catabolism of adipose tissue triglyceride with release of nonesterified fatty acids. In the liver, these are reformed into triglycerides and packaged as VLDL, with larger VLDL numbers and size, a lower HDL, and proportionately more LDL_3. This partly explains the threefold CHD increase seen in men with type 2 diabetes and the three- to fivefold increase in women.

Table 3 Features of the Insulin Resistance Syndrome

Syndrome X (The Insulin Resistance Syndrome)
Hyperinsulinemia
Impaired glucose tolerance
Hypertension
Increased triglyceride
Decreased HDL cholesterol

Mixed Hyperlipidemia

Mixed hyperlipidemia with elevated triglycerides and cholesterol is most commonly caused by polygenic elevation of VLDL exacerbated by lifestyle or environmental factors. It can manifest in FCH or FH.

Remnant Hyperlipidemia

Remnant hyperlipidemia is also known as dysbetalipoproteinemia, broad beta disease, or type III hyperlipidemia, and has been recognized as a distinct disease for 40 years. Remnant particles (IDL or β-VLDL) of partial chylomicron or VLDL degradation accumulate in about one in 5000 individuals, although the gene defect affects about 1% of the population. The diagnostic features are palmar crease and tuberous xanthomata (Figure 7). Important complications are premature CHD and peripheral vascular disease, the predisposition to the latter being more than with other dyslipidemias. It is more prevalent in men than women, manifesting at age 25–40. The clinical disorder is brought out by factors such as obesity, diabetes, and untreated hypothyroidism.

Apolipoprotein E(apoE) is a 299-amino-acid glycoprotein on all lipoproteins except LDL, serving as a high-affinity ligand with the LDL, LRP, and apoE receptors. A single gene controls ApoE expression, with three common alleles, ε2, ε3, and ε4, giving rise to the major isoforms, E2, E3, and E4. Six different phenotypes result: E2/E2, E2/E3, E2/E4, E3/E3, E3/E4, and E4/E4. E3/E3 is the most common, being found in 50–70% of populations. Isoforms differ in amino acid composition, apoE2 having a

Figure 7 Palmar crease xanthomata of dysbetalipoproteinemia (remnant hyperlipidemia). Reproduced from Hyperlipidaemia, *Encyclopaedia of Food Science, Food Technology and Nutrition*, Macrae R, Robinson RK and Sadler MJ (eds), 1993, Academic Press.

cysteine-for-arginine substitution at amino acid 158. This reduces binding to the apoE receptor to $\sim 1\%$ of normal. Homozygosity for apoE2 is the commonest genotype in remnant hyperlipidemia. However, the abnormality does not usually lead to hyperlipidemia, but rather to marginally lower LDL cholesterol levels, for it is only with secondary factors or an additional primary lipemia that the syndrome is clinically expressed.

Dietary Effects

Body weight

Obesity is an often ignored factor in hyperlipidemia, but it is important, not least because it is linked to other CHD risk factors such as blood, diabetes, and glucose intolerance. Weight control is important in treating hyperlipidemia, coupled with increased exercise.

Fatty Acids and Cholesterol

In Western societies, reducing saturated fat intake as a percentage of total food energy is associated with a reduction in total cholesterol and, to a lesser extent, triglycerides. Levels of LDL fall, possibly as a result of a direct reduction of cholesterol synthesis in the liver, or increased excretion as bile acids. If saturated fatty acids, such as palmitic acid, are replaced by mono- or polyunsaturated fatty acids, such as oleic or linoleic acids, similar falls in serum cholesterol occur.

Polyunsaturated fats of the n-6 series are primarily of plant origin. In addition to the above, they help reduce cholesterol by taking the place in the diet of saturated fats, which tend to be of animal origin and high in cholesterol. The n-3 series of fatty acids come mainly from oily fish. These fatty acids may also have beneficial effects on hemostatic variables of benefit in thrombosis prevention. They can lower triglyceride levels in some moderately hypertriglyceridemic individuals, but may have the disadvantage of increasing LDL cholesterol. Plant sterols and stanols may also reduce LDL by $\geq 10\%$.

The assumption that the amount of cholesterol in the diet is the major factor causing hyperlipidemia is false. It is the total fat intake as a percentage of the total energy intake, and also whether or not the fat is saturated, that matters most. Only a proportion of cholesterol in the diet is absorbed, and for each 100 mg eaten, the serum cholesterol will rise by only approximately $0.1\ \text{mmol}\,\text{l}^{-1}$. This response to dietary cholesterol shows a considerable variation between individuals.

Carbohydrate and Fiber

A high carbohydrate intake (particularly refined carbohydrate and simple sugars) may induce hypertriglyceridemia. Substantial amounts of soluble or mucilaginous fiber in the diet can lower LDL cholesterol, possibly by increasing the fecal loss of sterols. Individuals who eat a high-fiber diet also tend to eat less saturated fat, and less total fat.

Alcohol

Alcohol, a rich source of energy, can contribute to obesity and hypertriglyceridemia, and increase hepatic triglyceride synthesis and VLDL secretion. Substrates that undergo oxidation in the liver have to compete with alcohol, and therefore tend to be available for increased triglyceride synthesis. The tendency to develop severe hypertriglyceridemia secondary to alcohol is variable, but the risk of acute pancreatitis is also increased.

Introduction

An elevated blood arterial blood pressure is one of the more important public health problems, being asymptomatic, easily detectable, and often leading to lethal complications.

Definition

In adults a diastolic pressure below 85 mmHg is normal, between 85 and 89 mmHg is high normal, 90–104 mmHg is mild hypertension, 105–114 mmHg moderate hypertension, and 115 mmHg or greater is severe hypertension. When the diastolic pressure is below 90 mmHg, a systolic pressure below 140 mmHg indicates normal blood pressure, between 140 and 159 mmHg is borderline isolated systolic hypertension, 160 mmHg or higher is isolated systolic hypertension. Patients with arterial hypertension and no definable cause are said to have primary, essential, or idiopathic hypertension. More than 90% of all patients with arterial hypertension are considered to have essential or primary hypertension.

The various forms of arterial hypertension are listed below as a simplified classification of arterial hypertension:

1. Systolic hypertension with wide pulse pressure
   a. Decreased compliance of aorta
   b. Increased stroke volume
2. Systolic and diastolic hypertension (increased peripheral vascular resistance)
   a. Renal
   b. Endocrine
   c. Neurogenic
   d. Miscellaneous
   e. Unknown etiology

Individuals with a specific organ defect which is responsible for hypertension are defined as having a secondary form of hypertension.

The following information relates to the primary form of arterial hypertension. Cardiac output and peripheral vascular resistance are two basic hemodynamic parameters regulating mean arterial pressure. Cardiac output is usually normal in patients with essential hypertension. Elevated blood pressure appears to be associated with increased peripheral vascular resistance. Some investigators have speculated that the increased resistance may be due to lack of nitric oxide, the locally produced vasodilator that is produced by endothelial cells.

Genetic Factors in Hypertension

Animal studies and human investigations have indicated an important role of genetic factors in essential hypertension. Most studies support the concept that inheritance is probably multifactorial or that a number of different genetic defects each have elevated blood pressure as one of their phenotypic expressions.

Three monogene defects – glucocorticoid-remediable aldosteronism (GRA), syndrome of apparent mineralocorticoid excess (AME), and Liddle's syndrome – and susceptibility genes such as angiotensinogen gene (AGT), renin gene (RN), pseudohipoaldosteronism type II, and α-adducin gene (ADDI) have been reported which have as one of their consequences increased arterial pressure.

Environmental Factors

A number of environmental factors are involved in the development of hypertension. These include: obesity, salt intake, alcohol intake, family size, and occupation. The influence of these factors increases with the age of patients.

Salt Sensitivity

In hypertensive population the blood pressure in about 60% is responsive to level of sodium intake. The cause of this special sensitivity to salt varies, and includes primary aldosteronism, bilateral renal artery stenosis, and other factors.

Renin and its Importance in Hypertension

Renin is an enzyme secreted by the juxtaglomerular cells of the kidney. It interacts with aldosterone in a negative-feedback loop. Some hypertensive patients are defined as having low-renin and high-renin essential hypertension. About 20% of hypertensive patients have suppressed plasma renin activity. Approximately 15% of patients with essential hypertension have plasma renin activity levels above the normal range, which suggests that in these patients plasma renin plays a significant role in the pathogenesis of arterial hypertension, activating the renin–angiotensin–aldosterone axis. However other findings have led some investigators to postulate that the elevation of blood pressure and elevated renin levels may be secondary to an increase in adrenergic system activity.

Cell Membrane Defect

The hypothesis about the role of a generalized cell membrane defect in the pathogenesis of salt-sensitive hypertension is derived from data from studies on red blood cells, in which abnormalities in the transport of sodium across the cell membrane have been documented. This abnormality in sodium transport reflects an alteration in cell membrane, and this defect may occur in all cells of the body. An abnormal accumulation of calcium in vascular smooth muscle results in an increase in vascular responsiveness to vasoconstrictor agents.

Reflex Mechanisms in Regulation of Blood Pressure in Arterial Hypertension

The reflex mechanisms regulating blood pressure include: arterial baroreceptors, cardiopulmonary mechanoreceptors, arterial chemoreceptors, and visceral receptors localized in the kidney, liver, and intestine.

The baroreceptor reflex and from cardiopulmonary mechanoreceptors are primary homeostatic controls for blood pressure. Stretch-sensitive mechanoreceptors are tonically active and thereby tonically decrease a sympathetic activity. Additionally, local release of NO from vascular epithelium after each increase in blood pressure counteracts blood pressure elevation. The cardiac response to baroreceptor activation is vagal activation and a decrease in heart rate. Several studies have shown the impairment of baroreceptor function in arterial hypertension.

The carotid chemoreceptors, activated by partial pressure of oxygen in arterial blood and its decrease, showed an augmented resting drive in arterial hypertension. The pressor response to hypoxic stimulation is also augmented in young patients with essential hypertension. Reflex from arterial chemoreceptors is probably involved in the pathogenesis of arterial hypertension in obstructive sleep apnea syndrome. The episodes of nocturnal hypoxia during sleep seem to be responsible for an increase in sympathetic activity and blood pressure.

The kidney–kidney reflex inhibits sympathetic activity, increasing natriuresis and diuresis.

The osmoreceptors in the liver and in the digestive system increase natriuresis and diuresis, decreasing blood pressure.

The disturbance of interaction between the reflex regulatory mechanisms is discussed as a factor which may be involved in the pathogenesis of essential arterial hypertension.

Hypertension is a risk factor for atherosclerosis because high pressure in arteries damages the endothelial lining of the vessels and promotes the formation of atherosclerotic plaques. Additionally, elevated arterial pressure increases cardiac afterload.

Hypertension and Diet

B M Y Cheung and T C Lam, University of Hong Kong, Pokfulam, Hong Kong

Nutrition as a Cause of Hypertension

Hypertension is a common condition that affects more than one-tenth of the adult population. The complications of untreated hypertension include stroke, myocardial infarction, cardiac and renal failure. Its etiology is complex and probably involves the interaction of genetic predisposition and the environment in the widest sense. There is familial clustering of hypertension, which can be a reflection of both shared genes and shared environment or both. As a person's genes is probably not open to modification, especially when the disease-causing gene(s) have not been identified, prevention and treatment of hypertension should be targeted at altering the environmental factors. Results from many population and migrant studies show that environmental factors play an important role in the occurrence of hypertension. One such factor determining the development of hypertension is undoubtedly nutrition. Poor nutritional habits, alcohol consumption, excessive sodium and insufficient potassium intake are some of the nutritional factors leading to hypertension. These, together with socioeconomic status, physical inactivity, psychological stress, and obesity, influence blood pressure in an individual.

Fetal Origin of Hypertension

Barker and colleagues have put forward the 'fetal origins hypothesis' that links cardiovascular disease manifested in adulthood to poor nutrition *in utero* and infancy. Fetal undernutrition in middle to late gestation is thought to result in adaptive changes in fetal growth that predispose to coronary heart disease. The evidence comes from a longitudinal study of 25 000 middle-aged Britons. Those who were small at birth and not premature had relatively high rates of coronary heart disease, hypertension, hypercholesterolemia, and diabetes. Postnatal nutrition also appears to influence blood pressure in later life. Premature babies randomized in a study to breast milk had lower blood pressure in adolescence than those randomized to formula milk. If the fetal origins hypothesis, which is difficult to prove prospectively, is correct, optimizing prenatal care may prevent hypertension and other cardiovascular diseases in adulthood.

Dietary Pattern and Hypertension

There are striking differences in the blood pressure of populations worldwide. Blood pressure is higher and rises more steeply with age in industrialized than in nonindustrialized societies. A predominantly vegetarian dietary pattern is generally present in those populations that have low average blood pressure. In industrialized countries, vegetarians have lower blood pressures than nonvegetarians (**Figure 1**).

Epidemiological and intervention studies including the Multiple Risk Factor Intervention Trial (MRFIT) suggest a multitude of dietary changes that may reduce blood pressure. The Dietary Approaches to Stop Hypertension (DASH) Trial tested three dietary patterns: (1) a control diet that resembled the average US diet; (2) a combination diet high in fruit,

vegetables, whole-grain cereal products, low-fat dairy products, fish, chicken, and lean meats but low in fat and cholesterol; and (3) a fruit and vegetables diet that tested the effects of fruit and vegetables alone and was similar in other nutrients to the control diet. Sodium content was the same in all the diets and the subjects maintained their prestudy body weight throughout the trial. The combination diet was found to reduce the systolic pressure by 11 mmHg and the diastolic pressure by 6 mmHg (Figure 2). The fruit and vegetables diet reduced blood pressure by half this amount. Remarkably, the effect of the combination diet in the hypertensives approaches the effect of treatment with a single antihypertensive drug.

Sodium

Sodium is tightly regulated through a variety of coordinated homeostatic mechanisms involving the sympathetic nervous system, the renin–angiotensin system, and natriuretic peptides. A minute rise in blood pressure is sufficient to augment sodium excretion to achieve sodium balance in normal kidneys. In salt-sensitive hypertension, there is an exaggerated blood pressure response to increased sodium intake. Older patients, overweight type 2 diabetics, or those of African descent tend to have hypertension of this type. They have low renin levels and a lesser pressor response to sodium deprivation. In such hypertensive individuals, sodium restriction is effective and beneficial. The controversy surrounding salt and hypertension stems from the fact that not everyone is salt-sensitive and it has been argued that reducing the salt intake in the general population is neither practical nor effective, and may even be harmful to some people. However, the relationship between salt and blood pressure is now well established (Figure 3), and the higher the salt intake of the population, the steeper the rise in blood pressure with age. Interestingly, in primitive communities, blood pressure does not rise with age.

In many western countries, daily sodium intake is between 150 and 200 mmol. The Trial Of

Nonpharmacological Intervention in the Elderly (TONE) showed that a 40 mmol day^{-1} reduction is accompanied by significant reductions in blood pressure (5.3/3.4 mmHg). This modest salt restriction can be achieved by not adding salt at the table and avoiding foods that are high in sodium content (e.g., preserved food). Saltiness is a rather crude taste and is used by the industry to enhance the palatability of food cheaply and to boost the sale of beverages. Historically, salt was needed to preserve food for the winter months but nowadays, refrigeration renders this unnecessary. Fresh food is usually low in salt content and its flavors are better appreciated when not too much salt has been added in cooking.

Carefully controlled clinical studies have demonstrated a dose-dependent relationship between dietary salt intake and blood pressure, although trials of salt restriction do not always show a useful reduction in blood pressure due to their various trial designs. Salt restriction is particularly important when the patient is treated with an angiotensin-converting enzyme inhibitor (ACEI) or an angiotensin II antagonist (sartan). The efficacy of these drugs is diminished in the presence of high salt intake that suppress the renin–angiotensin system.

Potassium

In contrast to sodium, potassium is less tightly regulated physiologically. In diuretic therapy, the renal tubules will conserve sodium at the expense of potassium. Plasma potassium concentration is also linked to acid–base balance. Nevertheless, potassium is also closely associated with blood pressure. Cross-sectional studies in many countries worldwide had identified an inverse relationship between blood pressure and various measures of serum, urine, total body and dietary potassium. Low potassium intake may also underlie the high incidence and prevalence of hypertension in blacks and the elderly. Potassium supplementation alone will decrease blood pressure slightly. The effect is more pronounced in hypertensives than normotensives, in blacks than in whites, and in those with high sodium intake. In reality, higher potassium intake is usually associated with a diet rich in fruit and vegetables. Such a diet will in itself be conducive to a lower blood pressure, so one cannot always disentangle the components of a 'healthy diet' which are actively antihypertensive. High sodium intake and low potassium intake is a common scenario amongst hypertensive patients. Therefore, sodium and potassium should be considered jointly in our dietary recommendations. For example, using a salt substitute that contains potassium chloride increases potassium intake whilst reducing sodium intake.

Calcium

The relationship between calcium and hypertension is controversial. Dietary intake of calcium tends to be lower in hypertensives and calcium supplementation is associated with a modest reduction in blood pressure. A metaanalysis of 23 observational studies showed an inverse association between blood pressure and dietary calcium intake. The effect size was however small and heterogeneous across studies. Metaanalysis of randomized trials of calcium supplementation showed that systolic blood pressure is reduced by around 1 mmHg. Although it is possible that certain subgroups may be more sensitive to the effects of calcium, it is certainly not the major factor in the pathogenesis of hypertension, despite the recent identification of a parathyroid hypertensive factor. Therefore, calcium supplementation, though desirable for other reasons, is not currently recommended as an efficacious means of treating hypertension.

Fat

The relationship between lipids and coronary heart disease is now proven beyond doubt by epidemiological studies and large-scale trials of lipid-lowering drugs (statins) that reduce coronary events. Reduction in cholesterol by pharmacological means may not lower blood pressure, but should be viewed in the context of the overall reduction of cardiovascular risk and the reduction of complications of hypertension such as myocardial infarction. Hypertension and dyslipidemia are independent cardiovascular risk factors and, when they are both present in the same person, the cardiovascular risk is augmented. Therefore, it makes sense to address both risk factors. Nonpharmacological means of lipid lowering through diet and exercise is likely to have a beneficial effect on blood pressure in addition to improving the cardiovascular risk profile. The DASH study suggested that a healthy diet based on less fat and more fruit and vegetables reduces blood pressure, although precisely which component of the DASH diet lowers blood pressure remains to be elucidated.

The effects of saturated, monosaturated, and polyunsaturated fatty acids and carbohydrates have been studied in many clinical trials. Omega-3 unsaturated fatty acids (fish oils) reduce blood pressure but a large intake is needed, so this is not a practical treatment for hypertension.

Obesity

It has become clear in recent years that obesity is one of the major determinants of blood pressure. Our own observations in relatives of hypertensive patients suggest that the occurrence of hypertension is related to whether the relative is obese or not. It therefore appears that those who may be genetically predisposed to hypertension will develop the condition if they become obese.

Recently, two genes involved in the control of body weight, the OB gene and the OB receptor gene, which code for the hormone leptin and its receptor respectively, have been described in the mouse. Deletions in the OB gene or the OB receptor lead to profound obesity of early onset with excessive food intake, decreased energy expenditure, and insulin resistance. In humans, mutations in the corresponding genes have been reported. A high level of circulating leptin is found in the majority of obese people, suggesting that they have leptin resistance. Transgenic mice overexpressing leptin develop hypertension. However, the association of high leptin levels and hypertension has not been firmly established in humans, so the relevance of these genes to the pathogenesis of essential hypertension remains to be elucidated.

Obesity, especially abdominal adiposity, is more closely related to blood pressure than body weight. Moreover, obesity can lead to insulin resistance and ultimately overt type 2 diabetes mellitus. Lean, normoglycemic untreated hypertensive subjects are more insulin-resistant than comparable normotensive subjects. The relationship between insulin resistance and hypertension may involve a variety of mechanisms, including increased sympathetic nervous system activity, proliferation of vascular smooth-muscle cells, altered cation transport, and increased sodium retention. It is worth noting than one-third of diabetics have hypertension and a significant proportion of hypertensives have diabetes. The two conditions overlap to a large extent as components of the 'metabolic syndrome' or 'syndrome X.'

Measurement of blood pressure in those who are obese and have large arms is prone to overestimation if the cuff is not large enough. Nevertheless, the relationship between obesity and blood pressure is well established and indeed, for the overweight hypertensive, losing weight, if it can be achieved, is the most efficacious means of reducing blood pressure amongst the various nonpharmacological treatment options. Our own data and those of other investigators suggest that for each kilogram of body weight lost, there is approximately a 1 mmHg reduction in diastolic blood pressure and a 2 mmHg reduction in systolic blood pressure (Figure 4). Unfortunately, outside clinical trials, this is easier said than done. A coordinated approach involving a physician, nurse, and dietitian and attendance of classes is probably more effective than advice from a single professional. As with other nonpharmacological measures, weight control through diet and exercise will lead to benefits in addition to blood pressure control, such as a better lipid profile, better cardiovascular fitness, less stress on the joints, and so on.

Alcohol

The effect of alcohol on health in general and cardiovascular diseases in particular is dose-dependent. A modest regular intake is probably beneficial because of the increase in high-density lipoprotein cholesterol (HDL-C) and the relief of stress whilst a high intake is definitely harmful. With increasing levels of alcohol intake, more than 50 epidemiological studies from a variety of cultures have reported an increase in blood pressure or a higher prevalence of hypertension. An excessive alcohol intake raises blood pressure and moderation of alcohol intake leads to reduction in blood pressure (Table 1). In practice, hypertensive patients who do not drink alcohol should not be encouraged to start doing so whilst those who do drink large quantities must be encouraged to reduce

[a]A standard drink is defined as 14 g ethanol and is contained in a 12-oz/350 ml glass of beer, a 5-oz/146 ml glass of table wine, or 1.5/44 ml oz of distilled spirits.

their intake to the recommended levels. Currently, it is believed that men should not drink more than 21 units per week and women should not drink more than 14 units per week. Approximately one unit of alcohol, or 14 g ethanol, is contained in one glass of table wine.

Dietary Approach to Prevent or Treat Hypertension

Alteration of the diet to bring about a lower blood pressure is not only beneficial in those who are hypertensive, but is prudent in those who are not yet hypertensive and even in those who are normotensive. A shift in the distribution of the blood pressures to a lower mean for the population is expected to lead to a massive reduction in the incidence of coronary heart disease and stroke. Achieving a healthier diet will delay or even prevent the onset of hypertension. This may be especially relevant in young people who have a strong family history of hypertension or cardiovascular diseases. In those who have newly diagnosed hypertension, dietary intervention may obviate the need for drug therapy. In patients with mild hypertension who respond to diet and the nonpharmacological approach, cessation of therapy may be possible. In those hypertensive patients who still require drug therapy, an appropriate diet will reduce the intensity of treatment and facilitate blood pressure control.

There is no single diet that will fit everyone's needs. The elderly might be more responsive to salt restriction whilst the young obese hypertensive should have a diet low in fat and calories. Clinicians rarely have the time or the training to go through a diet with the patient so the help of dietitians and other health care professionals is crucial for successful implementation of dietary intervention.

Although most of the dietary recommendations are well accepted by health care professionals and the community, their implementation is a major problem since a change in behavior is needed. Eating and alcohol drinking are normally pleasurable experiences and many do not find regular exercise enjoyable, so diet, abstinence, and exercise require determination and commitment. There is a limit as to how much health care professionals can do in this regard. It is therefore important that the doctor, nurse, and dietitian complement each other and reinforce the message in a team approach.

There is another obstacle to a healthy diet: food sold in fast-food outlets is convenient, inexpensive, and therefore popular. Such food is high in salt and fat content and is generally not fresh. Tinned and other preserved food has a high salt content; McGregor has argued that reducing the salt intake in the general population requires the cooperation of the food industry to reduce the salt content in its products. Health care professionals need to be aware of the economical and social aspects in order to give advice that can feasibly be followed. In developing countries, the highest incidence of hypertension is found in people with high socioeconomic status. As countries become more affluent, hypertension becomes more prevalent in the lower socioeconomic classes. In developed countries, there is an inverse relationship between socioeconomic status and blood pressure. Proposed mechanisms include differences in diet (sodium, potassium, calories), physical activity, body mass, alcohol intake, psychosocial stress, and access

to health care (including acceptance of and use of services). In some respects, unhealthy diet is a form of malnutrition that afflicts poor people in developed countries. The striking differences in diseases between the socioeconomic classes, usually defined in terms of educational level and income, are clearly environmental rather than genetic in origin. Therefore, there is much the society, through governmental and nongovernmental agencies, can do to reverse this.

A healthier diet brings many dividends – it reduces calorie, sodium, cholesterol, and triglyceride intake and increases the intake of potassium and calcium, and the consumption of fruit and vegetables which are rich in fiber and vitamins. Therefore, we should strive to shift the dietary habit of the whole population, including children and adolescents, as much as patients with hypertension and other cardiovascular conditions. A family rather than an individual approach is often called for if the family eats together. The advantage of this is that the whole family can start to adapt to a healthy diet. Primary prevention of hypertension may then become a reality rather than just a possibility.

Nutrition in the Diabetic Hypertensive

S C Bain, University of Birmingham and Birmingham Heartlands Hospital, Bordesley Green East, Birmingham, UK
P M Dodson, Birmingham Heartlands Hospital, Bordesley Green East, Birmingham, UK

Hypertension as a Secondary Complication of Diabetes

Diabetes mellitus and hypertension are frequently associated: hypertension is approximately twice as common in subjects with diabetes mellitus compared with the general population. The prevalence of hypertension increases with age and is relatively greater in those with type 1 (insulin-dependent) diabetes than in those with type 2 (noninsulin-dependent) diabetes after adjustment for age. As in the general population, hypertension occurs more frequently in diabetic males than in diabetic females before the fifth decade and more frequently in diabetic women thereafter.

The etiology of hypertension in association with diabetes is poorly understood and is probably different in the two types of diabetes. Hypertension in type 1 diabetes is generally related to the development of diabetic kidney damage (diabetic nephropathy) which occurs in up to 40% of subjects. Diabetic nephropathy may also occur in type 2 diabetes but is less common (less than 20%). This form of hypertension may rightly be regarded as a secondary complication of diabetes.

In contrast, the majority of type 2 diabetic subjects with raised blood pressure have essential hypertension. This may be a consequence of the diabetic state but is more likely to be an association due to a common etiologic factor such as insulin resistance (see below). Type 2 diabetic patients are also prone to the development of isolated systolic hypertension but other 'secondary' causes of hypertension do not occur with increased frequency in the diabetic population.

Factors Associated with Hypertension in the Diabetic

Essential Hypertension

The reported prevalence of essential hypertension (previously defined as blood pressure more than 160/95 mmHg) among newly diagnosed type 2 diabetic patients is 40% in men and 53% in women. This prevalence is age-related in both sexes, consistently higher in women than in men, and greater than seen in an age- and sex-matched healthy population. Obesity explains part of the increased prevalence since approximately 75% of type 2 diabetics are overweight and obesity is independently associated with raised blood pressure. However, the association of type 2 diabetes and essential hypertension has yet to be fully explained.

In 1988 Reaven introduced the term 'Syndrome X' to describe the cooccurrence of hypertension, impaired glucose tolerance, dyslipidemia (raised triglycerides, low high-density lipoprotein cholesterol), hyperinsulinemia, and insulin resistance (**Table 1**). He proposed this as a cardiovascular risk factor complex and suggested that insulin resistance was causal in the development of the other abnormalities in the syndrome. There are a number of potential mechanisms by which insulin resistance, and the consequent hyperinsulinemia, could induce hypertension. For example, increased sodium retention, disturbed sodium/potassium transport, and sympathetic nervous system overactivity have all been reported. Since obesity is a state of increased peripheral resistance to insulin, this hypothesis provides an explanation for the association of obesity with both type 2 diabetes and raised blood pressure.

Since its original description, Reaven's syndrome has continued to be the focus of much research and has expanded to include postprandial hyperlipidemia, the presence of small dense low-density lipoproteins, hyperuricemia, and abnormal clotting factors. The persistence of the syndrome implies that it is important; however, the causal mechanisms have yet to be dissected and the precise role of insulin resistance remains controversial.

The definition of hypertension is also a rapidly changing area. Controlled clinical trials of drug intervention now suggest that target levels for systolic and diastolic blood pressure in patients with type 2 diabetes should be in the order of 140/85 mmHg. The goals are lower if patients have known ischemic heart disease (130 and 80 mmHg) and are lower still in patients with type 1 diabetes and evidence of diabetic

Table 1 Original components of Syndrome X (Reaven's syndrome)

Insulin resistance
Hyperinsulinemia
Impaired glucose tolerance
Raised triglycerides
Low HDL-cholesterol
Hypertension

HDL, high-density lipoprotein.

nephropathy. These targets are irrespective of age (although data concerning patients over the age of 85 years are lacking) and imply an aggressive treatment for isolated systolic hypertension. Attention should also be given to other modifiable cardiovascular risk factors (currently smoking and hypercholesterolemia; high-density lipoprotein cholesterol may be included in the future).

Renal Hypertension

This form of hypertension is associated with diabetic nephropathy. Diabetic renal damage develops in up to 40% of type 1 diabetics and is associated with high morbidity and mortality. Raised blood pressure may be present at the clinical onset of renal disease (persistent proteinuria), or emerge during the development of nephropathy, when the glomerular filtration rate begins to decline. There is good evidence that the presence of hypertension at this stage accelerates the progression to renal failure. Hence, hypertension may develop secondarily to renal involvement in diabetes and, once manifest, accelerates the decline in renal function. The pathogenesis of hypertension in diabetic patients with overt nephropathy is unclear. However, a predisposition to hypertension and ischemic heart disease (positive family history) increases the susceptibility of type I diabetics to renal disease. This is thought to imply the involvement of genetic factors but these have yet to be identified.

Dietary Management of Hypertension in the Diabetic

Drug treatment of established hypertension is inevitably lifelong. Side-effects of antihypertensive agents are common and metabolic sequelae could theoretically contribute to cardiovascular risk (for example, by increasing insulin resistance). In addition, overzealous lowering of blood pressure with drugs may have deleterious effects, especially in the elderly and in subjects with cardiac disease. The above considerations emphasize that nonpharmacological approaches should be recommended for all subjects with mild hypertension and dietary manipulation is the most important of these.

Weight Reduction

Weight loss is the first-line therapy for obese hypertensive diabetic subjects, since this may have a beneficial effect on both blood pressure and blood glucose control. Weight reduction was shown to lower blood pressure in the Hypertension Control Program study where 39% of patients who had previously required drug therapy for hypertension were controlled by dietary manipulation alone after 4 years. However, the effect of weight loss on blood pressure can be disappointing: a study of 60 mildly hypertensive obese individuals concluded that weight loss was not important in lowering blood pressure. Despite these reservations, weight reduction remains a sensible aim since achievement of a desirable weight for height, as indicated by the body mass index, may normalize glucose tolerance in a proportion of patients with type 2 diabetes as well as reducing insulin resistance.

Dietary recall histories are often used to assess the energy intake of a patient and a deduction of 500 kcal from this figure then determines the recommended energy intake to achieve weight loss of 1–2 kg per month. Unfortunately, this method consistently underestimates daily energy intake (by as much as 800 kcal) and, by setting impossible goals for patients, may lead to poor dietary compliance. It is possible to calculate the energy intake of a weight-stable individual using a nomogram in which age, sex, exercise status, and body mass are taken into account. A realistic weight-reducing diet aims for an energy deficit of not more than 500 kcal from the intake calculated by this method.

When placed on a low-energy diet in a controlled environment all obese subjects lose weight. In the clinical setting and despite realistic dietary targets, a substantial proportion of patients do not achieve weight reduction. Even those who lose weight in the short term often have difficulty in maintaining this desirable state. In both cases, this presumably reflects poor compliance with dietary advice. Second-line therapy, such as behavioral therapy, may then be tried as an adjunct to continued attempts at low energy intake. Behavior therapy is aimed at the identification and avoidance of cues that promote eating. Excellent results can be achieved but at great cost in time to both therapist and patient. In those grossly overweight subjects who are unable to muster the self-discipline to lose more than a few kilograms, surgical procedures may be indicated. Drug therapies have now largely been withdrawn due to their poor side-effect profiles.

The 'Prudent Diet'

Irrespective of the need to lose weight, the nutritional considerations for treating individuals with diabetes mellitus and hypertension are to improve glycemic control, lower blood pressure, and reduce hyperlipidemia. The composition of the most commonly prescribed dietary regimen is high in dietary fiber (40–45 g $24\,h^{-1}$) with more than 50% of total energy as unrefined carbohydrate. Dietary fat intake is reduced to less than 25% of total energy, with less than 10% in the form of saturated fat. This is known as the

'prudent diet.' In a study of 34 diabetic patients with essential hypertension, modification of dietary regimen in this way, without attempts to reduce overall energy intake, led to a significant fall in blood pressure over 3 months. Patients also lost a mean of 2 kg in weight, possibly due to the dietary fiber promoting satiety at a lower level of calorie and fat intake. Longer-term studies (up to 4 years) indicate that the effect on blood pressure is sustained.

Not all authors agree with this form of dietary manipulation. Reaven and coworkers claim that the replacement of fat by complex carbohydrate induces a rise in serum triglyceride levels. Since hypertriglyceridemia is a common abnormality in type 2 diabetes, it is argued that the prescribed diet should not aggravate this situation. It is claimed that replacement of saturated fat with polyunsaturates, without altering the relative proportions of energy derived from fat and carbohydrate, alleviates this problem whilst retaining beneficial effects on glycemic control and serum cholesterol levels. This alternative dietary manipulation is given further support by reports that even dietary enthusiasts find it very difficult to maintain the high fiber and carbohydrate intake of the 'prudent diet.'

Sodium Intake

Sodium intake is also linked with high blood pressure. Double-blind cross-over studies have shown that moderate sodium restriction (not adding salt, avoiding salt-laden foods) produces a beneficial effect on blood pressure. Diabetics appear to be especially sensitive to salt reduction and this may be related to the findings of impaired sodium excretion and a 10% increase in total body exchangeable sodium in diabetics. However, a study of obese patients treated by weight reduction found no difference in blood pressure in those subjects who did not alter their salt intake compared with those who restricted salt.

In the UK, the majority of salt intake comes from the preparation of processed foods and patients may have a large impact on salt intake by adopting a diet rich in fruit and vegetables, thereby reducing consumption of heavily salted products. In this setting, it may be counterproductive to advise further salt restriction and run the risk of diminished dietary compliance. An exception to this is the African-Caribbean diet which is often salt-rich; in this setting the use of other herbs and spices might effect a significant reduction in sodium intake.

Alcohol

Epidemiological studies have convincingly established a link between regular alcohol consumption and high prevalence of hypertension. In individual subjects regular alcohol intake has been shown to raise blood pressure and reduction of alcohol consumption is therefore recommended to reduce blood pressure, as well as to promote weight loss by reducing calorific intake.

Other Dietary Manipulations

There are published studies of other dietary manipulations that have been shown to be of benefit in lowering blood pressure. Calcium supplementation lowers diastolic blood pressure in young people with mild hypertension and potassium supplementation has been shown to reduce blood pressure. Magnesium supplements may also benefit hypertensive patients on long-term diuretics. In untreated subjects, changing to a vegetarian diet may bring about a worthwhile fall in systolic blood pressure. Until further evidence is forthcoming, it is premature to advise supplementation with these minerals; in addition, there is clearly a limited amount of dietary advice with which patients can comply.

Recommendations

At present, most physicians in the UK would advise the following measures as the mainstay of dietary therapy:

- weight reduction, so as to achieve a stable body mass index of less than 27 kg m^{-2}
- moderate alcohol restriction (less than two units of alcohol per day with one alcohol-free day per week)
- moderate salt restriction (no more than 3 g day^{-1})

These maneuvers may delay or limit the use of drugs and in some patients will achieve adequate blood pressure control. In subjects with mild hypertension, nonpharmacological treatment alone should be tried for at least 3 months. If the patient is making good progress, for example with regard to weight loss, these measures may be pursued for longer. If the improvement has been small then drug therapy is appropriate at this stage. In subjects with severe hypertension drug therapy may be commenced immediately, since nonpharmacological treatment alone is unlikely to be effective.

Special Considerations – Diabetic Nephropathy

In type 1 diabetics with established renal disease, there is evidence that protein restriction (to less than 40 g day^{-1}), in addition to the dietary measures outlined above, will retard the progressive decline in renal function. At this stage, however, hypertension should always be treated with drug therapy as well. Indeed, many would argue for the

angiotensin-converting enzyme inhibitor class of antihypertensive drugs to be introduced as a protective measure before hypertension is established.

Prognosis

Hypertension contributes to the leading causes of morbidity and mortality in the diabetic population, namely coronary heart disease, stroke, peripheral vascular disease, lower-extremity amputations, and end-stage renal disease. Raised blood pressure will also worsen diabetic retinopathy, a major cause of blindness in the western world. Clearly, the aim of therapy is to reduce the incidence of these sequelae, especially premature cardiovascular disease, which is quantitatively the most important.

The effectiveness of antihypertensive drug therapy in reducing elevated blood pressure levels is well established. In addition, major multicenter trials of antihypertensive drug therapy have consistently demonstrated a reduction in the rate of strokes by approximately one-third and a decrease in cardiovascular mortality by around 15%. Large long-term studies of antihypertensive therapy have now been performed in diabetic populations and have confirmed that this group of patients benefits from aggressive control of hypertension and other cardiovascular risk factors. Indeed, there are many guidelines suggesting that type 1 diabetics with incipient nephropathy (microalbuminuria at high risk of developing overt diabetic nephropathy) should receive antihypertensive drug therapy whilst their blood pressure is still within the normal range.

Prevention

Until the etiology of essential hypertension and diabetic nephropathy is more fully understood, prevention will remain difficult. As yet, there is no evidence that strict control of blood glucose can prevent the development of either condition, although once present, hyperglycemia may increase proteinuria. This is in keeping with evidence that both essential hypertension and diabetic renal disease have strong genetic components. Nevertheless, it is sensible to advise all diabetics to take a diet low in saturated fat, to moderate their salt intake, and avoid excessive alcohol consumption. Regular exercise is recommended and obesity should be avoided. These measures may delay, or even prevent, the onset of hypertension in type 2 diabetics but are unlikely to affect the development of hypertension in association with diabetic nephropathy.

Finally, since the main aim of treating high blood pressure is to effect a reduction in the number of cardiovascular events, it is appropriate to focus attention on other cardiovascular risk factors such as smoking and hypercholesterolemia. These also have important dietary aspects; stopping smoking is often associated with weight gain; treatment of hypercholesterolemia is through dietary manipulation, at least in the first instance.

HYPOGLYCEMIA (HYPOGLYCAEMIA)

M S Boyne, University of the West Indies, Mona, Jamaica

Background

Hypoglycemia was not clinically appreciated until the discovery of insulin by Banting, Best, Collip, and MacLeod. In 1921, they noted that unpurified insulin led to the sudden death of several test animals. Subsequently, patients with type 1 diabetes treated with insulin described the symptoms now attributed to hypoglycemia. It was soon observed that some nondiabetic patients demonstrated similar symptoms, and the concept of spontaneous hypoglycemia or 'hyperinsulinism' was promoted. The cause remained unclear until 1927, when Wilder *et al*. described a surgeon with a malignant pancreatic tumor that had insulin-like biological activity (i.e., an insulinoma). Hyperinsulinism was also described in children of diabetic mothers in the 1920s and was ascribed to 'compensatory hypertrophy of the pancreas.' By 1933, it was recognized that hypoglycemia was caused by several conditions, including adrenal insufficiency, starvation, cirrhosis, and critical illness.

In 1938, Whipple described the triad of criteria necessary for the diagnosis of hypoglycemia, i.e., symptoms consistent with hypoglycemia, blood glucose concentration less than 2.8 mmol l^{-1} and immediate relief by the ingestion of glucose. The ability to measure plasma insulin by radioimmunoassay in 1959 confirmed that not all hypoglycemia was due to hyperinsulinism. Also, the elucidation of the biochemical pathways of glucose, amino acid, and lipid metabolism has led to the recognition of a plethora of congenital causes of hypoglycemia. Consequently, in this chapter, the regulatory mechanisms of glucose homeostasis are first described to provide the basis for understanding the pathophysiology of hypoglycemia. The common causes of hypoglycemia are then outlined.

Definition

The Third International Symposium on Hypoglycemia in 1986 defined hypoglycemia as a blood glucose concentration less than 2.8 mmol l^{-1}, thus endorsing Whipple's criteria. Many clinicians, while suspicious of hypoglycemia at this threshold, do not diagnose hypoglycemia until levels are below 2.2 mmol l^{-1}. However, others argue that hypoglycemia could be defined at higher levels, as physiological responses to lowering of blood glucose begin at 4.0–4.2 mmol l^{-1} with the suppression of endogenous insulin secretion.

Physiological Defenses against Hypoglycemia

Plasma glucose in humans is maintained within the relatively narrow range of 3.6–7.8 mmol l^{-1}, whether in the fasting (postabsorptive) or fed (postprandial) state. This is accomplished by the tight regulation and coupling of glucose utilization and production, each $\sim$10–14 μmol glucose kg^{-1} min^{-1}. The incidence of hyperglycemia is vastly greater than hypoglycemia, as the body has developed several mechanisms to combat life-threatening hypoglycemia. This maintenance of glucose balance is necessary, since the brain has a critical dependence for glucose as an energy source. Other organs such as muscle, liver, heart, kidney, and adipose tissue can utilize other metabolic substrates to provide the energy necessary for maintenance and growth. The brain, however, has a respiratory quotient of 0.97–0.99 under physiological conditions, indicating its almost exclusive use of glucose. Despite this dependency, the brain has no enzymatic machinery for significant glycogen synthesis or gluconeogenesis. Consequently, it depends upon a continuous, high concentration of glucose in the arterial blood. In fasting conditions, the arterial concentration of glucose becomes limiting, the blood-to-brain glucose transport mediated by glucose transporters (GLUT-1 and 3) decreases, and neuronal function is impaired. The brain can subsist on ketone bodies (i.e., acetoacetate, β-hydroxybutyrate), if their plasma concentration rises to the threshold necessary to pass the blood–brain barrier, but this only occurs during prolonged fasting.

During hypoglycemia, counter-regulatory mechanisms convert the liver into an organ of net glucose export, provide alternative metabolic fuels, and decrease glucose utilization. During fasting (i.e., > 6 h after a meal), the liver maintains physiological concentrations of plasma glucose by glycogenolysis and gluconeogenesis. Initially, glycogenolysis takes precedence, accounting for 70–90% of the total glucose production. However, in the absence of gluconeogenesis, the liver's glycogen stores of 40–90 g are depleted in 8–10 h. Subsequently, hepatic gluconeogenesis becomes the prime source of glucose production. Renal gluconeogenesis only becomes important

during prolonged fasting when it may contribute up to half of the total glucose production. Proteolysis provides the main gluconeogenic precursors (alanine, lactate) catabolized from the carbon skeletons of amino acids via the Cori and lactate cycles.

The rate of lipolysis increases, providing nonesterified free fatty acids for conversion to ketone bodies by the liver. Muscle and fat can efficiently utilize fatty acids and ketones for fuel, so glucose utilization by these tissues almost ceases. After several days of fasting, the plasma concentration of ketone bodies rises to the level that supports transfer across the blood–brain barrier. Ketone bodies then become a source of energy for the brain, decreasing its need for glucose by approximately 50%. Thereafter, gluconeogenesis decreases, resulting in a protein-sparing effect. The rate of total glucose utilization eventually nadirs at $\sim 5\,\mu mol\,kg^{-1}\,min^{-1}$, and correspondingly, plasma glucose levels fall to a plateau of 2.5–3.3 $mmol\,l^{-1}$. These levels can be maintained for several weeks.

Hormonal Mechanisms

The above catabolic pathways are under hormonal regulation. When plasma glucose falls, intracellular signals in β-cells, possibly including glucokinase as a glucose sensor, lead to inhibition of insulin secretion (Figure 1). Consequently, glucose uptake by peripheral tissues, especially muscle, and glycogen synthesis in muscle and liver (via decreased glycogen synthetase activity and increased phosphorylase activity) is halted. Gluconeogenesis is stimulated as phosphoenolpyruvate carboxykinase and fructose-1,6-bisphosphatase activity is increased. Also, insulin's inhibition of hormone-sensitive lipase is released, leading to lipolysis (Figure 2). However, the suppression of insulin secretion is not the predominant factor in the correction of hypoglycemia. This is seen in the spontaneous recovery from acute insulin-induced hypoglycemia prior to the dissipation of insulin. Hence, other counter-regulatory factors must be involved to overcome the effects of the relative hyperinsulinemia.

Using the hyperinsulinemic stepped hypoglycemic clamp technique, it was shown that glucose levels $\leq 3.7\,mmol\,l^{-1}$ stimulate the secretion of the counter-regulatory hormones glucagon, epinephrine, growth hormone, and cortisol. Glucagon and epinephrine serve as the major glucose-raising hormones. Glucagon acts directly and rapidly on the liver, augmenting glycogenolysis (by increasing glycogen phosphorylase activity) and gluconeogenesis (via fructose-1,6-bisphosphatase activity). It has no extrahepatic effect on glucose uptake, and its effects are potent, accounting for approximately 40% of glucose recovery. However, they are transient, as its plasma half-life is only 5–10 min before hepatic degradation occurs.

Epinephrine, acting through plasma membrane adrenergic receptors, stimulates glucagon release, inhibits insulin secretion, promotes lipolysis and proteolysis thereby mobilizing gluconeogenic precursors, and decreases peripheral glucose utilization. Epinephrine's effects become extremely critical if glucagon is deficient. Growth hormone and cortisol contribute

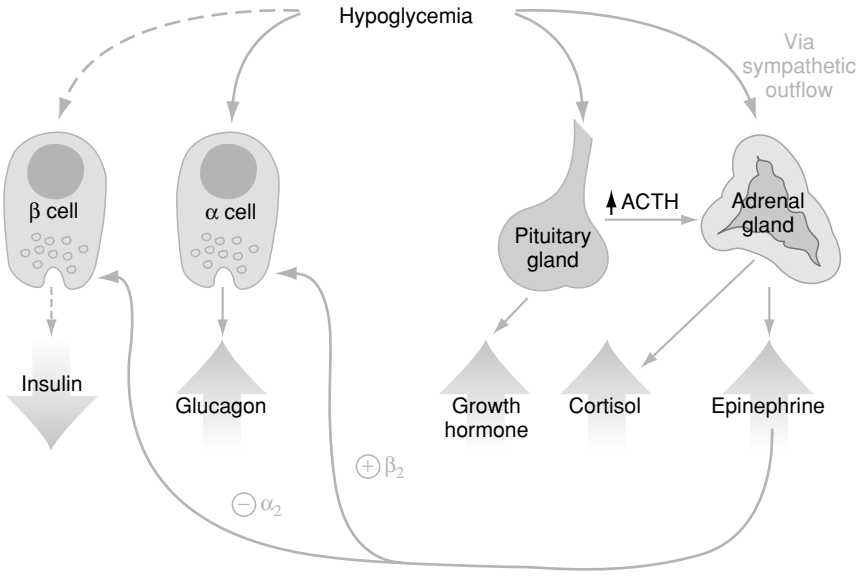

Figure 1 Effect of hypoglycemia on hormonal secretion. α_2 and β_2, receptor-mediated effects of epinephrine.

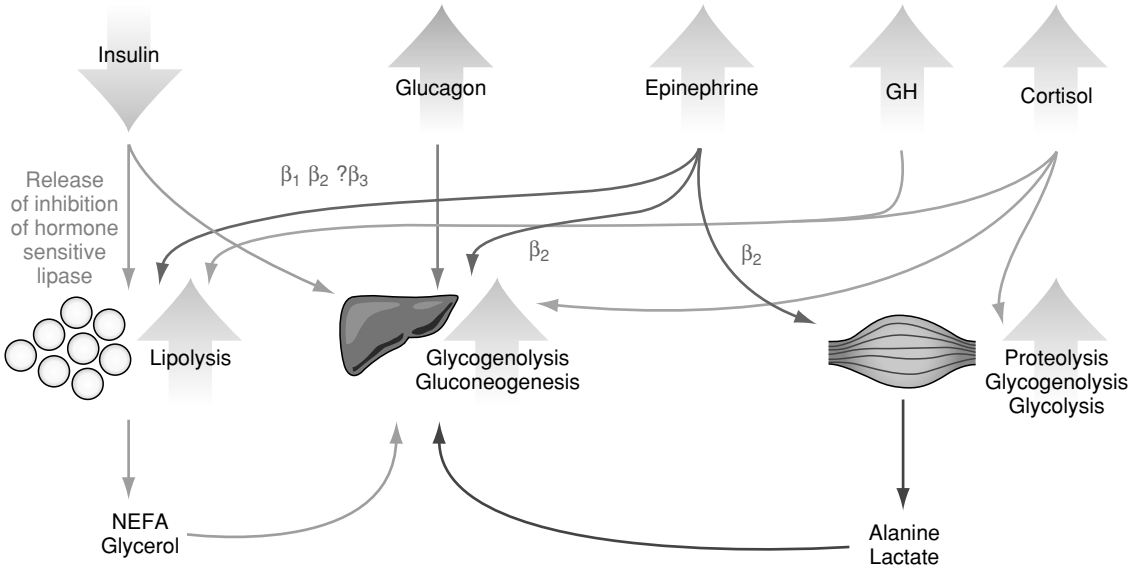

Figure 2 (see color plate 96) Hormonal effects on glucose metabolism during fasting. β_1, β_2 and β_3, receptor-mediated effects of epinephrine; NEFA, nonesterified fatty acids.

if hypoglycemia persists for several hours and is severe. They act by antagonizing insulin effects, inducing a slower recovery from hypoglycemia.

Thresholds for Symptoms of Hypoglycemia

The fall of blood glucose initiates physiological responses prior to the development of any clinical symptoms (Figure 3). A plasma glucose level $< 4.2\,\text{mmol}\,l^{-1}$ suppresses insulin secretion. Counterregulatory hormone secretion begins at $\sim 3.7\,\text{mmol}\,l^{-1}$ when sequential signals within the α-cells promote glucagon secretion. Autonomic nervous system (ANS) discharge is also increased, which augments the glucagon response and initiates the epinephrine response. Infusion of glucose into carotid and vertebral arteries in animal models reduces the epinephrine response by as much as 75%, and the ventromedial hypothalamus is one possible anatomic locus of the ANS signal.

Symptoms are not experienced until the blood glucose levels fall below $3.1\,\text{mmol}\,l^{-1}$. These symptoms are classified as neurogenic or neuroglycopenic. The former includes symptoms induced by the activation of the sympathetic (adrenergic) system and the vagal (cholinergic) system. They include sweating, tremor, anxiety, palpitations, pallor, tingling, and hunger. The neuroglycopenic symptoms occur when the blood glucose levels fall to $\sim 2.6\,\text{mmol}\,l^{-1}$, although there is individual variation. They include poor concentration, inattention, confusion, blurred vision, dizziness, weakness, and fatigue. If the blood glucose falls further, more severe cognitive disturbances develop such as behavioral changes, stupor, seizure, coma, and death.

Classification of Hypoglycemic Disorders

Traditionally, hypoglycemia is classified as either fasting or postprandial (Tables 1 and 2), but it can also be classified on the basis of insulin mediation, state of heath, or age of the patient. Irrespective of the method of classification, most cases of hypoglycemia are attributable to hyperinsulinemic hypoglycemia in individuals with diabetes mellitus from subcutaneous insulin injections, or oral sulfonylureas. (*See* **Diabetes Mellitus**: Problems in Treatment.) It should be noted that in the evaluation of hypoglycemia, artifactual causes i.e., improper sample collection or storage resulting in hemolysis, increased utilization of glucose after phlebotomy by the large number of leucocytes in certain leukemias, and errors in laboratory analysis, need to be excluded.

Postprandial or Food-stimulated Hypoglycemia

Postprandial hypoglycemia is hypoglycemia occurring 2–5 h after a meal. It is a self-limiting condition with no associated mortality, although its morbidity may have been underestimated. It has been described as an epidemic affecting the USA and Europe as more people are presenting self-diagnosed. The majority of

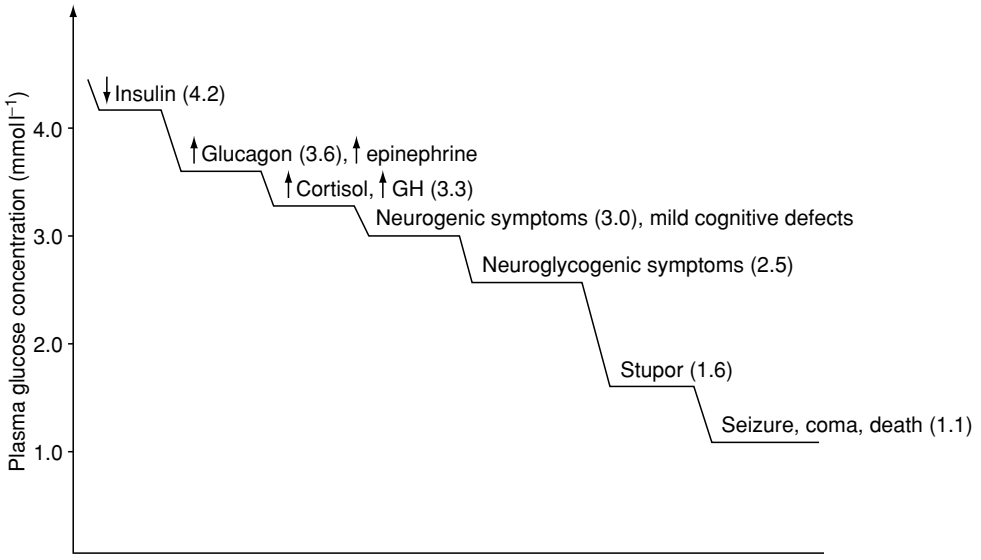

Figure 3 Glycemic thresholds during progressive hypoglycemia.

Table 1 Causes of postprandial hypoglycemia

Alimentary hypoglycemia
Secondary to previous gastrointestinal surgery, especially for peptic ulcer disease and gastrointestinal motility syndromes
Idiopathic postprandial hypoglycemia
Congenital deficiencies of enzymes of carbohydrate metabolism
Hereditary fructose intolerance
Galactosemia
Defective hepatic gluconeogenesis, e.g., fructose-1,6-bisphosphatase deficiency
Gin-and-tonic hypoglycemia
Leucine insensitivity
Causes of fasting hypoglycemia, especially insulinoma

Medications
Alcohol
Protein–energy malnutrition
Severe medical illness
Liver failure
Renal failure
Cardiac failure
Sepsis
Endocrinopathies
Adrenal insufficiency
Growth hormone deficiency
Isolated glucagon or epinephrine deficiency
Insulinoma (endogenous hyperinsulinemia)
Isolated
Part of multiple endocrine neoplasia-1 syndrome
Noninsulinoma pancreatogenous hypoglycemia
Noninsulinoma tumor-associated hypoglycemia
Factitious hypoglycemia
Malingering
Psychiatric disorders including Munchausen's syndrome
Pharmacy error
Autoimmune antiinsulin antibody syndrome
Ackee poisoning (Jamaican vomiting sickness)

patients, however, do not fulfill the requirements of Whipple's triad. Misdiagnosis also occurs due to the over-reliance on oral glucose tolerance testing (OGTT) and/or capillary ('finger-stick') glucose for diagnosis. Home reflectance meters for measuring capillary glucose are notoriously unreliable in the hypoglycemic range.

A common cause of postprandial hypoglycemia is *alimentary hypoglycemia*. This generally occurs in individuals who have had gastrointestinal surgery, e.g., gastric bypass, pyloroplasty, and gastrectomy, although a few have normal gastrointestinal tracts. The reported prevalence in postsurgical patients varies between 5 and 37%. The postulated mechanism is rapid transition of ingested food into the upper small intestine, leading to early, severe hyperglycemia (frequently $\geq 14\,\text{mmol}\,\text{l}^{-1}$). This induces the release of local gut factors (incretins), such as glucagon-like peptide-1 and glucose-dependent insulin-releasing peptide, resulting in insulin hypersecretion and glucose levels falling to $< 2.8\,\text{mmol}\,\text{l}^{-1}$ within 2–3 h. Dumping syndrome has to be considered in this setting as it has similar symptoms, but these occur within an hour after meals due to transluminal osmotic/fluid shifts. Treatment of alimentary hypoglycemia involves frequent feedings of high-fiber meals or low-carbohydrate/high-protein meals. Pectin, fructose, uncooked cornstarch, chromium, medium-chain triacylglycerol, octreotide, propanolol, sulfonylureas,

α-glucosidase inhibitors, metformin, and doxepin have also been proposed as alternatives, but none of these therapies have been properly evaluated in controlled trials.

It is controversial whether there really is an entity of *idiopathic postprandial hypoglycemia*. Most have been diagnosed on the grounds of diffuse symptoms and biochemical hypoglycemia by OGTT. In a study of 650 normal subjects, 10% had nadir values of $<2.6\,\text{mmol}\,\text{l}^{-1}$, and 2.5% were $<2.16\,\text{mmol}\,\text{l}^{-1}$ during a 100-g OGTT. Consequently, it would seem unwise to use an arbitrary diagnostic cut-off, since none of these patients had any significant symptoms or long-term adverse effects. In fact, 4.8% of normal individuals have blood glucose values $\leq 3.0\,\text{mmol}\,\text{l}^{-1}$ in free-living situations. When a group of 118 patients with suspected hypoglycemia were studied, only 16 had confirmed hypoglycemia (the mean was $2.2\,\text{mmol}\,\text{l}^{-1}$) during symptoms. The other 102 patients were symptomatic, but there was no relationship to blood glucose levels or meals, and their nadirs were similar to those of the control group. Fourteen of these patients also had placebo-OGTT tests, which provoked characteristic symptoms. Another group of investigators confirmed the invalidity of OGTT and also hypothesized that mixed meal tolerance tests of 550 and 825 kcal should provide a more physiological stimulus to provoke symptoms. The meals did not induce biochemical hypoglycemia, but the patients had characteristic symptoms. In another study, there was a poor correlation between the occurrence of symptoms and plasma glucose concentrations in ambulatory patients. Any abnormalities were not reproducible.

Based on these studies and others, it is generally agreed that an OGTT should not be used in the evaluation of idiopathic postprandial hypoglycemia, as its predictive power is poor (positive predictive value 21–31%, negative predictive value 68–100%). Instead, documenting hypoglycemia after meals that historically provoke hypoglycemia is more useful. It has been suggested that symptomatic individuals without biochemical hypoglycemia should be given the diagnosis of *idiopathic postprandial syndrome* or *pseudohypoglycemia*, since factors other than hypoglycemia are operative, while giving validity to their symptomatology. Other potential mechanisms, such as the rate of glucose decline, excessive insulin secretion, and plasma cortisol responses have not been proven to be significant. Increased tissue sensitivity to insulin may play a role in some individuals. Glucagon responses have not been consistent between studies, but may be subnormal. Exaggerated plasma epinephrine responses have been reported in uncontrolled studies. In any event, other investigators have shown that epinephrine and cortisol concentrations do not increase during the symptoms, indicating that no significant autonomic activation is present. It should be noted that over 50% of patients with idiopathic postprandial syndrome also have evidence of conversion reactions with high scores on the depression, hysteria, and hypochondriasis scales on psychological testing. In one study, 45% had somatoform disorders, 35% had depressive affective disorders, 20% had no evidence of a psychiatric disorder, and only 3% had true idiopathic postprandial hypoglycemia. Hence, idiopathic postprandial hypoglycemia is a rare entity, unlike the more common idiopathic postprandial syndrome. Treatment involves dietary restriction of refined carbohydrates and avoiding caffeine and alcohol.

Other conditions causing postprandial hypoglycemia include *galactosemia* and *hereditary fructose intolerance* that usually present during childhood. Rarely, *leucine* intake can cause hypoglycemia in susceptible individuals. As early as 1924, it was suggested that postprandial hypoglycemia occurs in the early phase of *type 2 diabetes mellitus*. However, this work was based on OGTTs, and only ~5% of patients were symptomatic. It was postulated that abnormal β-cell responses to glucose loads lead to hyperinsulinemia. Individuals with *fasting hypoglycemia*, especially insulinomas, may also have postprandial hypoglycemia. A high intake of alcohol with simple carbohydrates and no complex carbohydrates (such as *gin and tonic*) can lead to symptomatic hypoglycemia within 3–4 h in 10–20% of normal individuals. It is thought that the hypoglycemia is due to an insulinotrophic effect of ethanol in response to sucrose.

Fasting Hypoglycemia

The causes of fasting hypoglycemia are numerous and are outlined in Table 2. In many cases, the cause is evident, such as in an ill patient with multiorgan failure, but in others, especially ambulatory patients, it may not be obvious. In these individuals, it is necessary to measure *simultaneously* plasma glucose, insulin, C-peptide, and sulfonylurea levels during the episode of hypoglycemia. If insulin levels are not available, serum or urine ketone levels can give an indication of insulin mediation, as ketone levels are raised in hypoinsulinemic states.

Drugs

Drugs are a frequent cause of hypoglycemia, and some of the more common drugs are listed in Table 3 along with their putative mechanism. Other drugs have been alleged to cause hypoglycemia, but a causal

Table 3 Drugs associated with hypoglycemia

Drug	*Mechanism of inducing hypoglycemia*
Insulin	Increase glucose uptake by peripheral tissues
Sulfonylureas	Increase insulin secretion via sulfonylurea receptors on β-cells
Pentamidine	Increases insulin secretion
Quinine	Increases insulin secretion
Salicylates	Unknown mechanism – ? increase peripheral glucose uptake; need large doses (4–6 g)
Sulfonamides	Unknown mechanism
Angiotensin-converting enzyme inhibitors	? Increases insulin sensitivity
Acetaminophen	Hepatic necrosis in acute toxic overdoses
Disopyramide	Increases insulin secretion
Monoamine oxidase inhibitors	Unknown mechanism, rare
β-adrenergic antagonists	? Increase peripheral glucose uptake; ? inhibit gluconeogenesis; more common in patients with diabetes

relationship has not been established for many of them. These include benzodiazepines, ciprofloxacin, etomidate, enflurane, fluoxetine, furosemide, halothane, interferon-α, isoniazid, maprotiline, mefloquine, nefazodone, octreotide, phenytoin, and selegiline.

Alcohol

Alcohol inhibits hepatic gluconeogenesis by depleting nicotinamide adenine dinucleotide levels and by decreasing the flux of gluconeogenic substrates (i.e., alanine, glycerol, lactate). However, it does not affect glycogenolysis. Therefore, in the well-fed person, hypoglycemia does not occur until after depletion of glycogen stores by fasting > 12 h, along with consumption of 50–300 g of alcohol during the preceding 6–36 h. In the poorly nourished individual, less alcohol may induce hypoglycemia more quickly. Alcohol may also potentiate insulin and sulfonylurea-induced hypoglycemia. Intravenous glucose causes prompt recovery, unlike glucagon, which is ineffective. Without treatment, the mortality rate is 10% in adults and 25% in children.

Protein–Energy Malnutrition

There are many descriptions of hypoglycemia in severe protein–energy malnutrition (PEM), although there seems to be no consistent difference in the severity of hypoglycemia between marasmus and kwashiorkor. The frequency of hypoglycemia varies geographically, ranging from 10% in Jamaica to 24% in Uganda. Hypoglycemia is a poor prognostic factor, as its presence increases the mortality in marasmic infants by 1.6–3.1-fold, unless intravenous glucose is given immediately. The pathogenesis is not clear, but high rates of glucose utilization in the presence of total body fat depletion, limitation of substrate availability for gluconeogenesis, or diminished activity of gluconeogenic enzymes are possibilities. Hypoglycemia is also seen in anorexia nervosa.

Endocrine Deficiencies

Endocrine deficiencies are rare causes of hypoglycemia. Deficiencies of cortisol and/or growth hormone impair gluconeogenesis, especially in the very young, or if other hypoglycemic stressors are present. These endocrinopathies limit the availability of gluconeogenic substrate availability and decrease the activity of hepatic gluconeogenic enzymes. Combined deficiencies, e.g., in hypopituitarism, cause more severe hypoglycemia. Isolated glucagon or epinephrine deficiencies in infants can also cause hypoglycemia but are extraordinarily rare. They can occur as an acquired condition in individuals with long-standing type 1 diabetes. Hypothyroidism can reduce the rate of glucose absorption from the gut and decrease peripheral glucose utilization. However, although hypothyroidism has been said to be a cause of hypoglycemia, it rarely occurs in isolated thyroxine deficiency. The concurrence of hypoglycemia and hypothyroidism should suggest the presence of adrenal insufficiency.

Severe Medical Illness

Severe liver disease, e.g., hepatectomy or fulminant hepatitis can cause profound hypoglycemia, as the liver is the major source of endogenous glucose production. *Renal failure* is also associated with hypoglycemia. Multiple mechanisms are involved, including cachexia, uremic inhibition of hepatic gluconeogenesis, failure of renal gluconeogenesis, decreased renal clearance of insulin (in patients with concurrent diabetes), and dialysis. Hypoglycemia occasionally occurs in *congestive heart failure*, and it is suggested that it is due to hepatic congestion, cachexia, and inhibition of gluconeogenesis. *Sepsis* increases peripheral glucose utilization and inhibits hepatic gluconeogenesis, mediated by cytokines such as tumor necrosis factor-α, interleukin-1, and interleukin-6.

Ackee Poisoning (Jamaican Vomiting Sickness)

A toxic hypoglycemia syndrome occurs whenever the unripe fruit of ackee (*Blighida sapida*) is consumed, as first reported in 1875. Ackee was imported to the New World from West Africa in 1778 and is found in the Caribbean, Central America, and Florida. Poisoning is more common in children, especially if undernutrition is present. Adults generally have a chronic course with a self-limited cholestatic jaundice. The unripe arillus of the fruit contains hypoglycin, which is sequentially transaminated and decarboxylated to methylenecyclopropylacetyl-CoA. This metabolite irreversibly inhibits acyl-CoA dehydrogenases (especially butyryl-CoA dehydrogenase), leading to inhibition of fatty acid β-oxidation. The metabolic consequences are an acquired organic acidemia (mostly glutaric and ethylmalonic acid), the absence of ketosis or hyperinsulinemia, and impairment of hepatic gluconeogenesis. Patients have severe hypoglycemia, an acute encephalopathy similar to Reye's syndrome, and severe vomiting. Convulsion, coma and death can follow. Treatment involves intensive glucose infusions to maintain normoglycemia. Cooking renders the fruit nontoxic, reducing hypoglycin levels 100-fold.

Insulinomas

Insulinomas are rare tumors with an incidence of four cases per million person-years. Approximately 10% are malignant, 9% are multifocal, 8% are recurrent, and 8% occur as part of multiple endocrine neoplasia-1 syndrome. They are evently distributed throughout the pancreas, and ectopic locations are unusual. Some tumors cosecrete gastrin, adrenocorticotropic hormone, glucagon, and 5-hydroxyindole. The diagnosis relies on documentation of Whipple's triad with inappropriately high insulin ($\geq 36\,\text{pmol}\,\text{l}^{-1}$), C-peptide ($\geq 0.2\,\text{nmol}\,\text{l}^{-1}$), and proinsulin ($\geq 5\ \text{pmol}\,\text{l}^{-1}$) levels during hypoglycemia. Surreptitious use of exogenous insulin and sulfonylureas has to be ruled out, and a 72-h supervised inpatient fast may be required (Table 4). After biochemical confirmation, the tumor may be localized by conventional, intraoperative, or endoscopic ultrasonography. Magnetic resonance imaging or selective intraarterial injection of calcium with venous sampling for insulin may be useful. Some are localized by surgical exploration. Treatment is by surgical enucleation of the tumor, and chemotherapy is necessary for palliation in individuals with metastases.

Noninsulinoma Tumor-associated Hypoglycemia

There are various noninsulinoma tumors that induce hypoglycemia, most commonly mesenchymal cancers, hepatoma, adrenocortical carcinoma, lymphoma, and gastrointestinal cancers. Generally, hypoglycemia is a late presentation, the tumor burden is large (> 500 g), and metastases are commonly present. Many of these tumors produce insulin-like growth factor-II as the putative hypoglycemic agent. They rarely produce ectopic insulin. Occasionally, some induce hypoglycemia by increasing glucose consumption in excess of the liver's gluconeogenetic ability.

Miscellaneous Causes

Factitious hypoglycemia is due to the surreptitious use of insulin or sulfonylureas. This may be due to malingering, Munchausen syndrome, attempted suicide/homicide, or pharmacy error. A proper biochemical evaluation during a 72-h fast (Table 4) should reveal the diagnosis. Insulin levels $> 1200\,\text{pmol}\,\text{l}^{-1}$ should generate suspicion of factitious causes. Very rarely, in patients naïve to insulin, there may be a spontaneous autoimmune *antiinsulin antibody syndrome*. This has been reported in Japanese patients treated with thionamides or with other autoimmune disorders. The mechanism involves an insulinomimetic action when the antiidiotypic antibodies to antiinsulin antibodies interact with the insulin receptor. An insulinomimetic action of antibodies against the insulin receptor can cause hypoglycemia in *type B insulin resistance*. *Severe exercise*, as seen in marathon runners, has occasionally been associated with hypoglycemia.

Childhood Hypoglycemia

As children have an increased ratio of brain to body mass, they have higher rates of glucose flux. There is also limited substrate availability for gluconeogenesis due to their smaller muscle mass. Hence, they are not

Table 4 Interpretation of the results of a 72-h fast

Diagnosis	*Insulin*	*C-peptide*	*Proinsulin*	*Plasma or urine sulfonylurea*	*β-Hydroxybutyrate*
Insulinoma	Increased	Increased	Increased	Negative	None
Exogenous insulin	Increased	Decreased	Decreased	Negative	None
Sulfonylurea ingestion	Increased	Increased	Increased	Present	None
Noninsulin-mediated hypoglycemia	Decreased	Decreased	Decreased	Negative	Increased

able to tolerate hypoglycemia as easily as adults. Their clinical presentation is more variable with hypotonia, cyanosis, hypothermia, tachypnea, feeding difficulties, and poor neuropsychiatric development being prominent. Older children have more adrenergic symptoms and may have focal neurological deficits and movement disorders.

Most of the causes of hypoglycemia in adults are also seen in children. *Transient hyperinsulinism* is the most frequent cause of hypoglycemia in the infant, as seen in the children of diabetic mothers, premature infants, and small-for-gestational-age infants. *Congenital hyperinsulinism*, otherwise called *nesidioblastosis* or *persistent hyperinsulinemic hypoglycemia of infancy*, describes diffuse β-cell hyperplasia with hyperinsulinemic hypoglycemia. Subtotal pancreatectomy or medical treatment with diazoxide or octreotide is advocated for symptomatic infants. This is due to genetic mutations that affect the normal intracellular events controlling insulin secretion. The mutations include:

- mutations inactivating the ATP-sensitive potassium channel in β-cells leading to membrane depolarization (*SUR1* and *Kir6.2 subunit mutations*);
- activating *mutations of the glucokinase gene* increasing glycolysis; and
- activating mutations of the glutamate dehydrogenase gene causing an increased rate of glutamate oxidation in β-cells (*hyperinsulinism/hyperammonemia syndrome*, which includes leucine-sensitive hypoglycemia, as leucine is an allosteric activator of GDH and thus functions as an insulin secretagogue).

Hypoglycemia is also a consequence of inborn errors of metabolism involving gluconeogenesis, glycogen storage, fatty acid metabolism, and amino acid metabolism.

Ketotic hypoglycemia of childhood generally begins between the ages of 1.5 and 5 years, and resolves by age 10. It probably accounts for 90% of children with hypoglycemia beyond infancy, and it may represent a subset of children who are least tolerant of fasting, especially during an intercurrent illness. These children characteristically have relatively decreased muscle mass, and there may be a defect in mobilizing alanine for gluconeogenesis. Although alanine administration increases blood glucose levels, treatment generally involves avoiding any prolonged fasting.

HYPOVITAMINOSIS A

V Reddy, Panjagutta, Hyderabad, India

Introduction

Vitamin A is an essential nutrient required for normal vision, growth, and development, maintenance of epithelial cellular integrity, immune response, and a variety of metabolic functions. It is a fat-soluble vitamin and is stored in the body when intake exceeds need. Depletion of stores occurs over time when the diet does not provide enough vitamin A to replace the amount used by the tissues. Signs of hypovitaminosis A appear when the stores are depleted to the extent that physiological functions are impaired. A series of problems ranging from ocular changes to growth retardation and increased mortality have been documented in vitamin A-deficient animals, while in human vitamin A deficiency (VAD), attention is focused on xerophthalmia because of the striking changes in the eye. VAD is recognized as the most important cause of childhood blindness in developing countries. Apart from causing eye damage, VAD can also affect host defense mechanisms, increasing susceptibility to infection. There is evidence that VAD, even at subclinical level, increases the risk of morbidity and mortality in vulnerable groups. Recognizing the importance of the problem, heads of state and other high-level policy makers gathered at the World Summit for Children (1990) and the International Conference on Nutrition (1992) adopted the goal of elimination of VAD by the year 2000. Although considerable progress has been made in the past decade, VAD remains a public health problem in many developing countries. There is a need to accelerate the intervention efforts to eliminate VAD and its consequences.

Dietary Sources of Vitamin A

Vitamin A is obtained through the diet as preformed vitamin A or provitamin A carotenoids. Preformed vitamin A is present in animal foods such as milk, butter, eggs, liver, and fish. In most tropical countries, where consumption of these foods is low, the main sources of vitamin A in the diet are the provitamin A carotenoids. These are present in dark-green leafy vegetables, yellow/orange vegetables like carrots and pumpkin, and fruits like mango and papaya. Red palm oil, used mostly in African countries, has a very high concentration of β-carotene. Of the various carotenoids in foods, β-carotene has the maximum vitamin A activity. Other provitamin A carotenoids include α-carotene and β-cryptoxanthine, which have approximately half the vitamin A activity of β-carotene. Values of carotene/vitamin A given in most food composition tables are overestimates, as they are based on old analytical methods which do not distinguish between provitamin A and other carotenoids. Only recently have accurate values for provitamin A carotenoids been obtained, using high-performance liquid chromatography (HPLC) technique.

Recommended Dietary Intakes

The recommended intakes of vitamin A for different age groups are given in Table 1. These intakes are designed to prevent deficiency and provide a safe intake for a majority of the population. The values are expressed in terms of retinol equivalents (RE) per day, taking into account vitamin A activity of provitamin A carotenoids. The Food and Agriculture Organization/World Health Organization (FAO/WHO) expert committee has suggested a ratio of 6:1 for converting β-carotene to vitamin A, assuming that one-third of the carotene in the diet is absorbed and half of it is converted to vitamin A. However, recent studies showed lower bioavailability of carotene, with a ratio of 26:1 for vegetables and 12:1 for fruits. Bioavailability of dietary carotenoids is influenced by a number of factors, including the food source, method of preparation, amount ingested, and dietary fat. Any single/average ratio for the conversion of carotenoids to vitamin A is at best a rough estimate that is not valid for all diets.

Table 1 Recommended dietary intake of vitamin A

Group	*Age (years)*	*Recommended intake (μg RE day^{-1})*
Both sexes	0–1	350
	1–10	400
	10–12	500
	12–15	600
Boys	15–18	600
Men	18+	600
Girls	15–18	600
Women	18+	500
Pregnant women		600
Lactating women		850

RE, retinol equivalent.

Assessment of VAD

Several methods are available for assessing the magnitude and severity of VAD in a population. These include clinical, functional, and biochemical indicators. The WHO monograph on indicators of VAD provides guidelines on the selection and interpretation of practical indicators for population assessment.

Clinical Indicators

Clinical indicators are useful for assessing the extent of VAD in communities where clinical problem or xerophthalmia exists. The core indicators and the minimum prevalence criteria to define a public health problem are given in Table 2. Corneal xerophthalmia indicates a serious problem but the condition is relatively rare and requires a large sample size to estimate the prevalence. Night blindness (XN) and Bitot's spots (X1B) are the two indicators commonly used in community surveys. Conjunctival xerosis is not a reliable sign, while xerosis with Bitot's spot is more specific and a prevalence above 5% in preschool children indicates a public health problem.

Indicators of Subclinical Deficiency

Serum retinol is the most commonly used biochemical indicator. Values $< 0.70\,\text{mmol}\,l^{-1}$ are considered as indicative of VAD in children. The cut-off levels of prevalence used for defining a public health problem of moderate to severe degree are shown in Table 3. It is possible to estimate retinol concentration in finger-prick blood samples using a filter paper technique, which offers logistic advantages. Other indicators include relative dose response (RDR) test for assessing vitamin A stores and conjunctival impression cytology (CIC) for detection of conjunctival changes that precede clinical signs. However, these tests have limited application in field surveys.

Table 2 Classification of xerophthalmia and prevalence criteria constituting a public health problem

Criteria	*Minimum prevalence*
Night blindness (XN)	> 1.0%
Bitot's spots (X1B)	> 0.5%
Corneal xerosis/ulceration (X2, X3A, X3B)	> 0.01%
Corneal scar (XS)	> 0.05%

Data from: WHO (1995) *Global Prevalence of Vitamin A Deficiency*. Geneva: WHO, with permission.

Table 3 Classification of subclinical deficiency (serum retinol $< 0.70\,\text{mmol}\,l^{-1}$)

Public health problem	*Prevalence in children*
Mild	≥ 2– < 10%
Moderate	≥ 10– < 20%
Severe	≥ 20%

Data from: WHO (1995) *Global Prevalence of Vitamin A Deficiency*. Geneva: WHO, with permission.

Global Prevalence

Earlier estimates of VAD prevalence were based on clinical signs of xerophthalmia, while more recent surveys include data on subclinical deficiency based on blood levels of vitamin A $< 0.70\,\text{mmol}\,l^{-1}$. It is now estimated that VAD, including clinical and subclinical forms of moderate to severe degrees of public health significance, exists in 60 countries and it is likely to be a problem in at least an additional 13 countries. On a regional basis, South-east Asia and Africa account for just under 90% of the global problem (Figure 1). Although the prevalence of clinical deficiency has shown a marked decline from 14 million in 1994 to 3 million in 1996, estimates of subclinical deficiency have gone up to 251 million, with the increasing use of serum retinol concentration for assessment. About 254 million children in the world are thus at risk in terms of their health and survival.

Epidemiology

Socioeconomic Factors

VAD occurs within an ambience of ecological, economical, and social deprivations that characterize the poor in developing countries. At the macro level, adverse environment with infertile land and water shortage limit the availability of foods rich in vitamin A. Since animal foods containing preformed vitamin A are expensive, poor families rely on plant sources of provitamin A carotenoids. Illiterate and impoverished mothers tend to follow traditional feeding practices and do not fully utilize even the available resources. High infection rates associated with poor living conditions also contribute to hypovitaminosis A.

Clustering

The occurrence of VAD tends to cluster rather than to be evenly distributed. Clustering within high-risk households and within communities has been described primarily for clinical deficiency. Studies in Asia show that siblings of xerophthalmic children are 10 times more likely to have xerophthalmia than

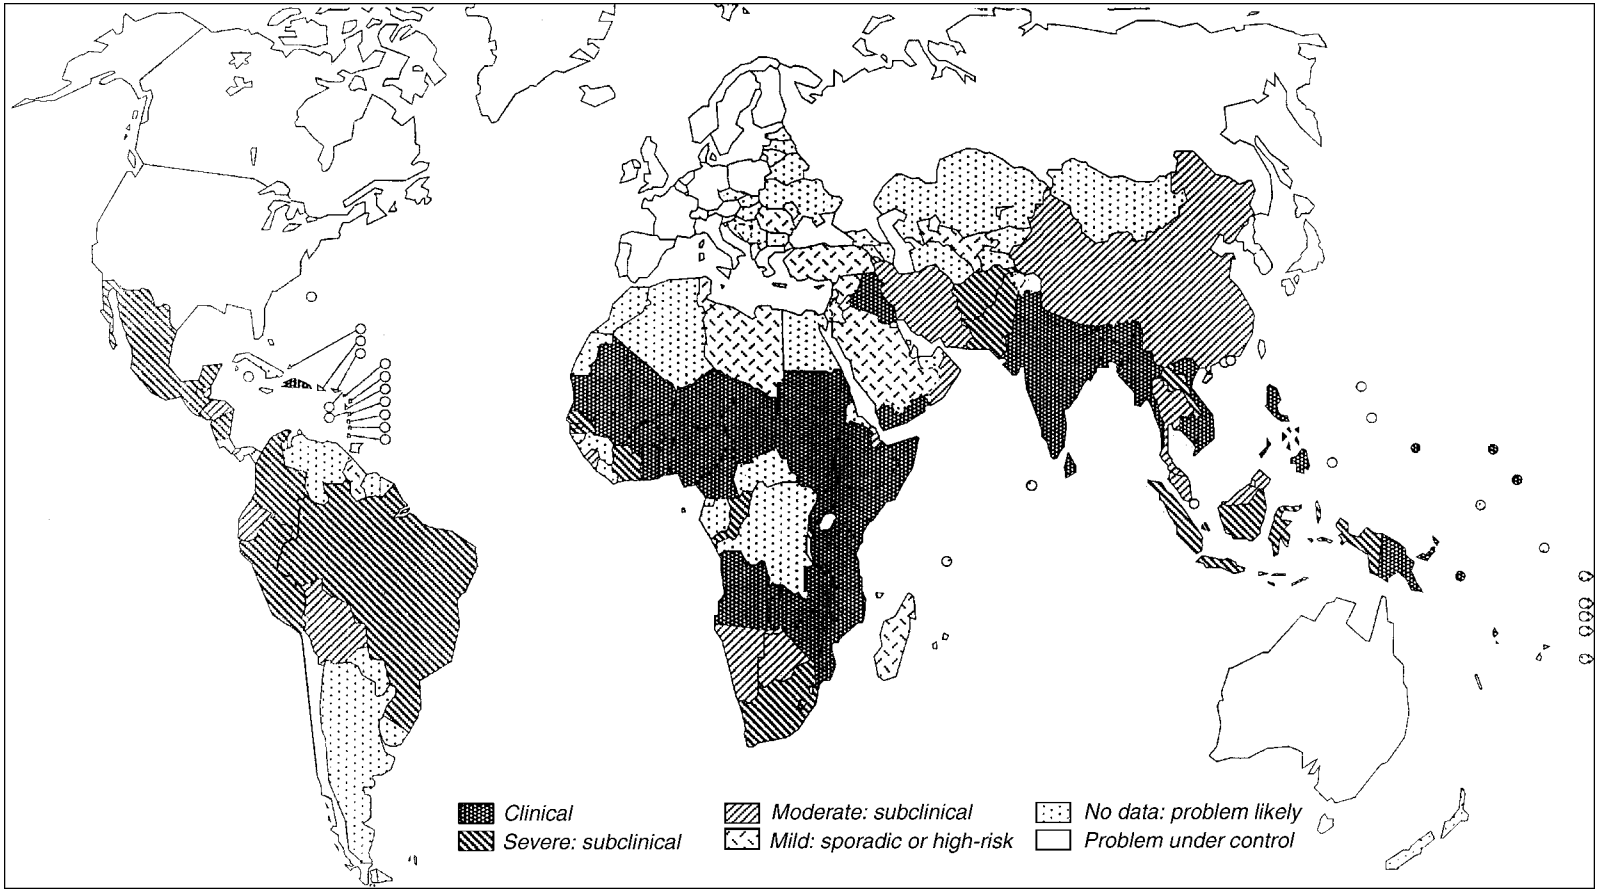

Figure 1 Global prevalence of vitamin A deficiency. Reproduced from WHO (1995) *Global Prevalence of Vitamin A Deficiency. Micronutrient Deficiency Information System*. Working Paper #2. WHO/NUT/95.3. Geneva: WHO, with permission.

those without. Neighboring children of xerophthalmic children are also more likely to develop xerophthalmia. This is due to sharing common sociocultural and economic conditions that result in frequent infections, limited food availability, and poor dietary practices that predispose to VAD.

Seasonal Patterns

The occurrence of xerophthalmia follows a seasonal pattern in different parts of the world. In South Asia, for example, a distinct peak in the incidence of xerophthalmia is observed in the month of May–June. The peak appears to be related to the total food intake and consequent growth spurt of children. It also coincides with a general scarcity of provitamin A-rich vegetables and fruits and a seasonal rise in the incidence of diarrhea and respiratory infection.

Host Factors

Age VAD is more common among children of preschool age. While xerophthalmia rarely occurs during infancy, children between 1 and 4 years are at greater risk. The potentially blinding corneal disease is most prevalent during the weaning period and is associated with severe protein-energy malnutrition (PEM). Symptoms of milder xerophthalmia like Bitot spots and night blindness are more common in older children. Hypovitaminosis A persists throughout adolescence and into adulthood, as judged by low serum retinol levels. Clinical signs of xerophthalmia are rare in adults except for maternal night blindness. Reports from Asia indicate that about 10–20% of women develop night blindness during pregnancy.

Sex No consistent sex difference is demonstrated based on physiological parameters. Differences have been reported in some communities, which are more likely to be related to sex differences in cultural practices of feeding and care rather than to physiological differences.

Dietary Practices

In poor communities, diets are deficient in several nutrients, including vitamin A. Pregnant and lactating women rarely take any extra food to meet their additional needs. As a result, the offspring are born with poor stores of vitamin A. During the first 6 months of life, breast milk is the major source of vitamin A for infants but the vitamin concentration of milk is low in undernourished mothers. Although clinical signs of VAD are rare in infants, their vitamin stores are depleted. Complementary feeding is delayed and foods rich in vitamin A are seldom given, increasing the risk of VAD during the weaning period. Diet surveys in countries of South Asia show that the daily intake of vitamin A among preschool children is less than half the recommended intake and most of it is derived from plant sources of provitamin A carotenoids. Bioavailability of plant carotenoids is low and it is difficult to meet the needs of young children from vegetable foods alone. Dietary fat is important for the absorption of carotenoids but the weaning diets contain little fat. These patterns signal the need to improve child feeding practices in high-risk families to sustain adequate vitamin A status.

Protein-Energy Malnutrition

VAD is often associated with protein-energy malnutrition (PEM) in children. Clinical studies show that the prevalence of xerophthalmia is higher in children with PEM than in those without. Almost all cases of corneal xerophthalmia/keratomalacia are associated with severe PEM. These observations suggest that protein deficiency may aggravate VAD (often associated with protein-energy malnutrition in children). Experimental studies show that there is a close metabolic relationship between protein and vitamin A. While the synthesis of retinol-binding protein (RBP) that carries vitamin A is influenced by protein nutrition, its release from the liver depends on vitamin A status. Studies in malnourished children with corneal xerophthalmia have shown that the concentration of serum retinol was reduced to a greater extent than that of RBP. Administration of vitamin A to such children not only raised serum levels of these components but also showed a rapid clinical improvement. These observations indicate that the role of vitamin A is more critical than that of protein in the development of corneal lesions. Appreciation of this fact has an important bearing on the treatment and prevention of xerophthalmia.

Infections

Keratomalacia is often preceded by an episode of infection: diarrhea and respiratory infection are common precipitating factors. Prospective studies also show that common childhood infections, including diarrhea, respiratory illness, measles, and chickenpox, induce hypovitaminosis A. During acute infection, not only is the food intake reduced but metabolic alterations are also known to occur. These include decreased absorption of vitamin A, impaired retinol transport, and increased renal excretion. Slow normalization of these mechanisms coupled with low dietary intake of vitamin A during the acute phase and recovery lead to VAD. Parasitic infections like ascariasis and giardiasis also aggravate VAD. Intestinal worms may directly compete for uptake of

vitamin A, besides their more general impact on health by suppressing appetite.

Xerophthalmia

Although hypovitaminosis A affects many tissues in the body, the most striking changes are seen in the eye. The conjunctival and corneal epithelium undergo keratinizing metaplasia. Columnar epithelial cells become squamous and mucus-producing goblet cells disappear, resulting in dryness/xerosis of the ocular surfaces. Hypovitaminosis A also affects the retinal function. Vitamin A is required for the synthesis of rhodopsin, a photosensitive pigment in the rod cells of retina that responds to light by releasing vitamin A. If the vitamin is not replaced, rhodopsin production is reduced, resulting in impaired dark adaptation and night blindness.

Night Blindness

Night blindness is one of the early manifestations of VAD and is marked by an inability to move around in the dark. It is common among pregnant women in endemic areas and often disappears after delivery without any treatment. Night blindness is also common among preschool children but its detection is difficult in children below 2 years. In endemic areas, a local term is often used for night blindness that translates into 'twilight blindness' or 'chicken eyes' (chicken have no rods and are therefore night-blind), making the condition readily detectable by history. Impaired dark adaptation is an early functional abnormality which can be detected using a dark adaptometer.

Conjunctival Changes

Conjunctival xerosis appears as a dry, unwettable surface of the bulbar conjunctiva. The conjunctival changes that precede clinical signs can be detected by filter-paper impression cytology. These include keratinization/distortion of epithelial cells and disappearance of goblet cells. In chronic cases, accumulation of keratinized cells appears as white foamy patches of oval or triangular shape called Bitot's spots. They are usually bilateral and seen on the temporal side of the corneal limbus.

Corneal Changes

Severe deficiency of vitamin A involves the cornea, affecting the vision. The earliest corneal epithelial changes appear as punctate defects, which can be detected by a slit lamp. Clinically, the cornea appears dry, hazy, and lusterless (X2). In severe cases, corneal ulcers (X3A) appear as round or oval defects that are usually shallow, but may progress to perforation of cornea. Healed ulcers appear as white scars (XS) and affect vision if they are centrally located. In more advanced cases, there is necrosis and softening of cornea (X3B). This condition, described as keratomalacia, often results in permanent blindness. Corneal xerophthalmia is invariably associated with severe PEM and infection. Hospital studies show high mortality in such cases, ranging from 5 to 25%.

Mortality

Childhood Mortality

Preschool age Vitamin A has been named as 'anti-infective vitamin' as early as 1928, based on the evidence obtained from animal studies. Although there were several reports on the association of xerophthalmia with increased mortality among malnourished children during the subsequent years, the importance of vitamin A in child health and survival was not fully recognized until late 1980s. Community studies in Indonesia showed that preschool children with mild xerophthalmia were two to three times more likely to have developed diarrhea and respiratory illness than those with normal eyes. The risk of mortality was also higher in such cases. The effect of VAD on infection may be mediated through several mechanisms, including impairment of mucosal epithelial barrier and of the immune response. Low T-cell count and impaired blast transformation have been reported in vitamin A-deficient children.

An intervention trial conducted in Indonesia showed that administration of 6-monthly doses of 200 000 IU vitamin A to preschool children resulted in 34% reduction in mortality. This stimulated a lot of interest worldwide and led to a series of field trials in Asia and Africa. Six out of eight controlled trials in children showed mortality reductions ranging from 19% to 54%. However, two studies reported from India and Sudan showed no significant impact. Metaanalysis of data from these studies has estimated a reduction of total mortality by 30%.

Thus, vitamin A supplementation has resulted in significant reductions in mortality in several, though not all, community studies. Vitamin A had a protective effect against death from measles and diarrhea but not from respiratory infection. The impact of vitamin A may vary in different situations depending upon the extent and severity of VAD, existence of concomitant nutritional deficiencies, particularly PEM, and the prevalence of infections in the community. The supplements are expected to have a greater impact in areas where VAD is highly prevalent.

Early infancy A few studies have examined the efficacy of vitamin A supplementation among apparently normal infants under 6 months of age. Administration of a single dose of 50 000 IU vitamin A to neonates in Indonesia resulted in a significant reduction in the risk of death while no effect was observed in a similar study in Nepal. Similarly, in a multicentric WHO study conducted in India, Peru and Ghana, administration of three doses of vitamin A along with diphtheria, pertussis, typhoid (DPT) vaccine in the first 4 months of age had no effect on infant mortality or morbidity.

Measles-related mortality Beneficial effect of vitamin A on measles-related morbidity and mortality in children was reported as early as 1932. In recent placebo-controlled hospital studies conducted in South Africa and Tanzania, administration of large doses of vitamin A to children on admission for severe measles resulted in a 60% reduction in case fatality. The mortality reduction was higher (70%) when measles was associated with pneumonia. The protective effect of the supplements was apparently greater among infants than in older children.

Pregnancy-Related Mortality

Although several studies have examined the impact of vitamin A on child survival, maternal health has not received much attention. Recently, a community trial conducted in Nepal showed that weekly supplements of vitamin A or β-carotene reduced pregnancy-related mortality (mortality during pregnancy up to 12 weeks postpartum). However, differences were only significant when the two groups were pooled. It is surprising to note that the carotene group with lower retinol concentration showed a greater reduction in mortality than the vitamin A group. Furthermore, supplementation was associated with protection from deaths due to injuries and miscellaneous causes but had no impact on mortality ascribable to infections and obstetric causes. Further studies are under way to determine the role of vitamin A in maternal health and survival.

Morbidity

Unlike the impact on mortality, the effects of vitamin A on morbidity have been more difficult to establish. This may be due to variation in disease sensitivity to vitamin A and inherent problems in assessing the prevalence and severity of morbidity. Vitamin A does not have much effect on the prevalence of common childhood diseases but it appears to reduce the severity of potentially fatal infections such as measles, persistent diarrhea, and malaria, especially in the presence of wasting malnutrition. The protective effect becomes stronger with the episode severity. In Bangladesh, administration of vitamin A had no impact on the duration of illness or stool output in children with watery diarrhea, although children with shigellosis who received vitamin A supplements were 32% less likely to be clinically ill as compared to placebo group. In Ghana, vitamin A supplementation was associated with fewer or less severe complications and reduced rates of hospitalization for severe measles. However, vitamin A has no effect on nonmeasles respiratory disease. In some cases, supplementation was associated with an increased risk of lower respiratory infection. This appears a paradox, considering the beneficial effect of vitamin A on the epithelial structures.

Recent studies suggest that vitamin A may have a role in other infections, particularly human immunodeficiency virus (HIV) infection. In adults, low plasma vitamin A concentration was associated with increased clinical progress of HIV infection and greater mortality. It was also found that low vitamin A concentration during pregnancy was associated with increased transmission of infection from mother to child and also increased infant mortality. However, clinical trials in South Africa and Tanzania showed that vitamin A supplementation during pregnancy had no effect on vertical transmission of the disease. In another study, vitamin A supplements reduced diarrheal morbidity in HIV-infected infants. Further research is needed to explore the role of vitamin A in HIV infection.

Treatment of Xerophthalmia

All individuals with xerophthalmia (except pregnant women) should be treated with large oral doses of 200 000 IU vitamin A according to the WHO guidelines (Table 4). The age-specific dose should be given on the first and second days and again 2 weeks later. This applies to all stages of active xerophthalmia, including night blindness, Bitot's spots, and corneal lesions. Corneal xerophthalmia is a medical emergency and should be treated immediately on diagnosis and then patients should be referred to a hospital

Table 4 Treatment of xerophthalmia

Age (months)	*Dose of vitamin A (IU)*
< 6	50 000
6–12	100 000
> 12	200 000

Three doses: on diagnosis + next day + 2 weeks later.

for further treatment as they often present complex problems. Topical application of antibiotic ointment (tetracycline or chloramphenicol) is recommended for corneal lesions to prevent secondary infection. In addition, patients should be provided nutritional support and medical therapy.

Corneal xerosis shows improvement within a week but in more advanced cases (corneal ulcer/keratomalacia), healed scars remain as white opacities, resulting in partial or total blindness. Night blindness responds in a couple of days while Bitot's spots take 3–10 days and some may persist, particularly in older age groups.

Pregnant women should be treated with small doses of vitamin A, not exceeding 10 000 IU daily or 25 000 IU weekly, for about a month. Large doses of vitamin A should be avoided during pregnancy to avoid the risk of teratogenicity.

Prevention of VAD

Inadequate dietary intake of vitamin A is the primary cause of VAD and therefore the most rational approach to prevent the condition would be to improve the diet and increase the intake of vitamin A. As a short-term measure, however, vitamin A supplementation of the high-risk groups is suggested for providing immediate relief. Food fortification is also an effective way of increasing vitamin A intake in the population.

Vitamin A Supplementation

Since vitamin A can be stored in the liver, periodic administration of large doses of vitamin A has been recommended for prevention of VAD. Children between 1 and 6 years of age are given an oral dose of 200 000 IU vitamin A every 4–6 months, while those between 6 and 12 months are given half the dose. Large-scale supplementation programs are now in operation in many developing countries where VAD is a major public health problem. Universal distribution, involving administration of the dose to all preschool children, is adopted by most countries. In addition, targeted distribution of vitamin A is recommended for the high-risk groups (severe PEM, measles, siblings of children with xerophthalmia). Even in areas where a vitamin A program is in operation, these children can be given an additional dose of vitamin A if they had not received the supplement in the previous month.

Although vitamin A supplementation is widely implemented, the coverage is inadequate in most areas. It has been suggested that supplementation may be linked with the national immunization program to take advantage of immunization contacts for the delivery of vitamin A. In most national programs, the first dose of vitamin A is given along with measles vaccine at the age of 9 months. In Bangladesh, vitamin A supplements are given earlier along with DPT immunization. A higher incidence of side-effects like nausea, vomiting, and bulging fontanel were observed with this regimen, raising concern about supplementation in early infancy. However, the symptoms were mild and transient, disappearing within 48 h and follow-up studies showed no long-term sequelae. A WHO multicentric study conducted more recently confirmed the safety of vitamin A supplements but this regimen had no significant benefit for the infants.

Administration of a large dose of 200 000 IU vitamin A has been recommended for lactating mothers within 8 weeks of delivery to raise vitamin A concentration of milk and thus improve vitamin A status of the infant. However, recent studies show that the dose is not enough to produce any beneficial effect. Increasing the amount of vitamin A (two doses of 200 000 IU each) has been suggested. Further studies are needed to determine the feasibility and safety of administering two large doses within 8 weeks.

Food Fortification

Although vitamin A supplementation is a simple and effective intervention, it does not correct the underlying dietary causes. In recent years, food-based approaches have been receiving increasing attention as a long-term sustainable strategy. Food fortification offers a direct, effective, and potentially sustainable way to correct VAD. Vitamin A fortification of sugar has been successfully implemented in Guatemala and other Central American countries. However, a recent survey in Guatemala showed a high prevalence of VAD in children < 3 years, suggesting that fortification of a single food may not ensure adequate vitamin A status of the entire population. Fortification of multiple foods, including complementary foods targeted to young children, has been suggested as an alternate strategy. Other foods fortified with vitamin A include margarine in the Philippines, monosodium glutamate in Indonesia, and edible oils in India. Selection of appropriate vehicle and adequate level of fortification are important to meet the population needs.

Since VAD often coexists with deficiencies of other micronutrients like iron, folate, and zinc, fortification of foods with multiple nutrients has been suggested. Further research is needed to understand the interactions of various nutrients and to establish whether fortification with multiple nutrients would facilitate each other's beneficial effects.

Dietary Diversification

Dietary diversification, including vitamin A-rich foods, is the most effective long-term sustainable solution. Since animal foods containing preformed vitamin A are expensive, attention is focused on plant sources of provitamin A carotenoids. Green leafy vegetables, yellow/orange vegetables and fruits like papaya and mango are common sources of vitamin A. Green leafy vegetables are abundant in most countries where VAD exists, but their consumption is low due to lack of knowledge. Dietary intake can be improved through nutrition education and social marketing strategies. In areas with limited availability, horticulture programs should be undertaken to increase the production of vegetables and fruits. Large-scale home gardening programs have been successfully implemented in some countries like Bangladesh and Thailand. Evaluation studies have shown that the consumption of vegetables was higher in families with home gardens.

Bioavailability of plant carotenoids is relatively low and it is difficult to meet vitamin A requirements of young children through vegetable foods alone. Programs to improve vitamin A status must encourage consumption of a variety of foods, including animal foods like milk and eggs, at least in small amounts to improve the quality of diet. Bioavailabilty varies not only with the food source but also the way it is prepared. Intervention programs should focus on high-carotene varieties of vegetables and promote appropriate methods of processing/cooking to minimize carotene losses. Fat content of diet should be increased to promote carotene absorption. However, effective dietary changes require a thorough understanding of the local sociocultural and behavioral factors that predispose to hypovitaminosis A.

Apart from dietary interventions, improvement in environmental conditions and control of parasitic infection are important to improve the vitamin A status of the population. VAD must be seen in the broader context of malnutrition that afflicts the poor. Greater emphasis should be laid on integrated multisectoral comprehensive strategies, taking into account the community's overall needs.

ICE CREAM

Contents

Methods of Manufacture

R T Marshall, University of Missouri, Columbia, MO, USA

Introduction

Ice cream is a frozen emulsion. The continuous phase consists of unfrozen syrup containing the dissolved substances, mostly sugars and minerals. The disperse phase consists of air cells, globules of milk fat (and in some countries other sources of fat), ice crystals, and insoluble substances including proteins and hydrocolloids.

Steps in the manufacture of ice cream are as follows: decide on composition; determine the availability and characteristics of ingredients needed to make the mix; calculate amounts of each ingredient needed; combine the ingredients of the mix; process the mix; store the mix cold until certain components have hydrated; add liquid flavorings; freeze the mix to a soft consistency while stirring and introducing air; to the soft-frozen product add desired syrups or solid types of flavorings; package; and harden and store the packaged product.

A product called Dippin Dots™ is made from ice cream mix but is not stirred while being frozen. Instead, droplets of ice cream mix are caused to fall into a bath of liquid nitrogen where they are frozen rapidly into small spheres. The frozen bead-like particles are removed, packaged, and stored at a very low temperature to prevent them sticking together. The beads can be dipped into containers for serving. These beads contain little or no air, and the ice crystals within them are very small compared with those in ice cream.

Deciding on Mix Composition

Ice cream is composed of milk fat, nonfat milk solids, sweetener, flavoring, stabilizer, and emulsifier. In a simple formulation cream provides the milk fat and some nonfat milk solids, the remainder of which is supplied by concentrated or dried skim milk. Sugar and corn syrup are the major sweeteners, vegetable gums are the stabilizer and mono- and diacylglycerols are the emulsifiers. There are many other sources of these basic ingredients (*See* **Ice Cream: Properties and Analysis**). Costs, availability, quality, stability and ease of handling are considered in deciding which ingredients to use. Once the ingredients have been chosen, amounts of each component must be calculated.

Calculating Ice Cream Mixes

As long as the sources of the major components of ice cream are few, mix calculation is relatively easy. However, multiple sources of components make the process complex. The illustration provided below is for a simple mix.

Let us assume a mix composition of 12% milk fat, 10% nonfat milk solids, 15% sugar, 0.2% stabilizer, and 0.1% emulsifier. Further assume that ingredients used are cream containing 30% fat and 6.3% nonfat solids, nonfat dry milk containing 96% solids (4% moisture), sugar, gum stabilizer and mono- and diacylglycerol emulsifier. To make 100 units of the mix we need 40 units of cream (12/0.3) and it provides 2.52 units of nonfat milk solids (40×0.063). We subtract 2.52 from the 10 units of nonfat milk solids needed and find we need to add 7.79 units of nonfat dry milk [$(10 - 2.52)/0.96$] to supply the remainder

of the nonfat milk solids. We add 15 units of sugar, 0.2 unit of stabilizer, and 0.1 unit of emulsifier. The latter two contain insignificant amounts of moisture. On addition ($40 + 7.79 + 15 + 0.2 + 0.1$) we find we have only 63.09 units of mix. Therefore, we make up to 100 units with 36.91 units of water. Had the combination of cream of lower fat content and concentrated skim milk been used, little or no water would have been required.

Compounding the Ice Cream Mix

In making the mix, liquid ingredients are combined in a vessel and solid ingredients are added while stirring. Because gums are in the form of particles that adsorb water but do not dissolve, they tend to clump when added to mix in the dry form. To overcome this they can be suspended in sugar syrup by blending for a short time. The suspension is then stirred into the mix and particles of stabilizer disperse well. Similarly, nonfat dry milk tends to form lumps when added in large amounts to a liquid. Instantizing of nonfat dry milk overcomes this problem, making it a desirable form of concentrated nonfat milk solids for use in the home. However, the cost of instantization and the high bulk of the product, compared to regular nonfat dry milk, restrict its use in industry. Instead, a device called a powder funnel delivers the dried milk into a rapidly flowing stream of water or of liquid ingredients of the mix where it disperses well and dissolves quickly. In the home or small industry, nonfat dry milk or stabilizers can be mixed with sugar before adding them to the liquid portion of the mix. When dry ingredients that tend to lump are added slowly to liquid that is being rapidly agitated, they usually disperse adequately. Therefore, some processors use this approach to combining the dry ingredients. Usually the mix is being heated as the ingredients are being combined.

Processing the Mix

Two processes are normally used in preparing the mix for freezing, namely, pasteurization and homogenization. Pasteurization destroys undesirable bacteria and enzymes while homogenization reduces the sizes of fat globules and particles of stabilizer, thus improving smoothness of the finished product. These processes necessitate heating and cooling. The minimal temperature for pasteurization depends on the amount of time the mix is to be held at pasteurization temperature.

When the process is done by the 'batch' method, the entire mix is heated in a vessel to at least 69 °C (155 °F) and held at that temperature for 30 min. Following this treatment, the mix is pumped through a homogenizer, then to a cooling device to lower the temperature to 4 °C or lower. Small batches of mix often do not receive the homogenization treatment.

The most common method of pasteurization involves pumping the mix through a high-temperature, short-time (HTST) pasteurizer (Figure 1). This device, called a platetype heat exchanger, employs hot and cold water to heat and cool the mix, respectively. In addition, a section of plates called the 'regenerator' is used to transfer heat from the outgoing pasteurized mix flowing on one side of thin stainless-steel plates to the incoming cooler mix flowing in an opposite direction on the opposite side of the same plates. This device can save up to 90% of the heat and refrigerant that would otherwise be needed. Minimal time and temperature requirements for this process are 25 s at 80 °C (175 °F). Higher temperatures with shorter times are also permitted in many countries.

Mixes must be heated before homogenization because fat must be in the melted rather than the crystalline state to be broken into smaller globules. Diameters of the fat globules of cows' milk range from about 1 to 10 μm. Homogenization reduces diameters to 2 μm and less. One globule 10 μm in diameter yields eight new globules 5 μm in diameter, and they have a combined surface area twice that of the original globule. Thus, homogenization increases the creaminess attribute of the product. The process is accomplished by pumping the mix through exceedingly small space (the homogenizer valve) at pressures of about 14 MPa.

Storing the Mix

The purpose of cooling the mix to lower than 5 °C and holding it for a few hours is to permit the added hydrocolloids, the gum-type stabilizers, to become hydrated and to permit some crystallization of the fat so it will partially churn in the freezer. The minimal time for this treatment is usually 2 h. Cooling at this stage of production decreases the amount of heat that will need to be removed in the freezer, thus increasing the capacity of the freezer by permitting a shorter time to reach the desired exit temperature.

Freezing the Mix

The Batch Process

Batch freezing involves introducing ice cream mix, often by gravity, into a cylinder containing a 'dasher' with scraper blades (Figure 2). The cylinder is open to the atmosphere and is surrounded by refrigerant. The dasher is caused to rotate within the cylinder so that

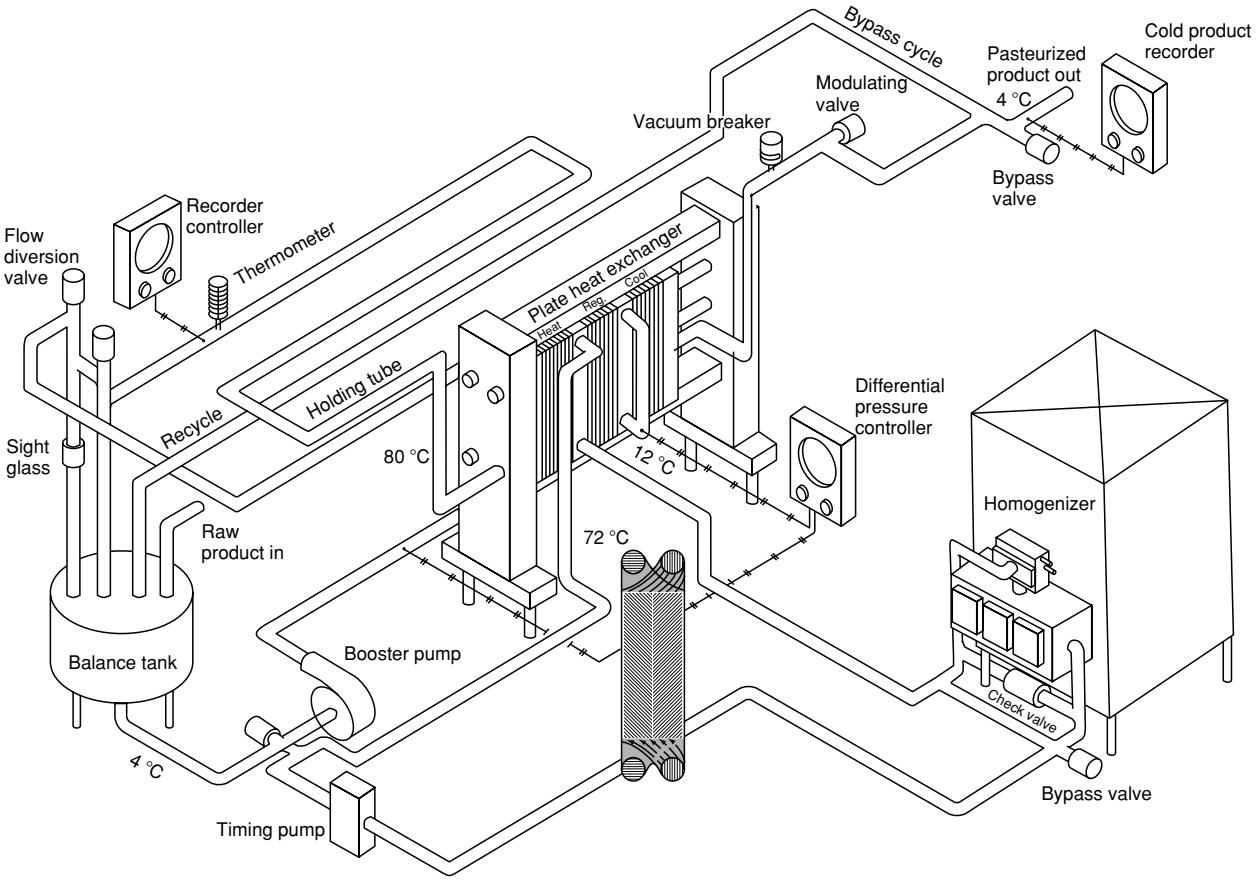

Figure 1 System for high-temperature, short-time pasteurization and homogenization of ice cream mix. The rippled surface of the heat exchanger plates is shown in the lower center. Temperatures (°C) appear near critical locations.

air will be incorporated into the mix, fat globules will be partially churned, and ice crystals that form on the inside wall of the cylinder will be scraped off by the sharp edges of the dasher blades. As the water is frozen into ice, the viscosity of the mix increases. Air bubbles are trapped in the viscous mix, increasing its volume and producing overrun. The maximal overrun permitted in ice cream is about 100%, but that amount of overrun is difficult to obtain in the batch-freezing process.

Capacities of batch freezers vary from less than 1 l (home freezers) to about 401 (commercial operations). Those freezer buckets that are refrigerated with ice and salt, mostly home freezers, must be completely closed to avoid entry of the salt brine into the ice cream. Therefore, any additives such as fruit must be placed in the mix prior to freezing or must be mixed into the soft-frozen product postfreezing. Batch freezers that are cooled with liquid refrigerant, such as the freons, usually have openings above the cylinder through which flavorings, such as fruits, nuts, and bakery products, can be added near the

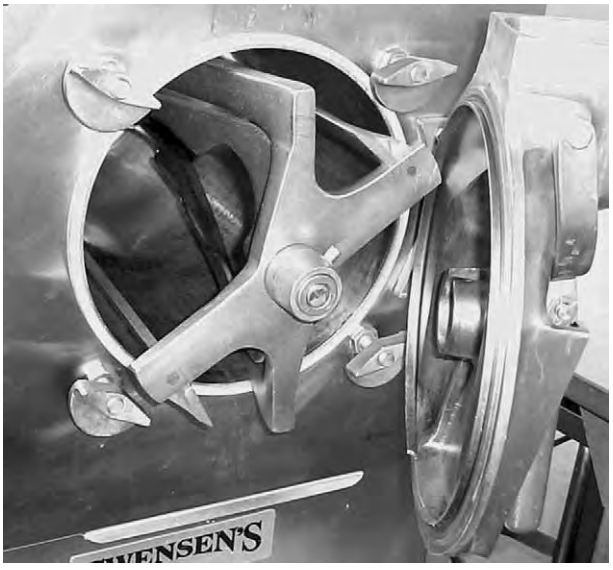

Figure 2 Batch-type ice cream freezer barrel containing beater and blades. The door has an opening through which particulate-type flavorings can be added near the end of the freezing cycle. Frozen product exits through a hatch in the door.

end of the freezing process. This allows the particles of additives to maintain their shape and reduces the adverse effect on incorporation of air bubbles. The refrigeration units are mostly contained within the freezer cabinet. These units pump liquid refrigerant into a chamber surrounding the freezing cylinder where a drop in pressure and migration of heat into the refrigerant change it to a gas. The gas is then mechanically compressed and cooled. On cooling, the refrigerant changes back to a liquid and begins another cycle through the freezer.

The Continuous Process

Most of the ice cream produced commercially is frozen in continuous freezers (Figure 3). They range in capacities from about 100 to 3000 l h^{-1} per freezer barrel. These freezers, except for small ones, are commonly refrigerated with ammonia supplied from a remote compressor unit. The refrigeration cycle starts with liquid ammonia being released into the barrel surrounding the freezing cylinder that contains the mix. The mix, being warmer than the ammonia, gives up heat to the liquid ammonia, transforming it into a gas. This gaseous ammonia is pulled into a compressor that compresses it and forces it through condensing coils where sufficient heat is removed to change the gas into a liquid. This liquid is then ready to be circulated into the freezer to take on more heat from the ice cream mix. At atmospheric pressure ammonia boils at a temperature of $-15.6\,^{\circ}C$. Reducing the pressure enables it to boil at much lower temperatures. Ice cream is frozen to -5 to $-7\,^{\circ}C$ in the continuous freezer. The internal structure of the ice cream never improves after the ice cream leaves the freezer. All of the air cells and ice crystals that can be formed are formed within the freezing cylinder. Subsequent treatments only reduce the numbers of these inclusions by forcing air cells to collapse or merge and ice crystals to grow in size while being reduced in number.

The design of the dasher of the continuous freezer affects the throughput and physical properties of the ice cream. Dashers with a solid core on to which scraper blades are attached may displace as much as 80% of the freezer cylinder volume. Rates of rotation of these dashers tend to be high. They churn the fat quickly, producing stiff ice cream that melts slowly and is favored by producers of extruded novelty products. However, the small annular space between the dasher and freezer cylinder limits the amount of mix that can be contained and increases the probability of freeze-up within the cylinder. Open dashers (Figure 4) that displace 15–50% of the freezer volume are commonly placed into freezing cylinders of comparatively large diameter. The large volume of mix within the

Figure 3 (see color plate 97) Continuous-type freezer with front removed revealing the freezing cylinder and dasher. To regulate the flow of mix and the extent of freezing, pressure is exerted on the freezing chamber by turning the handle located at the outlet for the frozen product in the cylinder cover.

Figure 4 (see color plate 98) Open-type dasher with sharp scraper blades. The dasher is partially inserted into the freezing cylinder of the continuous freezer.

chamber limits the effects of variations in refrigerant supply. Output is more uniform in temperature and overrun than the output from cylinders that have solid dashers, but the ice cream tends to appear wet and to melt rapidly. To prevent freeze-up of cylinders, most modern freezers provide for hot refrigerant gas to be turned into the space surrounding the freezing cylinder when current flow through an ammeter to the dasher motor gets excessively high, indicating very high mix viscosity. This procedure can also be done manually.

Quality of the finished ice cream can be improved by decreasing the sizes while increasing the numbers of ice crystals and air cells during freezing. Two approaches are taken to achieve these conditions. The first method is to use two freezing cylinders. The first is essentially the same as the usual chamber while the second cylinder has a dasher designed to agitate the mix vigorously and to cool it to about 3 °C lower than does a conventional freezer. Pressure within the freezing chamber is kept 4–6 times higher than in a conventional cylinder. The second method is to preaerate the mix by passing it through an emulsifier prior to entry into the freezing cylinder. The device adds air and breaks it into fine bubbles.

All continuous freezers have a variable-speed pump that supplies mix to the freezer chamber. Some also have a pump that operates at a higher speed to remove frozen mix from the freezer. A single pump must force the mix all the way to the filler, whereas placement of a pump at the outlet of the cylinder permits the mix pump to work against only the pressure in the cylinder. The outlet pump then works against the pressure within the cylinder and the downstream line pressures.

Programmable freezers are in wide use. Sensors feed data to the microprocessor that controls the system. Air input is set in proportion to the amount of mix entering the chamber. Some programmable freezers can be linked to filler machines so they sense the appropriate flow rate of the mix into the freezer.

Compared with batch freezers, the advantages of continuous freezers are: (1) volume frozen per freezer is much higher; (2) the product is usually much smoother in texture; (3) overrun can be more closely controlled and higher; (4) ingredient feeders and variegating equipment can be placed downstream from the freezer to introduce additives; and (5) ice cream can be more easily formed into special shapes and packaged with multiple flavors per package. Some continuous freezers have multiple cylinders, making it possible to extrude two or more flavors simultaneously (Figure 5).

Packaging the Ice Cream

Once the ice cream exits the freezer it can be eaten in the soft-frozen form or packaged and hardened. In the USA about 75% of frozen desserts are consumed

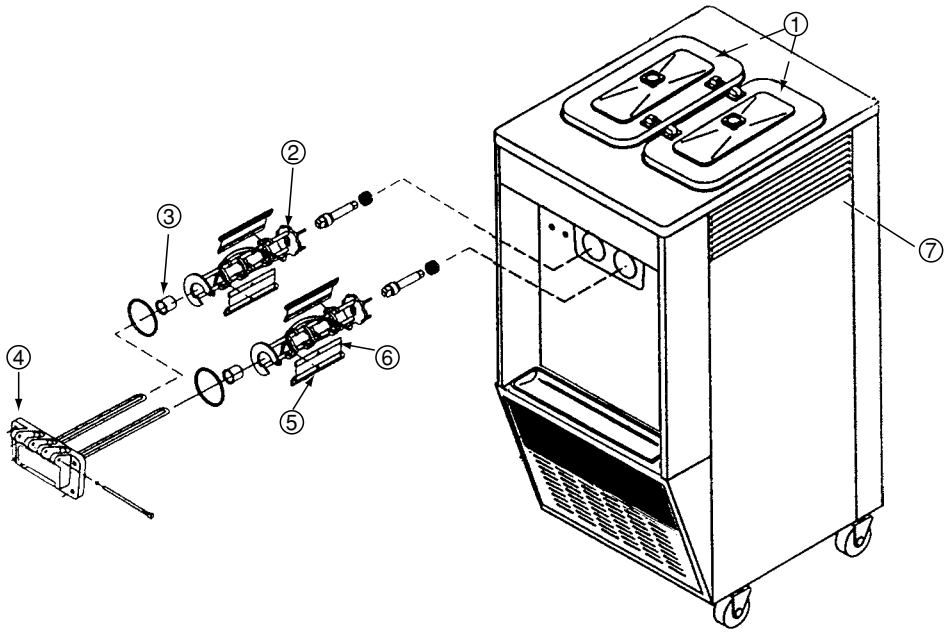

Figure 5 Twin-barrel ice cream freezer: 1, hoppers for mixes; 2, dasher (beater) assembly; 3, front bearing; 4, front cover with two outlet valves; 5, one of four scraper blades; 6, clip to attach scraper blade; 7, cabinet containing refrigeration unit. Adapted from Taylor drawing of Model H84.

in the hard-frozen form. It is imperative that packaging be done immediately after freezing to prevent melting of the frozen product and that the packages be transferred to the hardening facility quickly.

Container sizes vary from 90 ml to 11.36 l (3 to 384 fl. oz.), with most packages of the 1–2-l capacity (more than 80% of the ice cream sold in retail stores in the USA is of the 1.89-l (1/2 US gallon) capacity). Rectangular containers dominate the market. However, higher-priced premium and superpremium frozen desserts are commonly packaged in straight-wall cylindrical or nested cylindrical containers, because these containers connote high quality. A relatively new package is a tapered rectangle with rounded corners. The most popular packaging material is paperboard coated with plastic, but all-plastic containers hold a share of the market.

The package should be convenient to use; attractive; appropriately labeled, including the lot number; and capable of protecting the product from tampering, contamination, and chemical changes, especially oxidation.

Filling is done by volume, but weight per unit volume is controlled to prevent fraud. In the USA the minimal weight is $540\,g\,l^{-1}$ ($4.5\,lb\,gal^{-1}$) for regular ice cream, whereas ice creams with lowered fat content (reduced-fat, light, low-fat, and nonfat) may weigh as little as $480\,g\,l^{-1}$ ($4.0\,lb\,gal^{-1}$). Volume usually varies as little as 1% within a filling operation. In most commercial operations the container is formed on the premises from preprinted stock. Small operations may receive and fill preformed nested containers.

Hardening Frozen Desserts

It is essential to reduce the temperature of packaged ice cream to not more than $-18\,°C$ ($0\,°F$) within a few hours of packaging. Otherwise, ice crystals grow excessively in size and the product becomes coarse in texture. Lower temperatures of approximately $-30\,°C$ ($-22\,°F$) are needed if the product is to be held for more than a few days. To achieve the optimal rate of hardening, the environmental temperature is $-40\,°C$ ($-40\,°F$) or lower. Speed of hardening depends on the environmental temperature, rate of heat conductivity, distance the heat must travel, and speed of removal of heat from the surface of the container. Therefore, large volumes cool slowly because heat must travel far to get to surfaces and there is a low surface area per unit volume with large packages. Rate of removal of heat can be increased by placing packages in contact with cold surfaces. This is done effectively with rectangular packages that are placed between cold steel plates. Another way to remove heat quickly from package surfaces is to force cold air over the surfaces rapidly. This is best done with conical-shaped packages that allow passage of air between stacked packages. Stacking of packages reduces air movement, especially when package surfaces fit well together and when multiple packages are overwrapped with films to facilitate handling. Therefore, stacking and overwrapping should await completion of the hardening process. To maximize heat transfer in minimal space, manufacturers use hardening chambers through which packages are conveyed on trays, shelves, or belts as cold air is blown on to them (Figure 6). Since the environment of a

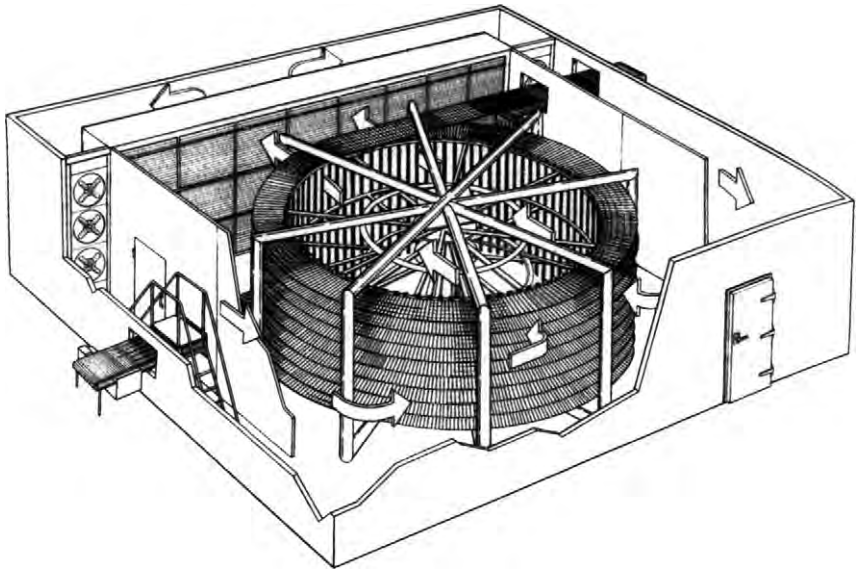

Figure 6 Hardening freezer equipped with a belt-type conveyor that spirals upward toward the storage freezer. Courtesy of Frigoscandia, Northfield, MN.

hardening facility is unfavorable to humans, it is desirable that the frozen product be unloaded mechanically so it can be stacked either mechanically or by hand on to pallets for transfer to the storage facility.

Storage of Frozen Desserts

The temperature of the storage facility need not be as low as that of the hardening facility, but the longer the product is to be held, the lower the temperature needs to be. Usually, $-30\,^{\circ}C$ ($-22\,^{\circ}F$) is satisfactory. Since the environment within a storage facility is unfavorable to humans, storage retrieval systems have been developed that allow workers to move product in and out of storage using computer-controlled mechanical devices. The system keeps a current inventory of numbers and locations of each flavor, package size, lot number, and time of production. Proper quality control and risk management procedures make it necessary that records be kept of ingredients and their sources, results of tests of composition and bacterial counts, and the net weight per unit volume. Temperatures of the storage facility should be monitored continuously, and alarm should be sounded when the temperature exceeds a specified maximum.

Introduction

Ice cream (glaces à la crème in French; Eiskrem in German; helado in Spanish; morozhenoe in Russian; roomijs in Dutch; fløde is in Danish) is a frozen emulsion. The continuous phase consists of unfrozen syrup containing the dissolved substances, mostly sugars and minerals. The disperse phase consists of air cells, globules of milk fat (and in some countries, other sources of fat), ice crystals, and insoluble substances, including proteins and hydrocolloids.

This article discusses the unique chemical, nutritional, physical, microbiological, and sensory properties of frozen desserts. Both objective and subjective methods are used to measure these properties.

Definition of Ice Cream

According to the US standard for frozen desserts, plain ice cream must contain at least 10% milk fat and 20% total milk solids. Manufacturers are permitted to substitute up to 25% of the nonfat milk solids content by the solids of cheese whey. Furthermore, milk fat may be substituted for nonfat milk solids in 1% increments up to 14% milk fat. For example, a product containing 12% fat need contain only 8% nonfat milk solids and 2% of this amount may be whey solids. Ice cream must weigh at least $540\,g\,l^{-1}$ ($4.5\,lb\,gal^{-1}$) and contain at least $192\,g\,l^{-1}$ of food solids ($1.6\,lb\,gal^{-1}$). This limits the maximum amount of air that can be whipped into the mix during freezing to approximately 100% or the same volume as the volume of the mix that goes into the package. Standards for ice cream having lowered fat content, namely reduced fat, light, lowfat and nonfat ice creams, permit the weight to be as low as $480\,g\,l^{-1}$ ($4.0\,lb\,gal^{-1}$).

The following are the US Food and Drug Administration requirements for labeling of foods with a lower fat content:

- Reduced fat: at least 25% less fat than the reference product.
- Light: 50% reduction in total fat from the reference product, or one-third reduction in calories if less than 50% of the calories are from fat.
- Lowfat: not more than 3 g of total fat per serving.
- Nonfat or fat free: less than 0.5 g of fat per serving.

When large amounts of flavoring ingredients, such as chocolate, nuts, and fruits, are added to plain ice cream mix, the requirements for percentages of milk fat and total milk solids are reduced in proportion to the weight of the 'bulky flavoring.' In no case, however, may there be less than 8% milk fat or 16% total milk solids.

Canadian standards differ somewhat from those of the USA. Whereas plain ice cream must contain at least 10% milk fat, Canada has no minimum for total milk solids. The minimum amount of solids permitted is essentially the same in the two countries. Canada requires a minimum of 36% of total solids in the ice cream and a solids weight of $180\,g\,l^{-1}$ in the finished product. The US standard calls for minimal foods solids of $1.6\,lb\,gal^{-1}$ ($192\,g\,l^{-1}$). As in the USA, Canada permits cocoa or chocolate, fruit, nuts, and confections to displace up to 2% of the milk fat.

Canadian standards permit sales of light ice cream with 5–7.5% milk fat and ice milk with 3–5% milk fat. Total solids in each must be at least 33% and comprise at least $160\,g\,l^{-1}$. The maximal fat permitted when bulky flavors are added to light ice cream is 6%. No reduction is permitted in fat content when bulky flavors are added to ice milk.

Although countries in the European Union (EU) are attempting to agree on common compositional standards, the current minimum fat content of ice cream ranges from 5% in the UK to 10% in Germany. Italy, where ice cream is called gelato, has no requirement. Most EU countries permit the sale of milk ice (ice milk) containing, variously, at least 2.5–5% fat. Some countries permit vegetable fat to replace milk fat, provided disclosure is by obvious labeling. However, products labeled with dairy or milk as part of the name must contain milk fat only. Most of the EU countries have a minimum total solids (dry-matter) requirement of 29 or 30% for ice cream. European standards generally do not specify minimum weights per unit of volume. Most do specify which nondairy ingredients are permitted, including fruits, nuts, flavorings, sweeteners, color additives, stabilizers, and emulsifiers.

In India, ice cream can be made from cows' or buffalo milk. The minima for content of fat, protein, and total solids are 10%, 3.5%, and 36%, respectively. Fat content may be reduced in proportion to the amount of bulky flavorings added but not below 8%. The limit for added stabilizers and emulsifiers is 0.5% and for added starch is 5%.

Chemical Properties

Since ice cream is composed primarily of cream, nonfat milk solids, sweeteners, and flavorings, the major components are milk fat, lactose, milk protein, sugar, and corn syrup solids. Minor ingredients are vegetable gums and mono- and diacylglycerols. Tests commonly used to determine the chemical composition of ice cream and to determine whether it meets regulatory standards include ether extraction for fat and the hot air oven for total solids.

The fat content of ice cream is measured by extracting the lipids from a weighed sample with organic solvents, evaporating the solvents, weighing the extracted fat, and calculating the percentage. Protein is measured with the Kjeldahl test, involving digestion of the sample with strong sulfuric acid, a catalyst, and heating then distilling and measuring the nitrogen in the sample. Nitrogen content is then multiplied by a factor of 6.38 to calculate the protein value. Calories are assayed by burning a sample in a bomb calorimeter to determine how much heat is produced per unit sample. Minerals are quantified using flame photometry or atomic adsorption spectroscopy. Biometric or spectrophotometric assays are used for several vitamins.

To analyze for total solids, about 3 g of melted ice cream is weighed into a dried and weighed pan. Moisture is evaporated on a steam bath and then in an oven at 100 °C for 3.5 h. On cooling, the pan with its dry contents is weighed and the percentage of total solids is calculated.

Tests for total milk solids are not performed by regulatory agencies because of the complexity of ice cream formulae. Rather, control agencies have the option to check records of production and of dairy ingredient utilization to ascertain whether, on a general basis, a firm has met the ice cream standard.

Nutritional Properties

Ice cream products vary widely in nutrient content, primarily because of the differences in content of water, fat, nonfat milk solids, and air per unit of serving. Water content varies from about 70% in soft-serve low-fat or light ice creams to 57% in superpremium ice creams. Fat content varies from 0.5 to 16%, and air displaces ice cream mix on a volume basis from 10% in some superpremium ice creams to over 50% in fat-free ice creams. Based on nutrition labels, a serving of 120 ml (4 fl. oz. and a minimum of about 70 g) of vanilla ice cream varies in caloric content from 90 in the nonfat to 240 in the premium full-fat type.

Ice cream mix contains 3–4.5% protein so that a 70-g serving furnishes 2–3 g. Ranges of other components per 120-ml serving of nonfat through premium plain ice creams, excluding the sugar-free types,

are: carbohydrate 13–19 g; sugar 13–15 g; fat 0–10 g; and calcium 58–135 mg. Because milk fat is a good source of vitamin A, manufacturers are required to add this nutrient to lowfat and nonfat ice creams. Additionally, a serving of ice cream provides about 10% of the daily value of riboflavin plus significant amounts of thiamin, pyridoxine, and pantothenic acid. (*See* **Vitamins**: Overview.)

A serving of regular ice cream contains about 3.5 g of lactose, enough to cause intestinal discomfort in some persons who digest lactose poorly. Such persons produce insufficient lactase (β-galactosidase) in the small intestine. Lactose can be removed from nonfat milk by ultrafiltration and diafiltration or can be hydrolyzed to glucose and galactose by the addition of lactase enzyme. By using a combination of the two treatments, the freezing point of a mix can be maintained while reducing the amount of lactose below biologically significant levels.

Analyses for lactose in milk can be done by both chemical and instrumental methods. However, the presence of significant amounts of other sugars in ice cream precludes using the polarimetric method for it. In milk and milk products to be used in ice cream the concentration of lactose can be determined by removing the fat and protein by precipitation and filtration followed by measuring the degree of rotation of polarized light, which is proportional to the concentration of lactose. The 9.610-nm wavelength of infrared light is highly absorbed by the hydrogen bonds that are abundant in lactose, and this is the principle of a widely used instrumental method of analyzing for lactose in milk. For ice cream itself, high-pressure liquid chromatography is the method of choice for determining the concentration of lactose. (*See* **Lactose**.)

Physical Properties

The major physical characteristic of frozen desserts that concerns regulatory agencies is weight per unit volume of product, and this is affected by the overrun developed in the product. When enough air is whipped into a mix during freezing to cause doubling of the volume, 100% overrun has been obtained. Thus, a mix weighing 1.1 kg l^{-1} would produce 2 l of ice cream weighing 0.55 kg each. Ice creams are classified by industry as superpremium, premium, regular or trade-brand, and economy. The overrun of superpremium ice creams may be as low as 20%, whereas that of economy ice creams is usually at the maximum limit.

Overrun can be calculated for individual containers by determining the portion of mix displaced by air in the specific package as follows:

$$\%\text{Package overrun} = [(\text{mix weight} - \text{product weight})/\text{product weight}] \times 100$$

'Plant overrun' is an expression of the increase in volume of an entire lot of ice cream mix. For example, if 5000 l of mix is frozen into 9000 l of ice cream, the overrun is 80%.

$$\%\text{Plant overrun} = [(\text{volume of product} - \text{volume of mix})/\text{volume mix}] \times 100$$

Hardness of the product at the temperature at which it has the optimum consistency for dipping is an important consideration. Hardness is affected by several factors: principally, melting point, total solids, overrun, and amount and type of stabilizer. When an ice cream store keeps several containers of product in a single cabinet from which each is to be dipped or scooped, only one temperature setting is available. Therefore, it is desirable to have the melting points and overruns of all flavors of ice cream nearly the same. This is not easy to accomplish, because formulae involve several variables that affect the concentration of dissolved substances and, therefore, the melting point. The higher the concentration of water-soluble substances, the lower the freezing and melting points. The ice cream formulator must carefully choose amounts of monosaccharide sweeteners, such as glucose, to use. On an equal-weight basis, glucose lowers the freezing point twice as much as does the disaccharide sucrose while providing only three-fourths as much sweetness.

Choice of the amount and type of stabilizer depends on factors other than hardness, and especially on the need to bind water to increase shelf-life. Hardness can be determined with a puncture probe placed on a texture analyzer. The resistance to penetration of the probe is measured repeatedly in ice cream that is adjusted to a precise temperature. Comparisons to a reference curve enable decisions to be made regarding needs for changes in formulation.

When fat globules are very large, the melting rate of ice cream becomes quite slow because of excess churning of the fat during freezing. The critical mean fat globule diameter is slightly more than 1 μm. Single-stage homogenization at a pressure of 10 MPa is sufficient to produce a favorable size distribution.

Characteristics of the emulsified components of ice cream are not easily determined in tests. Sizes of ice crystals, air cells, and fat globules can be measured by examining a thin film of product using a light microscope equipped with a 'cold stage.' Application of image analysis enables large data sets to be analyzed, thus increasing accuracy in determinations of sizes of emulsified components. Electron microscopy

is a sensitive tool. However, the method is costly and time-consuming. To prevent or minimize changes in structure of ice cream during preparation for scanning electron microscopy, samples are frozen and fractured in liquid nitrogen. They are then freeze-dried and coated with a 3.0-nm-thick layer of platinum while under a high vacuum. Confocal scanning microscopy has the advantage of permitting examination of the ice cream in the native state. The instrument scans thin parallel layers of a sample and develops a three-dimensional image from the data. Laser diffraction spectroscopy is reliable for measuring fat globule size distributions in ice cream. Images obtained by microscopy can be transferred to a microcomputer for analysis. The extent of destabilization of the fat in ice cream can be estimated by comparing the absorbance of diluted samples of both melted ice cream and the mix from which the ice cream was made.

Other approaches to determining the physical characteristics of ice cream mixes include: (1) measuring the electrical charge on the fat globules by observing their electrophoretic mobilities in charged fields; (2) measuring mix viscosities over a wide range of shear and calculating the mean diameter of the fat globules from the data; and (3) determining the stability of the emulsion of fat by observing the rate of coalescence of fat globules.

Microbiological Properties

Although ice cream is not a sterile product, it contains no harmful microorganisms when it is produced by an approved process and under hygienic conditions. Furthermore, freezing destroys many bacteria, and the frozen condition of the product prevents growth of microorganisms. Except for a large outbreak of salmonellosis (see below), few cases of food-borne illness have been traced to commercially manufactured ice cream. Sporadic cases of salmonellosis have been traced to home-produced ice cream, especially that containing raw eggs. (*See* ***Salmonella***: Salmonellosis.)

Most regulatory agencies require that ice cream mixes be pasteurized. Additionally, they exercise controls over manufacturers to see that mixes receive an adequate heat treatment and that hygienic practices are followed throughout the processing plant.

The primary area of concern about microorganisms in frozen desserts is contamination of the frozen product during the addition of fruits, nuts, and flavorings, as well as during filling of containers. The microorganisms that present significant risk are *Listeria monocytogenes* and *Salmonella*.

Although illnesses are rarely, if ever, traced to *L. monocytogenes* in frozen desserts, there have been numerous recalls of frozen desserts found to contain these bacteria. Presently, in many countries detection of any *L. monocytogenes* in ready-to-eat foods is reason for recall by the processor. Infants and persons with low immunity are susceptible to infections by *L. monocytogenes*, whereas the normal healthy adult tolerates them well. They are widely distributed in the environment, including plants and animals, and are capable of living in moist, cool places. Unlike most pathogenic bacteria, *L. monocytogenes* grows at temperatures as low as 3 °C. These factors raise the probability of contamination of frozen desserts from the environment by *L. monocytogenes* compared with other foodborne pathogens. A 1989 survey of 530 samples of ice cream mix (85), ice cream (394), and ice cream novelties (51) by Health and Welfare Canada revealed only two samples that contained *L. monocytogenes*. The Working Group of the World Health Organization found that the incidence of *L. monocytogenes* in frozen desserts varied from 0 to 5.5% and that the number of colony-forming units was usually less than 15 per gram of sample.

Salmonella cells are easily killed by pasteurization, but their frequent presence in raw milk and eggs means that all frozen dessert mixes containing these ingredients should be treated to destroy the organism. The multistate outbreak of salmonellosis from ice cream that occurred in the USA during 1994 was believed to have been caused by the transport of pasteurized ice cream mix in tanks of trucks in which liquid raw eggs had been hauled. Apparently, the tanks that were used had been inadequately cleaned and sanitized prior to receiving the ice cream mix. The mix was not repasteurized prior to freezing at the plant to which it was delivered.

Microbiological analyses routinely done with frozen dairy desserts are the aerobic plate count (APC), also called the standard plate count, and the coliform count (CC) or the Enterobacteriaceae count. Standards are commonly set at 20 000 g^{-1} for the APC and 10 g^{-1} for the CC. Whereas the APC method reveals numbers of most of the bacteria capable of growing in an atmosphere of air and at moderate temperatures of about 30 °C, the CC method selects for Gram-negative, facultatively anaerobic bacteria capable of fermenting lactose and of growing in the presence of certain dyes and bile. The enterobacteria include the coliform bacteria plus other similar Gram-negative bacteria that are able to ferment glucose.

Counts can be made of culture bacteria in frozen yogurt by using a medium that is both selective and differential in function and incubating the plates at 37 °C in an atmosphere of CO_2. On modified Elliker's lactic agar colonies of *Streptococcus thermophilus* appear small and red, whereas those of *Lactobacillus*

bulgaricus appear large and white. (*See* **Lactic Acid Bacteria**.)

Sensory Properties

Ice cream has many attributes that make it a favored food of most people. Among these are a rich sweet flavor, a smooth and resistant texture, and a cold sensation that contrasts with the warmth of most other foods. The chemical and physical properties imparted by the ingredients and the processes used in manufacture and handling largely determine the sensory properties.

The human senses most used in evaluating ice cream are taste, smell, touch (feel), and sight. Only infrequently does a frozen dessert affect hearing. Although it may seem strange that smell is involved with a frozen food, it is only by smell that humans can detect flavors other than sour, bitter, salty, and sweet. These four flavors are detected by taste buds on the tongue, whereas odors are sensed in the back of the mouth and in the nasal cavity. Substances detected by smell are volatile, and the warmer the food, the higher the degree of volatility of these substances. Therefore, for the most flavors to be sensed, a frozen dessert should be consumed at as high a temperature as practicable, and it should be eaten slowly so it does not cool the mouth excessively. (*See* **Sensory Evaluation**: Practical Considerations.)

Since physical abilities vary among individuals, as do preferences for various attributes, it is necessary to select the proper sensory analysts and to insure that they meet the requirements imposed by the purpose of the analysis. Whereas trained analysts are needed to describe sensory attributes and to determine whether products meet specifications, untrained analysts are desired to determine acceptability to the public.

High-quality unflavored ice cream tastes sweet, heated (cooked), nutty, and creamy or buttery. Depending on the type and amount of flavoring added, all of these flavors except sweet may become imperceptible except to the expert evaluator. Mild flavors like vanilla tend to mask little of the background flavor, whereas chocolate masks other flavors well. The task of the ice cream formulator is to describe a mix that will provide the balance of ingredients that will give consumers a product with the most desirable flavor, texture, color, appearance, and keeping quality at a price that is acceptable. The engineer must provide a process that enhances, or at least does not damage, these properties. The manufacturer must insure that the ingredients are of high quality and that the process is performed correctly. Unfortunately, there are many factors that can affect the sensory properties adversely.

The International Dairy Federation (IDF) has established standards for evaluation of dairy products, including ice cream (IDF standard 99C). This standard defines an expert assessor as a person 'with a high degree of sensory sensitivity and experience of sensory methodology, who is able to make consistent and repeated sensory assessments of various products.' A panel consists of 'a group of expert assessors.'

The standard gives instruction on the sampling and preparation of samples; the test room; recruitment, selection, training, and monitoring of assessors; requirements for a panel; supervision; documents and equipment; and assessment. Furthermore, a scale is recommended that rates each chosen attribute in relation to the preestablished sensory specification as follows: 5, conforms; 4, deviates minimally; 3, deviates noticeably; 2, deviates considerably; 1, deviates very considerably, and 0, unfit for human consumption. Descriptions of the deviations should be given for samples scoring 1, 2, or 3. Furthermore, when scores of individual assessors fail to agree within one point, rescoring of the attribute is required. The mean value of the final score is then recorded. Terms used to describe sensory attributes should be listed in the order of most to least significance for the quality of the product.

Samples within a type should be examined in random order and presented so analysts do not know the identity. Products with a mild flavor and low fat content should be examined ahead of those with strong flavors and/or high fat content. Prior to assessment, samples should be tempered from their storage temperature of $-18\,^{\circ}C$ or below to $-13\,^{\circ}C \pm 2\,^{\circ}C$.

For calibration, at least one negative and one positive sample should be presented to the analysts who should discuss them prior to assessment. These samples should be available during the assessment session, but there should be no intercommunication among analysts during this time.

Appearance is evaluated by observing the cut surface of the frozen sample. Texture and body are determined by cutting the sample with a spoon then chewing it and letting it melt in the mouth. Flavor and odor are observed as the sample melts in the mouth. Melting quality is assessed by observing samples of equal size and temperature as they melt in flat dishes at $22 \pm 2\,^{\circ}C$.

Defects in the flavor of ice cream

These defects result from an improper balance of ingredients, the use of ingredients of poor quality, or improper processing or storage. Defective dairy ingredients can impart the following off-flavors: sour (acid), stale (oxidized), rancid (lipolyzed),

lacking freshness, or unclean. The amounts of sweeteners and flavorings used can be excessive or insufficient. Furthermore, flavorings can cause an unnatural flavor when they fail to match the true flavoring. For example, vanillin is the major component of vanilla extract, but it fails to provide many other flavor notes of vanilla extract. Additionally, some sweeteners, such as corn syrup and aspartame, impart flavors other than sweetness. Ice creams, especially the mildly flavored types, tend to absorb off-flavors during storage if not protected. Surfaces exposed to air tend to dry and to become oxidized.

Defects in texture of ice cream

Most consumers prefer ice cream that feels smooth and moderately firm when eaten. Degree of smoothness (opposite of coarseness) depends on the sizes of the substances suspended in the disperse phase of the product. These suspended substances are ice crystals, fat globules, casein micelles, particles of other proteins, and air cells. Particles that are 0.1–2 μm in diameter impart creaminess to ice cream whereas particles larger than about 3 μm cause a gritty texture. Ice crystals in freshly frozen ice cream are generally too small to be detected in the mouth, but they grow during storage when minute ice crystals melt and the water migrates to other crystals on to which it is frozen. Fat globules provide a creamy mouth feel but are usually too small to be detected individually. However, when the churning action of the ice cream freezer causes aggregation of too many of the emulsified fat globules, a slick and greasy mouth feel is imparted. Casein micelles are too small to be sensed individually, but collectively they add to firmness. Air cells affect primarily the firmness of frozen desserts. Too little air results in a heavy product, whereas too much air results in fluffiness. When air cells are quite large, smoothness is diminished.

Texture is affected by the melting point of the unfrozen dissolved phase of the frozen product. A high concentration of dissolved substances results in a low freezing point, a relatively small amount of ice crystals formed, and soft ice cream. Conversely, a low concentration of dissolved solids results in hard ice cream. Stabilizers and emulsifiers affect texture. Stabilizers bind water, reducing the amount available to form ice crystals. Emulsifiers contribute to formation of small air cells as well as moderate clumping of the fat. When used in desired amounts, emulsifiers provide stability to the emulsion, dryness, and a slowed rate of melting.

Defects in color and appearance

Consumers expect the color of foods to be properly distributed and suggestive of the flavor and freshness. Colors that are dull, faded, or uncharacteristic of the labeled flavor are defective. Inclusions, which are usually fruit pieces, nuts, candies, or bakery products, need to be abundant and evenly distributed. Syrups and preserves that are pumped into the soft-frozen dessert should be distributed evenly and with minimal spreading of the column of variegate (swirl).

Defects in melting quality

Ice cream should melt to a smooth and uniform consistency within about 20 min at room temperature. The ice cream on cones or stick novelties should melt relatively slowly to permit consumption in the frozen state. However, adjusting an ice cream formula to produce slow melt can cause slow release of delicate flavors. Slow melting can result from overuse of stabilizer gums, emulsifiers, and corn syrup solids. Products containing a high amount of air (high overrun) or fat tend to melt slowly. Air cells act as an insulator. Fat stabilizes foam structure. Treatments that destabilize proteins cause the curdy and free whey appearance of melted ice cream.

Methods of determining sensory quality

Three basic approaches are used to evaluate frozen desserts for sensory quality. These are: (1) by trained experts working alone or in small numbers; (2) by trained panelists; or (3) by untrained consumers in large numbers. Research into the effects of various treatments on specific sensory properties of ice creams usually requires use of trained panelists who employ techniques such as descriptive analysis and free-choice profiling. Development of new products commonly involves screening of several formulae by a few experts followed by tests of a small number of prospective products by large numbers of consumers. A small panel of experts usually monitors the quality of finished products.

Descriptive analysis involves selection of qualified panelists, training these panelists and using them to describe the product attributes. Training consists of several sessions during which panelists, through examination of the type of product to be evaluated and related samples, produce a list of applicable descriptive terms on which they have come to agreement by discussion and consensus. Reference samples are developed for each descriptor. Similarly, free-choice profiling involves development of descriptors, but each judge develops a personal list of terms. Panelists then rate on a point scale the intensity of each of the terms selected, with 1 = low and 9 = high intensity. Results of these types of analysis are tested statistically by analysis of variance and multivariate analysis of variance. Maps of the attributes, as they relate to treatments and to each other, can be drawn

by canonical variate analysis for descriptive analysis or by general Procrustes analysis for free-choice profiling.

A useful technique for testing the time and intensity of flavor release in a food is called time–intensity evaluation. The technique can be applied in evaluating the effect of ingredients on the release of volatile flavors such as vanilla and chocolate. In one application to ice cream, it was determined that the higher the amount of milk fat, the slower the release of vanilla flavor.

Experts who evaluate samples on an informal basis commonly refer to score cards and scoring guides such as those developed by the Committee on Dairy Products Evaluation of the American Dairy Science Association. The score card lists the defects most often found in ice cream, and the scoring guide suggests scores that reflect the seriousness of the respective defects. For example, a sample that has no observed defects is given a flavor score of 10 and a body and texture score of 5. A deduction of one point is made for a minor defect of flavor, such as lacking flavoring, or of texture, such as slightly coarse (icy). Serious defects in flavor, such as oxidized, rancid, or acid, merit lower scores of no more than 6. Color, melting quality, and package are also scored on a scale of 1–5.

Consumer panelists are chosen to represent the target market. Because they are untrained, numbers of panelists should be more than 50 and preferably 100. Panelists may be asked to indicate preferences by ranking a few samples, or they may indicate their degree of liking on a numerical scale (called hedonic evaluation). A typical scale consists of seven points where 1 = dislike extremely, 2 = dislike moderately, 3 = dislike slightly, 4 = neither like nor dislike, 5 = like slightly, 6 = like moderately, and 7 = like extremely. Hedonic tests can be analyzed statistically when sufficient panelists are used.

Energy Content

Ice cream is a much maligned product, frequently being considered, at best, a 'fun food' – unworthy of serious consideration – and, at worst, a 'junk' food, or even downright harmful! These perjorative statements have dogged the industry virtually from its inception.

In reality, ice cream is a relatively well-balanced, wholesome, easily digestible, and delicious food. It is

because ice cream is a nutritious element of the diet that it is frequently used as a meal component for hospital patients.

The composition of ice cream varies according to legislation and to the complexity of ice cream products, e.g., 'Cornetto', fancy gateaux, etc. It is therefore difficult to define precisely an average composition and energy content.

Most reputable sources seem to agree on energy values of between 180 and 210 kcal per 100 g. An average portion of ice cream – which is measured by volume, rather than weight – is taken to be between 100 and 125 ml (50–79 g), giving a calorie count of roughly 100 kcal per portion. This calorie density is modest in comparison with other desserts and confectionery, and there is a good nutritional balance of macronutrients.

Macronutrient Composition

Classically, the major ingredients of ice cream are milk solids, milk or vegetable fat, and a variety of added carbohydrates. The macronutrient composition of a typical ice cream, according to Souci, Fachmann, and Kraut, and that according to the 'Euroglace' proposal, are given in Table 1. In both instances, the nutritional quality of the milk-derived protein enhances its value. In comparison with many other dairy-based products, ice cream offers a more nutritionally balanced dietary contribution. (*See* **Carbohydrates**: Requirements and Dietary Importance; **Fats**: Requirements; **Protein**: Requirements.)

Finally, ice cream, derived as it is from milk, can be an important source of minerals, notably of calcium, and especially for children.

Micronutrient Composition

The vitamins, macrominerals, and microminerals present in dairy ice cream are listed in Table 2. Refer to individual nutrients.

Sources of Micronutrients

The total micronutrient composition of ice cream varies with the amounts and types of ingredients used in its manufacture. Because of this variation, the data given are only approximate.

Water-soluble Vitamins

In ice cream, the concentration of water-soluble vitamins, such as vitamin C and vitamins of the B complex, are similar to, or slightly higher than, those in pasteurized milk. The concentrations of these vitamins in both dairy and nondairy ice creams are generally similar. Ice cream is rich in vitamins B_{12} and B_2: a 100-g portion supplies 20 and 14% of the US recommended dietary allowance (RDA) respectively.

Fat-soluble Vitamins

The type and concentration of fat-soluble vitamins in ice cream depend on the type and level of fat used. A 100-g portion of dairy ice cream provides 11% of the US RDA of vitamin A.

Minerals

The minerals found in ice cream are similar to those in milk (Table 2). The one mineral that is clearly abundant in ice cream, and which would contribute over 10% of the US RDA if 100 g of ice cream were consumed, is calcium.

Effect of Storage on Micronutrients

Very few studies have been conducted on micronutrient losses in ice cream during storage at constant temperatures and at fluctuating temperatures. Freezing is generally regarded as the best method of preservation when judged on the basis of retention of nutrients. Substantial losses in micronutrient content during the storage of ice cream are unlikely.

Health and Nutritional Issues

As well as being rich in calcium, ice cream contains significant levels of lactose and amino acids such as

Table 1 Ice cream composition and energy levels compared to 'Euroglace' proposal

Nutrient	*Ice cream*[a]		*Ice cream*[b]	
	(g per 100 g)	*(Percentage energy)*	*(g per 100 g)*	*(Percentage energy)*
Energy (kcal)	210	100	173	100

lysine and arginine. These are known to enhance the absorption of calcium and to promote bone mineralization. Although rich in some micronutrients, ice cream is, in common with other milk-based products, comparatively deficient in iron and vitamins C, D, and E. (*See* **Amino Acids**: Properties and Occurrence; **Lactose**.)

Comparison of Dairy and Nondairy Ice Cream

Ice Creams made from cream or butter (dairy ice creams) and from vegetable fat (nondairy ice creams) are essentially comparable in nutritional value. There are differences, however, in the vitamin A content, which is higher in dairy ice cream, and the vitamin E content, which is higher in nondairy ice cream.

There are also differences in the proportion of saturated and unsaturated fats present. Ice cream made from palm oil is lower in saturated fat than dairy ice cream, whereas ice cream made with coconut oil has a higher saturated fat content than a butterfat product. (*See* **Fatty Acids**: Properties; **Vegetable Oils**: Dietary Importance.)

Sugar Content

Sugars are major ingredients in ice cream manufacture and have an important influence on the nutritional status of the product. Carbohydrates contribute 40–50% of the calories in ice creams. Sucrose is most widely used, but most ice creams contain at least three types of sweetener: sucrose, lactose (from milk) and maltodextrins (from corn syrup). The preferred level of sweetness varies form country to country, with products containing the equivalent of between 13 and 19% of sucrose, and a total of up to 25% carbohydrate by weight. (*See* **Sucrose**: Dietary Importance.)

Nutritional and Health Issues

The nutritional issues relevant to sugars in ice cream are as follows:

- the need for functional lower-calorie sweeteners;
- the interest in products more suitable for diabetics;
- the search for noncariogenic products.

Cariogenicity has not been discussed here because of a lack of information specific to ice cream. Previous extensive reports on nutritional aspects of the diet in the UK and USA have commented on the role of sugars in general in promoting the incidence of dental caries. However, to put these problems in perspective, it should be borne in mind that ice cream contributes only 1–4% of the total intake of sugars in the diet. (*See* **Dental Disease**: Role of Diet; **Sweeteners**: Intensive.)

Nutritional Claims

A number of products with specific nutritional claims have been developed, e.g., lower-calorie ice creams and diabetic products. The basis of these nutritional claims, and the compositional changes needed to support them, are considered below.

Lower-calorie Ice creams

Standard ice creams already have a fairly low-calorie density because of the high percentage of air and water in the product. Nevertheless, further calorie reduction is possible by reducing the fat or sugar content, or by replacing some of the sugars by sugar alcohols, or other synthetic sweeteners such as saccharin or Nutrasweet (aspartame).

Three sugar alcohols – lactitol, maltitol, and Palatinit (isomalt) – are now in manufacture as lower-calorie substitutes for sugars. Compared to sugars at $4\,kcal\,g^{-1}$, maltitol provides only $3\,kcal\,g^{-1}$, and lactitol and Palatinit (a mixture of mannitol and glucitol) only $2\,kcal\,g^{-1}$. (*See* **Sugar Alcohols**.)

Total replacement of sugars by zero-calorie synthetic sweeteners such as saccharin is, however, only practical if some other ingredient can substitute for the other functional characteristics normally provided by the sugars. Polydextrose, a new food ingredient, exhibits some of the functional properties of sugars without contributing any sweetness to the product. It is a randomly bonded polymer of dextrose, resistant to attack by acid and digestive enzymes. Consequently, it is only partially metabolized, with a calorie contribution of only 1 compared to $4\,kcal\,g^{-1}$ for saccharides. Polydextrose has been cleared for use in ice cream by, for example, the Food and Drug Administration (FDA) in the USA and by the UK authorities, although regulations in the UK prohibit its use in foods specially prepared for babies or young children. (*See* **Saccharin**.)

Diabetic Products

Sorbitol and fructose are the most common substitutes for sugars in products designed for diabetics. However, synthetic sweeteners and the more recently developed sugar alcohols are available as alternatives (see above).

Importance of Ice Cream

The recommendations for a healthy and balanced diet made by many governmental bodies emphasize the importance of eating a variety of different foods and the enjoyment of food. Ice cream can be delicious and a pleasure to eat, but it is also a nutritious food. It contains all the macronutrients and many micronutrients, and is a valuable source of energy.

In terms of energy, a 50-g serving of ice cream yields approximately 100 kcal. This is about that of the same weight of whole milk yogurt but two and a half times less than that of chocolate. Volumetrically, owing to the inclusion of air, the ice cream portion is twice as large as that of the yogurt and chocolate. For a child with a RDA of 2000 kcal, a 50-g portion of ice cream would provide 5% of the RDA of energy.

In conclusion, ice cream is particularly valuable for its content of high-quality protein and easily assimilated calcium. It provides many nutrients and can make a useful, as well as enjoyable, contribution to the daily intake of energy in a healthy and balanced diet.

Microbiology

A Kambamanoli-Dimou, Technological Education Institute, Larissa, Greece

Introduction

Ice cream is composed of a mixture of milk products, sweetening materials, stabilizers, flavors, or egg products, which are referred to as ingredients. The wide variety of ingredients that may be used to produce different kinds of ice cream and their microbiological standard and quality greatly affect the quality of the ice cream. The specific production, processing and postprocessing storage, and storage or distribution conditions also considerally affect the quality of the final product. So, the microbiological quality of ice cream depends on many factors, the most important of which are described here.

Raw Materials (Major Components and Additives)

Although the best ice cream can be made from cream, concentrated or condensed milk, sugar, stabilizer, and high-quality flavoring, ice cream manufacturers have found it highly desirable to use a variety of ingredients available from numerous sources. Any of these can contribute bacteria, molds, and yeasts to the final product. Of course the ice cream mix is pasteurized before freezing. This heat treatment gives an adequate reduction in bacterial numbers as well as the destruction of pathogenic organisms. It cannot, however, entirely correct the hygienic quality of poor ingredients. So, carefully selected ingredients are essential for the manufacture of ice cream of the highest quality.

Liquid milk, cream, skim milk, and concentrated skim milk should have been subjected to efficient heat treatment, and must be kept under refrigeration and be used properly. Otherwise, they may contain appreciable numbers of bacteria, including some which are pathogenic (*Mycobacterium* spp., *Streptococcus* spp.). Naturally, the main organisms present in these dairy materials, which have been handled and stored under sanitary conditions, are a few spore-forming bacilli, micrococci, psychrotrophic, and thermoduric microorganisms. They are not a major health hazard but they may sometimes spoil the mix. Milk powders may also contain large numbers of spore-forming bacilli or may be contaminated by salmonellae. Numerous outbreaks of food poisoning attributed to salmonellae or staphylococci from milk powder provide evidence that these pathogens do on occasions survive in the final product. A special hazard of staphylococcal enterotoxin in ice cream may be present if whey powder is used as a source of milk solids. Careful control and storage of these powders under dry and cool conditions are necessary. (*See* **Cream**: Types of Cream; **Milk**: Liquid Milk for the Consumer.)

Several sugars are used as sweetening ingredients. These products rarely undergo microbial spoilage if properly prepared, processed, and stored. Certain yeasts and molds could be the principal spoilage flora, though some species of bacteria have also been suggested as possible spoilage problems, including *Bacillus* and *Leuconostoc* species. Also, sugar syrups are used. Osmophilic yeasts may be able to grow in these syrups, and molds may grow on the surface, so tests for yeasts should be carried out in order to minimize contamination of the ice cream from these ingredients.

Butter and butter oil (anhydrous milk fat), used as a source of milk fat, are made from pasteurized cream so they should not contain pathogenic bacteria, and a high microbiological quality is to be expected when satisfactory hygienic conditions are applied during their production and if they are properly handled. Relatively small numbers of mesophilic bacteria, coliforms, and lipolytic organisms, particularly the *Pseudomonas* species responsible for butter spoilage, as well as molds and yeasts, can be found. Butter commonly is kept refrigerated and during commercial storage is kept at about $-20\,^{\circ}C$, at which temperature no microbial growth can occur. For these reasons bacteria usually do not grow in butter, and when they do, their growth is not extensive. The flavor of good butter is so delicate, however, that small amounts of growth may cause appreciable damage to the flavor. When satisfactory hygienic conditions are applied during the production of the above ingredients and if they are properly handled (storage temperatures of no more than $-20\,^{\circ}C$ for butter, and dry, refrigerated conditions for butter oil), combined with tests for the above-mentioned microorganisms, a high microbiological quality will be insured. Fats other than milk – commonly vegetable fats – may also be used. The high temperature used during their processing and their low moisture content give raw materials containing very few microorganisms. Dry, refrigerated conditions should be used for their storage. (*See* **Butter**: The Product and its Manufacture.)

Stabilizers do not constitute an important source of bacteria, as they are usually produced by methods involving high temperatures. So, if they have been packaged under hygienic conditions they do not contribute to microbiological contamination of the ice cream mix. Attention must be paid to gelatin, which, as an animal product, may be a hazard if

produced under insanitary conditions, so it should be obtained from a reputable supplier and kept under cool, dry conditions. Emulsifiers should not present a problem, except for eggs, which may be contaminated by *Salmonella* spp., and pasteurization is required to avoid any hazard arising from their use. (*See* ***Salmonella***: Properties and Occurrence.)

Fruits (fresh, canned, or frozen) and nuts, chocolate, and cocoa, flavoring materials such as vanilla, colors and so forth are added to ice cream or are used as coatings. All of them are potential sources of hazard, particularly if they are added after the heat treatment of the mix. Fresh fruits are used and yeasts and molds, which predominate their microbial flora, may be a problem. Fruit pulps and concentrates are commercially available and manufactured at a high standard of hygiene. Canned fruits, because of their heat treatment, should be of satisfactory microbiological standard. Several types of nuts may be used in the ice cream or as a coating. They could be a hazard because they may contain molds and, possibly, mycotoxins. Coconuts can also contain salmonellae. For these reasons, it is much better if all these materials are used after heat treatment (roasted nuts, for example, or pasteurized chocolate), especially if they are added to the mix after its pasteurization. Also, they should be stored under cool, dry conditions. The examination of these materials should include a visual inspection and the enumeration of mesophilic bacteria, coliforms, yeasts, and molds.

Colors, if manufactured carelessly, may cause problems of microbial origin, especially when they are added after pasteurization. This can be avoided if they are obtained from a good supplier and stored properly.

In conclusion, a very wide variety of ingredients are used in ice cream manufacture and variations in their quality affect the microbial load of the final product. The need to use high-quality raw materials, purchased from a reputable supplier, carefully stored under good conditions which will not allow the proliferation of microorganisms, is evident. In addition, it is suggested that appropriate microbiological tests should be performed on raw materials, and the use of strict stock rotation is essential.

Hygiene During Production

The manufacture of ice cream is a relatively complex operation which includes a series of steps, all of which have some effect on the microbiological quality of the final product. So, a high-quality ice cream demands good ingredients along with sanitary conditions of processing, freezing, hardening, and distribution. As all these factors are important, they must be carefully controlled in order to produce a safe product, safeguarding the consumer's health.
